The sensitivity and specificity of ELISA are similar to those in cattle, although cross-reactions to *C. pseudotuberculosis* occur, so absorbing sera with those heat-treated organisms does give improved results. In Australia, in a population of sheep with a high prevalence of subclinical infection, the sensitivity of an absorbed ELISA was 34% to 54% compared with 38% to 56% for the AGID test. The AGID was much better at detecting infected sheep in low body condition than the ELISA, but the latter was superior in detecting infected sheep with localized lesions or those with small numbers of MAP. These tests have also been evaluated and compared in adult sheep culled from severely affected flocks, with sensitivity and specificity evaluated using histopathologic findings as a reference. The sensitivity and specificity of the AGID was 37% and 100%, respectively, whereas the sensitivity of the ELISA was 48%, but its specificity was only 89%.

As discussed previously, in sheep a spectrum of infection is defined by two widely differing forms of the disease: a tuberculous form, with strong cell-mediated immune response and lesions characterized by small granulomata composed of a few epithelioid cells surrounded by a large number of lymphocytes, and with no or few bacilli in the lesions; and a lepromatous form, with a strong humoral immune response accompanied by lesions with macrophages full of mycobacteria. The sensitivities of ELISA and the AGID test in sheep with lepromatous lesions were 86% and 100%, respectively, but only 10% to 50% and 30% in sheep with tuberculous lesions. Thus there is a close correlation between serologic response to AGID and the presence of acid-fast bacilli in the intestinal tissues, and the diagnosis of tuberculous cases remains difficult.

Nevertheless, the AGID is rapid, inexpensive, easily available, and technically easy to perform. Thus it is useful for
The control of Johne's disease is challenging because of the widespread nature of the organism, long incubation period, and the fact that most cases are subclinical. The available tests lack sufficient sensitivity to identify a large proportion of subclinically infected animals, which allows undetected infection to spread within and between flocks. Because of this lack of efficacy, and the failure of any of the antimicrobials to provide a bacteriologic cure, treatment is not recommended.

**CONTROL**

The control of Johne's disease is challenging because of the widespread nature of the organism, long incubation period, and the fact that most cases are subclinical. The available tests lack sufficient sensitivity to identify a large proportion of subclinically infected animals, which allows undetected infection to spread within and between flocks. Because of this low sensitivity, it is currently not possible to eradicate the disease other than by complete depopulation of the flock or herd and restocking with noninfected animals. Thus eradication is usually not practical, both for economic reasons and the difficulties in acquiring noninfected animals. Consequently, the preferred option is to limit economic loss by keeping the disease at a very low prevalence, such as by vaccination. However, a large proportion of flocks vaccinating for more than 5 years still had infected severe or mild. Severe lesions consist of extensive macrophage granulomata and numerous giant cells, with many intracellular acid-fast bacteria in the small intestine.

**DIFFERENTIAL DIAGNOSIS**

The characteristic features of clinical Johne's disease include progressive weight loss, and emaciation in a single animal or group of animals within a mob, and chronic diarrhea, which does not respond to therapy. A definitive diagnosis can be obtained by using a combination of serologic tests, fecal culture, and biopsy of intestine.

**Sheep and goats**

The characteristic features of clinical Johne's disease in sheep and goats are emaciation, weakness, and normal feces with intermittent bouts of mild diarrhea. The other causes of unexplained weight loss in sheep and goats include *caseous lymphadenitis*, internal abscesses, gastrointestinal parasitism, *caprine arthritis-encephalitis*, ovine progressive pneumonia, dietary deficiencies, and dental disease.

The major difficulty encountered in the diagnosis of Johne's disease is the accurate identification of subclinically infected animals. These are usually negative to the serologic tests but in the intermediate stage of the diseases and excreting the organism in their feces. Thus tests are usually flock-based or herd-based rather than useful for an individual animal. Pooled fecal culture or serologic tests of a cross section of the flock or herd will usually indicate if the infection is present or absent.

**NECROPSY FINDINGS**

Sheep and Goats

On necropsy, ascariasis and subcutaneous edema are usually present, but gross necropsy lesions are often minimal despite severe clinical signs. In sheep there may be a...
sheep shedding MAP, so vaccination of young sheep or goats needs to be ongoing to reduce this risk. Successful control requires a long-term commitment by the flock or herd owner. In addition, because of its subclinical nature, producers often fail to practice adequate control measures because they do not recognize the importance of the disease.

The lack of integrated national control programs in countries in which the disease is endemic also allows the disease to spread continuously from herd to herd and region to region.

**Control on a Flock Basis**
The control of Johne's disease is based on two major principles:

- **Identification and elimination of infected animals**
- **Prevention of new infections**

For flocks known or thought to be free of Johne's disease, measures should be taken to avoid the introduction of infected animals by maintaining a closed herd or by carefully screening purchased animals. The purchase of stock is the most common way MAP is introduced into a flock or herd. Thus purchasing only from flocks or herds documented to be of low risk of Johne's disease is preferable to testing specific animals before introduction because of the low sensitivity of available tests for individual animals. This is difficult because very few countries or jurisdictions have assurance programs, and few livestock producers participate in these.

The control of Johne's disease in sheep flocks has been widely implemented in Australia. This program is based on flock testing and management procedures, such as secure boundary fencing and introducing sheep only from flocks of similar MAP status. Testing is by pooled fecal culture of 350 animals (50 animals per pool), or negative serologic testing (ELISA or AGID) of a sample of 500 animals from the adult flock, defined as animals 2 years or older. This flock-sampling program has a 95% chance of detecting a 2% or greater prevalence of infection. Its purpose is to identify mobs or age groups of sheep that may have been more heavily exposed to infection. These become a priority for culling before they develop a large proportion of clinical cases, preventing further contamination and exposure of susceptible sheep to MAP.

A disadvantage of bacterial culture techniques is the relatively long incubation period needed to obtain results, typically from 2 to 3 months. Consequently, a high-throughput direct qPCR test (the HT-J test) has been developed and validated and was accepted in 2013 as a flock test suitable for use in Johne's disease control programs in Australia and New Zealand.

Eradication by destocking for at least two summers was attempted in Australia, but the disease was often reintroduced in newly purchased stock. This arose due to a lack of sheep with a known reduced risk of infection and due to relatively low numbers of flocks participating in the Market Assurance Program. Persistence of the organism in the environment, up to 1 year or more, contributes to reinfection. Grazing management to reduce pasture contamination, such as selective grazing with more resistant hosts (e.g., adult cattle) or reducing shade (pasture length) are ways to more rapidly decontaminate paddocks known to be contaminated with MAP.

**Vaccination**
Vaccination is now a common method of controlling OJD. The most common strategy is to vaccinate the replacement ewes. However, in self-replacing Merino flocks with a high proportion of castrate males (wethers) infection can still be propagated from the unvaccinated portion of the flock, with the prevalence of shedding of MAP organisms from unvaccinated sheep six times that from vaccinates (1.27% versus 0.21%). Mortalities and the proportion of sheep shedding MAP are reduced by up to 90% after the flock is vaccinated, although the response is variable. In a longitudinal study involving 37 flocks, there was a decline in the prevalence of fecal shedding, from 2.72% before vaccination to 0.72% following 5 years of vaccination. However, more than 80% of these flocks had detectable fecal shedding. Thus it is advisable for them to continue vaccination, otherwise production losses and mortalities could rapidly increase. A higher initial prevalence of fecal shedding and less stringent biosecurity, such as straying or a greater number of introduced sheep, was associated with a higher prevalence of shedding.

The widespread use of a killed OJD vaccine in a mineral oil adjuvant does have the disadvantage of being a significant occupational health and safety problem, because producers have accidentally self-injected and suffered severe and debilitating injuries, often necessitating the amputation of affected digits or extensive debridement of necrotic tissue. However, vaccination in sheep is not impeded by interference with tuberculin testing, although it will produce positive CF test titers that can interfere with serologic testing for export and diagnostic purposes. Newer vaccines may offer a more targeted cell-mediated immune response and less reactivity, but they are yet to be released commercially.

**Goats**
A high prevalence of clinical Johne's disease in goats has been controlled by vaccination using a commercial inactivated vaccine. In small or intensively managed flocks, attempts to control and eradicate the disease have been made by undertaking pooled fecal culture and blood testing two to four times annually and weighing all goats monthly to detect any individuals losing weight. This is a relatively costly program and has a high risk of failure. Environmental and management changes were also undertaken, including altering trough design to minimize contamination of feed and water, restricting movement of goats between pens, cleaning pens three times weekly, eliminating grazing of pasture, spreading and ploughing manure into fields, isolating young and newly goats from the herd until their test status was determined, and strict attention to disinfection of footwear before entering or exiting barns and pens.

**Control on a Countrywide Basis**
There are wide variations in how Johne's disease is controlled by national, state, or provincial agencies. In some jurisdictions, the disease is reportable and in others it is not. In many areas, health certificates are required for interstate or intrastate movement of livestock, and most certificates require a statement that the animals are free of certain diseases. However, often the livestock owner or certifying officer has no knowledge of the presence of Johne's disease, or relatively insensitive serologic tests are used, so infected animals are still traded. Voluntary national and regional Johne's disease control programs for sheep and goat flocks have been introduced in Australia, and the disease is notifiable in many other countries including Greece, the Republic of Ireland, Luxembourg, Norway, Switzerland, Spain, and Sweden. Often the emphasis in the early stages of programs is to control clinical disease.

In Australia, an accreditation program for negative sheep and goat flocks, the Johnes Disease Market Assurance Program (SheepMAP, GoatMAP), was launched in 1999. It is a voluntary, audited, quality assurance program based on negative pooled fecal culture (50 sheep per pool) or serologic testing of a sample of the adult flock (animals 2 years and older). Testing is combined with prudent flock management, such as secure boundary fencing, restricting introduced sheep to flocks with a similar flock status, and abattoir monitoring, to assure owners and clients that participating flocks have a very low risk of being or becoming infected with OJD. SheepMAP is part of a national OJD control program, jointly funded by the sheep industries and Commonwealth and State Governments, and managed by Animal Health Australia. In 1999 a control and surveillance program was enacted for 1 year to limit further spread of OJD and to determine the distribution of this disease. Known infected and suspect flocks were subject to movement restrictions, and movements of sheep onto and off known infected farms were traced and investigated. Proposals for development of a market assurance program and zoning according to prevalence of OJD...
within a state, as well as advisory and research programs, were developed as part of the National Ovine Johnes’s Disease Control and Evaluation Program. By 2000, OJD had been confirmed in every Australian sheep-producing state except Queensland. As part of the control program, some states, such as Victoria, provided an industry-funded subsidy to encourage the use of OJD vaccine in known infected flocks. Subsequently, the program was reviewed and modified, with 5-year programs enacted from 2007 to 2012 and 2013 to 2018. At each time, modifications to zoning were made based on the estimated prevalence of the disease, with a reduction in prevalence areas from four in 2004 (high, medium, low, and very low) to three in 2008 (high, medium, and low), and to none in 2013. In addition, an assurance-based credits (ABC) scheme was introduced to facilitate sheep trading. At first, points were allocated based on the location of a flock (the prevalence area), the use of vaccination, and any whole-flock or part-flock testing undertaken, including monitoring at abattoirs. Subsequently, with the recognition that vaccinated animals can still transmit OJD, because vaccination reduces clinical disease but does not eliminate shedding of MAP, and the abolition of officially recognized prevalence areas in 2013, the ABC system is no longer used to support sheep trading. Despite the efforts invested by the program, OJD has continued to spread in Australia. This was noted in the review of the 2007 to 2012 program and incorporated into the objectives of the national OJD Plan for 2013 to 2018, which were to (1) minimize the risk of MAP infection spreading to properties and regions that currently appear disease free, and (2) reduce the financial impact and adverse animal health and welfare effects of OJD, both for individual flocks and the sheep industry as a whole.

**RINDERPEST (CATTLE PLAGUE)**

**Synopsis of the Disease**

Rinderpest, or cattle plague, caused by the rinderpest virus (RPV), was declared globally eradicated in 2011. The disease often occurred as epizootics associated with a very high mortality rate, and its eradication is arguably the greatest veterinary achievement of our time. Death usually resulted from severe diarrhea/dysentery and dehydration. A detailed account of the disease can be found in the 10th edition of this book. Because RPV is related to other members of the morbillivirus group causing disease in humans (measles), small ruminants (peste des petits ruminants [PPR]), dogs (canine distemper), and some marine mammals and wildlife, some lessons can be learned from a knowledge of the processes and historical background leading to rinderpest eradication.

Several authors have reviewed the history of rinderpest since its eradication. Long before its etiology was known, cattle plague was recognized as a most devastating epizootic disease that spread from Asia to Europe, the Middle East, and eventually Africa, initially as a sequel to wars and later through trade-related livestock movements and seasonal migrations for water and pasture (nomadic pastoralists). The disease affected not only cattle but also over 40 other domestic and wildlife species. It is described in ancient Chinese writing, historical Asian drawings, and in documents from the Roman Empire. It had been credited with decimation of native African wildlife and the decline of the European bison. The virus does not cause human disease. Nevertheless, rinderpest was indirectly responsible for countless human deaths resulting from agricultural losses that led to famine, poverty, and disease for centuries. In the nineteenth century, an epidemic in Ethiopia caused rapid loss of virtually all of the cattle, buffaloes, elands, and wild swine, as well as many sheep, goats, and wildlife species, such as antelopes, gazelles, giraffes, hartebeests, and wildebeests and resulted in the Great Ethiopian Famine of 1887 to 1892.

The need to combat rinderpest outbreaks was instrumental in the establishment of the world’s first veterinary school in 1762 in Lyon, France, and the Office International des Epizooties (OIE) in 1924, also in France. Furthermore, it led to the development of national veterinary institutions in many parts of the world. With a simple transmission chain and the environmental fragility of the virus, rinderpest was always open to control and even eradication within a zoosanitary approach.

**Steps Leading to Eradication**

The geographic distribution of the disease had been shrinking steadily since the beginning of the twentieth century. Rinderpest never appeared in North America, and single outbreaks in Brazil and Australia were quickly eradicated. The disease was also eradicated from southern Africa, Europe, and China by the middle of the last century but was still endemic in other parts of Africa (as lineages 1 and 2) and in Asia (as lineage 3). African countries successfully initiated the Joint Project 15 from 1962 to 1976.
followed later with a Pan-African Rinderpest Campaign to rid the whole continent of the disease. The initial step was to vaccinate all animals in each national herd annually until the immune status exceeded 90%. Thereafter, calves were vaccinated annually and revaccinated the following year until there were no more outbreaks for at least 5 years. This was followed by periodic surveillance to monitor the immune status of each national herd and to deal quickly with any new outbreaks by control of animal movement and ring vaccination of all surrounding herds. As a result, the disease was cleared from West Africa and most of East Africa, but there was a dangerous resurgence less than 10 years later. Outbreaks of lineage 3 were also occurring occasionally in parts of Asia. In 1994 the Global Rinderpest Eradication Program (GREP) was created to undertake complete eradication of the disease. GREP was funded by the EU, the United States Agency for International Development, the International Atomic Energy Agency, the African Union-Interafrican Bureau of Animal Resources, Food and Agriculture Organization (FAO), and the OIE. The principal vaccine used to control rinderpest was the tissue culture rinderpest vaccine (TCRV) produced in calf kidney cells for cattle. Plowright and others developed the vaccine in Kabete, Kenya, in 1957. TCRV is easy and cheap to produce and can be freeze-dried or lyophilized; therefore has a long shelf-life before it is reconstituted and can be refrigerated for a few hours after reconstitution. Furthermore, it is capable of varying degrees of attenuation and is thus safer in all situations. Finally, it produces a life-long immunity and does not spread from vaccinated to in-contact cattle.

One key to global eradication was to ensure that vaccination programs were performed in a synchronized manner across all regions in which the disease was endemic—an objective to which the funding agencies fully subscribed. Innovative strategies were deployed for the last mile to overcome diagnostic and surveillance challenges, unanticipated variations in virus pathogenicity, circulation of disease in wildlife populations, and to service remote and nomadic communities in often unstable states. An example was the situation in the Greater Horn of Africa, a region with weak governance, poor security, and little infrastructure, that presented profound challenges to conventional control methods. However, success was achieved because of the superior vaccine and the application of participatory epidemiologic techniques that allowed veterinary personnel to interact at a grassroots level with cattle herders to more effectively target control measures. The last recorded outbreak of lineage 3 virus was in Pakistan in 2000 and of lineages 1 and 2 in Africa in 2001. Ten years later, and after much surveillance, testing, and certification of disease freedom, a joint meeting of the 79th General Session of the OIE and the 37th FAO Conference adopted a resolution declaring the “Global Freedom from Rinderpest” on June 28, 2011. Factors leading to success can be summarized as follows:

1. Although the virus could infect wildlife, it did not have a reservoir of asymptomatic host animals capable of carrying it for prolonged periods;
2. A stable vaccine that provided good immunity was developed;
3. Animals that recovered from infection became immune for life.
4. There was a concerted, well-funded, and unparalleled international response to eradicate rinderpest.

**Lessons From the Eradication**

It must be remembered that although rinderpest has been eradicated, the virus still exists in research laboratories in the world. Adequate care should be taken in handling diagnostic specimens to avoid accidental infection and spread. A recent survey revealed that 44 laboratories in 35 countries in different continents were holding laboratory-attenuated strains, field strains, or diagnostic samples of RPV. Rigorous standards are necessary to ensure that stocks are kept under safe conditions. Under intensive system of management, any accidental infection can be easily curtailed and eradicated, but large-scale intentional introduction (agricultural bioterrorism) can have a devastating effect in a fully susceptible livestock and wildlife population before the disease is wiped out again. Nevertheless, the risk of rinderpest reintroduction in the posteradication era is estimated to be very low.

Experience with smallpox eradication in humans was found to be valuable in planning rinderpest eradication even though their viral agents are unrelated. RPV is closely related to the human measles virus (MeV), and there is molecular evidence to suggest that MeV could have originated from RPV around the eleventh to twelfth centuries. Furthermore, PPR in sheep and goats may have also originated from RPV. Therefore the experience with rinderpest should guide in the control of measles in humans and PPR in small ruminants. From the veterinary perspective, the focus is currently on PPR eradication. PPR shares similarities with rinderpest in etiology, epidemiology, pathogenesis, and pathology; there is solid immunity following immunization or recovery from natural infection; and a good vaccine is available. Therefore there is optimism that PPR can be eradicated. The triumph of rinderpest eradication should challenge the current scientific generation to view disease eradication as the ultimate means of control and prevention, to pursue eradication when the tools become available, and to seek to develop those tools when they are not available.
ETIOLOGY

PPR, kata, or goat plague is caused by peste des petits ruminants virus (PPRV), a morbillivirus (family Paramyxoviridae) closely related to the morbillviruses of rinderpest, measles (in humans), carnivores, and marine mammals. Morbillviruses are enveloped virions that contain a nonsegmented, negative-stranded RNA genome that encodes a single envelope-associated matrix protein (M), two glycoproteins (hemagglutinin H and fusion protein F), two RNA polymerase–associated proteins (phosphoprotein P and large protein L), and a nucleocapsid protein (N) that encapsulates the viral RNA in addition to two nonstructural proteins C and V. The H and F external glycoproteins are responsible, respectively, for the attachment and the penetration of the virus into the cell to be infected. Both proteins also elicit protection against the disease in infected or vaccinated animals. The viral genomic RNA and N, P, and L proteins form the ribonucleoprotein, which is the minimal essential structure for viral replication in cells.

PPRV has only one serotype but four genetically distinct lineages that are based on the sequence analysis of the F and N genes of various strains of the virus originally isolated from Africa and Asia. Lineage I and II viruses were first isolated from West Africa, lineage III from East Africa, and lineage IV from Asia. Whereas lineages I and II viruses are still largely confined to West Africa, the lineage III virus appears to have spread from East Africa to Sudan, Yemen, and Oman; the lineage IV (Asian) virus has recently been introduced to some African countries including Cameroon, Gabon, Central African Republic, Uganda, Sudan, Egypt, Algeria, and Morocco. In Asia, this lineage has been identified in the Middle East and in many South Asian countries, including Pakistan, India, Nepal, Bangladesh, and Tibet/China.

When different isolates of PPRV from outbreaks in Africa and India were investigated for virulence in West African dwarf goats, it was observed that the isolates from Ivory Coast and Guinea (corresponding to lineage I) caused a peracute disease; those from India-Calcutta (lineage IV) caused an acute disease; the Sudan-Sennar strain (lineage III) produced an acute to mild disease; and the Nigerian 75/1 wild strain (lineage II) caused a mild disease and the animals recovered. However, there is considerable variation in virulence within isolates and strains in a given lineage. Based on genetic differences in the lineages, there have been suggestions that the African and Asian lineages of the virus may have evolved separately. Although PPRV is closely related to rinderpest and measles viruses antigenically, all four PPRV lineages have been shown to be genetically distinct from the RPV, raising some doubt to the notion that PPRV might have evolved from
goose-adapted rinderpest vaccines developed in the first half of the twentieth century.

EPIDEMIOLOGY

Occurrence
The disease occurs mostly in goats and sheep and has spread extensively across national and continental boundaries in the last few decades. Outbreaks were first described in West Africa in 1942, but the disease is now endemic in many African countries as well as in the Middle East and South Asia, and there is concern that it could spread to Europe. In Africa, outbreaks have been reported as far north as Morocco, Algeria, and Egypt and as far south as Cameroon, Gabon, Uganda, and Tanzania. Since the 1990s, outbreaks have been reported from the Arabian Peninsula as far north as Turkey and extending through Pakistan and India to Nepal, Bangladesh, and China where the disease is now endemic.

It is possible that some of the earlier reports of rinderpest in sheep and goats in Asia might have been PPR outbreaks because the two diseases in these species are not easily distinguishable on clinical examination only. Cattle and pigs develop serum-neutralizing (SN) antibodies but no disease following experimental infection. Natural disease may occur in wild sheep and goats, gazelle, deer, and other small ruminants in zoos or parks, but there are no known reservoirs in domestic animals and wildlife. Phylogenetic analysis of N and F genes so far indicates that all PPRV’s isolated from wildlife ungulate outbreaks belong to lineage IV, but the role of wild ungulates in the epidemiology of PPR is still uncertain.

Camels are occasionally infected with PPRV, and the disease can be fatal. Based on clinical signs and detection of antibodies, PPR and RPVs were suspected to be involved in a highly contagious disease of Ethiopian camels in 1995. A fatal disease of camels in Sudan was investigated in 2004 and diagnosed as PPR based on positive results with the agar gel diffusion test, reverse transcription-PCR, and virus isolation in tissue culture.

Outbreaks in sheep and goats invariably occur when new stock is introduced into a farm. In West Africa, this usually takes place when Sahelian goats and sheep thought to have high innate resistance to the virus are moved southward and commingle with the dwarf breeds in the humid and subhumid tropics. Such mingles occur during seasonal migrations and during religious festivals. Market goats do harbor and can transmit the virus. The first outbreaks in Saudi Arabia were associated with the importation of sheep from Africa or the return of unsold lambs from livestock markets.

In Tanzania, the disease was first introduced to some southern villages in 2009 through newly purchased goats from a market located about 700 km away in the outskirts of Dar es Salaam city. Factors that contributed to the spread of that outbreak included communal grazing and the cheap prices of sick animals bought by livestock keepers for slaughtering in other villages. In Pakistan, at least one outbreak was traced to the introduction of PPRV-infected sheep and goats from Sindh Province (northwest) to Punjab Province (central) during the flood relief campaign of 2011.

Morbidity and Case–Fatality Rate
Infection rates in enzootic areas are generally high (above 50%) and can be up to 90% of the flock during outbreaks. The percentage of sheep and goats with antibodies rises with age. The clinical prevalence of PPR in India, as measured by analyzing clinical samples from suspected cases submitted from all over the country between 2003 and 2009, was 20% confirmed outbreaks in sheep, 38 in goats, and 11 in combined sheep and goat populations. Furthermore, PPR was diagnosed in samples from 24.5% of 592 sheep and in 38.2% of 912 goats. The disease is generally more severe in goats than in sheep and is rapidly fatal in young animals.

Case–fatality rates are also much higher in goats (55%-85%) than in sheep (less than 10%). An exception to the rule was the recent (2011) outbreak in Gabon in which the case fatality in sheep was 98.9% (91 of 92 sheep) and only 18.2% in goats (2 of 11 goats). In the Democratic Republic of the Congo, an outbreak in 2012 was reported to have killed over 75,000 goats, and there was the risk of spread to neighboring southern African countries that have not had the disease. In Kurdistan, over 750 wild goats died between August 2010 and February 2011 from PPR, but no disease was reported in domestic animals that had been routinely vaccinated. On the other hand, mortality rate ranged between 0% and 50% with a mean of 7.4% in an outbreak in camels in the Sudan in 2004.

There is no significant seasonal variation in the prevalence of the disease but because maternal antibodies are lost at about 4 months of age, the number of susceptible animals is likely to increase 3 to 4 months after peak kidding and lambing seasons. In India, there are more outbreaks during the summer and in September and October corresponding to the wet season.

Methods of Transmission
PPRV is transmitted mainly by aerosols when animals live in close contact. Large amounts of the virus are present in exhaled air and in all body excretions and secretions including feces, saliva, ocular and nasal discharges, and urine that can contaminate fomites. Diarrheic feces are especially infectious. Infection is mainly by inhalation but could also occur through the conjunctiva and oral mucosa. Goats experimentally
infected with PPRV can shed the virus a few days during the incubation period. Naturally infected goats can continue to shed virus in feces up to 1 month after vaccination and for 2 months without vaccination.

**Risk Factors and Immune Mechanisms**

Kids over 4 months and under 1 year of age are most susceptible to the disease, corresponding to waning maternal antibody from immune dams. The long-legged Sahelian breeds of sheep and goats are thought to be more resistant than the West African dwarf breeds in the humid and subhumid zones. In a particular flock, the risk of an outbreak is greatly increased when a new stock is introduced or when animals are returned unsold from livestock markets. Recovered animals have lifetime immunity.

**Experimental Reproduction**

The disease can be experimentally transmitted through close contact with an infected animal or through inoculation of infected tissues or blood. Alpine goats experimentally infected with a Moroccan strain were highly susceptible and the mortality rate approached 100%, as opposed to local breeds of sheep that were less susceptible.

**Economic Importance**

PPR is regarded as the most important disease of goats and sheep in all countries in which the disease occurs. In many of those countries, these animals are a major source of animal protein and are reared by nomadic or poor farmers. In view of the fact that the disease has spread to more African and Asian countries, it has been estimated that more than one billion sheep and goats worldwide are at risk of contracting PPR. According to the FAO estimates, the morbidity, mortality, and production losses and treatment cost of PPR altogether will be nearly $3000 million per year during 2012 to 2017 in the South Asia region. Furthermore, PPR is an important transboundary animal disease and there are concerns it could spread to Europe from Turkey and Morocco.

**Zoonotic Implication**

The virus of PPR does not affect humans.

**Biosecurity Concerns**

PPR requires close contact with an infected animal for transmission to occur. Nevertheless, because live goats and sheep are traded and may be carried over long distances, the disease can be easily introduced to a new herd or even a new country unknowingly from animals incubating PPR or showing only mild clinical signs.

**PATHOGENESIS**

The pathogenesis of the early events following experimental infection of goats with a PPRV isolate was has been recently investigated and has been comprehensively reviewed. The initial site of virus multiplication is not within epithelial cells of the respiratory mucosa, as had been previously reported for PPRV and RPV, but is within macrophages and dendritic cells and is transported to local lymph nodes for multiplication before the virus enters the circulation and causes a viremia (like the viruses of measles and canine distemper). Following viremia, the virus specifically damages epithelial cells of the alimentary and respiratory systems as well as lymphocytes in the lymphoid system. Infected cells may undergo proliferation and formation of syncytial giant cells before they undergo necrosis/apoptosis.

In goats, death may occur from severe diarrhea and dehydration, before respiratory lesions become severe, or is hastened by concurrent diseases such as pneumonia, pasteurellosis, coccidiosis, or coliform enteritis. Lymphoid necrosis is not as marked as in rinderpest, and the possibility of immunosuppression has not been properly investigated. Most sheep and some adult goats recover. Although the nasal mucosa is often affected along with the oral mucosa, lower respiratory involvement is usually a late event, occurring only in the face of high viral load, and may be absent in animals that die early from dehydration or those that recover from a mild disease.

**CLINICAL FINDINGS**

The disease can be peracute, acute, or subacute. The peracute and acute forms are seen mainly in goats and are similar to rinderpest in cattle except that severe respiratory distress is a common feature of caprine PPR. Signs generally appear 3 to 6 days after being in contact with an infected animal. A high fever (above 40°C) is accompanied by dullness, sneezing, and serous discharge from the eyes and nostrils. A day or two later, discrete necrotic lesions develop in the mouth and extend over the entire oral mucosa, forming diphtheritic plaques. There is profound halitosis and the animal is unable to eat because of a sore mouth and swollen lips. Nasal and ocular discharges become mucopurulent and the exudate dries up, matting the eyelids and partially occluding the external nares. Diarrhea develops 3 to 4 days after the onset of fever. It is profuse and feces may be mucoid and blood tinged. Dyspnea and coughing occur later, and the respiratory signs are aggravated when there is secondary bacterial pneumonia. Erosions have been described in the vulva and prepuce. Abortions have been reported during outbreaks in India. Death usually occurs within 1 week of the onset of illness and earlier in peracute cases. Subacute forms are more common in sheep but they also occur in goats. The signs and lesions are less marked and a few animals may die within 2 weeks, but most recover. Contagious ecthyma (Orf) may complicate the labial lesions or develop in surviving animals.

The clinical disease reported in camels in the Sudan was characterized by sudden death of apparently healthy animals and yellowish and later bloody diarrhea and abortion. That outbreak coincided with seasonal movement of animals toward autumn green pasture. Death was preceded with colic and difficulty in respiration.

**CLINICAL PATHOLOGY**

A leukopenia occurs but is transient and not as marked as in rinderpest. As diarrhea develops, there is a progressive hemococoncentration and low serum sodium and potassium. Diagnostic techniques used in the past were virus neutralization test (VNT), AGID, CF, counter immunoelectrophoresis (CIEP), virus isolation in cell cultures, and animal inoculation. Some are still used on a herd basis, and VNT is the prescribed test for international trade. More recently, competitive or blocking ELISAs (c-ELISAs) have been developed based on monoclonal antibodies specific for the N or H proteins of PPR and RPVs, which enable differential diagnosis of the two viruses. The efficacy of c-ELISA compares very well with the VNT for detection and titration of antibodies to PPRV in goats and sheep. Viral antigen can also be detected in buffy coat, body secretions, feces, lymph nodes, and tonsils by immunocapture ELISA, dot-ELISA methods, and by IFIC, AGID, and CIEP methods. PPR viral antigen, unlike that of rinderpest, is still high in tissues of animals dying from the disease. A rapid chromatographic strip test has also been developed for the detection of PPRV at pen side and can be used on eye swabs.

Molecular techniques for detecting PPRV genome are now the preferred methods for definitive diagnosis, lineage determination and typing of PPR outbreaks, and for epidemiologic studies. The techniques are based on the phylogenetic analysis of the N and/or F genes of PPRV by the PCR. Reverse transcription (RT)-PCR assays that target the N gene have been shown to detect all four genetic lineages of PPRV in tissues, ocular and nasal swabs, and in blood and tissue samples collected in the field. Furthermore, a rapid and sensitive real-time (rt) RT-PCR has been described that can detect PPR nucleic acid as early as 3 days and up to 20 days postinfection in swab materials from experimental animals.

**NECROPSY FINDINGS**

The carcass is severely dehydrated; the hindquarters are soiled with fluid feces; and crusts of exudate are present around eyes.
nose, and lips. Discrete or extensive areas of erosion, necrosis, and ulceration are present in the oral mucosa, pharynx, and upper esophagus and may extend to the abomasum and distal small intestine. Hemorrhagic ulceration is marked in the ileocecal region, colon, and rectum in which they may produce typical “zebra stripes.” Regional lymph nodes are enlarged and wet and the spleen may be enlarged. Severe lesions are often present throughout the respiratory tract. A mucopurulent exudate extends from the nasal opening to the larynx, whereas the trachea and bronchi may be hyperemic and contain froth caused by pulmonary congestion and edema. An interstitial pneumonia is usually present. Grossly, the pneumonia is diffuse or more commonly, anteroventral or apical. With bacterial complications, there will be purulent or fibrinous bronchopneumonia and pleuritis.

In a recent outbreak of PPR among sheep and goats in India, the common postmortem findings were congestion, red hepatization, raised patches of emphysema in the lungs, hemorrhages and frothy exudates in the intestine, enlargement and hemorrhages of the mesenteric lymph nodes. The main lesions observed during an outbreak involving camels in the Sudan were lung congestion and consolidation, paleness and fragility of the liver, enlarged lymph nodes, and congestion and hemorrhage of the small intestine and stomach.

Microscopic lesions in the alimentary tract are often very severe. In the early stages, syncytial cells are present in the oral mucosa and intracytoplasmic cosinophilic inclusion bodies in intestinal crypt epithelium. The respiratory tract shows proliferative rhinitis, bronchitis, bronchiolitis, proliferation of type II pneumocytes, and formation of huge syncytial giant cells. Intracytoplasmic and intranuclear inclusion bodies are common in these cells, and viral antigens can be detected in infected cells by immunohistochemistry. Lymphoid organs are depleted of lymphocytes but not usually as marked as in rinderpest.

For diagnostic purposes, specimens should be collected from several live animals and should include swabs of conjunctival, nasal, and buccal mucosae, as well as whole blood in anticoagulant for virus isolation and other tests. At necropsy, the following specimens should be collected for histopathology and virology, including PCR detection:
- Lungs
- Small and large intestines
- Oral mucosa
- Tonsil
- Mesenteric lymph nodes

### Differential Diagnosis

Other diseases that cause diarrhea or pneumonia in sheep and goats may pose a diagnostic challenge, but a history of recent introduction of new stock and the clinical and postmortem findings of stomatitis, enteritis, and syncytial giant cell pneumonia are typical for peste des petits ruminants. Laboratory tests are required to rule out rinderpest. Other diseases to be considered include the following:
- Heartwater
- Pneumonic pasteurellosis
- Contagious caprine pleuropneumonia in goats
- Contagious bovine pleuropneumonia
- Helminthiosis
- Coccidiosis
- Contagious ecthyma
- Possibly Nairobi sheep disease

### Treatment

#### Treatment and Control

**PPRV, peste des petits ruminants virus.**

Treatment of goats showing clinical signs of PPR is of little value and is generally not recommended. However, valuable sick animals in the early stages of the disease could be isolated and given hyperimmune serum, which may be obtained from cattle hyperimunized against rinderpest. Supportive treatment includes fluid therapy for dehydration and antibiotics to prevent secondary bacterial infections. Lesions around the eyes, nostrils, and mouth should be cleaned and good nursing provided.

### Control

The disease can be prevented by vaccination and by not introducing new stock from unknown sources, especially animals bought at livestock markets. In addition, animals returned unsold from markets should be segregated unless the entire herd or flock has been vaccinated. The TCRP was used for some years before a live-attenuated PPRV vaccine was developed following serial passages in Vero cells in the 1980s. This vaccine is now widely used for the control of PPR in Africa, the Middle East, and Asia. The homologous vaccine has the advantage that it avoids confusion with rinderpest vaccine when serologic surveys are performed. However, for the purpose of disease eradication, it is difficult to differentiate naturally infected and vaccinated animals when a live-attenuated virus vaccine has been used (the so-called DIVA concept). Furthermore, the vaccine is thermolabile and requires cold chain storage facilities, thus posing a serious problem in many developing countries. In India, a lyophilized, thermo-adapted PPR vaccine has been developed that keeps for 24 to 26 days at ambient temperature (25°C).

Kids and lambs born to immunized or exposed dams should be vaccinated at 3 to 4 months of age by which time maternal antibodies start to wane.

To fulfill the DIVA concept, recombinant vaccines from vaccinia or capripox viruses expressing the F and H protein genes of the PRRV have been used for both rinderpest and PPR control. This led to the development of similar recombinant vaccines specific for PPRV. Recently a recombinant PPRV-caneous adenovirus vaccine expressing the F and H proteins was most effective in inducing both humoral and cell-mediated immune responses in goats, and vaccinated goats maintained seroconversion for 21 weeks. The authors suggested that such recombinant vaccines might be a valuable means to differentiate infected from vaccinated animals, which is a useful tool to shorten and reduce the cost of the final eradication of PPR.

Considering the wide distribution of PPRV and its multiple target host species that have an intense mobility, PPRV eradication from the Earth will be a long process that cannot exclusively rely on mass vaccination. Its specific epidemiologic features that cannot exclusively rely on mass vaccination. Its specific epidemiologic features and socioeconomic considerations will also have to be taken into account, and sustained international, coordinated, and funded strategy based on a regional approach of PPR control will be the guarantee toward success.

Based on the experience with rinderpest eradication, it has been proposed that the following steps would be required to control PPR in India:
- Focused vaccinations in high-risk populations of sheep and goats
- Mass vaccination campaigns to achieve 70% to 89% herd immunity
- An understanding of the cultural and socioeconomic circumstances of owners
- A keen watch on the endemic nature of PPR in neighboring countries
- Coordinated efforts from all stakeholders
- Proper funding and execution of control programs
These steps might be applicable in other countries. PPR shares similarities with rinderpest in such characteristics as etiology, epidemiology, pathogenesis, and pathology; there is solid immunity following immunization or recovery from natural infection; and a good vaccine is available. There is optimism that PPR can eventually be eradicated.9,10,33 The FAO is playing a crucial role just as it did with successful rinderpest control.

BOVINE VIRAL DIARRHEA, MUCOSAL DISEASE, AND BOVINE PESTIVIRUS DISEASE COMPLEX

SYNOPSIS
Etiology Bovine viral diarrhea virus types 1 and 2 and subtypes. Noncytopathic and cytopathic biotypes. Antigenic diversity and cross-reactivity among strains of virus.

Epidemiology Worldwide occurrence with major economic importance. Prevalence of infection high in cattle population. Persistently infected calves are a major source of virus. Young and unvaccinated cattle in herd are most susceptible.

Pathogenesis Virus causes subacute infections, purulent infections, thrombocytopenia, hemorrhagic syndrome, immunosuppression, and fetal infections, which result in persistent infection until and after birth. Persistently infected cattle are immunolotent to the BVDV strain they are infected with and may develop mucosal disease.

Signs Inapparent subclinical bovine viral diarrhea, acute mucosal disease in persistently infected cattle 6–24 months of age with fever, diarrhea, oral erosions and high case–fatality rate, purpura bovine viral diarrhea in cattle of all ages including adults with severe diarrhea, fever, agalactia and rapid death within few days, thrombocytopenia and hemorrhagic disease, and reproductive failure (decreased conception rate, abortion, stillbirth, weak neonates, and congenital defects).

Clinical pathology Leukopenia, lymphopenia. Virus isolation from transiently and persistently infected animals, serology for serum neutralizing antibodies.

Diagnostic confirmation Virus isolation from blood and tissues. Antigen detection (antigen capture ELISAs and immunohistochemical tests). Polymerase chain reaction amplification of viral RNA. Viral neutralization serum antibody and ELISA tests.

Differential diagnosis list Diseases with oral erosions and diarrhea (rinderpest and bovine malignant catarrh). Diseases with oral lesions and no diarrhea (foot-and-mouth disease, vesicular stomatitis). Diseases with oral erosions and diarrhea, acute mucosal disease in persistently infected calves 6–24 months of age with fever, diarrhea, oral erosions and high case–fatality rate, purpura bovine viral diarrhea in cattle of all ages including adults with severe diarrhea, fever, agalactia and rapid death within few days, thrombocytopenia and hemorrhagic disease, and reproductive failure (decreased conception rate, abortion, stillbirth, weak neonates, and congenital defects).

ETIOLOGY
Pestiviruses are nonsegmented, enveloped, single-stranded RNA viruses with positive polarity. Phenotypic diversity, such as antigenic variation, infectivity, and replication rates, which can affect viral virulence, can be attributed to genomic reassortments, mutations, or recombinations. The viruses are classified in the virus family Flaviviridae and are members of the genus Pestivirus. Although pestivirus species are named according to the species from which they were first isolated, most pestiviruses are not host specific.1

Currently there are four recognized species of the genus Pestivirus: 1. Bovine viral diarrhea virus type 1 (BVDV-1) 2. Bovine viral diarrhea virus type 2 (BVDV-2) 3. Border disease virus of sheep (BDV) 4. Classical swine fever virus (CSFV also called hog cholera virus).

Phylogenetic analysis identified 12 subgenotypes for BVDV-1 (BVDV-1a to BVDV-1l) and two subgenotypes for BVDV-2 (BVDV-2a and b).

BVDV-2 genotypes are antigenically distinct, and some isolates cause severe disease outbreaks. Not all BVDV-2 isolates cause clinically severe disease; avirulent strains do exist. Virulent BVDV-2 strains inoculated into calves produce disease characterized by fever, diarrhea, leukopenia, lymphopenia, neutropenia, thrombocytopenia, and death. Infection with avirulent BVDV-2 strains causes leukopenia and low-grade fever.

A tentative fifth pestivirus species is represented by a single virus isolate from a giraffe termed Giraffa-1.1 In recent years a group of atypical pestiviruses, apparently forming a separate species, termed “HoBi-like pestiviruses” and of which cattle are the most likely host species, have been isolated. Since the first identification of D32/00_HoBi in 2004, more than eight other related atypical HoBi-like pestivirus strains have been isolated from FCS and from infected cattle in South America and Asia.2 HoBi-like pestivirus strains might already be circulating in cattle populations outside South America or Asia after having been introduced either with contaminated vaccines produced with infected batches of FCS or imported semen.
or embryos. Infection with HoBi-like strains in cattle has been associated with clinical signs similar to BVDV infection and persistent infection, which has led to incentives to rename the HoBi-like species BVDV-3.

Among the ruminant pestiviruses, particularly BVDV-1 and BVDV-2, there are two biotypes designated as noncytopathic (NCP) and cytopathic (CP). These biotypes are classified by their ability or lack of ability to cause overt CP change and cell death. The CP biotype does not cause cellular vacuolation and cell death. The biopsy does not make reference to the ability to cause disease in the animal because clinical disease in most cases is caused by the NCP virus strains. The two biotypes of BVDV are not distinguishable serologically. In most cases RNA recombination is responsible for the generation of the CP viruses. A second method is based on the introduction of a set of point mutations within the NS2 gene. The NCP virus is thus the “wild-type” virus predominant in the field, whereas the CP biotypes are rarely encountered in nature and are mainly associated with clinical cases of mucosal disease (MD).

Although virus strains of both biotypes can cross the placenta to invade the fetus only NCP virus strains can establish persistent infection in the fetus, which is crucial for spread of the virus. It is the cause of a wide range of congenital, enteric, and reproductive diseases. In contrast, the CP biotype of the virus is usually encountered in association with clinical cases of MD in animals already PI with the NCP biotype. Both biotypes can be isolated from animals with clinical MD, and there is evidence that the CP biotype evolves by mutation from the NCP biotype within persistently infected (PI) animals. Genomic recombination can occur in NCP viruses from either genotype resulting in CP viruses. Only NCP BVDVs cause severe acute BVD.

Cross-infection between animal species has been documented for several pestivirus species. Infections of cattle with BVDV have recently been documented under field conditions resulting not only in seroconversion but also in persistent infection of calves with BVDV and incidentally also in clinical cases resembling cases of acute BVD as well as MD. This recently recognized possibility of infection of cattle with BVDV is likely to present a challenge for the control of BVD in regions in which BVD eradication programs are in place and cattle and sheep are kept in close proximity to each other. Infections of small ruminants with BVDV-1 and BVDV-2 are common and may even be the primary pathogen causing border disease in sheep in some countries. Experimental infection of pigs with BVDV was possible and caused reproductive disease and growth retardation in piglets. Some strains of the BVDV inoculated into pigs caused false-positive reactions to tests for swine fever antibodies and may protect against subsequent challenge with CSFV. CSFV infections have only been detected in domestic pigs and wild boars thus far.

**EPIDEMIOLOGY**

**Occurrence**

Diseases associated with the BVDV have been recorded in most countries in which cattle are raised, and in some countries may be the single most important viral infection of cattle. The prevalence of infection is high, but the incidence of clinical MD is low. The BVDV causes several different diseases including the following:

- Mild BVD, which is usually subclinical
- Fatal MD, which occurs in persistently viremic animals and those specifically immunotolerant as a result of an infection acquired in early fetal life
- Peracute, highly fatal diarrhea
- Thrombocytopenia and hemorrhagic disease
- Reproductive failure
- Congenital abnormalities in calves as a result of fetal infection in midgestation
- Immunosuppression

**Prevalence of Infection**

Data of serologic surveys conducted throughout the world suggest that BVDV is endemic in the cattle population of most cattle-producing countries. The prevalence of pestivirus infection in cattle varies greatly between geographic regions and countries because of vaccination practices, population densities of cattle, and housing and management practices. Surveys conducted in North America reported animal-level seroprevalences between 40% and 90% and herd-level prevalences between 28% and 53% depending on the geographic region. In Europe animal-level seroprevalences before implementing control programs ranged from below 1% in Finland, over 19% in Sweden, 46% in Denmark, and 95% in England and Wales. In feedlot cattle in western Canada a mean animal-level seroprevalence of 27% with a range from 0% to 63% was reported.

In dairy heifers a high rate of BVDV infection has been observed between weaning and 9 months of age. The risk of BVDV infection increased from 150 to 260 days of age, which coincided with moving animals from individual calf boxes or hutches to group housing and the waning of the protection from colostral antibodies. In feedlot cattle seroepidemiological surveys revealed that animals seroconvert during the first several weeks following the arrival in the feedlot due to the presence of PI animals.

The estimated mean prevalence of PI animals in herds is about 1% to 2%. The 2007 to 2008 census of the National Animal Health Monitoring System of Beef in the United States reported an animal-level prevalence in beef cattle (determined on ear notches) of 0.12%. Within herds the prevalence of PI animals ranged between 0% and 16%. The herd-level prevalence of persistent infection was 8.8% of studied beef herds.

Congenital infection with the BVDV during late pregnancy resulting in seroconversion without persistent infection of the fetus at a rate of about 10% has been reported. These calves with congenital infection without persistent infection were found to have a twofold higher risk of a severe illness, compared with calves without congenital infection.

Over a 20-year period in the northwestern United States from 1980 to 2000, there was a shift in disease profiles associated with the BVDV infection and in the age of animal at onset of disease. In 1980 data indicated a low fetal infection rate (<5%), followed by steady increases of clinical cases and peaking at 6 months of age (30%). In contrast, by 2000 BVDV infections resulted in a biphasic occurrence of disease. The first phase was fetal infections with infection rates above 25%, followed by a second phase at 6 months of age (>35%). The changing patterns have been attributed to increased susceptibility of pregnant cattle to BVDV infection and the emergence of the new BVDV-2 species. Over a 2-year period (1998–2000) BVDV-2 isolates were most common and associated with abortion-open cows. BVDV-1a was associated least with early infection (<100 days' gestation) and most with late infections (>100 days); BVDV-1b was intermediate, followed by BVDV-2, which was associated more with early infection (45%) and less with late infections (35%) compared with BVDV 1a and 1b.

Different subtypes of bovine pestiviruses predominate in different geographic regions. Within the U.S. cattle population BVDV-1a, 1b, and 2a are the predominant subtypes. Surveys conducted on material submitted for virus isolation before 2001 reported mean percentage prevalences for BVDV-1a, 1b, and 2a in U.S. cattle herds of 21, 43, and 36%, respectively. In contrast, after 2001 the percentage prevalences of BVDV-1a and 2a decreased markedly, whereas BVDV-1b strains accounted for 75% to 100% of all samples. It was hypothesized that this shift in prevalence of BVDV strains is attributable to the effectiveness of commercial vaccines of which most are based on BVDV-1a and 2a strains. Genetic typing of bovine pestiviruses from both Northern Ireland and the Republic of Ireland revealed BVDV-1a as the most prevalent strain, whereas most strains in England and Wales are BVDV-1b.

**Other Ruminant Species**

Pestivirus-associated infection, disease, or both have been described in a wide range of ruminant and other animal species such as cattle, sheep, goats, pigs, bison, alpacas,
llamas, and several captive and free-living ruminant species. Serologic surveys indicate that many species of free-living ruminants in North America, Europe, and Africa such as antelope, giraffe, buffalo, bison, chamois, bighorn sheep, mountain goat, Old World camels, and various cervidae were exposed to pestivirus with prevalences rates varying by ruminant species and geographic region between below 1% and above 13%. Antibodies against BVDV were found in 31% of free-ranging American bison but less than 1% of European bison. The role of pestiviruses as a causative agent for disease in wild ruminants is unknown, and outbreaks of disease are recorded only occasionally and usually as single fatal cases. The clinical and pathologic findings in some animals are similar to those of MD in cattle.

Although New World camels historically were thought to be largely resistant to pestivirus infection, cases of clinical disease and persistent infection in association with specific bovine pestivirus strains have been documented more recently. Pestivirus infection in llamas and alpacas has been associated with early pregnancy loss, abortion, premature birth, congenital malformations, and persistent infection. Surveys conducted in the United States revealed animal-level prevalences ranging between 0.9% and 11.5%. A census conducted among 63 alpaca herds revealed a herd seroprevalence of 25.4% with 6.3% of all herds having PI cria. The pestivirus strains predominantly isolated in New World Camels were BVDV-1a and b and BVDV-2. Pestiviruses have also been associated with outbreaks of disease among captive ruminants in zoologic collections.

Border disease in sheep and goats can be caused by three of the four currently recognized species of pestivirus: BDV, BVDV-1, and BVDV-2. The importance of exchange of pestivirus from PI cattle to sheep appears to vary by country. In Norway and Sweden border disease was found to be caused exclusively by BVDV-1, whereas BDV and BVDV-1 were isolated in cases of border disease in the UK. In the United States all three species, BDV, BVDV-1, and BVD-2, were found in sheep.

**Morbidity and Case–Fatality Rates**

MD in PI immunotolerant seronegative animals occurs in all classes of cattle mostly between 6 and 24 months of age, rarely in calves as young as 4 months of age, or cattle older than 2 years of age. The incidence of MD in a herd is usually less than 5% of the animals up to 2 years of age. Occasionally, epidemics have been observed in which up to 25% or more of the animals of the most commonly affected age group will develop MD.

Outbreaks of the more recently recognized peracute BVD occur in immunocompetent non-PI animals, which are characterized by a high case rate among all clinically affected animals. Morbidity rates may reach 40% and population mortality rates 20%. Herd outbreaks of acute disease associated with BVDV inveal calves caused population mortality rates ranging between herds from 10% to 25%.

**Methods of Transmission**

The major source of infection is the PI viremic animal. The virus can be isolated from nasal discharge, saliva, semen, feces, urine, tears, and milk, each of which would allow wide dissemination of the virus.

**Direct Contact**

The virus is transmitted by direct contact between animals and by transplacental transmission to the fetus. Discharges from the reproductive tract of an infected cow, whether PI or systemically immune, including aborted fetuses, can be potent sources of the virus. Nose-to-nose contact is an effective method of transmitting the virus from PI to susceptible animals. Thus PI animals may introduce the infection into a herd; or when infected animals are mixed with susceptible animals at the time of breeding; or under conditions requiring emergency movement because of drought, flood, or fire. The accidental mixing of a PI bull with susceptible breeding females during the breeding season in a beef herd may result in a major herd outbreak of MD.

Transmission of the virus between healthy immunocompetent animals is probably insignificant because they produce antibodies and eliminate the virus. However, the spread of transmission from transiently viremic cattle to seronegative animals in a dairy herd is slow. Primary infected animals are not effective transmitters of the virus. Susceptible animals introduced into a herd, typically heifers, become infected by contact with persistently viremic animals, and major economic losses can occur if they are at a vulnerable stage of pregnancy. The introduction of an unknown PI cow or heifer into a susceptible herd can also cause major economic losses.

The fetuses can be infected by transplacental transmission of the virus from the infected dam, whether the dam is transiently or PI. Fetal infection has been produced by inoculation of nonimmune pregnant dams. Epidemics of abortion and congenital defects of calves have occurred when transplacental virus infection of the fetuses of cows in the first trimester, in previously virus-free herds, has followed the introduction of BVDV-infected animals.

PI females can remain clinically normal for several years, during which time they may breed successfully and their progeny may be apparently normal but are invariably also PI. In this way a maternal viremic family can be established that can persist for several generations and provides one of the major mechanisms for maintenance of the virus as endemic in the herd.

**Indirect Contact**

**Airborne Transmission**

Indirect airborne transmission of the virus can occur in calves housed near a PI calf, without having direct contact. Infection can also occur in calves housed in a pen directly after removal of a PI calf, but without the pen being cleaned and disinfected.

**Flies**

The virus has been experimentally transmitted by allowing blood-feeding flies to feed on a PI animal followed by feeding on BVDV-free seronegative recipients. The virus was isolated from some of the flies and from the recipient animals, which also seroconverted.

**Fomites**

BVDV has been transmitted from a PI animal to susceptible heifers that were examined per rectum using the same glove. Reusing a hypodermic needle on susceptible animals shortly after the needle had been used on a PI animal or reusing a nose tong shortly after it had been used on a PI animal could also transmit the infection. The virus can be spread by hypodermic needles used on vaccine bottles contaminated by the nasal discharge of PI calves.

**Artificial Insemination/Embryo Transfer**

BVDV can be associated with semen, oocytes, oviducal cells, cumulus cells, follicular fluid, or semen used in media for flushing the uterus. The virus survives cryopreservation in liquid nitrogen. BVDV was isolated from semen of transiently and PI bulls without necessarily affecting semen quality. Specifically PI bulls shed large amounts of virus in semen and seronegative cows consistently seroconvert following natural or artificial breeding with semen from a PI bull. In many cases cows conceived and clinically healthy calves were born. Once the infection is established in such a herd there is the potential for its amplification through a secondary cycle of transmission from heifers that were infected from the semen. In transiently infected bulls the virus can persist in the semen for several months after experimental exposure. There is also a record of a postpubertal bull in an artificial insemination unit that was shedding the virus in semen over a period of 11 months while not demonstrating any evidence of viremia but with a high level of serum antibodies. The virus could not be isolated from numerous blood samples and somatic organ tissues, but at necropsy the virus was sequenced in the testes. It was hypothesized that infection occurred shortly before the blood–testes barrier became fully functional, thus allowing the virus to enter the seminiferous
tubes but excluding the ensuing high levels of antibody from the site.

Oocytes or embryos obtained from transiently or PI donor cows can be contaminated with BVDV virus through infected cumulus cells, follicular fluid, oviductal cells, or uterine fluid. Transfer of embryos of a transiently or PI dam thus presents a risk of infection for the recipient. Several studies showed that transfer of embryos from PI donors can produce clinically normal BVDV-free calves.13

Vaccines Contaminated With Bovine Viral Diarrhea Virus

Because of the widespread use of fetal calf serum (FCS) in the production process of animal cell lines that, among others, are required for vaccine production, contamination of fetal serum with adventitious viruses presents a serious risk. With an estimated prevalence of 1% to 2% of persistent infection in bovine fetuses, BVDV is the most common contaminant of bovine fetal serum. FCS contaminated with BVDV presents a major risk for the production process of modified live vaccines produced for species susceptible to pestivirus infection such as ruminants and pigs.15 Batches of FCS must undergo a series of tests for the presence of viral contaminants. Contaminated batches are generally not discarded but are subject to an inactivation treatment according to validated methods. Application of a modified live infectious bovine rhinotracheitis (IBR) vaccine contaminated with NCP BVDV-2 to cattle has led to outbreaks of BVDV in the past.16

Risk Factors

Host Risk Factors

Host factors that influence the clinical outcome of BVDV infection include the following:

- Immune status of the host
- Immunocompetent or immunotolerant (PI) to the virus
- If immunocompetent passive immunity (colostal antibodies) or active immunity (previous infection or vaccination)
- Age of the animal
- Pregnancy status
- Gestational age of the fetus
- Presence of stressors
- Presence of concurrent infection

Generally, young cattle are most susceptible to BVDV infection, but adult cattle may develop severe disease if infected with a highly virulent virus strain. Persistent infection can be established only during approximately the first half of fetal life. Compared with many other pathogens, fetal survival following early intrauterine infection with NCP BVDV is common and can be as high as 70%. Unvaccinated animals, improperly vaccinated animals, or animals whose immune status has waned are most susceptible to infection and the potential for clinical disease. Vaccinated animals may be susceptible if field isolates of the virus are distinct from those used in the vaccine. PI animals are susceptible to the development of MD following superinfection with the homologous CP virus strain. They are also susceptible to other infectious diseases such as pneumonia. Genetic diversity among isolates may account for differences in the clinical response to infection.

Environmental and Management Risk Factors

The major management risk factors are the introduction of PI animals into a susceptible herd and the failure of a vaccination program or an inadequate vaccination program. In the recent outbreaks of severe disease in cattle herds in Ontario and Quebec, failure to vaccinate or failure to use the vaccine properly was a common historical finding.

Pathogen Risk Factors

BVDV isolates vary genomically, antigenically, and biotypically. These pathogen characteristics are important in the pathogenesis of the different clinical presentation of BVDV infection, the virulence of different virus isolates and the host’s immune response to different virus isolates, and the laboratory diagnosis.

The genetic diversity among isolates of BVDV is the result of the high frequency of mutation, which is characteristic for single-stranded RNA viruses, the propensity for recombination, and the selective pressure from immune responses stimulated by natural infection or vaccination. The consequences of diversity include diversity of clinical disease, diagnostic difficulties, and vaccination failures.

Different isolates that are antigenically related are immunologically distinct. Differences in neutralizing antibody titers against specific isolates of BVDV are detectable in polyclonal serum from convalescent cattle. Monoclonal antibodies that have neutralizing activity differentiate BVD viruses into several groups. The antigenic variability of this virus may also explain the wide range of lesions and disease complexes that have been observed. The practical consequences of antigenic diversity are that neither natural infection nor vaccination can provide complete protection against most of the naturally occurring strains. There is also considerable cross-reactivity between isolates of the virus, which explains why poorly vaccinated animals have considerable immunity.

Genotypes of pestiviruses known to be able to infect cattle under field conditions are BVDV-1, BVDV-2, BDV, and the HoBi-like genotype. Whereas BVDV-1 is most often associated with subclinical or mild clinical disease, BVDV-2 isolates are more often isolated from severe clinical cases. Experimentally, BVDV-2 induces the highest degree of viremia and more pronounced lesions and more extensive distribution of viral antigen compared with BVDV-1, which induced the lowest degree of viremia. In the late 1980s and early 1990s in the northeastern United States, Ontario, and Quebec, virulent BVD virus strains emerged that caused severe acute disease in both calves and adult cattle. The majority of viral isolates were NCP and were typed BVDV-2. Thrombocytopenia and hemorrhagic disease associated with NCP BVDV has been recognized in adult dairy cattle and weaned beef calves. The disease occurred in veal calves in the same geographic area. In addition, highly virulent BVDV are causing severe diarrhea and death in adult cattle with clinical findings and lesions similar to those of acute MD. There are now reports of severe illness resembling acute MD in adult cattle in Great Britain, Germany, and other parts of Central Europe attributed to infections with NCP BVDV-2. Only NCP BVDV has been isolated from these animals. All of the available evidence suggests that these animals are immunocompetent and not PI. Infection of cattle with BVDV has recently been reported resulting in persistent infection, and incidentally clinical disease has recently been recognized. Infections with virus strains of the HoBi-like genotype under field conditions have been documented and were associated with the development of persistent infection.

Immune Mechanisms

Transient immunosuppression occurs in acutely infected animals. The virus infects cells of the innate immune system affecting the function of neutrophils, monocytes, macrophages, and dendritic cells. Neutrophils are impaired in microbicidal, chemotactic, and antibody-dependent cell-mediated cytotoxicity.

In vitro or in vivo infection with BVDV, either CP or NCP biotype, depresses various aspects of macrophage function that can adversely affect normal defense mechanisms of the lung, facilitating bacterial colonization. In the acquired or adaptive immune response, BVDV infections have their major effect on thymic and follicular T lymphocytes. The effect on the number of circulating T lymphocytes is strain dependent and varies from a mild to severe lymphopenia with highly virulent strains. The virus also affects T-helper lymphocyte and cytotoxic T-lymphocyte responses. BVDV infections have their major effect on follicular B lymphocytes. The effect on the number of circulating B lymphocytes varies, but depletion of B cells occurs in the lymphoid follicles of the lymph nodes with highly virulent NCP BVDV and in Peyer’s patches with both MD and highly virulent BVDV infections.

There are four major structural antigenic polypeptides. Glycoprotein E2 is the major glycoprotein and antigenic target for antibodies. E2 is highly antigenic and elicits the
production of neutralizing antibodies in the host after infection or vaccination with modified-live (MLV) or inactivated vaccines. The ability of BVDV antibodies to protect against BVDV infection and the development of long-term virus infection is dependent on the virus strain and the level and isotype of antibodies produced. BVDV antibodies are indicators of the presence of a particular immune response rather than an indicator of a protective immune response. High levels of neutralizing antibodies prevent disease following homologous challenge. However, animals with neutralizing antibodies may develop viremia. Shedding of the virus in nasal secretions may occur in the presence of SN antibodies.

In vitro cross-protection studies with serum from cattle vaccinated with either MLV or inactivated vaccine demonstrated wide cross-neutralization against 12 to 22 different BVDV strains, although this extensive cross-neutralization was not entirely reproducible in vivo in field studies.

The immune response in the calf is influenced by two factors: the development of active immunity and the decay of maternal or passive immunity. Young calves at 10 to 14 days of age seronegative to BVDV can develop a protective immune response following vaccination with MLV vaccine. However, the presence of maternal antibody in calves interfered with the immune response and the animals were not protected from a challenge 4.5 months later. A predictive study estimated that calves must be 142 days of age to become seronegative for BVDV-1 antibodies and 114 days for BVDV-2 antibodies. Pregnant heifers carrying PI calves develop BVDV antibody titers 5 to 10 times higher than heifers carrying non-PI calves. The inability of NCP BVDV to induce IFN-α in the fetus is one of the major immune evasion mechanisms that allow BVDV to establish persistent infection. The major mechanism for persistence is tolerance of the CD4+ cells. The specificity is very high, because PI animals can respond to homologous virus changes as small as a single amino acid. This explains why some PI animals can develop an antibody response to the homologous virus from the multiple BVDV subtypes. Experimental infection of PI animals with antigenically related CP BVDV resulted in 50% developing MD. Those that did not develop MD had higher levels of circulating gamma-delta T cells before the challenge with CP BVDV.

Following natural infection of seronegative immunocompetent cattle with most of the strains of BVDV that do not cause severe disease, there is a transient viremia; SN antibodies develop within 2 to 3 weeks, peak at 8 to 10 weeks, and remain detectable for many months. The humoral immune response after natural BVDV infection in cattle is considered to be lifelong and includes antibodies to a range of virus-encoded proteins, including the immunodominant surface glycoprotein gp53 and the highly immunogenic, nonstructural, catalytic serine protease NS2-3. Experimentally and naturally infected animals may have moderate to high levels of SN antibodies to the virus for 3 years after being infected.

The high percentage of animals that are seropositive in the cattle population or in herds that have experienced the disease is due to the presence of PI animals in the herd. Vaccination of immunocompetent cattle with the live virus vaccines induces a broad-spectrum and durable immunity. It is generally accepted that cattle respond to natural infections or vaccination with MLV vaccines with a long-lasting immunity, and it is likely that the immune response includes cell-mediated immunity. Immunization with an inactivated virus vaccine may result in an only short-lived immunity with a narrow antigenic spectrum. Existence of neutralizing antibodies is generally considered to be the most significant predictor of an effective immune response. The presence of neutralizing antibodies in breeding females will protect the fetus against BVDV infection during pregnancy. Passively acquired antibodies, usually IgG, protect against nasopharyngeal shedding of the virus and reduce viremia in challenge-inoculated calves. There is considerable antigenic variation among strains of the virus, but there is also considerable cross-protection against heterotypic strains of the virus.

Colostral antibodies in calves are detectable at least until 4 to 6 months of age depending on the initial level achieved after the ingestion of colostrum. The half-life of the antibody is 21 days in normal calves, but in PI calves antibodies decline more rapidly and by 4 to 8 weeks no antibodies may be detectable. About 50% of calves become seronegative for BVDV-2 by 114 days of age. Rate of antibody decay was significantly associated with antibody titer at 1 to 3 days of age and whether calves were congenitally infected with the virus.

PI calves are infected during early fetal life and are born seronegative and immunotolerant to the specific strain of virus in their tissues. Most PI calves remain seronegative to a specific virus but will respond immunologically to other pathogens.

**Economic Importance**

BVDV infections are considered one of the economically most important viral infections affecting the dairy and beef industry. Although economic losses are to a large part attributed to increased incidence of reproductive disorders, BVDV infections are known to result in significant production losses originating from impaired calf health, increased risk of infectious disease in adult cattle, decreased milk production, growth retardation in sick non-PI and PI animals, premature voluntary culling, and mortality losses. Reproductive losses are primarily associated with abortion, congenital defects, stillbirths, increased neonatal mortality, increased occurrence of other infectious diseases, prenatal and postnatal growth retardation, and suboptimal reproductive performance caused by infertility.

Economic losses caused by BVDV infection on a herd level vary depending on the immune status of the population and the pathogenicity of the infecting virus strains. Introduction of the infection into a totally susceptible population invariably causes extensive losses until a state of equilibrium is reached. Infection with highly virulent strains causes severe clinical disease and death. The magnitude of the losses in an infected herd may be expected to fluctuate. They may be relatively large with the occurrence of disease on an epidemic scale after initial horizontal transmission to nonmune pregnant cows, but they may be considerably lower when endemic infection is maintained in the herd through the presence of viremic families. However, a further phase of high losses may occur should management allow heifers to reach breeding age without being exposed to infection or vaccinated.

Calculation of the losses associated with BVD outbreaks in dairy herds vary widely. Estimates of losses at herd level are often based on case history of “classical” BVD outbreaks in which most infections occur without clinical signs and in which losses mainly are associated with reproductive disorders and persistent infection. These were estimated to range between €21 and €135 per cow in the herd.17 Outbreaks associated to more virulent BVDV strains causing severe clinical disease have been estimated to be above €340 per animal in the herd.17 Estimates on a national level from the UK, Norway, and Denmark under endemic conditions range between €8.5 and €34 per calving for the classical BVD infection and €48 per calving for BVD infections associated with highly virulent virus strains.17

**PATHOGENESIS**

Pathogenesis depends on multiple interactive factors. The consequences of infection with the BVDV are divided into the following categories based on the status of the animal. There is a spectrum of clinical responses based on the host factors and the virulence of the isolates involved.

**Immunocompetent Nonpregnant Cattle**

**Subclinical Bovine Viral Diarrhea**

This is a subacute infection in seronegative, immunocompetent cattle usually under colostral immunity has waned; it occurs in both sexes and any class of cattle. It is usually a clinically unrecognized infection with the development of SN antibodies
and elimination of the virus from normal immunocompetent animals. This accounts for the high percentage of normal animals that are serologically positive to the virus. A mild transient clinical disease characterized by inappetence for a few days, depression, fever, mild diarrhea, transient leukopenia, and recovery in a few days may occasionally occur.

In some cases, outbreaks of diarrhea occur in animals ranging from 6 months to 1 year of age, characterized by high morbidity and low or no mortality. The most likely source of infection is PI animals in the herd.

**Peracute Bovine Viral Diarrhea**

In the late 1980s and early 1990s, a peracute form of the enteric form of the disease and thrombocytopenia in young and adult immunocompetent animals infected with highly virulent BVDV-2 strains were recognized. Outbreaks were most common in dairy herds with inadequate vaccination programs and that recently introduced animals into the herd.

**Thrombocytopenia and Hemorrhagic Syndrome**

Thrombocytopenia and the hemorrhagic syndrome occurs in adult cattle andveal calves affected with the peracute form of BVDV infection. Platelet counts are reduced to below 25,000 cells/µL, and clinically there are bloody diarrhea, petechial and ecchymotic hemorrhages of the sclera of the eyes, epistaxis, and abnormal bleeding from injection sites. Hyphema may also occur. Thrombocytopenia caused by destruction of platelets has been reproduced experimentally in young calves by inoculation with NCP. BVDV-2 strains, which are the strains most commonly associated with the hemorrhagic syndrome. Experimentally, altered platelet function occurs in calves infected with BVDV-2 but not with BVDV-1 isolates. The important virulence characteristics are duration of neutropenia, severity of thrombocytopenia, delayed increase in proliferating myeloid cells, and the presence of virus in bone marrow precursor cells. Infection of bone marrow megakaryocyte myeloid cells may also be involved. The hypervirulent BVDV-2 genotype induces severe thrombocytopenia, profuse diarrhea, and pneumonia in all experimentally infected calves, whereas none of the BVDV-1 isolates tested induced significant pathologic signs, even though they were isolated from cases of hemorrhagic syndrome. It is suggested that induction of sporadic hemorrhagic syndrome by BVDV-1 requires the presence of other cofactors.

Osteopetrosis, anemia, thrombocytopenia, and bone marrow necrosis can occur in beef calves naturally infected with BVDV-2 strains. Experimental infection of calves with the NCP virus causes thrombocytopenia, whereas CP virus did not.

**Diarrhea of Neonatal Calves**

The causative role of BVDV for diarrhea in neonatal calves is uncertain. Naturally occurring cases of acute neonatal diarrhea caused by infection with the virus in immunocompetent calves under 6 weeks of age have been reported only rarely. PI calves may be unthrifty and be affected with chronic diarrhea and pneumonia as young calves. However, if the virus causes diarrhea in calves the pathogenesis is not clear. Immunocompetent dams provide colostal immunity to their calves, which should have a protective effect during the first months of life. Fetal enteritis has been reproduced experimentally by infecting colostrum-fed and colostrom-deprived neonatal calves with the virus. In older colostrom-fed calves, experimental infection resulted in mild disease with rapid recovery. Experimentally, calves from 7 to 50 days of age with colostral virus neutralizing antibody titers below 1:256 or lower developed a fever and systemic spread of the virus when challenged with the virus. Calves with titers below 1:16 developed severe clinical disease characterized by fever, leukopenia, thrombocytopenia, and diarrhea. The severity and duration of clinical signs decreased as titers of passively acquired viral neutralizing antibody increased. Although antibodies against BVDV are generally widely cross-reactive, maternal antibodies may not protect the calf against all circulating BVD virus strains.

**Meningoencephalitis**

BVDV-2 strain has been isolated from the brain tissue of a 15-month-old heifer with neurologic clinical findings and pathologic lesions. Severe fibrinopurulent bronchopneumonia and pleuritis involving 40% to 75% of lung volume developed in calves experimentally inoculated sequentially with the BVDV and *M. haemolytica*. However, it is also possible that the virus may be coincidentally present in some animals and have no adverse effect. Field observations suggest that following the introduction of BVDV infection into a susceptible herd, there may be an increased incidence of viral and bacterial pneumonia in the calves, which may continue for up to 2 years.

**Immunosuppression**

An immunosuppressive effect of BVDV infection is widely accepted, but the underlying mechanisms, the duration, the extent of recovery, and possibly ensuing long-term effects are not entirely understood. BVDV infections with either biotype have been associated with lymphopenia and impaired function of the cells associated with the innate and acquired immune system. A decreased number of circulating lymphocytes can be the result of increased chemotaxis, impaired leukogenesis, or increased cell death. The large number of apoptotic and necrotic lymphocytes observed in infected animals suggests that cell death is a major contributing factor to this effect. Along with a decrease in the number of circulating lymphocytes, BVDV infection also causes depletion of lymphoid tissue such as lymph nodes and Peyer’s patches which further contributes to the immunosuppressive effect of BVDV. In addition to reducing lymphoid cell numbers, infection with BVDV hampers the function of immune cells by suppressing phagocytosis, IFN production, chemotaxis, and microbial killing.

**In Vivo Evidence of Immunosuppression**

Primary postnatal infections cause a transient reduction in the absolute number of T lymphocytes and B lymphocytes and in the percentage of T lymphocytes. The evidence incriminating the virus as a predisposing pathogen in naturally occurring cases of bovine respiratory disease is largely circumstantial. The presence of the virus in the respiratory tract tissues of cattle affected with pneumonia is difficult to interpret. Several different viruses have been incriminated in the cause of acute bovine respiratory disease but experimental evidence to support their involvement has centered on the IBR and PI-3 viruses.

In outbreaks of respiratory disease in calves and adult cattle associated with multiple viral infections, the BVDV is often the most frequent viral agent. This could indicate that the virus is an important contributory pathogen in respiratory disease of cattle.

Experimentally BVDV can facilitate the colonization of *Mannheimia haemolytica* in the lungs, resulting in severe pulmonary lesions. Severe fibrinopulent bronchopneumonia and pleuritis involving 40% to 75% of lung volume developed in calves experimentally inoculated sequentially with the BVDV and *M. haemolytica*. However, it is also possible that the virus may be coincidentally present in some animals and have no adverse effect. Field observations suggest that following the introduction of BVDV infection into a susceptible herd, there may be an increased incidence of viral and bacterial pneumonia in the calves, which may continue for up to 2 years.

**Bovine Viral Diarrhea Virus in the Feedlot**

There is epidemiologic evidence that BVDV may be one of the most economically important infectious pathogens of feedlot cattle. The immunosuppressive potential of the virus or its synergistic effects with other pathogens are considered to be associated with bovine respiratory disease in feedlot cattle. Individual, unknown PI animals that are purchased and introduced into the feedlot serve as reservoirs of the virus for naive cattle that are subsequently comingle in the feedlot. BVDV has been incriminated in bovine respiratory disease in feedlot cattle from which pathogens such as *M. haemolytica*, *M. bovis*, *Histophilus somni*, and IBR virus, have been isolated from lung lesions.

There is considerable seroepidemiological evidence that the BVDV titers of feedlot cattle on arrival are associated with subsequent respiratory disease. Cattle arriving with a titer were at decreased risk of respiratory disease; those cattle that seroconverted after arrival were associated with increased
risk of disease. Seroepidemiological studies of undifferentiated fever in recently weaned beef calves arriving in the feedlot indicate that animals arriving with a higher BVDV antibody titer were associated with a decreased risk of undifferentiated fever compared with those with lower levels on arrival. The risk of initial treatment for respiratory disease was 43% greater in cattle exposed to a PI animal compared with those not exposed to PI animals. Overall, 15.9% of initial respiratory tract disease events were attributable to exposure to a PI animal.

Primary BVDV infections occur in feedlot cattle that are not PI and may be the inapparent or subclinical form or the peracute form of the disease. The thrombocytopenic form of BVDV infection has also been described in feedlot cattle.

Ovarian Dysfunction
Ovarian dynamics may be changed in cattle infected with BVDV. Ova exposed to the virus in vitro can have virus particles attached to the zona pellucida, but the intact zona pellucida protects the developing embryonic cells from infection. However, following removal of the zona pellucida, CP BVDV may have detrimental effects on survivability of blastocysts. Bovine follicular cells and oocytes are permissive to BVDV at all stages of follicular development, and there may be a transient fall in estradiol secretion following acute infection. Both of these may reduce fertility. Infection during the critical period of growth of preovulatory follicles causes varying degrees of necrosis of the granulosa cells, which can result in a spectrum of ovarian dysfunction including retarded follicular growth, delayed ovulation, and anovulation. Return to ovarian function following BVDV infection may take several months in some cases.

Immunocompetent Pregnant Cattle and Fetal Infections
Both biotypes of the BVDV can cause significant early reproductive loss in nonimmune pregnant cattle including fertilization failure, embryonic mortality, and abortion. In addition, infection of the fetus with an NCP strain of the virus between 42 and 125 days' gestation may result in PI fetuses, which are carried to term and the calf may be born alive and thrive normally or be unthrifty.

The experimental and clinical observations of the effects of the virus on early parts of the reproductive cycle are conflicting. The virus can be transmitted by natural service or artificial insemination with the possibility of fertilization failure or early embryonic mortality, which in turn leads to repeat breeding. The principal determinant of the outcome of in utero infection in cattle is the age of the conceptus and fetus when infection occurs. The BVDV can cause reproductive failure in susceptible cattle during the following stages of the reproductive cycle:

1. **Infection before insemination.** Exposure of cattle to the virus during the estrus cycle before insemination can result in a decrease in conception rate caused by failure of ovulation or delayed ovulation. BVDV has been associated with ovarian in fertile heifers. PI cows may have morphologic changes in their ovaries, suggesting a reduction in normal ovarian activities. It is not known if similar findings occur in cows acutely infected with the virus.

2. **Insemination of cattle with semen containing bovine pestivirus.** The insemination of seronegative and virus-free heifers with semen containing viable BVDV can result in poor conception rates initially, followed by normal conception following seroconversion to the virus, and the birth of normal calves with no evidence of intrauterine infection. Experimentally, the intrauterine infusion of the virus into cattle at the time of insemination has prevented conception and has been attributed to prevention of fertilization or simply recognized as an empty uterus at 5 weeks after breeding. It seems that intrauterine infection at the time of breeding may have some effects on the very early stages of reproduction, in addition to those that could be attributed to infection by other contact routes. Infection of susceptible cows either 9 days before or soon after insemination can result in a marked reduction in conception rates and significant embryo–fetal loss.

The BVDV can be present in the semen of bulls because of a persistent or transient infection of the bull. The semen of a PI bull may be normal, and the pregnancy rates of heifers bred by him may be normal. In other situations the quality of the semen of PI bulls may be abnormal. Acute infection of immunocompetent BVDV seronegative bulls with the virus can result in transient shedding of the virus in semen and to a marked deterioration of semen quality. The amount of virus in the semen of acutely infected bulls is much less than that found in the semen of PI bulls. Experimental acute infection of bulls with the BVDV can result in shedding of the virus in raw, unprocessed, and diluted and extended semen during and after the end of the period of viremia. The most productive sites of virus replication are in the seminal vesicles and prostate gland.

3. **Infection during embryonic period: 0 to 45 days’ gestation.** Natural BVDV infection of seronegative heifers 4 days after insemination results in viremia between 8 and 17 days and a decrease in conception rate and pregnancy rate compared with uninfected heifers.

Infected heifers that fail to conceive return to estrus approximately 20 days later. Experimentally there is no indication of impairment of in vitro development of bovine embryos when they are exposed to the BVDV. The zona pellucida appears to prevent the virus from gaining access to the embryonic cells.

4. **Infection during late embryonic–early fetal period: 45 to 125 days’ gestation.** Following the infection of a nonimmune pregnant animal, both biotypes of the virus are capable of crossing the placental barrier and invading the fetus. In experimental infection of pregnant heifers with an NCP strain of the virus at 85 days’ gestation, fetal infection can occur 14 days postinfection without preceding or simultaneous high concentration of the virus in the uterus or placenta. This supports the proposition that the passage of virus can occur via the vasculature and not via local cell-to-cell spread and that fetal infection can occur in the absence of significant levels of virus in the placenta.

Fetal infection can result in a wide spectrum of abnormalities from death of the fetus to congenital defects, to a persistent infection of the fetus until term and birth of a calf with lifelong infection without clinical signs. The results are mainly dependent on the stage of fetal development at which infection takes place. Generally, the risk for the fetus is highest during early pregnancy. Infection of the fetus from 50 to 100 days’ gestation may result in fetal death and expulsion of the fetus (abortion) from days to several months after fetal infection or mummification. However, fetal survival following infection is common and can be as high as 70%.

**Persistent Viremia. One of the most important effects of BVDV infections of the fetus is the development of PI animals. If a fetus survives infection with an NCP isolate of the virus occurring approximately between 45 and 125 days’ gestation, it will become immunotolerant to the specific virus strain and not develop virus-neutralizing antibodies. The fetus may be carried normally to term, in which case it will invariably be born with a PI. MD occurs in a proportion of these, and only in these, PI animals. From birth to the time of clinical disease, which usually occurs between 6 and 24 months of age, and rarely up to 3 years of age, these animals are persistently viremic and specifically immunotolerant to the homologous strain of the persisting virus. They may appear clinically normal or unthrifty and small for their age. Occasionally, PI cattle may survive and
remain healthy for up to 5 years during which time they shed the virus in their mucous secretions and may be seropositive to a range of BVDV strains, including their own persisting strain. PI animals are infected only with the NCP biotype of the virus, and they excrete large quantities of the virus into the environment and serve as the major source of the NCP virus in a herd. MD was first recognized in 1946 and for the following 35 years it was assumed that the disease was the result of an infection before the onset of illness. It is now clear that MD occurs only in PI animals as a result of a congenital infection with an NCP strain of the virus acquired in early fetal life.

Animals that are immunotolerant to the BVDV are immunocompetent to other antigens. They will also produce SN antibody titers, following the administration of commercial MLV-BVDV vaccine and against the vaccine virus as well as other laboratory strains. Furthermore, in spite of this antibody formation, the original virus will persist.

Spontaneous insulin-dependent diabetes mellitus associated with persistent BVDV infection in young cattle has been described. Lesions were present in the pancreatic islet cells. Calves with either transient or persistent infections with BVDV have lower than normal serum concentrations of thyroid hormones which may be associated with the retarded growth.

5. Infection during fetal period: 125 to 175 days’ gestation. Transplacental infection of the fetus approximately between 125 and 175 days’ gestation can result in numerous congenital defects. This period of development corresponds to the final stages of organogenesis of the nervous system and the development of the fetal immune system, which can result in the generation of an inflammatory response to the virus. Congenital abnormalities of the central nervous system along with ocular abnormalities are most common. Other congenital defects include thymic hypoplasia, hypotrichosis, alopecia, curly hair coat, hyena disease, deranged osteogenesis, mandibular brachygathism, and growth retardation.

6. Infection during fetal period between 180 days’ gestation and term. Infection of the fetus with BVDV after approximately 150 days’ gestation results in a fully competent immune response and elimination of the virus. At birth, the fetus has antibody to the virus but is virus free. The effects of late-gestation infections are not well documented, but abortions, stillbirths, and weak calves are reported.

### Immunotolerant Persistently Infected Cattle

During the postnatal period, superinfection of PI animals with a CP biotype of the homologous BVDV strain may precipitate fatal clinical MD. Following the experimental production of MD, the CP biotype of the virus can be found in lesions of the lymphoid tissue of the small and large intestines, in Peyer’s patches, in intramural ganglia, and in duodenal glands. Severe tissue damage is also related to the presence of the CP virus. Both biotypes of the virus are present in animals that develop fatal MD.

It is assumed that superinfection with the CP virus strain occurs following a mutation of the NCP virus to the CP biotype within the animal rather than the introduction of a CP virus from outside. Once a homologous CP virus has arisen, it can quickly spread to other PI animals within the same group, and this may explain the rapid development of an outbreak of fatal MD. Recombination between an NCP BVDV-1 virus and a CP BVDV-1 vaccine virus causing MD 3 months after vaccination, a condition termed post-vaccinal MD, has been described but is probably rare.

Typical MD occurs within 2 to 3 weeks following development of the antigenically homologous CP virus in the PI animal. The affected cattle do not respond serologically to the homologous CP virus. Superinfection with an antigenically heterologous CP virus does not result in typical, but rather atypical, MD several months later, or not at all, and infected animals respond serologically to the heterologous CP virus.

The pathogenesis of the lesions of MD remains obscure. The viral antigen can be detected in many tissues including the following:

- Lymph nodes
- Peyer’s patches
- Illeum and lymphoid tissue in the proximal colon
- Palatine tonsils
- Spleen
- Bronchiolar epithelial cells
- Crypts of the intestinal mucosa
- Salivary glands
- Tongue
- Esophagus
- Skin

The pathologic changes that characterize the disease involve the integument and the epithelia of the respiratory and alimentary tracts as well as lymphoid tissues.

The basic lesion is a small vesicle ulcer that affects only epithelial cells. The erosions occur throughout the following:

- Oral cavity
- Esophagus
- Foregutmachs
- Abomasum
- Small intestine
- Cecum
- Colon

Vascular injury leading to vasculitis is a characteristic feature of the disease caused by the pestiviruses, which may explain the type and distribution of the lesions that occur in fatal MD. The vascular injury may be initiated by degenerative changes of the endothelial cells; this may lead to formation of a thrombus, which can detach and circulate as emboli, resulting in generalized vasculitis.

Death from acute MD usually occurs within 2 weeks of the onset of clinical signs, and both CP and NCP isolates of the virus can be recovered from the tissues of affected cattle.

### CLINICAL FINDINGS

#### Inapparent or Subclinical Infection (Bovine Virus Diarrhea)

The most frequent form of BVDV infection in cattle is nonclinical or a mild disease of high morbidity and low case fatality characterized by a mild fever, leukopenia, inappetence and mild diarrhea followed by rapid recovery in a few days and the production of virus-neutralizing antibodies. This form occurs in immunocompetent seronegative cattle that are infected in postnatal life, accounting for the high proportion of adult animals that possess SN antibodies. The literature commonly refers to this subclinical infection as bovine viral diarrhea. A similar infection, with no long-term consequences other than the development of antibody, can occur in fetuses over about 150 to 180 days’ gestation.

#### Acute Mucosal Disease

The acute mucosal form of the disease is characterized by the sudden onset of clinical disease in animals in most cases from 6 to 24 months of age that are PI. Depending on the prevalence of persistent infection with BVDV in the herd, several animals in this age group may develop MD over a period of few days or sporadic cases may occur over several weeks or months. Morbidity rates of 44% and case–fatality rates of 100% have been reported in isolated herds. Well-nourished, thrifty, and previously clinically normal animals can be affected. Following outbreaks of MD in a herd, there may be a rapid decline in the number of PI animals born in the subsequent few years because of spread of the infection and development of acquired immunity in the breeding females.

Affected animals are depressed, anorexic, and drool saliva, wetting hair around the mouth. Fever 40°C to 41°C (104°F–105°F), tachycardia, and polyneua are common. Ruminal contractions are usually absent, and a profuse and watery diarrhea occurs 2 to 4 days after the onset of clinical illness. The feces are foul smelling and may contain mucus and variable quantities of blood. Occasionally, small tags of fibrinous intestinal casts are present. Straining at defecation is common, and the perineum is usually stained and smeared with feces.
Lesions of the oral cavity mucosa consist of discrete, shallow erosions, which become confluent, resulting in large areas of necrotic epithelium becoming separated from the mucosa. These erosions occur in the following locations:
- Inside the lips
- On the gums and dental pad
- On the posterior part of the hard palate
- At the commissures of the mouth
- On the tongue

The entire oral cavity may have a "cooked" appearance with the grayish colored necrotic epithelium covering the deep-pink, raw base. Similar lesions occur on the muzzle and may become confluent and covered with scabs and debris. Although the oral lesions are significant in the identification of the disease, they may be absent or difficult to see in up to 20% of affected animals.

Chronic Mucosal Disease

Some acute cases of MD do not die within the expected time of several days and become chronically ill. There may be intermittent bouts of the following:
- Diarrhea
- Inappetence
- Progressive emaciation
- Rough dry hair coat
- Chronic bloat
- Hoof deformities
- Chronic erosions in the oral cavity and on the skin

Shallow erosive lesions covered with scabs can be found on the perineum, around the scrotum, preputial orifice and vulva, between the legs, and at the skin–horn junction around the dew claws, in the interdigital cleft, and at the heels, and there may be extensive scurfiness of the skin. The failure of these skin lesions to heal is an important clinical finding suggesting chronic MD. Chronic cases will sometimes survive for up to 18 months during which time they are unthrifty and ultimately die of chronic inanition.

The chronic clinical form of the disease described earlier must be distinguished from the unthrifty persistently viremic animal described next.

Unthrifty Persistently Infected Calves

Calves that are born PI may be smaller in body size than their contemporaries and may fail to grow normally. A curly hair coat is characteristic of some PI calves. They may survive and appear unthrifty for several months or more until they develop fatal MD or some other infectious disease such as pneumonia. Although these calves are stunted and unthrifty in appearance, they do not have detectable clinical evidence of MD and they may be seronegative to the BDVD. The birth of a high percentage of PI calves may result in a high incidence of fatal respiratory disease when the calves are 7 to 9 months of age.

Peracute Bovine Virus Diarrhea

This is a severe form of the enteric form of the disease; it is often highly fatal, occurs in immunocompetent cattle in postnatal life, and is associated with highly virulent isolates of BDVD-2. Dairy herds, beef breeding herds, and beef feedlots have been affected in the outbreaks recorded in Ontario, Quebec, and Pennsylvania (in the United States), and in the UK in the late 1980s and early 1990s. Inadequate biosecurity of animals imported into the herd and the failure to vaccinate for BDVD or an inadequate BDVD vaccination program were common risk factors in affected herds. In affected herds, all ages of cattle are affected including calves, yearlings, and adults. Mortality was highest in the young-age groups.

The most common complaint given by the owners was the presence of respiratory disease in affected animals. The outbreaks were slowly progressive and lasted for several weeks. Severe depression, respiratory distress, anorexia, profuse watery diarrhea, dysentery, conjunctivitis, fever up to 42.0°C, and agalactia in adult lactating dairy cows were common. Oral erosions were inconsistent. Abortion, usually in late gestation, was a common but inconsistent occurrence. Morbidity rates may be up to 40%, and crude mortality rates may reach 25%. Many animals may die within a few days after the onset of clinical signs, and PI calves were commonly born several months following the outbreaks.

Thrombocytopenia and Hemorrhagic Disease

Thrombocytopenia and hemorrhagic disease have been associated with NCP BDVD-2 strains but whether or not the affected animals were previously PI is uncertain; only NCP BDVDs have been isolated. Bloody diarrhea, petechial and ecchymotic hemorrhages of the visible mucosa, hypHEMA, epistaxis, and prolonged bleeding from injection sites or insect bites have been observed. Cattle have platelet counts of less than 25,000 cells/µL and clinically there is bloody diarrhea. Fever, diarrhea, rumen stasis, and dehydration are also common.

The case–fatality rate is approximately 25%; survivors can recover and thrive normally or remain unthrifty. A similar syndrome of thrombocytopenia has been described in weaned beef calves, but the virus could not be isolated from affected calves.

Reproductive Failure and Neonatal Disease

The introduction of BDVD infection into groups of susceptible breeding females around the time of insemination and during the embryonic early to midfetal period can result in conception failure; increased embryonic mortality; fetal mummification; abortion; premature births; stillbirths; congenital defects; the birth of stunted weak calves; and the birth of PI calves, which subsequently may develop MD. Following introduction of infection into a beef herd, losses may be insidious and characterized by reduced pregnancy rates, abortions, excessive postnatal calf losses, and the premature culling of young cows because of their failure to wean a well-grown calf. These losses, including those from MD in PI animals, may continue for 2 to 4 years. Studies in dairy herds in Switzerland indicate that infection with the virus during the first 45 days’ gestation did not influence the rate of return to estrus. In contrast, there was an increase in the abortion rate in midterm gestation (days 46–210), whereas no such effect occurred in animals that seroconverted during the later stages of gestation. At least 7% of fetal deaths were attributable to infection with the virus.

A large-scale assessment of the effect associated with BDVD infection on fertility of dairy cows in France found that the virus was associated with an increase in the risk of embryonic death and fetal death.

Under field conditions, the effect of subclinical BDVD infection on subsequent dairy heifer fertility may be caused by a complex interrelationship among multiple BDVD infections dependent on the type of and timing of infection relative to reproductive performance. A high BDVD-2 antibody titer in dairy heifers at 10 months of age was associated with 32 more days to conceive compared with a low titer. Conversely, infection with BDVD by 5 to 6 months of age and a high BDVD-2 titer 1 month before conception or breeding was associated with improved fertility. Heifers with evidence of congenital BDVD infection had lower fertility than noninfected heifers, which depended on BDVD-2 titers at 10 months of age.

In beef herds, although abortions caused by BDVD may occur at any time during gestation, typically several cows in a herd abort during a short period of time before the start of the calving season. At the beginning of the calving season, premature births and stillbirths occur. Some calves are born alive, take a few breaths, and then die. Weak calves are generally born during the first 2 to 4 weeks of the calving season. Affected calves are
weak and flaccid at birth and may appear small or normal. Death usually occurs within several hours despite intensive care and the feeding of colostrum. In a study of health and performance in Sweden, the risks for clinical mastitis, retained placenta, and estrus-stimulating treatments were higher, and the calving intervals were longer in those herds with an increasing or maintained high prevalence of BVDV antibody-positive cows.

**Congenital Defects in Calves**

The following congenital defects have been associated with fetal BVDV infection:

- Cerebellar hypoplasia
- Microencephalopathy
- Hydrocephalus
- Hydroaencephaly
- Foreencephaly
- Hypomyelination
- Cataracts
- Microphthalmia
- Retinal degeneration
- Optic neuritis
- Thymic hypoplasia
- Hypotrichosis/alopecia
- Deranged osteogenesis
- Mandibular brachygnathism
- Growth retardation

Cerebellar hypoplasia was the first recognized teratogenic effect of the virus and has been well documented. At birth, affected calves exhibit varying degrees of severity of ataxia, wide-based stance, stumbling gait, and falling backward when attempting to walk. Mildly affected calves may survive if hand fed and managed carefully, but severely affected cases usually die or are euthanized. Defects of the eyes result in varying degrees of blindness; the cataracts are obvious when they occur. Calves may be smaller than normal and have a curly hair coat.

**CLINICAL PATHOLOGY**

The clinical diagnosis of MD is usually made on the basis of the presence of characteristic clinical and pathologic findings. A severe leukopenia and lymphopenia is characteristic of acute MD. The decrease is usually to below 50% of normal and total leukocyte counts of 1000 to 3000 cells/µL are common and may persist for weeks.

The laboratory diagnosis of BVDV infections relies on the isolation or detection of the virus or components and/or the demonstration of a serologic response to the virus. The type of samples to be submitted depends on the clinical and herd history and whether acute or persistent infections are suspected. The vaccination history is needed to interpret laboratory results.

**Virus Isolation**

Despite recent advances in BVDV diagnostic science, culture and identification of the BVDV from clinical specimens remains the gold standard diagnostic technique. Strains of virus can be characterized in vitro as CP or NCP biotypes. CP strains cause characteristic in vitro cell changes that are evident in inoculated cell cultures within 48 hours. Most BVDV isolates obtained from field cases are NCP in cell culture. The isolated virus is recognized by identifying viral antigen in positive cell cultures by immunofluorescence or immunoenzyme staining. Virus isolation can be attempted by inoculation of nasopharyngeal and ocular swabs, semen, intestinal tissues, spleen, or other tissues, or the buffy coat or serum of blood to cell cultures. In the live animal, the best sample for BVDV isolation is whole blood from which white blood cells (buffy coat) are extracted and used as inoculum. Along with the sample type, the timing of sample collection relative to the time of infection is important to maximize the chance for successful virus isolation specifically in transiently infected animals. Both CP and NCP viruses have been isolated from the spleen or blood of individual cattle with MD. Whole blood or serum from PI animals is used for the isolation of the virus.

For handling of large numbers of samples such as in a whole-herd screening for PI animals, a microtiter virus isolation method, the immunoperoxidase monolayer assay (IPMA), using serum as the diagnostic specimen is widely used. The assay requires approximately 5 to 7 working days, which allows for two passages to be completed. The main limitation of IPMA in PI testing is its nonapplicability on sera from animals under 3 months of age in which maternal antibodies can interfere with growth of the virus in cell cultures. Some adult PI cattle have been IPMA negative on serum but virus can still be isolated from the buffy coat cells. However, the prevalence of such animals is extremely low, and IPMA is widely accepted as a reliable test for detecting PI cattle of 3 months or older.

The indirect immunoperoxidase staining technique is recommended for certification of BVDV-free bovine semen for artificial insemination units when the immunofluorescent test is not available.

**Antigen Detection**

**Immunofluorescence or Immunohistochemistry.** The BVDV antigen can be identified rapidly in tissue samples using IHC methods such as immunofluorescence or immunoenzyme staining. A monoclonal antibody 1S5, which reacts with the E0 protein, has been shown to react broadly with most strains of BVDV and can be used to detect BVDV antigen in formalin-fixed, paraffin-embedded tissues. This has broad diagnostic and research applications. Using these methods, the identification of BVDV antigen in fixed tissues can be used as positive laboratory confirmation of BVDV infection without positive virus isolation and is useful when investigating disease syndromes such as enteric disease, respiratory tract disease, and reproductive tract disease.

**Skin Biopsy.** IHC staining for BVDV in formalin-fixed, paraffin-embedded skin biopsies is an effective method for the diagnosis of PI cattle because BVDV antigens are present in large quantities in epithelial cells of the skin in persistently but not transiently infected cattle. The technique is an easy, accurate, and affordable antemortem diagnostic test for the detection of PI animals that is not affected by the presence of maternal antibodies. It is suitable for herd screening because samples can be taken from cattle of any age, sample collection is simple, the samples are stable for transport and handling, and the test is both sensitive and specific for BVDV PI cattle. Positive IHC staining is most pronounced in the keratinocytes and in the hair follicle epithelium, hair matrix cells of the hair bulb, and the dermal papilla. IHC on skin samples is an effective method for screening neonatal calves for persistent infection. Skin samples from cattle with acute BVDV infection or transient infection may stain positive with IHC, but the distribution of staining is confined to the epidermal keratinocytes and follicular ostia, in contrast to PI animals with antigen-positive staining cells in all layers of the epidermis. Identification of PI animals is therefore possible with single skin biopsy sample. Uncertain cases should be retested a few weeks after the first test.

A monoclonal antigen-capture ELISA (ACE) test is capable of rapidly and accurately detecting pestivirus-specific antigens in peripheral blood leukocytes, blood clots, milk, and tissue samples of PI cattle. It has demonstrated good agreement with conventional virus isolation procedures and is suitable for routine diagnostic and certification testing. Antigens used in those ELISA are highly conserved among BVDV strains, ensuring that most strains are recognized. Nonetheless one viral variant escaping detection by IHC staining and ACE has been identified, and the prevalence of similar viral variants in the field is not known. Monoclonal antibody techniques have also been used to detect the virus antigen in the central nervous system of PI cattle. Four commercially available ELISAs for the detection of BVDV antigen in the blood of PI cattle have been compared and are highly sensitive and specific and considered valuable in eradication programs when monitoring large numbers of animals. The ACE is most commonly run on serum which, through the presence of maternal polyclonal BVDV antibodies, has the potential to block antigen detection. In order to circumvent problems resulting from interference of maternal antibodies with ACE in very young calves, this test is not recommended for calves less than 3 months of age. Skin biopsies or ear notches became popular specimens for ACE because viral antigen detection in skin is not affected by the presence of maternal antibodies. Most commercially available tests are...
not designed to detect transiently infected animals; thus positive animals are frequently referred to as PI animals after a single test. Nonetheless, positive results on acutely infected animals have infrequently been reported.  

Polymerase Chain Reaction Amplification

PCR amplification of an RNA genome involves the binding of specific DNA oligonucleotides to cDNA target sequences, resulting in amplification of size-specific DNA fragments that are detectable by gel electrophoresis.

The PCR test is able to detect small amounts of viral nucleic acid from samples of blood and tissues including preserved material. Factors such as cost, technical expertise, equipment and automation, and RNA extraction methods are considerations when comparing with the standard methods of virus isolation.

The reverse transcriptase (RT)-PCR amplification has gained widespread use as a routine diagnostic method for BVDV. The high analytical sensitivity of RT-PCR allows for pooling of specimens to reduce unit cost test. Pooling is especially applicable for persistent infection testing in which a single positive specimen can still be detected in a pool of several dozen samples. A positive RT-PCR does not define the clinical status of an animal because it detects transiently and PI animals as well as animals vaccinated with modified live BVD vaccine with a modified live BVD vaccine. Follow-up tests after 2 to 3 weeks are required to identify PI animals. The high sensitivity of this analytical method makes RT-PCR more susceptible to false-positive results from contamination.

The RT-PCR test has been used to detect the presence of the BVDV in somatic cells from bulk milk samples. Compared with existing methods, RT-PCR showed 100% specificity and sensitivity in detecting PI lactating cattle in milking herds.

The RT-nested PCR (RT-nPCR) assay is a rapid and sensitive method to detect BVDV in extended semen samples. Although the prevalence of persistent testicular infection with BVDV is very low, use of the rapid, sensitive RT-nPCR assay on extended semen samples can be used to ensure that the virus is not transmitted in cryopreserved semen.

Serology

Serologic techniques are used to detect and measure antibodies. Following acute infection, serum antibodies are first detectable at 2 to 3 weeks, and peak antibody levels occur 8 to 10 weeks later. Following successful vaccination, SN titers will be high for many months.

PI animals are frequently seronegative but can be seropositive because of the presence of colostral antibodies, exposure to a BVD field strain that is heterologous to the persistent strain, or vaccination with a vaccine containing heterologous virus strains. Antibodies are usually not detectable in the sera of most cattle with MD. The specific immune tolerance of the persisting virus is also not broken by the CP virus if it is antigenically similar or identical to the persisting virus and results in fatal MD.

Precolostal serum from calves infected in utero as immunocompetent fetuses may have virus-specific neutralizing antibodies, and their demonstration is meaningful for the diagnosis of past infection.

In North America the serum neutralization test is the most frequently used BVD serology test, whereas in Europe the antibody ELISA is also widely used as serologic test for BVD.

Serum Neutralization Test

The serum neutralization test has been the standard test to determine the occurrence of a rising BVDV titer between acute and convalescent sera. The serum neutralization test gives endpoint values that may be more biologically relevant and it is the only test that assesses antibody status regarding BVD virus strain variation. The test is performed in microtiter plates and takes 3 to 5 days to complete and is relatively simple to interpret. A CP virus is used to easily detect the neutralization of the virus. Because of the different virus strains and cell systems used, results can vary considerably between different laboratories.

Antibody Enzyme-Linked Immunosorbent Assay

ELISAs are available to measure serum antibodies to BVDV and are a rapid and economical alternative to the serum neutralization test. The ELISA simply determines the presence or absence of BVDV virus antibodies, which is often considered of limited value in regions with high infection prevalence and common vaccination as seen in North America. In contrast in regions with BVD control programs in place and limited use of vaccines, the antibody ELISA presents a useful diagnostic tool. The blocking ELISA for BVDV antibodies is a simple, rapid, and reliable test for the detection of specific antibodies in serum, plasma, or bulk tank milk. Test results correlate well with VNT results and may be useful for large-scale screening and eradication programs.

Using a blocking ELISA test, the level of antibodies in bulk milk is a valuable aid to indicate the infectious status of a dairy herd and for identifying herds suspected of harboring an active infection. A herd with two consecutive bulk milk results 4 months apart of 60% (percentage inhibition) is more likely to have a very high percentage of infection. Testing of bulk tank milk for antibody using the ELISA can be used to determine the prevalence of dairy herds with antibodies; the relationships between the ELISA values in bulk milk and the location, milk yields, and somatic cell counts of the herds; the annual incidence risk of new infections; and combined with the RT-PCR to detect viral RNA, it can be used to obtain an estimate of the herd prevalence of lactating PI animals.

Use of Laboratory Tests in the Herd

Because of the complex nature of BVDV infections, it is often difficult to obtain a definitive etiologic diagnosis. The type of samples to be submitted to the laboratory and the interpretation of the results depend on clinical and herd history and the vaccination status of the herd. The testing strategies to be used will depend on the specific disease history of the herd, the age of animals to be tested, the cost of the test, the needs of the owner of the herd, and the reasons for doing the testing.

Acute Infections

The diagnosis of acute infections by virus isolation must be done as early as 3 days after infection to 8 to 10 days after infection. A whole-blood sample is the best sample for virus isolation to identify acutely infected animals. Other specimens such as serum, nasal swabs, feces, semen, or different tissue may be less suitable because of a possible interference by neutralizing antibodies. In herd outbreaks, blood samples from normal animals should also be submitted. For serology, paired acute and convalescent samples collected 30 days apart are required to identify a fourfold increase in serum antibody titers. In abortions, the dam may have already seroconverted before the abortion and there may be no seroconversion between acute and convalescent sera. However, some aborted fetuses may be serologically positive, which confirms intrauterine infection in the later part of fetal life. If the dam is negative, BVDV can be ruled out as a cause of abortion. Calves born with congenital defects may have antibodies, but blood samples must be taken before the ingestion of colostrum.

Persistently Infected Animals

The PI animals in a herd can be identified using any or a combination of the following testing procedures:

1. Collect whole blood from all animals in the herd including calves to conduct virus isolation, ACE, or RT-PCR. Virus can be isolated from mononuclear cells in the buffy coat. Virus in mononuclear cells is unaffected by colostral antibodies. An RT-PCR can be done on pools of whole blood or on individual animal samples, which is very expensive. Because of its high sensitivity PCR will also detect transiently infected animals. Follow-up testing is required to define the status of positive animals as PI.

2. Collect serum on all animals over 3 months of age. Test younger calves as they age or use an alternative test. With
serum testing colostral antibodies may interfere with the test or eliminating detectable virus from the fluid fraction of blood for some variable period of time. Tests that can be done on serum include the microplate virus isolation, antigen-capture ELISA, or RT-PCR. Although ACEs are not developed to identify acutely infected animals, these occasionally may yield positive results. When using a single sample, there is thus a chance to label an acutely infected animal as PI. Animals tested positive with RT-PCR must be retested after 3 weeks to confirm PI status.

3. Collect skin biopsies (ear notches) from all animals in the herd including calves. The tests of choice are the IHC on formalin-fixed tissues or ACE using fresh samples. Use of fresh tissue samples eliminates the need for formalin. A single positive test is confirmative for PI status.

4. For dairy herds, collect composite milk samples from lactating cows and screen the remainder of herd using procedure 1 or 3 in this list. Somatic cells from the milk are screened for the virus by RT-PCR or virus isolation. Positive animals must be retested after 3 weeks to confirm PI status.

5. Test calves as they are born with 1 or 3 in this list. If the producer has accurate calving records, the determination that the calf is not PI automatically defines the status of the dam as not being PI. Using this protocol, ongoing surveillance is maintained with a single test defining the status of two animals. For dairy herds, bull calves must be tested as well as the heifer calves to achieve a complete herd screening program.

By testing 30 days apart, it is also possible to test for a fourfold increase in antibody titer should the first virus isolation be the result of an acute infection. In most cases, serum is adequate for virus isolation in PI animals. In young calves under 3 months of age, colostral antibody may decrease the level of free virus in the serum and may result in a false-negative test. For this reason, the use of whole blood, which allows isolation of the virus from the buffy coat, is recommended in calves under 3 months of age.

Most PI animals are seronegative after the colostral immunity has waned, but they may develop SN antibodies to heterologous strains of the virus.

**Prenatal Diagnosis of Persistent Infection**

Pregnant dams with PI fetuses (PI carriers) have exceptionally high antibody titers. Testing pregnant dams can be used to identify and exclude PI carriers from livestock markets without completely blocking the trade with pregnant seropositive cattle.

Testing is most reliable when done in late pregnancy (not before the seventh month of gestation). In dams carrying PI fetuses, the immune response was markedly higher than those in dams carrying uninfected fetuses. The BVDV has also been detected in amniotic and/or allantoic fluid from both cattle and sheep with infected fetuses. A blind puncture technique for collection of fetal fluid in late pregnancy is used to collect fetal fluid. The site of collection is over the right ventral abdominal wall approximately 10 cm cranial of the udder and 10 cm medial of the flank. A nested PCR test is used to amplify the viral RNA.

**Herd Screening**

When a diagnosis of BVDV infection has been made in a herd, for example in the case of MD in a yearling, then further investigation for the detection of infected animals at the herd level is indicated. The most common strategy for herd screening is to submit serum samples from all animals over 3 months of age and whole-blood samples from calves under 3 months of age. All animals in the herd should be tested. The samples may be tested for SN antibodies and/or the presence of the virus. Virus isolation using the microtiter immunoperoxidase test and ACE are the most common methods used for large numbers of samples. Milking cows may be tested through a bulk tank milk sample analyzed with PCR. Calves born for the next 9 months should also be tested to detect any additional PI animals born that may have been infected in utero at the time of the herd infection. The goal is to ensure that no additional PI animals appear and that the maternal–fetal transmission cycle is broken. In herds in which cases of MD have been recognized, most of the normal animals will have high levels of SN titers.

During the 9- to 12-month period of testing, management strategies should ensure that all young stock and breeding females are not in contact with infected animals. However, in some countries in which vaccines are unavailable, breeding females are placed in direct contact with PI animals before the breeding season as a method of natural vaccination.

The serologic evaluation of unvaccinated heifers 6 to 12 months of age is an accurate method for identifying herds containing PI animals. Both BVDV-1 and BVDV-2 antibody titers should be determined to prevent misclassification. In regions in which border disease is endemic and cattle are kept together with small ruminants, testing for BDV antibody titers may also be indicated. The sensitivity and specificity of serologic evaluation of five heifers for identifying these herds were 66% and 100%, respectively, in herds that contained PI cattle. Pooled-sample testing using PCR/probe testing can be used as a herd screening test for detection of BVDV PI cattle. Whole-herd screening by use of one of the methods for detecting virus or viral antigens such as IHC of skin (ear notch) specimens is required for detection and elimination of PI animals with BVDV in a herd.

**NECROPSY FINDINGS**

**Acute Mucosal Disease**

The gross abnormalities are usually confined to the alimentary tract. Characteristic shallow erosions with very little inflammation around them and with a raw, red base are present on the muzzle, in the mouth, and to a lesser extent in the pharynx, larynx, and posterior nares. In the esophagus these erosions are linear in shape and lie in the direction of the folds of the esophageal mucosa. Erosive lesions may be present in the forestomachs, but are usually confined to the pillars of the rumen and the leaves of the omasum. Histologically, the lesions of the squamous mucosa of the alimentary tract begin with necrosis of individual cells and groups of cells. These foci enlarge and result in areas of necrosis with little or no inflammation of the lamina propria. If the necrotic foci are abraded, erosions and ulcers develop. In the abomasum, there is often a marked erythema of the mucosa accompanied by multiple submucosal hemorrhages and gross edema of the wall. Erosions and ulcers are common on the sides of the rugae of the abomasum and may be punctuate or more than 1 cm in diameter. The lesions have raised margins with a distinct pale halo. Histologically, there is epithelial necrosis of the deep parts of the glandular epithelium.

The mucosa of the small intestine often appears normal except for patchy or diffuse congestion and edema in some cases. In cases with a short clinical course it is common to find coagulated blood and fibrin overlying and outlining the mucosal aspect of Peyer’s patches, which are also eroded. This is a very distinctive lesion that is paralleled only by rinderpest and sometimes bovine malignant catarrh. Severely affected Peyer’s patches may be obvious through the serosa as red-black oval areas up to 10 to 12 cm long on the antimesenteric border of the intestine. In the large intestine the mucosa may be congested, often in a “tiger stripe” pattern following colonic folds. The characteristic microscopic lesion in the intestinal mucosa is destruction of the epithelial lining of the crypts of Lieberkühn. In Peyer’s patches, there is lysis of the follicular lymphoid tissue, collapse of the lamina propria, and often consequent downgrowth of cryptal epithelium. A less frequently noted microscopic finding is a vasculitis with fibrinoid necrosis of the media; this change may also be observed in a variety of other organs.

Nonalimentary tract lesions that may be seen on occasion include ulceration of the muzzle, interdigital skin, and conjunctival membranes. Growth arrest lines in the long bones may be seen, and secondary bacterial bronchopneumonia can also occur.
**Peracute Bovine Viral Diarrhea**

The lesions of this form of the infection are similar to acute MD and it is usually not possible to differentiate between the two forms based on gross and histopathological findings. There may be an absence of gross enteric lesions, especially in animals that die within 24 hours after the onset of clinical signs and in calves less than 6 months of age. In these peracute cases, pneumonia may be the most obvious lesion. Cases in which there is widespread hemorrhage attributable to thrombocytopenia may also be a form of peracute infection. Experimental infections with NCP BVDV-2 strains have resulted in viral infection and necrosis of marrow precursor cells, especially megakaryocytes, as well as peripheral thrombocytopenia and leukopenia.

**Chronic Mucosal Disease**

The necrotic epithelium may not be eroded by alimentary movements but instead remain in situ as slightly elevated, yellow, friable plaques, especially on the tongue and in the rumen. Subacute cases with a very prolonged course may show very few gross lesions in the mouth, some in the esophagus, and no lesions in the stomachs and intestines. Peyer’s patches may be difficult to locate in these animals and when examined histologically the lymphoid follicles are hypocellular.

In naturally occurring MD, NCP and CP viruses can be found in the spleen, intestines, and esophagus. Viral antigens are also detectable in mucosal cells of the nares, rumen, abomasum, gallbladder, and salivary glands. In PI animals, viral antigen can be found in myenteric ganglion cells, cells within crypts, mononuclear cells of gut-associated lymphoid tissue, and mononuclear cells of mesenteric lymph nodes. Viral antigen can also be found in adenocortical cells, cerebral neurons, endocrine cells of the pituitary gland, thyroid follicles, and pancreatic islets.

The virus can be demonstrated in sections from formalin-fixed, paraffin-embedded tissue using various IHC techniques, including a method using a monoclonal antibody, and the detection of viral antigen in formalin-fixed sections of skin collected at postmortem remains strongly indicative persistent infection. Such IHC techniques have also enabled the demonstration of viral antigen in association with specific lesions, such as within the Purkinje fibers and conduction system of the myocardium of a 4-month-old calf, pancreatic islet cells of diabetic cattle, and various cells of the central nervous system in a heifer with meningoecephalitis. This virus is also recognized as a cause of myocarditis, which may include a mild lymphoplasmacytic myocardial arteritis with or without fibrinoid necrosis. It must be remembered that the demonstration of BVDV antigen, or the isolation of the virus from necropsy material, does not mean that the animal suffered from MD or the peracute form of infection unless supportive lesions are observed. The virus is often found in animals dying as a consequence of other disease processes, such as pneumonia. Confirmation of the presence of the virus is nevertheless significant. In terms of the individual animal, the virus may have caused a degree of immunosuppression. For the herd, the presence of circulating virus has important implications for the animals of breeding age.

**Abortion**

The pathologic criteria for the diagnosis of BVDV as a cause of abortion have not been established. Finding antibody in a fetus, as in an unsuckled neonate, indicates that intrauterine infection has occurred but its diagnostic significance regarding the abortion is not clear. The recovery of virus from the fetus, or demonstration of viral antigen within fetal tissues, is only suggestive of a diagnosis of perinatal abortion. Recognized BVDV-associated congenital defects in calves, including cerebellar hypoplasia, cataracts, retinal degeneration and dysplasia, hypoplasia and neuritis of the optic nerves, and musculoskeletal deformities are clear-cut indicators of compromised fetal health. However, microscopic lesions associated with BVDV abortion have been described in fetal eyelid, lung, and myocardium yet at the present time their diagnostic value is still controversial. Growth arrest lines are sometimes noted in the long bones of aborted fetuses infected with the BVDV and in utero the infection may also produce osteopetrosis. Osteoporotic lesions, as well as anemia, thrombocytopenia, and marrow necrosis have been described in 2-month-old beef calves infected with an NCP strain of BVDV. Infection of megakaryocytes with NCP strains of BVDV has been confirmed experimentally. IHC analysis of cryostat sections of brain, skin, thyroid gland, abomasum, and placenta is a rapid, sensitive method for detecting persistiviruses in bovine and ovine fetuses. However, in most bovine fetuses, IHC testing of formalin-fixed, paraffin-embedded tissues is recommended, because the detection of BVDV antigen in formalin-fixed fetal tissues appears to be superior to traditional virus isolation techniques and fluorescent antibody techniques.

**Samples for Confirmation of Diagnosis**

- **Histology**: formalin-fixed oral/esophageal lesions, thymus, Peyer’s patches, colon, abomasum, rumen, mesenteric lymph node, heart, ear. For abortions eyelid, lung, thymus, spleen, intestine, liver, kidney, heart, brain, eye (LM, IHC)
- **Virology**: thymus, thyroid, Peyer’s patch, spleen, lung, mesenteric lymph node (ISO, FAT, PCR)

**Differential Diagnosis**

The differential diagnosis of diseases associated with BVDV infection must be considered according to the many different subclinical and clinical forms of the disease affecting many body systems. Each manifestation of clinical disease must be differentiated clinically and pathologically from similar diseases. The distinguishing features of each manifestation and the diseases they resemble are summarized here.

The differentiation of the diseases causing erosive lesions of the oral cavity mucosa (such as mucosal disease) can be perplexing both clinically and at necropsy. The similarity between them is the more important because rinderpest and foot-and-mouth disease are major plague diseases. The situation is so dangerous that if there is any doubt as to the identity of the disease under examination, samples should be submitted for laboratory examination.

There are many diseases of the alimentary tract of cattle that can be grouped according to the presence or absence of oral lesions with or without diarrhea. These have been summarized in Table 5.10. An erosive stomatitis and gastroenteritis are characteristic of rinderpest, bovine virus diarrhea, and bovine malignant catarrh. The stomatitis and hyperemia are remarkably severe in bovine malignant catarrh along with a corneoscleral opacity, lymph node enlargement, hematuria, and terminal encephalitis. Rinderpest was eradicated in 2011.

The **vesicular diseases**, foot-and-mouth disease and vesicular stomatitis, are characterized by the presence of vesicles on the tongue and buccal mucosa, teats, and coronets and should be distinguishable from erosions.

Diseases causing diarrhea with no oral lesions include **winter dysentery**, salmonellosis, Johnne’s disease, molybdenum poisoning (conditioned copper deficiency), parasitism (ostertagiosis), and arsenic poisoning.

A definitive diagnosis depends on isolation of BVDV from theuffy coat or serum of blood and other tissues. Calves with congenital defects can be provisionally identified as bovine virus diarrhea by detection of specific antibodies in calves that have not sucked; this is not an easy specimen to obtain in beef cattle running at pasture.

Although bovine virus diarrhea is not a disease of the respiratory tract it is not uncommon for respiratory signs to be evident and confusion in diagnosis between it and infectious bovine rhinitis, and even pneumonic pasteurellosis, does arise. It is necessary to depend on a careful clinical examination of oral and nasal mucosa to ensure that there are no mucosal lesions. It is also necessary to include bovine virus diarrhea in the list of diagnostic possibilities when considering the causes of abortion and

stillbirth in cattle. Immunoglobulin determinations in aborted fetuses may be of diagnostic value. The definitive diagnosis of chronic mucosal disease presents problems because often the affected animal has no specific neutralizing antibody because of immunosuppression or the inability to secrete antibody. A presumptive diagnosis can be made on the basis of the clinical characteristics of the acute disease and the absence of other lesions to account for the chronic form of the disease. Virus isolation must be attempted along with detailed pathologic examination.

- **Inapparent subclinical BVDV infection.** Common diseases include acute undifferentiated fever and acute undifferentiated bovine respiratory disease.
- **Peracute bovine virus diarrhea.** Malignant catarrhal fever. Acute salmonellosis, bluetongue.
- **Respiratory disease.** All common causes of bovine respiratory disease. See Table 18-5.
- **Thrombocytopenia and hemorrhagic disease.** Malignant catarrhal fever. Moldy sweet clover poisoning, bluetongue.
- **Unthriftiness persistently infected calves.** General malnutrition. Copper deficiency. Chronic pneumonia.
- **Reproductive failure.** Common causes of reproductive failure in dairy and beef cattle. Herds are characterized by anestrus, failure to breed, unsatisfactory semen, failure of fertilization, embryonic mortality, fetal resorption, fetal mummification, abortion, stillbirth, and perinatal mortality.
- **Neonatal calf diarrhea.** All common causes of acute undifferentiated diarrhea of calves under 30 days of age.
- **Congenital defects of calves.** All inherited defects of the nervous system of calves manifested clinically at birth, and diseases of uncertain etiology characterized by nervous system involvement.

**TREATMENT**

There is no specific treatment for any of the diseases associated with BVDV. The prognosis for severe cases of MD with profuse watery diarrhea and marked oral lesions is unfavorable, and slaughter for salvage or euthanasia should be considered. Animals with chronic BVD should be culled and destroyed.

**CONTROL AND PREVENTION**

BVDV continues to cause significant economic losses because of failures in implementing a sound immunization program, failures in establishing herd-monitoring programs, and failures in developing effective biosecurity and biocontainment programs. The ultimate goal of BVDV prevention and control measures is to eliminate the potential for the birth of PI calves. A combination of biosecurity, vaccination, and biocontainment strategies are necessary to control and prevent BVDV infection and its consequences in a herd and country.

The goal of a BVDV biosecurity program is to prevent the introduction of the virus into the cattle herd and preventing transmission of the virus to susceptible animals. Biocontainment strategies target minimizing the occurrence or severity of disease associated with BVDV infection. The most important subpopulation to protect from exposure is pregnant cattle, especially those in early gestation. The herd must be protected from direct exposure to cattle from other herds that may be transiently or persistently infected with BVD. Examples of these exposures include fence line contact, movement to and from fairs and exhibitions, and new herd additions. Quarantine of new additions for 2 to 3 weeks after arrival prevents exposure of the native herd to unknown infected animals. Each addition must be tested for BVDV PI while in quarantine or before arrival to identify primary reservoirs of virus before they are commingled with the native herd. New additions that arrive pregnant should not calve in the presence of pregnant cattle from the native herd. The calves born to pregnant new additions must be isolated from the native herd until their BVDV status has been determined.

Beef feedlots and heifer rearing operations present a special biosecurity challenge because the opportunity to introduce BVDV PI animals into these systems is increased by the frequent introduction of cattle usually commingled from multiple sources. The introduction of PI cattle may affect the health and performance of penmates. Dairy and beef heifers exposed to BVDV during gestation at a heifer development facility may later give birth to PI calves in destination herds. BVDV exposure could be minimized in these facilities by testing all new arrivals and removing PI cattle during a quarantine period of 2 to 3 weeks and before entering into the primary facilities.

Elimination of BVDV PI cattle early in the production system, such as at the cow-calf herd level, benefit the cattle industry at subsequent points, such as at the feedlot and heifer development enterprises. Ideally, procurement of animals from biosecure herds and animals previously tested negative for BVDV PI would eliminate the risk for virus exposure from PI animals in these types of operations (Figs. 8-28 through 8-30).

The successful control and prevention of the BVD/MD complex depends on the following:

- Identification and elimination of PI animals from the herd
- Prevention of introduction of infection into the herd (biosecurity)
- Immunization programs and biocontainment
- Eradication of the virus from herds

**Identification and Elimination of Persistently Infected Animals From the Herd**

Identification and elimination of PI cattle is an essential component of a control program in an infected herd. Elimination of such animals, also known as “clearance of infection,” will result in the improved health of the herd. The testing procedures to detect PI animals are described under Clinical Pathology in this section.

In beef herds, to prevent contact with pregnant cows, PI animals should be identified and removed before the start of the breeding season. All calves, all replacement heifers, all bulls, and all nonpregnant dams without calves must be tested for PI status. Any female pregnant at the time the herd is tested should be isolated from the breeding herd and kept isolated until her calf is tested and found to be negative. In most whole-herd testing situations, IHC testing of skin samples is the test of choice because it can be accurately performed on animals of any age, and a single sample is all that is usually required.

Herd monitoring for PI animals can be done with pooled whole-blood or serum samples for PCR testing. By pooling samples, the expense of screening herds with a low prevalence of PI animals is minimized. The maximum number of samples per pool should be determined at the diagnostic laboratory conducting the analysis. If the initial pool is PCR positive, then it must be split and retreated to identify the viremic animal(s) within the pool. Once the viremic animals are identified, they must be classified as transiently infected or PI with either a subsequent PCR, virus isolation, or IMPA test in 3 weeks, or using the IHC testing of a skin sample. Using a two-test strategy to screen feeder calves with a PCR assay of pooled samples and IHC testing only of those animals represented in pooled samples with positive assay will reduce the cost of screening incoming feedlot cattle compared with IHC testing of all animals.

Following the successful detection and removal of PI animals, “self-clearance” or elimination of all evidence of the infection from the herd will occur. Transient infections that occur in nonpregnant animals are inefficient in transmitting the virus. The main route of transmission within a herd is from PI animals to susceptible animals. The virus is commonly maintained in a herd when seronegative animals in early pregnancy are exposed to PI animals. Self-clearance is also more likely in small herds compared with large herds that usually have rearing conditions that increase the risk of exposure of PI animals to susceptible seronegative animals in early pregnancy.
Prevention of Introduction of Infection Into Herd (Biosecurity)

After identification and elimination of the PI animals, the new virus-free status of the herd should be maintained by a program of testing all introduced animals for freedom from infection. In many cases introductions can be guaranteed, as far as is reasonably possible, to be free of infection by selecting animals that have convincing titers of serum antibody or are negative and are derived from a totally negative herd or stable subherd. According to the period over which the herd of origin has been established and has been free from introductions, its free status may be established by testing an adequate sample of animals. In other cases, antibody-negative introductions should be examined for virus or held for a period of on-property quarantine in close contact with a few serologically negative test animals that are subsequently examined for antibody.

Significant reproductive wastage caused by BVDV infection can be prevented by testing introductions to the herd or management of the herd to maximize immunity before breeding. Cattle producers purchasing pregnant heifers to expand their herds must be aware of the possibility their fetuses may already be PI. At that stage there is no simple test to identify those heifers pregnant with a PI fetus. Calves from these purchased heifers of unknown vaccination history should be considered infected until proven otherwise.

Artificial insemination units are now adopting comprehensive testing programs to identify PI bulls and immunocompetent bulls with the transient acute BVDV infection. PI bulls are detected by virus isolation from blood and not by serologic testing. The semen of PI bulls will usually contain the virus, but the quality of the semen will not necessarily be abnormal. This emphasizes the need for virological surveillance of breeding herds and artificial insemination and embryo transfer centers. It is also important to prevent contamination by this virus of the fluids used for recovery, in vitro manipulation, and transfer of bovine embryos.

Immunization Programs and Biocontainment

Vaccination is effective in reducing the spread of BVDV but is unsuitable as a stand-alone control strategy because vaccination cannot provide complete protection from infection or remove PI animals from the herd. Historically, widespread, nonsystematic use of BVD vaccines has been commonplace in many countries including the United States without any noticeable overall reduction in the prevalence of the disease. 

Vaccination programs target one of two of the following objectives:

- Prevention of clinical disease after exposure to BVDV
- Prevention of fetal infection leading to PI calves

Considering the high prevalence of BVDV infection that causes high economic losses, vaccination of cattle herds is certainly indicated, provided efficacious and safe vaccines are available. To be effective, vaccination against BVDV infection should protect against viremia and block infection of target cells of the reproductive and lymphatic systems to avoid occurrence of fetal infection and immunosuppression, respectively. Antibodies present in the systemic circulation effectively neutralize viral infectivity, promote clearance of the virus, and prevent seeding of target organs such as the fetus. The goal of immunization is to stimulate both the B-cell and T-cell arms of the immune systems. The B-cell arm of the immune response has the major responsibility for inactivating free virus. This is achieved primarily by immunoglobulin, which neutralizes the BVDV infectivity and secondarily aggregates BVDV and enhances clearance. Cell-mediated immunity, particularly CD4+ cells, which are type-2 like, is important for the resolution of acute infection with NCP BVDV. The antibody titers required to provide protection from intrauterine infection or clinical disease are not known. A titer of 1:16 was reported to protect from severe clinical disease, whereas a titer of 1:256 was found to prevent systemic virus shedding in experimentally challenged calves.

An important strategy for successful control is vaccination of the breeding female at least several weeks before breeding. Experimental exposure of pubertal heifers to the virus 6 weeks before breeding stimulates the production of SN antibodies, which protects against transplacental infection of the fetuses. However, immunization in terms of protecting the fetus may not be effective against strains that are different from those contained in the vaccine, and the ultimate precaution is to prevent cows or heifers from making new contacts shortly before or...
during the first half of pregnancy. Control of the infection, and of MD, depends entirely on control among the breeding stock. Infection among nonbreeders is of no long-term consequence, except that they may be a source of infection to breeders and compromise the continuing freedom from infection of that group.

The aim of a vaccination program is to ensure that all breeding females have antibodies to the virus before they become pregnant. Independent of the vaccine used, vaccination should be done at least 3 weeks before breeding so that the breeding females become seropositive to the virus before conception.

Infectious disease models demonstrate that after BVDV is eliminated from a herd, cattle become increasingly susceptible to new infection and the possibility of an outbreak with severe clinical signs following a new BVDV exposure increases. Thus in the absence of strict biosecurity, recurring patterns of reinfection with severe clinical signs are expected every few years once the virus is eliminated from the herd. In North America and other regions in which BVDV is endemic and reexposure is likely, it remains prudent to continue vaccination after eliminating the virus from the herd.

**Bovine Viral Diarrhea Virus Vaccines**

Both MLV and inactivated-virus vaccines are available. Currently there are many BVDV vaccines that are federally licensed in North America alone and all meet or exceed requirements for purity, potency, and safety. These requirements ensure that vaccines elicit an immune response, are free from extraneous agents, and do not induce disease.

The important variables to consider when selecting a vaccine for use in different production systems include immune response; cross-reactivity, fetal protection, duration of immunity, immune-suppression, reversions to virulence, effect of maternal antibody on immune responses, and purity.

The MLV vaccines usually contain one or two single strains of attenuated BVDV of either biotype that pertains to the BVDV-1 and BVDV-2 genotype. The most commonly used strains are BVDV-1a, 1b, 1c, and BVDV-2a. Several inactivated BVD vaccines are also widely available.

**Modified-Live Virus-Bovine Viral Diarrhea Virus Vaccines**

MLV-BVDV vaccines are attenuated so that replication of the virus is restricted, reducing both viral virulence and shedding of the vaccine virus by the vaccinate. The advantages of MLV-BVDV vaccines are numerous and significant. Because antigen is amplified by replication in the animal, only small numbers of viral particles are necessary; thus the vaccines are inexpensive and only a single vaccination is necessary for adequate immunization. Within 3 weeks after vaccination, antibody is detectable, which will neutralize an antigenically wide range of BVDV strains. Although antibody titers after vaccination with MLV vaccines were found to be lower than after natural infection, increase and decay of the titer follow a similar pattern. It is suggested that protective antibody titers following vaccination persist for more than 1 year. Immunization of calves with MLV vaccine is not inhibited by colostral antibody at titers up to 1:32. Assuming both a half-life of 21 days for colostral antibody and an initial viral neutralizing titer of 1:2000 after ingestion of colostrum, immunization should be successful in most calves 4 to 6 months of age. Revaccination before the first breeding is recommended.

The disadvantages of MLV vaccines include failure of immunization if the vaccine is not stored or handled properly. MLV vaccines may cause disease if the vaccine virus regains virulence. Development of MD following vaccination with an MLV vaccine has been reported occasionally (a condition termed postvaccinal MD). It is now recognized that postvaccinal MD exclusively occurs in PI animals. Although the economic loss from postvaccinal MD is negligible, from an animal welfare standpoint vaccination of PI animals should be avoided when possible. MLV vaccines are also potentially fetopathyigenic and should not be used in pregnant cows. The possible effects of such vaccination are variable and dependent on the stage of gestation when the vaccination occurs. The vaccination of pregnant cattle, without detectable neutralizing antibodies to the virus, between 51 and 190 days’ gestation with a commercial modified BVDV live vaccine can result in transplacental transmission of the vaccine virus and
is not recommended. Abortions, congenital abnormalities of the nervous and musculoskeletal systems, perinatal deaths, growth retardation, and persistent viral infection are all possible outcomes of vaccinating pregnant cattle with an MLV before 120 days’ gestation. Between 120 and 190 days, the fetus can be expected to become immunocompetent and produce serum-neutralizing antibodies that can be detected in the precolostral serum of the calf at birth. The vaccination of pregnant cattle without neutralizing antibodies to the virus between 190 and 265 days’ gestation will also result in transplacental transmission of the virus and the presence of neutralizing antibodies in the precolostral serum of calves at birth. A temperature-sensitive BVDV vaccine will cause seroconversion and, when used experimentally in pregnant cows, does not result in fetal infection as evidenced by lack of virus isolation and absence of precolostral antibodies in the calves, which are born healthy. Immunosuppression and genetic recombination are other potential risks associated with MLV vaccines. Few studies have documented impaired lymphocyte function with the use of at least one MLV vaccine, but the extent of immunosuppression is largely undefined.

Inactivated Bovine Viral Diarrhea Virus Vaccines

The disadvantages of the MLV vaccines stimulated the development of inactivated-virus vaccines.

The advantages of inactivated BVDV vaccines include the following:
- Lack of infectivity
- Unlikely presence of adventitious agents
- Absence of postvaccinal disease
- Safe use in pregnant animals

The disadvantages of inactivated BVDV vaccines include the following:
- High cost of the vaccine
- Need for two vaccinations to achieve primary vaccination
- Lower and shorter protective antibody titers

Adverse reactions at the site of vaccination may occur and are associated with the adjuvant in the vaccine. Maternal antibody may interfere with inactivated vaccines, and calves may need to be revaccinated periodically from 6 months of age to just before breeding. Vaccination of naive cattle with inactivated BVDV vaccines results in virus neutralization peak titers at about 5 weeks after the second vaccination with a return to seronegativity within 12 weeks of vaccination. This pattern of response is typical of inactivated vaccines. General consensus is that the protection afforded by inactivated BVD vaccines is narrower and of shorter duration than the protection obtained from MLV vaccines.

Combination Vaccines

BVDV vaccines are often incorporated in multivalent vaccines to prevent respiratory diseases of cattle. These vaccines include combinations of the live and inactivated antigens of bovine herpesvirus-1 (BHV-1), parainfluenza-3 virus, bovine respiratory disease virus, and *M. haemolytica* and *H. somni* for administration all at the same vaccination time.

Efficacy of Bovine Viral Diarrhea Virus Vaccines

The main concern of BVDV vaccine development and protective efficacies of current vaccines results from the extensive genetic and antigenic diversity of pestiviruses. Although there is considerable antigenic similarity between the biotypes of the virus and among isolates of either biotype, there is also antigenic diversity among the isolates. Neutralizing antibodies induced by vaccination might therefore not react with certain isolates of the virus. This antigenic variance may interfere with the efficacy of a vaccine because immunity against strains that are homologous to the vaccine strains are less pronounced against heterologous field strains. Vaccination of yearling cattle with either of two commercially available monovalent modified live BVD vaccines stimulated the production of SN antibodies to each of 10 CP and 10 NCP isolates of the virus by one or more of the animals by 14 days after vaccination. No animal produced detectable SN antibodies to all 20 viruses. The cross-protective efficacy of BVDV vaccines according to genotypes has been examined with contradictory results. Prior exposure of cattle to BVDV-1 (as either an MLV or inactivated vaccine) does not always provide protection against infection with BVDV-2. A commercial inactivated BVDV-1 vaccine provided significant but not complete clinical and virological protection against challenge with a heterologous BVDV-2 strain. Properly used vaccines containing BVDV-1 strains may therefore reduce the incidence and severity of disease associated with BVDV-2 but not provide complete protection.

---

**Fig. 8-30** Flow chart for testing a dairy herd to detect and eliminate bovine viral diarrhea virus persistently infected (PI) carrier cattle. **PCR**, polymerase chain reaction.
The efficacy of BVDV vaccines for the prevention of fetal infection has been studied in several experimental trials. Most trials using either MLV or inactivated BVDV vaccines revealed a high degree although not complete cross-protection against transplacental infection with heterologous virus strains. The use of multivalent vaccine containing strains of BVDV-1 and BVDV-2 appears to provide better cross-protection against fetal infection.

### Commercially Available Vaccines

Most of the commercially available vaccines for the BVDV are combined with other antigens such as the IBR, PI-3, and BRV viruses. In one study, the serologic responses of beef calves 6 to 8 months of age were compared following vaccination with eight commercial vaccines containing IBR, PI-3, bovine respiratory syncytial virus (BRSV), and BVDV. Generally, the serologic responses to the viruses varied among different commercial vaccines, between and within MLV and killed-virus vaccines, and routes of administration. All vaccinated calves developed higher antibody titers to the antigens than unvaccinated controls. The serologic responses to the BVDV were low; only 20% of the calves had a fourfold seroconversion to the virus after two vaccinations. There are wide variations in onset of antibody responses and duration dependent on vaccine type and virus involved.

Field observations indicate that vaccine potency may vary considerably. Some lots of vaccines have failed to induce seroconversion in calves following carefully controlled vaccination. Unpublished observations by some clinicians found a wide variation in the amount of virus present in vaccines, and manufacturing processes may vary considerably resulting in destruction of live virus. Thus part of the vaccination program may necessarily include evaluation of the vaccine by SN testing before and after vaccination, and submitting a sample of the vaccine to a laboratory for PCR testing or viral isolation.

### Strategies for Bovine Viral Diarrhea Virus Vaccination Programs

The strategies for effective vaccination against BVDV infections are prevention of fetal infection and control and prevention of postnatal infections.

### Prevention of Fetal Infection in Dairy and Beef Herds

With the present state of knowledge, a rational vaccination program to prevent fetal infection, for both beef-breeding herds and dairy herds, consists of vaccinating all calves at 4 to 6 months of age with an MLV vaccine. The emphasis must be on immunization of the heifers before breeding so that the virus does not reach the fetus before 120 days’ gestation. All heifer replacements and cows are vaccinated 3 to 6 weeks before breeding with an MLV vaccine. To ensure a level of herd immunity, all breeding females are revaccinated annually 3 to 6 weeks before breeding. All bulls are revaccinated annually.

**Colostral immunity** is present for up to 6 months of age in calves born from immune cows. Calves with even higher titers of colostral BVDV antibody may have an active response to vaccination, but it is questionable whether this is of any useful purpose. If vaccination of the dam before conception is the vital part of the program, the vaccination of calves born from immune cows may be unnecessary until they approach breeding age.

### Postnatal Bovine Viral Diarrhea Virus Infections

A rational vaccination program for the control of the new BVDV infections occurring in immunocompetent animals would be similar to the earlier mentioned program in dairy and beef breeding herds. However, in herds experiencing outbreaks of BVD infection caused by the highly virulent strains of the virus, it would seem rational to vaccinate all animals in the herd with the precaution that pregnant animals will have to be vaccinated with the inactivated virus vaccine.

### Vaccination Schedules

Strategic vaccination schedules for the various situations should emphasize induction of maximal protective responses to correspond with the stage of the production cycle when the risk and consequences of BVDV infections are greatest. This means well-timed administration of vaccines pre-breeding and preweaning to protect against reproductive losses and respiratory tract disease, respectively. Recommendations for vaccination schedules for beef and dairy cattle herds are outlined here.

**Beef Cow–Calf Herd**

All beef heifer replacements should be vaccinated with an MLV-BVDV vaccine at least 3 weeks before breeding. Cows should be vaccinated annually, at least 3 weeks before breeding.

Beef calves should be vaccinated at least 3 weeks before weaning to have maximum protection during subsequent periods of high risk at and after weaning.

**Beef Feedlot**

There is no indication for vaccination of feedlot cattle for MD in PI animals. In a population of feedlot cattle originating from several sources, the risk for a PI animal to develop MD cannot be reduced by vaccinating. Postvaccinal MD may occur in some cases. If there is a risk of the postnatal forms of BVDV, such as the paraeure BVD associated with the highly virulent strains of BVDV, the thrombocytopenia, and the immunosuppressive effects of benign BVDV infection, then feedlot cattle should be vaccinated on arrival, with an MLV vaccine. A review of bovine respiratory disease vaccine efficacy concluded that there were no reliable reports of field trials evaluating the clinical effects of BVDV vaccines in North American feedlot cattle.

The use of multivalent MLV viral vaccines containing IBR, PI-3, BVDV, and BRSV have been evaluated in fall-placed, auction market–derived, feedlot calves in western Canada. Those cattle receiving the multivalent vaccine had significantly lower treatment rates than those in the univalent vaccine group. Cattle receiving the multivalent vaccine had higher carcass weights, weight gain, and average daily gain throughout the feeding period. There was a net economic advantage when the multivalent vaccine was used compared with a univalent IBR vaccine.

### Dairy Herd

Dairy heifer calves should be vaccinated at about 4 months of age, and with a booster at 5 to 6 months of age. MLV-BVDV vaccines containing both type 1 and type 2 genotypes should be used.

Heifer replacements are vaccinated with an MLV-BVDV vaccine about 45 days before being bred for the first time. This will boost serum neutralizing titers as much as possible to prevent fetal infection in the first 140 days’ gestation. Dairy bulls are vaccinated at 8 to 12 months of age.

Recently calved cows are vaccinated with MLV-BVDV vaccine at about 30 days before breeding. This will ensure high SN titers to prevent fetal infection and thus prevent some congenital infections, abortions, and stillbirths. This practice furthermore stimulates high colostral antibody titers so that calves receive a large mass of BVDV antibody.

Inactivated BVDV vaccines can be used in pregnant cows when BVDV abortions are occurring in the herd. Two vaccinations, 2 to 3 weeks apart, beginning at the time of pregnancy diagnosis or 1 month before the estimated time of abortion. Vaccines containing both type 1 and type 2 genotypes are recommended. Inactivated vaccines have also been used at drying off and 3 to 4 weeks later to enhance colostral antibody titers. Booster vaccination of dairy cows 35 days after calving with an MLV-BVDV vaccine greatly increased the antibody response compared with saline controls and cows vaccinated with inactivated vaccines containing BVDV, IBR, BRSV, and PI-3 viral antigens.

Vaccination of pregnant cows and heifers with a multivalent vaccine containing MLV BHV-1, BVDV, PI-3, and BRSV during all three trimesters of pregnancy is safe provided the animals have been previously vaccinated before breeding with the same MLV components.
Veal calves should be vaccinated after arrival with an MLV vaccine containing type 1 and 2 genotypes.

Current Vaccination Practices
The most recent available survey of U.S. live stock producers indicates that the percentage of dairy operations vaccinating against BVD increased from 58% in 1991 to 74% in 2007. The same survey revealed that in 1996 over 58% of the dairy producers were using inactivated BVD vaccines, whereas over 62% were routinely using MLV vaccines in 2007. The proportion of improperly vaccinated herds is unknown. In the 1993 outbreaks of peracute/acute forms of BVD in the United States and Canada, it was found that many affected herds had not been vaccinated or had been vaccinated improperly. Surveys in Pennsylvania indicate that many producers did not vaccinate all susceptible groups of cattle in the herd, and many producers did not administer the secondary vaccination of the inactivated vaccine. Although 82% of dairy producers indicated they routinely vaccinated their herds, only 27% of the herds were found to be adequately vaccinated. A survey of vaccination practices in Saskatchewan dairy herds indicated that only 34% of dairy herds were vaccinated against BVDV. In addition, only 25% of producers who vaccinate follow the label directions for administering inactivated virus vaccines, and more specifically, the requirement to give two doses at the recommended interval. The three most common practices were annual vaccination (50%), vaccination before breeding (19.5%), and biannual vaccination (7.3%).

Inadequate vaccination practices can be minimized by the veterinarian who can play an important role in clearly outlining in written form the vaccination program for individual herds. Constant surveillance of the health management strategies is necessary. Good and reliable records that keep track of vaccinations—when they were given, which animals were vaccinated, and which vaccines were used—are vital. Veterinarians must work with their clients to develop a specific vaccination and biosecurity protocol for each herd.

Vaccine failures may occur because of improper use and storage of the vaccine. Syringes must be not washed with water or solutions containing chemicals or ingredients because this will readily kill any live virus in the vaccine.

Eradication of Bovine Viral Diarrhea Virus Infection Without Vaccination
The BVD disease complex has been known since the late 1940s and early 1950s. Since about 1985, veterinarians have attempted to control the disease by culling PI animals, vaccination, and using certain levels of biosecurity. The diverse and vague clinical signs of the infection have made diagnosis difficult, costly, and often elusive and frustrating. Several diagnostic tests have been developed to aid in diagnosis of BVDV infections, and most importantly for the detection of PI animals. Many vaccines have been developed since about 1960 that have reduced losses but not adequately enough because none of the vaccines will provide complete protection given the antigenic diversity of BVDV isolates. Anything less than absolute fetal protection by vaccines will still allow some PI animals to be present in the herd. Because of these difficulties and the high economic losses associated with BVDV, total eradication of the virus from herds of cattle and from countries has now become a reality.

A control and eradication program against BVDV without vaccination has been successfully implemented in the Scandinavian and other European countries with (near) complete elimination of BVD from their cattle population. The Swedish BVD control program was among the first of the BVD eradication programs implemented on a national level and is the basis for many voluntary or national BVD control and eradication programs in other countries.

Concepts that are common to most control and eradication programs for BVDV include the following: (1) a herd is not infected until one or more persistent infections have been established; (2) the high incidence of self-clearance will reduce the prevalence of BVDV infections in cattle populations even without active disease clearance, provided virus is not reintroduced; and (3) BVDV cannot persist within a herd when contacts between PI animals and susceptible animals in early pregnancy do not occur. Thus the “test and cull” strategy is the major principle for effective eradication.

Before considering an eradication program in a region or country, an overall assessment of the economic importance of the BVDV disease complex should be conducted. Cost is an important factor in determining whether any measures against the infection should be initiated. Ideally, the overall cost of an organized an eradication program should be administered by dairy and beef cattle associations and animal health organizations. Diagnostic laboratories must be able to assist with the planning of sampling and providing information on the epidemiology of the infection to cattle producers in general, ensuring that known risk factors are identified and minimized.

The components of an organized eradication program based on test and cull include several factors:

- **Population dynamics.** In the region of concern, basic cattle population data such as average size of herd, production type (dairy, beef or others), and population density should be available. Basic knowledge of the dynamics of the cattle industry such as movement patterns, restocking of breeding herds, vaccination programs, livestock markets, community pastures, and cattle exhibitions and sales is necessary.

- **Prevalence monitoring.** A comprehensive knowledge of the prevalence of infection is necessary to identify herds with an ongoing infection with BVDV as well as those susceptible to infection.

- **Diagnostic tests.** Reliable diagnostic tests for test and cull programs are necessary. The tests must be as sensitive and specific as possible, and they must be easy to use, be reproducible, be suitable for large-scale testing, and be of reasonable cost.

- **Education.** All those involved in the actual program must be fully informed with the latest information about the various aspects of the BVDV disease complex, including how the virus is transmitted, diagnostic testing and interpretation of results, and the strategies to be used.

- **Biosecurity.** Biosecurity measures to prevent introduction of infection into virus-free herds must be given high priority. This includes consideration of the possibilities of direct and indirect contact with infectious animals outside of the herd, and ensuring that all replacement animals imported into a herd cleared of BVDV are kept in quarantine facilities until they are verified free of the virus. If different herds share common pastures, rules should be set out to ensure that only BVDV-free animals are allowed onto the pastures. Other means of reinfection are by biologic products, including semen, embryos, colostrum, vaccines, and other veterinary drugs, which should be verified free from BVDV before being used.

- **Logistics.** The overall plans for sampling and testing should be outlined by an advisory body with access to all available data on epidemiology and laboratory capacity. On a regional basis, organization of testing, actions after initial screening of herds, and follow-up testing could be organized advantageously by a district veterinary officer or someone with similar experience in surveillance for notifiable animal diseases.

- **Animal identification.** Individual animal identification with easily read ear tags or electronic identification is a strict requirement.

- **Legislation.** Organized efforts to control BVDV on a national level requires legislation or some means of regulating free movement of potentially viremic animals. Initially, this may become a requirement of herd managers who have successfully cleared their animals of...
BVDV or livestock trade or breeding companies who want to promote a specific health status of their animals. At later stages, test certificates documenting freedom from BVDV issued by district veterinary officers engaged in organization of BVD control activities may evolve as mandatory documentation to allow access to livestock auctions, exhibitions, or communal grazing land.

Bovine Viral Diarrhea Control Programs in Different Geographic Regions and Countries

Scandinavian Countries

Scandinavian countries have successfully implemented BVDV control programs without the use of vaccines and have or are about to achieve complete eradication. The seroprevalences of BVDV in the cattle populations of these countries before implementing control measures ranged from very high to low. In the early 1990s, the herd-level seroprevalence of BVDV was 40% in Denmark, 25% to 40% in Norway, and 1% in Finland. No vaccines against BVDV have been licensed or used in these countries; thus the seroprevalence was from natural infection.

The basic elements of the control programs in all Scandinavian countries are similar. Three different activity levels can be distinguished. The first level included screening of all cattle herds with the principal aim of identifying BVDV-free herds and maintaining them free. Bulk milk samples collected for milk-quality monitoring or sera from a limited number of animals representing all epidemiologic groups of the herd are tested for antibodies to BVDV. Next they are scored to indicate freedom from BVDV or a more or less likely ongoing infection with BVDV. This populationwide screening is repeated annually to monitor the spread of BVDV or the effect of the control program. The second level of activity aims to identify herds with an active infection among those positive for BVDV, for example, those with one or more PI animals. By limiting the number of herds that require a full-herd screening, efforts can be focused where needed and the overall cost minimized. The aim of the third level activity is to identify all PI individuals in herds with active infection. This involves an initial sampling of all cattle on the farm, plus a follow-up phase to test calves born to BVDV antibody–positive dams that were pregnant during or shortly after the initial testing. After the herd clearance is completed, surveillance at level 2 serves to verify success and eventually to certify that cleared herds are free from BVDV, despite still strongly positive by level 1 antibody surveillance results.

United Kingdom

In 1999, in the UK, the cattle industry established Cattle Health Certification Standards (Checs) as a nontrading organization to promote and regulate voluntary schemes for the control of BVDV and other pathogens. The basis of Checs is the identification and removal of PI animals from herds, combined with changes in husbandry procedures to prevent infection from being reintroduced. There are three programs, allowing the farmer to work with the veterinarian to formulate a BVDV health strategy to meet the particular needs of that farm. The accreditation program demonstrates the herd is free from BVDV and to maintain freedom from the virus and to allow the sale of animals as accredited free of the virus. In the screening and eradication program the objective is to implement a control program to reduce the detrimental effects on the herd productivity associated with the BVDV and to allow sale of animals of known status. The program applies where there is already evidence of recent BVDV infection in the herd or where positive results have been found in the course of an accreditation program. In the vaccination monitored free program the objective is to control BVDV infection through vaccination of the breeding herd and, by regular monitoring of young animals, to demonstrate that the control is effective and exposure of young animals to the virus has not occurred. The goal is to allow the sale of animals that are accredited as being from a vaccinated herd and monitored free of active BVDV infection. This program is considered appropriate for commercial herds selling animals for finishing. The status of these herds is lower than that of BVDV-accredited herds.

Continental Europe

Countrywide BVDV control schemes involving entire cattle populations have recently been launched in several countries on the European mainland such as Austria, Germany, and Switzerland. In Austria, which is currently considered free of BVD, the national BVDV control program requires cattle herds to conduct a herd screening on a yearly basis. The objective of the annual screening is to identify herds with recent or ongoing BVD infection by detecting seroconversion. A herd can be tested through serologic examination of a bulk milk sample, serologic examination of a subset of young lactating cows, or a subset of animals between 6 and 24 months of age. Herds with negative serologic results are classified as free of BVD, whereas herds with positive serology are classified as suspect of BVD infection. These herds must undergo further examination, consisting among others of a compulsory virus antigen screening of all newborn calves in their first 5 weeks of life. The PI animals must be euthanized or slaughtered within 14 days. Animals leaving or entering a herd must be tested for persistent infection before they can be marketed. With the control program being based on detection of seroconversion, vaccination against BVD is evidently not permitted. Although sample collection and laboratory costs are the producer’s expenses, compensation is granted for every PI animal that is to be destroyed.

After several years of BVD control at a state level, Germany implemented a nationwide BVD control program in 2011 that is based on compulsory screening for persistent infection (ear notch) of every calf in the first 6 months of life or before it leaves the herd of origin. A virus-negative result of a calf automatically grants the same status to its dam. The status of “not persistently infected with BVDV” is recorded in a national database, and only animals with this status on record are allowed to be marketed. Because the program is based on virus or virus antigen detection the use of BVD vaccines remains possible and permitted. Costs for sample analysis are covered by the authorities, and the producer is eligible for a compensation for every PI animal.

In the United States the Academy of Veterinary Consultants published a position statement encouraging the implementation of BVD control programs. Since then, several voluntary control programs, mainly for dairy but also for beef herds, on a state level have been developed and implemented in Colorado, Alabama, Montana, Washington, New York, and Michigan. The main pillars of these programs include the following:

- Educating the producers about the biology of BVDV infection and the routes of transmission
- Definition and implementation of required testing strategies
- Implementation and documentation of standard biosecurity measures
- Implementation of specific vaccination strategies and schedules

Some programs provide subsidies for expenses related to testing and destruction of PI animals. Currently there are no plans to eradicate BVDV as is being done in the Scandinavian countries. However, it is very realistic and possible that the virus could be eradicated on a herd-by-herd basis using detection and elimination of PI animals, the judicious use of effective vaccines, regular diagnostic testing for PI animals, and implementation of biosecurity measures to ensure that reinfection of the herd of does not occur.

FURTHER READING

Winter dysentery is associated with the bovine coronavirus (BCoV), a single-stranded RNA virus, which is a member of the family Coronaviridae, order Nidovirales. BCoV has been associated with diarrhea in calves and adult cattle (winter dysentery) as well as with respiratory disease in calves and adults. Virus strains isolated from the respiratory tract have been designated as bovine respiratory coronavirus (BRCov), whereas those strains isolated either from adult cattle or calves with diarrhea have been designated as bovine enteropathogenic coronavirus (BECov). For clinical purposes strains isolated from diarrheic calves are often referred to as BCoV—calf diarrhea (BCoV-CD) and those from adult diarrheic cattle BCoV-winter dysentery (BCoV-WD).

There is ongoing debate over whether the strains of BCoV isolated from the respiratory and gastrointestinal tract are the same or dissimilar. It is still unclear whether the different isolates can be distinguished antigenically, but it has been proposed that enteropathogenic and respiratory strains may be the same virus at different stages of its infectious life cycle.\(^1\)

Several studies have found a close serologic relationship between the coronavirus causing winter dysentery and the coronavirus causing diarrhea in calves, but there are antigenic differences between the different isolates. The oral and intranasal inoculation of gnotobiotic and colostrum-deprived calves with BCoV-WD results in diarrhea in the calves indistinguishable from that seen in calves inoculated with the calf diarrhea coronavirus. The BCoV has also been isolated from the diarrheic feces of adult wild ruminants (samar deer, one waterbuck, and white-tailed deer) affected with diarrhea in both England and the United States. The BCoV has tropism for both the intestinal and respiratory tracts.

**ETIOLOGY**

**Etiology** Bovine coronavirus.

**Epidemiology** Northern climates. Adult lactating dairy cows, usually during winter months when housed. Immunity develops and lasts variable periods. High morbidity with outbreaks; low mortality. Transmitted by fecal–oral route.

**SYNOPSIS**

**Winter Dysentery of Cattle**

**Epidemiology** Northern climates. Adult lactating dairy cows, usually during winter months when housed. Immunity develops and lasts variable periods. High morbidity with outbreaks; low mortality. Transmitted by fecal–oral route.

**ETIOLOGY**

Winter dysentery is associated with the bovine coronavirus (BCoV), a single-stranded RNA virus, which is a member of the family Coronaviridae, order Nidovirales. BCoV has been associated with diarrhea in calves and adult cattle (winter dysentery) as well as with respiratory disease in calves and adults. Virus strains isolated from the respiratory tract have been designated as bovine respiratory coronavirus (BRCov), whereas those strains isolated either from adult cattle or calves with diarrhea have been designated as bovine enteropathogenic coronavirus (BECov). For clinical purposes strains isolated from diarrheic calves are often referred to as BCoV—calf diarrhea (BCoV-CD) and those from adult diarrheic cattle BCoV-winter dysentery (BCoV-WD).

There is ongoing debate over whether the strains of BCoV isolated from the respiratory and gastrointestinal tract are the same or dissimilar. It is still unclear whether the different isolates can be distinguished antigenically, but it has been proposed that enteropathogenic and respiratory strains may be the same virus at different stages of its infectious life cycle.\(^1\)

Several studies have found a close serologic relationship between the coronavirus causing winter dysentery and the coronavirus causing diarrhea in calves, but there are antigenic differences between the different isolates. The oral and intranasal inoculation of gnotobiotic and colostrum-deprived calves with BCoV-WD results in diarrhea in the calves indistinguishable from that seen in calves inoculated with the calf diarrhea coronavirus. The BCoV has also been isolated from the diarrheic feces of adult wild ruminants (samar deer, one waterbuck, and white-tailed deer) affected with diarrhea in both England and the United States. The BCoV has tropism for both the intestinal and respiratory tracts.

**EPIDEMIOLOGY**

**Occurrence and Prevalence of Infection**

BCoV is highly prevalent in the cattle population all over the world. The virus is recognized as an important causative agent for diarrhea in neonatal calves. In contrast winter dysentery is a sporadic condition associated with watery, bloody diarrhea in adult cattle. Winter dysentery has been reported from many countries including the United States, Canada, Sweden, Germany, France, Israel, Australia, and New Zealand. It is common in dairy cattle in Sweden. A nationwide survey of antibodies to BCoV in bulk tank milk in Swedish dairy herds found that 89% of samples were positive and 52% had very high levels of antibodies.

Winter dysentery is most common in recently calved adult dairy cows. Young cattle and even calves may be affected but with only mild clinical signs. Highest incidences are observed during the colder months of the year when animals are housed with close contact to each other. In Sweden, 75% of all outbreaks occur between November and January. Winter dysentery has also occurred in adult beef cattle and in feedlot cattle 6 to 9 months of age. A typical outbreak lasts for 1 to 2 weeks and spreads in an epizootic manner throughout an infected herd.

A moderate immunity, which persists for about 6 months, develops after clinical disease, and recurrent clinical disease seldom occurs in less than 2 to 3 years. In herds regularly exposed to the infection, epidemics are mild; when the intervals between recurrences are more than 3 years, the epidemics are more severe. Serologic examination of paired serum samples from affected herds reveal that almost all cows seroconvert to BCoV and BVDV. The titers to BCoV are still high 1 year after the outbreak, and antibody is transferred to colostrum and to the calves in which it persists for up to 4 to 6 months of age.

A coronavirus indistinguishable from BCoV has been isolated from wild ruminants with diarrhea similar to winter dysentery in cattle. The virus was isolated from the feces of sambar deer, waterbuck in a wild animal habitat, and from a white-tailed deer on a wildlife farm in Ohio. In a serologic survey of coronaviruses among wild deer, 8.7% and 6.6% of sera from mule deer in Wyoming and from white-tailed deer in Ohio, respectively, were seropositive against the wildlife isolates and selected bovine coronaviruses. Thus coronaviruses exist in wild ruminants, which may be a source of infection transmissible to cattle.

**Morbidity and Case–Fatality Rates**

The morbidity rate may be as high as 30% to 50% within a few days after the first case is encountered and up to 100% after 1 week. The case–fatality rate is less than 2%. In recent years an increase in case–fatality rates as been reported in the Great Britain, for which changes in the virulence of circulating viral strains may have been the cause.\(^2\) The disease is important in dairy herds because, although few animals die of the disease, it
may cause serious loss of body condition and milk production. In mild epidemics, the maximum decrease in milk production compared with a theoretical lactation curve ranges from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 11%. Drops in daily milk yield in more severe cases can range from 25% to 95%. The overall decrease in milk yield in more severe cases can range from 6% to 95%. The overall decrease in milk production may persist for 8 to 15 days.

Outbreaks of the disease exhibit space-time clustering within a 30-day time and a 5.5-km radius. Large herds with more than 60 cows and a history of an outbreak in the previous year were at increased risk of an outbreak. In Sweden, one-third of the affected herds had experienced an outbreak within the previous 4 years and 18% had a least one further outbreak during the following 2 years.

Methods of Transmission

Feces and, to a lesser extent, secretions from the upper airways from clinical and subclinically infected animals are the main source of infection, and contamination of feed or drinking water is the method of spread. Vertical transmission has not been documented. The disease is highly contagious and can be introduced to farms by human visitors, carrier animals, and fomites. Infection of the respiratory tract with BCoV may enhance the transmission of the infection in addition to the usual fecal–oral route of transmission for enteric pathogens.

Experimental Reproduction

Both winter dysentery and calf diarrhea can be reproduced using the same strain of BCoV. Calf diarrhea and winter dysentery strains of the virus can cause diarrhea in adult cows in conjunction with host or environmental factors. Winter dysentery can be reproduced in seronegative lactating dairy cows by direct contact with an experimentally infected calf. All experimental cattle shed the virus in the feces at the onset of profuse watery diarrhea with small amounts of blood in the feces of the most severely affected animals including both cows and calves. The cows are commonly more depressed, and their appetites are decreased, which is associated with a marked decrease in milk yield. Following infection, all cattle will produce early IFN type 1 in serum and in nasal secretions and milk. All cattle develop high IgM antibody responses and long-lasting IgA antibody responses both systemically and locally. Prolonged IgM antibody responses occur in all infected cattle. The IgA antibody response in serum may be detectable for up to 17 months after infection. Bovine-specific IgG can be detected in all cattle during the experimental period of up to 22 months.

Risk Factors

Host and Environmental Risk Factors

Various host and environmental risk factors potentially contributing to the occurrence of clinical disease have been identified in epidemiologic studies. The risk of clinical disease for an individual animal was found to be the highest for recently calved cows between 2 and 6 years old. Pregnant cattle were less likely to develop the disease compared with nonpregnant animals, and cows with high acute antibody titers to BCoV had greater odds of developing disease, compared with cows with lower titers.

On a herd level a history of previous episodes of winter dysentery and a herd size of 60 head or larger increased the risk of a winter dysentery outbreak. Housing cattle in tie-stall or stanchion barns rather than free stalls and use of equipment to handle manure and subsequently handle feed were factors that further increased the risk of winter dysentery outbreaks.

Other factors considered to contribute to the occurrence of clinical disease include environmental stress (e.g., inclement weather or shipping), human visitors that had recent contact with infected cattle, and purchase of animals potentially carrying the virus. Pathogen Risk Factors

Coronaviruses are divided into at least three antigenic groups, and antigenic cross-reactivity exists within an antigenic group. BCoV, mouse hepatitis virus, murine enteric coronavirus, rat coronavirus, human coronavirus, and porcine hemagglutinating encephalomyelitis virus belong to the same group. BCoV is an important cause of neonatal calf diarrhea and winter dysentery, but BCoV also possesses tropism for the respiratory tract of young cattle.

Some BCoV strains isolated from the respiratory tract of cattle had different biological, antigenic, and genetic properties compared with enteric strains of the virus. Strains isolated from feedlot cattle and compared with those with the originally described Mebus prototype (from neonatal diarrheic calves) reveal that the respiratory strains of BCoV may differ genetically from the classical calf enteric and adult winter dysentery strains.

Cross-protection studies between respiratory and calf diarrhea and winter dysentery coronavirus strains in calves have been examined using RT-PCR and nested PCR for their detection. Calves inoculated with BRCoV, calf diarrhea coronavirus, winter dysentery coronavirus and then challenged 3 to 4 weeks later with either BRCoV, CD, or WD strains of BCoV developed diarrhea, then recovered, and were protected from BCoV-associated diarrhea after challenge exposure with either homologous or heterologous BCoV strains.

Nasal and fecal shedding of BCoV, which was detectable only by nested PCR, after challenge exposure confirmed field and experimental data documenting reinfection of the respiratory and enteric tracts of cattle. This indicates that in closed herds, respiratory or enteric tract infections may constitute a source of BCoV transmission to cows or young calves.

PATHOGENESIS

The pathogenesis of BCoV-WD infection is not completely understood. Because BCoV is considered to be ubiquitous in the cattle population, persisting in subclinically infected animals, it is assumed that environmental risk factors are required to trigger clinical disease. Environmental stress in the form of inclement weather, overcrowding, or shipping may result in increased virus shedding through feces and nasal secretions.

After oral infection the virus initially replicates in the enterocytes of the digestive tract and epithelial cells of different sections of the respiratory tract. Within the intestinal tract the enteropathogenic BCoV, which has a known tropism for the small and large intestinal tract, appears to spread from the small to the large intestines. Ultimately mucosal lesions may be found in all sections of the intestinal tract including jejunum, ileum, cecum, colon, and rectum, with the colon most severely affected. This virus-associated tissue trauma consists of progressively worsening villous atrophy and fusion of the intestinal mucosa. The morphologic changes associated with winter dysentery have been termed virus-induced enterocolitis. Within the respiratory tract, experimental infection with the enteropathogenic winter dysentery strain of BCoV was associated with epithelial damage in nasal turbinates, trachea, and lungs, as well as interstitial pneumonia. Mucosal lesions in the intestines result in malabsorptive diarrhea and shedding of variable amounts of blood into the gut. Lesions in the respiratory tract may become clinically apparent as upper and/or lower respiratory tract disease if severe enough.

CLINICAL FINDINGS

Cattle

After an incubation period of 3 to 7 days there is an explosive outbreak of diarrhea which, in the course of the next 4 to 7 days, affects the majority of adult cattle in the herd. The youngest animals of the mature group may have only mild signs. A fever (39.5°C–40.5°C; 103°F–105°F) may preceed the onset of diarrhea, but when clinical signs are evident the temperature is usually normal. There is a marked fall in milk yield that lasts for up to 1 week, anorexia of short duration, and some loss of body condition. The feces are liquid, often hemorrhagic and homogenous without much odor, and with no mucous or epithelial shreds; the color is dark green to almost black (depending on the amount of blood shedding into the gut). Feces are often passed with little warning and considerable velocity. A nasalalcrimal discharge and cough may precede or accompany the epidemic. The frequency of
coughing may be higher in those herds that have not experienced a more recent outbreak. In most animals the course is short and the feces return to normal consistency in 2 to 3 days. In occasional cases the syndrome is more severe, dehydration and weakness are apparent, and dysentery—either with feces flecked with blood or the passage of whole blood—occurs. The disease in the herd usually subsides in 1 to 2 weeks but in some cases production may not return to normal for several weeks or a few months. Case fatalities associated with winter dysentery were primarily associated with severe blood loss into the gut and ensuing anemia rather than dehydration.7

In feedlot cattle, 6 to 9 months of age, the disease has been characterized by an acute onset of diarrhea with high morbidity and mortality, dyspnea, coughing, and nasal discharge, and high body temperature (40°C–41°C) in most severe cases. The diarrhea is characterized by fluid dark (brown-black) feces sometimes containing frank blood.

**CLINICAL PATHOLOGY**

The laboratory diagnosis is dependent on detection of the virus in feces or upper respiratory tract secretions and serology. Fecal and blood samples should be submitted from both affected and normal cows.

**Detection of Virus**

Fecal samples or oropharyngeal fluid can be examined for the presence of BCoV using ACE or electron microscopy. For routine purposes, direct electron microscopy viral identification and/or ELISA is sufficient. This can be complemented by the protein A gold immune electron microscopy because of its high sensitivity and specificity in the detection of viral particles. A reverse transcriptase (RT)-PCR can be used to detect BCoV in clinical samples. A LFT has been established in Europe for the BCoV antigen detection in feces.1

**Serology**

Attempts at diagnosing these infections serologically are often problematic because in adult cattle high BCoV-specific IgG levels are often encountered in the acute samples, presumably due to reinfections with the virus, obscuring the detection of a possible increase in titer in paired samples. In addition, adult cattle are usually seropositive and maternal antibodies frequently obliterate the detection of infection in calves.

A capture ELISA test for BCoV-specific IgA and IgM in milk and sera has been developed and is useful for discriminating between primary infection and reinfection. In adult cattle, testing of paired serum samples using the antibody-capture ELISA may be a better indicator of recent BCoV exposure than testing of serum samples with virus neutralizing assays. Antigen–antibody binding in feces may interfere with results of the ACE for BCoV.

**NECROPSY FINDINGS**

In the rare fatalities available for necropsy, there is severe hemorrhage and hyperemia of the colon and cecal mucosa.6 Frank blood may be present in the lumen of the large intestine.2 Microscopically there is widespread necrosis and degeneration of the epithelium of the large bowel. Lesions consist of pyknosis and karyorrhexis, and granular degeneration, hydropic degeneration, and hyaline droplet degeneration of crypt epithelial cells. Similar but less severe gross and microscopic changes have been observed in experimentally infected cattle.1

**Samples for Confirmation of Diagnoses**

- **Histology:** formalin-fixed cecum, colon (IHC)
- **Virology:** colonic content (Electron microscopy, ACE), colon (FAT).

**DIFFERENTIAL DIAGNOSIS**

Winter dysentery must be differentiated from the following:

- **BVD/mucosal disease** affects primarily younger cattle in small outbreaks (BVD) or individual animals. Erosions of the oral cavity are present and the diarrhea and systemic effects are much more severe. BVD serotype II may affect cattle of all ages including adult cattle and is a severe, highly fatal disease.
- **Coccidiosis** affects cattle from 3 to 12 months of age and is characterized by frank blood in the feces, tenesmus, and diarrhea of longer duration. Fecal sample is usually diagnostic.
- **Enteric salmonellosis** is a severe toxemic enteritis with diarrhea and dysentery, fibrinous casts in the feces, a high fever, severe depression, and rapid death. Culture of the feces is important.
- **Paratuberculosis** characterized by chronic intractable diarrhea in mature cattle with loss of body weight and eventual emaciation. The condition in its clinical stage generally affects single or few animals within a herd at a time.
- **Group B rotavirus**. Rare cases of diarrhea in mature lactating dairy cows associated with group B rotavirus have been described. The onset of diarrhea is sudden, milk production decreased, the feces were liquid, and recovery occurred in 3–5 days.
- **Schmallenberg virus**. Outbreaks of profuse watery, but not bloody diarrhea in dairy herds that were associated with mild systemic disease and a marked transient drop in milk production were reported in Northern Europe in the fall of 2011. Symptoms were later linked to an epidemic Schmallenberg virus infection in the region.6

**TREATMENT**

Treatment is of doubtful value because affected cattle usually respond spontaneously in 24 to 36 hours. Occasionally dehydration will become severe and is best treated with fluids and balanced electrolytes as indicated.

**CONTROL**

No specific and effective methods to control or prevent outbreaks of winter dysentery are available. Control measures should focus on assuring adequate host immunity, minimizing stress, and reducing exposure to clinical cases whenever this is feasible. Every effort must be made to avoid the spread of infection on inanimate objects such as boots, feeding utensils, and bedding, but even the greatest care does not appear to prevent the spread of the disease within a herd.

**Vaccination**

Some preliminary studies have tested the potency of BCoV vaccine to induce serum antibodies, but randomized controlled trials to test the efficacy of the vaccine have not been done.

**FURTHER READING**

**REFERENCES**

**BOVINE PAPULAR STOMATITIS**

**SYNOPSIS**

**Etiology** Bovine papular stomatitis virus, member of the parapoxvirus genus.

**Epidemiology** Worldwide occurrence; cattle of all ages can be infected, clinical signs most common in young animals. Outbreaks of BPS in dairy herds have been reported. BPS is a zoonosis causing skin lesions after direct contact in animals handlers.

**Signs** Lesions on the muzzle, inside the nostrils, the oral cavity, teat and udder skin, occasionally also esophagus and...
Lesions on teat and udder skin were painful reddish papules (3–10 mm in diameter) and scabby proliferative lesions that frequently appeared on several teats simultaneously. A few days after the appearance of the first lesions, papules, coalescent scabby erosions, and ulcerations were noticed. The clinical course of the condition lasted 7 to 12 days and lesions tended to regress in the third week of the disease. Affected animals resisted to being milked because of severe local pain. Secondary mastitis of undetermined etiology was reported in some cases.1,2,4

Because repeated infection with BPSV has been documented, it is suggested that no immunity occurs and the virus may only cause lesions when intermittent disease causes lowering of the animal's resistance. The disease, known as "rat-tail syndrome" in young cattle in feedlots, is probably a manifestation of sarcocystosis. However, there is also a high prevalence of bovine papular stomatitis lesions and virus in these cattle and it is possible that it may contribute to the development of the disease. A concurrent infection of bovine papular stomatitis and BVD has been described in a calf.

The disease in reindeer associated with a virus closely related to the PCPV is characterized clinically by erosions, papules, pustules, and ulcers in the oral cavity. Outbreaks have occurred in Finland, particularly during the winter, and the case-fatality rate can be up to 25%.

CLINICAL PATHOLOGY
Histologic examination of surgically excised vesicles and papules reveals a characteristic ballooning degeneration and the presence of cytoplasmic inclusions in affected cells. Diagnosis of the presence of the virus can be made by electron microscopy and immunohistochemistry of scabs. Virus isolation on cell culture can be attempted.

PCR methods have been developed and established in recent years to differentiate between different parapox virus infections in both domestic and wild animals. The serologic tests used for detection of different PPV infections include VNT, AGID, CF test, and agglutination test. The value of serology has been questioned because of the presumed high seroprevalence of parapox antibody–positive cattle.2,4

DIFFERENTIAL DIAGNOSIS
Clinical differential diagnoses for bovine papular stomatitis include the following:

- Foot-and-mouth disease
- Pseudocowpox virus infection
- Bovine viral diarrhea infection (BVD type 2 and mucosal disease)
- Bovine herpesvirus-2 (BHV-2, causing bovine mammillitis) in cases where teat skin and udder skin are affected
- Orthopoxvirus infection

ETIOLOGY
Bovine papular stomatitis is caused by the bovine papular stomatitis virus (BPSV) that is a member of the Parapoxvirus (PPV) genus within the Poxviridae family. The PPV family includes four species:

- Prototype Parapoxvirus ovis or Orf virus (ORFV, causative agent of contagious ecthyma)
- BPSV (causing bovine papular stomatitis)
- Pseudocowpox virus (PCPV, causing "milker's nodules")
- PPV of reads dear in New Zealand

BPS was associated with a decrease in milk production or even an interruption of lactation.1

BPSV infection is an often neglected zoonosis causing primarily mild papular skin lesions after direct contact with infected animals. Reports of confirmed BPSV infection in humans that were associated with severe skin lesions affecting 50% of the dorsal skin surface of both hands have been published recently.3

Transmission
The transmission appears to occur fairly easily either through direct contact with skin lesions or through fomites that may play a role in the spreading of the disease during outbreaks in milking herds (milking machine).2 Experimentally the infection can be transmitted by the inoculation of scrapings from lesions into the oral mucosa of susceptible calves and by submucosal inoculation of undiluted tissue culture virus.

CLINICAL FINDINGS
The classic presentation of the disease is in young animals from 2 weeks up to 2 years of age and in a group the morbidity often approximates to 100%. Typically lesions occur in the form of papules on the muzzle, inside the nostrils, and in the oral cavity. Lesions on the muzzle may be difficult to see if the area is pigmented. In the mouth the lesions occur on all mucosal surfaces except the dorsum of the tongue and are most common inside the lips and in close proximity to the teeth. Occasional cases occur in which the only lesions are in the esophageal and forestomach mucosa.

In recent years there have been several reports of confirmed BPSV infection in adult dairy cattle that were associated with severe dermatitis on teat and udder skin, that resembled bovine herpes mammillitis, and that were clinically and histologically indistinguishable from PCPV infection.1,2,4

Lesions commence as small (0.5–1 cm) papules that become dark red in color, develop a roughening of the surface, and expand peripherally so that the lesions are always round or nearly so. Confluence of several lesions may cause the development of a large irregularly shaped area. As the lesion expands, the periphery becomes reddened and the center depressed, gray-brown in color and rough on the surface, and eventually covered with necrotic tissue or on external lesions by a scab. Individual lesions heal quickly, sometimes in as short a time as 4 to 7 days, but evidence of healed lesions in the form of circular areas of dark pink mucosa usually surrounded by a slightly paler raised zone may persist for weeks.

There may be transient anorexia, weight loss, ptyalism, and a slight fever (39.5°C; 103°F), but in most instances the disease goes unnoticed unless a careful examination of the mouth is made.

EPIDEMIOLOGY
BPS is a generally mild viral disease of cattle with worldwide occurrence. It is characterized by proliferative skin lesions without systemic clinical disease. Primarily calves and young cattle present clinical signs, but outbreaks of BPS in dairy herds with skin lesions on teat and udder skin have been reported from Brazil and Japan.1,2 The infection prevalence of BPSV infection does not appear to have been studied in detail but is likely to be underestimated as most infections may pass unnoticed. A serologic survey conducted in Japan found a seroprevalence of PPV antibodies in cattle of over 50%, with a likelihood of seropositivity increasing with age.3

The primary importance attributed to this condition was that it presents an important differential diagnosis for foot-and-mouth disease. Economically BPS was considered to be of minor relevance because most infections pass unnoticed, skin lesions are minor and rarely associated with systemic disease, and healing occurs spontaneously. Notwithstanding outbreaks of BPSV infection in dairy herds in Brazil and Japan were associated with painful skin lesion on the teats of milking cows.1,2,4 In these cases infection in dairy herds in Brazil and Japan are minor and rarely associated with systemic disease, and healing occurs spontaneously. Notwithstanding outbreaks of BPSV infection in dairy herds in Brazil and Japan were associated with painful skin lesion on the teats of milking cows.1,2,4 In these cases infection in dairy herds in Brazil and Japan are minor and rarely associated with systemic disease, and healing occurs spontaneously. Parasitic Diseases of the Ruminant Alimentary Tract

Parasitic Gastroenteritis in Ruminants

SYNOPSIS

Etiology: The nematode genera Trichostrongylus, Ostertagia, Cooperia, and Nematodirus (known locally as scour worms or hair worms) often occur together in the alimentary tract of ruminants. Their combined effects on the host, together with those of other alimentary nematodes such as Oesophagostomum and the hookworms, are commonly known as parasitic gastroenteritis (PG). The main species are listed in Table 8-11 together with their hosts and anatomic preferences. The listed worms are from the same nematode family and are collectively known as the trichostrongylids. Haemonchus also belongs to this group but is considered separately because the disease processes it provokes are more complex. Taxonomists now think that the Ostertagia species of sheep should be assigned to a different genus and Teladorsagia and Nematodirus to a different family, but the clinical convenience of the older nomenclature has been retained for the purposes of this chapter. Related species from other hosts, for example, O. leptospicularis from deer, sometimes cause disease outbreaks in cattle.

LIFE CYCLE
The trichostrongylids all have direct life cycles (i.e., there is no intermediate host). Eggs passed in the feces hatch under suitable environmental conditions, producing two nonparasitic larval stages and then the infective third-stage larva. This is ensheathed, i.e., it retains the shed cuticle from the previous molt for protection. The eggs of Nematodirus spp. are different from the others. They are larger and do not hatch initially. Instead, an infective ensheathed larva develops within the egg, gaining even greater resistance to harsh environmental conditions. When infective trichostrongylid larvae are ingested by the host, they exsheath and, depending on species, enter either the gastric glands of the abomasum or the crypts of the small intestine. Here they molt, return to the lumen, and after a fourth molt mature to become adult. The time from ingestion of larvae to appearance of egg-laying females (the prepatent period) normally takes about 3 weeks, except for Nematodirus, which takes a week or so more. This period may become extended as third-stage or early fourth-stage larvae, depending on species, can become arrested in development (hypobiotic), delaying emergence from the mucosa for weeks or months.

Hypobiosis is probably an adaptation phenomenon similar to diapause in insects and happens during periods of adverse pasture conditions. For example, strains of O. ostertagi from northern Europe, the northern United States, and New Zealand undergo hypobiosis in autumn with worms resuming development in spring, whereas strains in the southern United States and Australia hypobiose in spring to emerge after the dry season in autumn. Thus hypobiosis ensures that a new generation of adults is ready to lay eggs when the external environment again becomes favorable. The environmental stimuli that condition infective larvae to become hypobiotic in the host vary with species and locality, and in most cases are unknown. For O. ostertagi in Europe, exposure of infective larvae to low temperatures in the autumn is the trigger. The proportion of ingested larvae becoming arrested varies greatly with locality and, in some places, also from year to year.

EPIDEMIOLOGY
Natural trichostrongylid infestations mostly comprise a mixture of species. The relative importance of each varies with locality and season. In sheep and cattle, Ostertagia tends to be of greatest clinical significance in winter rainfall areas, whereas Haemonchus is predominant in summer rainfall zones. Other genera may dominate in some areas or under some management practices. Sheep and goats share many trichostrongylid species but cross-infection between sheep and cattle occurs only to a limited extent. Patterns of disease are determined by factors influencing the susceptibility of the host, the numbers of infective larvae accumulating on the pasture, and the numbers of larvae undergoing hypobiosis in the host.

Resistance to trichostrongylid infections is complex and involves genetically determined physiologic and acquired immunologic components. Age resistance is seen particularly in the case of Nematodirus, in which 3- to 4-month-old lambs are better able to withstand larval challenge than younger animals. Differences in susceptibility occur between breeds and between individuals within a group. Acquired immunity in sheep and cattle develops quickly after exposure to Nematodirus but takes much longer with other gastrointestinal trichostrongylids. Consequently, disease associated with Nematodirus is only likely to occur at first exposure, but animals remain susceptible to the other trichostrongylids for most or all of the first grazing season. In cattle, exposure to Cooperia leads to immunity earlier in the season than is the case with Ostertagia. Lambs can develop high resistance to Trichostrongylus by about 6 months of age when larval intake is high, but this period is extended when challenge is low. In sheep infected with T. colubriformis, high IgA levels in response to T. colubriformis L3 carbohydrate surface antigen (CarLA) can prevent larvae from establishing in the gut, resulting in rapid expulsion larvae. Using a commercial test to measure saliva...
IgA antibody response to CarLa in animals under parasite challenge, high levels of IgA have been associated with lower fecal egg counts, and improved growth under challenge. Immunity may be expressed as the counts, and improved growth under parasite challenge, high levels of IgA antibody response to CarLa in animals.

For milk production over immune functions, as allocation of scarce metabolizable protein to feed intake at weaning increases susceptibility to trichostrongylid infection occurs in sheep but not in cattle before or at the time of parturition and reaches a peak 6 to 8 weeks after lambing. This happens because priority is given for allocation of scarce metabolizable protein to milk production over immune functions. As a result, ewes pass large numbers of worm eggs onto the pasture over a period of several weeks. This is known as the periparturient egg rise (PPER) and is an important source of pasture contamination.

† Trichostrongylus axei also occurs in the stomach of horses.

The genus name Teladorsagia is often used in place of Ostertagia for these species.

The term “resilience” is used to describe the ability of an animal to withstand the damaging effects of parasitic infestation (as distinct from limiting worm numbers). Resistance and resilience can be affected adversely by stress and nutritional deficiencies. Moderate infestations can be tolerated by animals on a good plane of nutrition when similarly infected but poorly nourished animals would succumb. In weaner lambs, the reduction of food intake at weaning increases susceptibility, whereas the poor quality of winter feed has the same effect in older stock. Massive infestations can overwhelm even well-fed animals.

A relaxation in immunity to trichostrongylid infection occurs in sheep but not cattle before or at the time of parturition and reaches a peak 6 to 8 weeks after lambing. This happens because priority is given for allocation of scarce metabolizable protein to milk production over immune functions. As a result, ewes pass large numbers of worm eggs onto the pasture over a period of several weeks. This is known as the periparturient egg rise (PPER) and is an important source of pasture contamination.

Nematodirus spp. behave differently from other trichostrongylids. This genus does not contribute to the PPER in ewes so lambs are the sole source of contamination on sheep pastures. Nematodirus eggs containing the infective third-stage larvae hatch only after exposure to specific stimuli, particularly warmth after a period of low temperatures. Thus most hatch in the spring of the year following that in which they were deposited (although a proportion may hatch in the autumn of the first year). Unlike the other trichostrongylids, therefore, Nematodirus is transmitted from one lamb crop to the next. N. battus is more pathogenic than the other species because its hatching requirements are more precise. This results in many eggs hatching simultaneously to produce a sudden overwhelming wave of pasture contamination.

The eggs and free-living larvae of Trichostrongylus, Ostertagia, Cooperia, and Nematodirus can survive and develop at much lower temperatures than those of Haemonchus. The eggs and larvae of Ostertagia and Nematodirus are particularly resistant to cold temperatures. The eggs of the latter worm contain trehalose, which acts as an antifreeze. All these trichostrongylids can survive a moderate winter but the spectrum of endemic species declines as regional winter conditions become more severe. Snow cover, however, protects infective larvae from extreme cold. Upper temperature limits for survival are also lower than for Haemonchus and this is why the clinical importance of Ostertagia spp. diminishes in warmer climates. Moisture is necessary for infective larvae to ascend the herbage and so transmission by all species is low in the absence of dew, rain, or irrigation. Desiccation will kill larvae on the pasture but those still within fecal deposits can survive to emerge when rainfall resumes. Severe outbreaks of disease may occur after the first rains following a prolonged drought. Summer storms during a dry period reduce risk as released larvae quickly die when the pasture dries out. In temperate climates, larvae leaving accumulated dung pats in the autumn after a dry summer may be conditioned for hypobiosis, increasing the risk of type II disease (see later section).

Potential sources of contamination on sheep pastures at the start of the grazing season are larvae that have overwintered on the herbage and, most important, larvae from eggs more recently shed by ewes during the PPER. On cattle pastures, overwintered larvae are of greatest significance as yearling and adult cattle generally deposit insignificant numbers of trichostrongylid eggs. In...
both cases, overwintered larvae do not survive long in the warmer spring weather because the food stores on which they depend are soon exhausted. In the meantime, however, some will be ingested by susceptible lambs or calves. Disease does not occur at this stage unless massive numbers of larvae have survived the winter. Most often, these first infections are small and asymptomatic. They are nevertheless of great epidemiologic significance as the eggs produced are responsible for the infective larvae that appear on the pasture later in the season.

The rate of larval development is temperature dependent, and occurs faster in warmer weather. The life span of infective larvae is, however, shorter at higher temperatures as food stores are used more quickly. The number of larvae accumulating on pasture is therefore a balance between these two opposing factors and tends to follow a stereotyped pattern in each locality. Computer models are being developed to investigate these trends in different climatic zones and under different husbandry systems. The general pattern of pasture infectivity may, however, be temporarily disrupted by short-term weather fluctuations. For example, with *O. ostertagi* in grazing calves in temperate climates, the new wave of infective larvae (the “autoinfection peak”) will not appear before midsummer, but this event may be delayed or interrupted by periods of dry weather. As larvae of each trichostrongylid species have different optimum developmental conditions, peak numbers will occur at different times. In England, for example, the “succession of species” in sheep is *N. battus* followed by *O. circumcincta* then *H. contortus* and finally *Trichostrongylus spp.*

Outbreaks of disease caused by trichostrongylid infection can occur in different ways. Clinical signs are normally initiated when developing worms emerge from the mucosa of the alimentary tract. With normally developing mucosal larvae, this will happen when the daily intake of infective larvae has risen to a level sufficient to overwhelm any immunity that may have developed. This is sometimes termed “type I” disease. The onset of clinical signs will be considerably delayed, however, when damage is produced by previously hypobiotic larvae resuming their development. This often occurs during the winter housing period and is known as “type II” disease. Additionally, hypersensitivity responses to incoming larvae can occur under some circumstances when immune animals graze heavily contaminated pasture. This has been proposed as an explanation for the so-called nonparasitic scouring syndrome in southern Australia, which occurs in pregnant and lactating ewes grazing contaminated pasture.

**Trichostrongylosis in sheep** is favored by cool, wet weather and is a disease of the winter months in those areas in which rainfall occurs chiefly at this time of the year. Although the eggs and larvae of *Trichostrongylus* spp. tolerate cold, they are not resistant to freezing temperatures. Consequently, in very cold climates disease may be more common in the late summer and autumn. In arid areas the disease is of little significance except in unusually wet years. *T. axei* can infect a range of species but is primarily a parasite of cattle and is usually only seen in other hosts when grazing cattle pastures.

The epidemiology of bovine ostertagiosis is complex. Type I disease is mostly seen in first-season grazing animals, particularly dairy calves heavily stocked on permanent calf paddocks. Large numbers of adult worms are present and egg counts are high. In areas with warm climates, Type I ostertagiosis may be seen in almost any season but is particularly important in winter and spring. In areas with harsher winters, as in northern Europe, larvae overwinter in sufficient numbers to infect autumn-born calves after spring turnout. The resulting small worm burdens produce eggs that give rise to a new generation of infective larvae. These autoinfection larvae are responsible for the disease outbreaks that occur from mid-July to the end of the grazing season. Type I ostertagiosis also occurs in beef cattle if placed on heavily infected pastures immediately after weaning. It is less often seen in calf suckler or extensive management systems because of the relatively low number of susceptible animals per unit area of grazing land.

When hypobiosis occurs, many fourth-stage larvae accumulate in the gastric glands. Few if any clinical signs will be apparent, and egg counts will be zero or low. This condition is called pre-type II ostertagiosis and occurs at a definite time each year depending on the region—autumn in northern Europe and spring in Australia. Type II disease occurs when waves of hypobiotic larvae emerge from the parasitized glands some 4 to 5 months later. This is typically when cattle are 12 to 24 months of age, although type II disease is sometimes seen in older animals. Few adult worms will be present and egg counts will be correspondingly low.

**Goats** do not build up an effective immune response against trichostrongylid worms and remain susceptible to disease throughout their lives. The risk is enhanced if they are forced to graze rather than browse. Problems are frequently encountered on hobby farms in which goats are overstocked on small paddocks.

**PATHOGENESIS**

Each trichostrongylid species differs in its habit and in the damage it causes so details of the corresponding disease processes will vary correspondingly. The major mechanisms leading to diarrhea, weight loss, and production deficits can, however, be described in general terms.

**In abomasal infection** with *Ostertagia* spp., developing larvae distend the gastric glands and produce small white nodules on the mucosal surface, but these are of little clinical significance. More important changes take place 18 to 21 days after infection when worms start to emerge from the glands. This triggers a hyperplastic reaction in neighboring glands causing larger nodular lesions which, if numerous, may coalesce. Many of the cells lining affected glands are nonfunctional. The resulting reduction in acid-secreting parietal cells leads to increased gastric pH, which may rise to 6 to 7. This produces several domino effects. First, incoming bacteria and ruminal protozoa are not killed. Second, pepsinogen is not converted to pepsin because this only happens in an acid environment, thus, no pepsin is available for protein digestion. Accumulating amounts of the precursor molecule are reflected in elevated blood pepsinogen concentrations. Third, blood gastrin rises as the body attempts to stimulate more acid secretion. The hyperplastic mucosal reaction also results in increased permeability of the epithelial sheet. This leads to protein loss into the lumen of the abomasum. In mild uncomplicated cases, this protein leak and the disrupted protein digestion are both compensated by digestive/absorptive intestinal mechanisms. In severe cases, hypalbuminemia, tissue edema, and weight loss are apparent. Between these extremes, these processes lead to reduced muscle protein synthesis and consequent productivity losses.

**Intestinal trichostrongyloid infections** are associated with inflammatory changes, a thickening of the mucosa, and a stunting or flattening of the villi. Epithelial enzyme activity is reduced. *Nematodirus* and *Cooperia* lie in close contact with the mucosa but *Trichostrongylus* spp. larvae and adults form superficial tunnels, causing additional tissue disruption. Lesions are confined to the anterior small intestine and their severity is determined by the density of worms. Surprisingly, malabsorption is not a marked feature of pathogenesis because unaffected parts of the intestine can usually compensate. Consequently, protein digestibility and absorption may be normal. There is, nevertheless, poor retention and utilization of nitrogen caused by a protein-losing enteropathy, together with excessive losses from sloughed cells and mucus production. This contributes to production losses and causes hypoalbuminemia and edema in severe cases. Wool growth is affected and the fleece becomes brittle. Mineral absorption is impaired, resulting in reduced skeletal growth, bone density, and mineralization. *T. colubriformis* infection reduces the absorption of phosphorus and increases the loss of endogenous phosphorus, thus leading to a phosphorus deficiency. As with abomasal parasitism, the precise reason for the diarrhea associated with these infections is unknown.

**Reduced productivity** in both abomasal and intestinal parasitism is mostly caused by a reduction in appetite that is a constant feature of these infections. In one field study, untreated heifers spent on average 105
minutes less per day grazing compared with a matched treated group, and their daily herbage intake was 0.78 kg dry matter per day lower. Experimental studies show that inappetence accounts for over 60% of the difference in weight gains between Ostertagia-infected and worm-free sheep and cattle. The associated mobilization of adipose tissue gives rise to increased nonesterified fatty acid levels. Voluntary feed intake may be significantly depressed even in parasitized animals showing no clinical signs. The elevated gastrin levels in abomasal trichostrongyld infections impair reticuloruminal motility and slow abomasal emptying, leading to a stasis of ingesta and hence a reduction in feed intake. Other, as yet unknown, mechanisms must also be involved because gastrin levels are not affected by intestinal worms, yet these also depress appetite.

**CLINICAL FINDINGS**

In sheep the two most susceptible age groups are weaner lambs and yearlings. Those over 18 months of age are less prone because of immunity gained from previous infestation. The onset of disease is generally insidious and, less often, adults are sometimes affected during their first grazing season, although yearlings can be high and deaths may start within 2 days of the first observed illness. There is profuse watery diarrhea and the losses can be high and deaths may start within 2 days of the first observed illness.

**In cattle,** calves are most vulnerable in their first grazing season, although yearlings and, less often, adults are sometimes affected and do the following:

- Lose weight rapidly
- Pass soft feces that eventually become very thin and dark-green to yellow in color
- Develop a long, dry hair coat
- Become dehydrated with sinking of the eyes in the terminal stages

Until the last they continue to eat, although the amount of food taken is below normal. Gross anemia is not evident, but the mucosa are pale and dry. Submucosal edema is common, especially in type II disease. The temperature may be elevated (39.5°C; 103°F) and the heart rate increased (120 beats/min) in calves showing dehydration. In the terminal stages the calves become weak and emaciated. Type I ostertagiosis in calves is characterized by high morbidity and low mortality. Although morbidity is low in type II disease, clinical signs are generally more severe and the prognosis poorer.

**CLINICAL PATHOLOGY**

Fecal egg counts have to be interpreted with caution as they are only well correlated with worm burdens in young animals. Egg counts are, however, often over 1,000 eggs per gram (epg) feces in type I ostertagiosis. Zero or low epg values may be recorded if the following occurs:

- The worm burden comprises mainly immature stages (as in type II disease or some outbreaks of nematodirosis)
- Intestinal damage persists after the worm population has been expelled by immunity or anthelmintic treatment
- Disease is associated with hypersensitivity to incoming larvae

Different trichostrongyld eggs, other than *Nematodirus*, cannot easily be differentiated, and cultures must be made if species determination is necessary.

**Plasma pepsinogen** estimations are performed routinely in many laboratories as an aid in the diagnosis of ostertagiosis. Elevated values also occur in hemochromatosis. The test is difficult to standardize so results from different laboratories cannot be compared but, in calves, levels higher than 3,000 IU tyrosine are generally considered to indicate a pathogenic worm burden. Pepsinogen levels decline after effective anthelmintic treatment but do not return to preinfection values.

Other immune cattle may show elevated values when grazing contaminated pasture, even though few incoming larvae are able to establish. Plasma gastrin concentrations reflect the size of the abomasal worm burden in both young and older animals, but currently can only be measured by radioimmunoassay, which limits their field application. Gastrin occurs in several molecular forms and, consequently, test kits have to be validated before use with bovine blood because not all are suitable for this purpose.

**Moderate anemia** often occurs with hemoglobin levels around 6 to 8 mg/dL and is more evident in *Cooperia* and *Ostertagia* spp. infestations than in trichostrongylosis in which there may be polycythemia. Serum protein concentrations may be as low as 4 to 5 mg/dL with a marked reduction in serum albumin in cases.

**Species-specific** ELISA tests are being developed for use with samples from bulk milk tanks but are currently only available for epidemiologic research.

**NECROPSY FINDINGS**

Adult worms are found in the abomasum or small intestine depending on the predilection site of the individual species. A total worm count is the critical measure of the degree of infestation. Counts less than 2000 in mixed species of sheep are considered to be light, whereas counts over 10,000 are heavy, but massive counts of 50,000 and more are often seen. In cattle, burdens of 40,000 and above are seen in type I ostertagiosis outbreaks (the majority are adults), whereas in type II disease worm numbers may be 100,000 to 200,000, with occasional animals harboring a million or more. In these cases about 90% are in the fourth larval stage. Trichostrongylids are small, translucent, and threadlike so even adults can easily evade detection by the naked eye at necropsy. Worm counting therefore involves washing the mucosa, sieving the washings and luminal contents, resuspending the residue, taking aliquots, and picking out and identifying the nematodes. A more rapid but effective field technique for demonstrating intestinal worms is to do the following:

- Roll a loop of duodenum inside out over a test tube or glass rod
- Immerse this first in aqueous iodine solution (iodine 30 g, potassium iodide 40 g, water 100 mL) for several minutes
- Immerse in a 5% solution of sodium thiosulfate for a few seconds

The mucosa is decolorized but the brown-stained worms retain their color and are easily seen. Mucosal larval stages have to be released by digesting the tissues with acid pepsin.

**Gross pathologic findings** are often not striking, apart from the nonspecific lesions of emaciation, dehydration, moderate anemia, and evidence of scouring. In severe cases, the mucosa of the abomasum and upper small intestine may be hyperemic and swollen, and local lymph nodes enlarged. In ostertagiosis there will be numerous raised nodules that may be discrete or confluent forming a “Morocco-leather” appearance. Abomasal folds are edematous and diphtheretic sometimes be apparent. A putrid smell may reflect the growth of microorganisms in the ingesta, and estimation of the pH will confirm loss of acidity.

Heavy *T. axei* infection in lambs, calves, and horses causes circumscribed plaque-like hyperplastic lesions on the abomasal mucosa, sometimes with an eroded center. Close inspection is needed to see the villous atrophy associated with intestinal *Trichostrongylus* species. Initially this is diffuse but later appears as discrete patches (“fingerprint lesions”).

**DIAGNOSTIC CONFIRMATION**

PGE should not be diagnosed on the basis of a fecal egg count alone. In sheep, a total worm count should be performed whenever possible, preferably with a peptic digest of the mucosa. The results should be considered together with the following:

- Clinical signs
- Age of the animal
- Season of the year
- Nutritional status
- Grazing history
The critical test in an outbreak of disease is the response to treatment. Because the epidemiology of the various species differ, it is important that the main contributing species are determined so that adequate control measures can be taken. In calves, clinical diagnosis can be confirmed by plasma pepsinogen estimation, but this assay is less helpful in adult cattle. Experimental real-time (RT)-PCR and multiplex PCR techniques have been developed for specific identification of *H. contortus, T. circumcincta, Trichostrongyulus* spp., *C. oncophora, Nematomorbus*, and other nematodes in fecal samples.\(^1\)\(^2\)\(^3\)

### Differential Diagnosis

Parasitic gastroenteritis has to be differentiated from other common causes of emaciation and diarrhea in groups of young animals such as:

- Malnutrition
- Copper deficiency (in cattle)
- Coccidiosis (in particular, nematodiosis and coccidiosis occur in lambs of the same age)
- Johne’s disease
- Chronic fascioliasis.

### Treatment

#### Treatment and Control

| Local geographic factors have a large influence on optimal control programs; consult local authorities (R-1) |
| PO, orally; SQ, subcutaneously; TOP, topical pour on. |

Many broad-spectrum anthelmintics are now available that combine high efficiency against larval and adult worms with low toxicity in sheep and cattle. Most, however, belong to just three major chemical groups:

1. Avermectins/milbemycins, also known as the macrocyclic lactone anthelmintics (MLs), which interfere with nerve transmission by opening chloride channels.
2. Benzimidazoles (BZDs)/probenzimidazoles, which bind to tubulin and disrupt nutrient uptake.
3. Imidazothiazoles/tetrahydropyrimidines, which act as cholinergic agonists.

Two recent anthelmintics, namely monepantel\(^14\)-\(^16\) and derquantel,\(^17\) are commercially available for the treatment of nematode infections in sheep. Derquantel is used in a formulated combination with abamectin. Monepantel has very high efficacy against adult and larval stages of nematodes, including multianthelmintic-resistant nematodes.\(^18\)-\(^20\) The derquantel-abamectin combination has been demonstrated to have lower efficacy against larval stage of multianthelmintic-resistant nematodes.\(^21\)

#### Dosage rates and label claims

May vary with formulation and from country to country according to local conditions and regulatory requirements. Figures given in this chapter should therefore be regarded only as a general guide.

### Cattle

In cattle, ivermectin, doramectin, and moxidectin are given at 0.2 mg/kg by injection or 0.5 mg/kg as a pour-on formulation. Eprinomectin pour-on 0.5 mg/kg is the compound of choice for adult dairy cattle because it has a no milk withdrawal period. Albendazole 7.5 mg/kg, febantel 7.5 mg/kg, fenbendazole 7.5 mg/kg, netobimin 7.5 mg/kg, and oxfendazole 4.5 mg/kg are given orally. Levamisole can be used orally or by injection at 7.5 mg/kg or as a pour-on at 10 mg/kg.

#### Sustained-release intraruminal devices (“boluses”) for use in cattle provide extended periods of protection. For example, fenbendazole is released for up to 140 d from one bolus, whereas a biodegradable bolus releases morantel tartrate for at least 90 days. There are also pulse-release boluses containing oxfendazole, which release five or six anthelmintic doses at 3-week intervals.

### Sheep

In sheep, the dose rate for ivermectin, doramectin, and moxidectin (which are given orally or parenterally) is 0.2 mg/kg. Dose rates for the BZDs (given orally) are albendazole 5 mg/kg, febantel 5 mg/kg, fenbendazole 5 mg/kg, netobimin 7.5 mg/kg, mebendazole 15 mg/kg, and oxfendazole 5 mg/kg. However, there are recent reports of resistance of *Trichostrongylus*, *Teladorsagia*, and *Nematodirus* to ML and BZD treatment of sheep in the UK.\(^10\)\(^11\)\(^12\)\(^22\) Levamisole can be used orally and parenterally at 7.5 mg/kg. Morantel citrate monohydrate is also used as a drench in sheep. Pour-on formulations are not used in sheep because the wool grease does not allow absorption through the skin. Intraruminal devices for use in sheep have been developed that release albendazole or ivermectin over 100 days.

### Goats

Goats metabolize some anthelmintics more rapidly than do sheep, and elevated dose rates are sometimes required to obtain a satisfactory level of control. Even then, there may be more surviving worms and, consequently, anthelmintic resistance tends to develop much more quickly in goats than sheep.\(^23\) Examples of special dose rates for goats include albendazole 10 mg/kg PO and levamisole (which should be used with caution in goats) 12 mg/kg orally. Ivermectin can be given at the normal dose rate of 0.2 mg/kg SC or PO.

### Choice of Anthelmintic

The choice of anthelmintic depends on a number of considerations. Anthelmintic resistance is a real or emerging problem in many sheep-rearing areas. Side resistance occurs within chemical groups and multiresistant strains have been reported. This can impose a severe constraint on product choice. Other factors include the following:

- Price
- Safety (including meat and milk residues and effect on environment)
- Ease of administration
- Spectrum of activity

Older products were most active against adult worms, but many now have activity against larval stages. Fewer, however, have consistently high efficacy against hypobiotic larvae and care is needed in selecting a suitable product to treat or prevent type II disease. Products with claims for this purpose at standard dose rates include avermectins/milbemycins, albendazole, fenbendazole, oxfendazole, and thiophanate, whereas netobimin is active at an elevated dose rate (20 mg/kg). The BZDs are ovicidal, which may be beneficial if stock are moved to a new pasture after treatment. Animals with PGE may also be harboring other parasites. The avermectins/milbemycins have a very broad spectrum of activity including some ectoparasites but are inactive against cestodes and trematodes. Some broad-spectrum BZDs are effective against cestodes and one, albendazole, is also active against mature *Fasciola hepatica*. The
Avermectins/milbemycins are excreted in the feces and may affect insects colonizing the dung pat. The environmental impact of this has probably been overstated because only a small proportion of the fecal mass on a property will contain anthelmintic, allowing adequate refugia for maintenance of insect populations. This class of compound should, however, be used with caution if there is concern that beneficial insects may be vulnerable, for example, dung beetles in some arid zones.

**Novel methods for increasing drug availability** and anthelmintic effect within the body are under investigation and should be adopted by veterinarians as they become available. There is uncertainty when, or even if, new chemical classes will become commercially available for nematode control, so it is essential that existing products are used as efficiently as possible to extend their effective life. Using measures that maximize the potency of anthelmintics can slow the onset of resistance and increase efficacy against partially resistant strains. The efficacy of the BZDs and orally administered avermectins depends on their residence time in the rumen, and some simple measures can be taken to increase this. Using the correct drenching procedure (gun tip over tongue and drench dispensed directly into esophagus) will avoid stimulation of the esophageal groove reflex and ensure that the dose does not bypass the rumen. As there is an inverse relationship between feed intake and ruminal residence time, a reduction in feed intake (e.g., by penning) for 24 hours before prophylactic drenching retards transit time and significantly enhances the activity of BZDs and ivermectin. With BZDs, drug residency time in the rumen can be further increased and efficacy enhanced by dividing the dose and giving it at 12- or 24-hour intervals. This principle is reflected in medicated lick blocks and intraruminal boluses, which provide daily low-level BZD doses.

**Continued protection** must be given to animals after treatment for clinical PGE. Irrespective of the drug used, treated animals should be moved to a clean paddock (i.e., one not contaminated with large numbers of infected larvae) that provides an adequate plane of nutrition. The oviducal action of the BZDs is particularly useful if animals are being placed on very clean areas such as cereal stubble. However, it is probably of lesser importance on many farms where residual pasture contamination is always present. If clean pasture is not available, protection can be provided by use of an anthelmintic with persistent activity against incoming larvae. In cattle, ivermectin provides up to 21 days’ protection against *O. ostertagi* and up to 14 days’ protection against *Cooperia* spp. A new injectable formulation of eprinomectin is effective in removing existing gastrointestinal nematode infections and provides effective control of nematode infections in cattle for up to 150 days after treatment.24-26 Corresponding figures for doramectin are 35 and 21 days (by injection) and 35 and 28 days (pour-on) and for moxidectin are up to 28 days against *O. ostertagi*. The persistent anthelmintic effect of avermectins in sheep is much shorter and there is probably little useful effect against intestinal trichostrongylosis.

Moxidectin given by injection has a label claim for 5 weeks’ protection against *O. circumcincta* and 2 weeks against *T. colubriformis*.

**CONTROL**

Control measures are aimed at reducing pasture contamination to minimize the uptake of infective larvae, preventing disease, and avoiding optimal productivity. The cost of any program and treatments must be in accordance with potential economic benefits. Where individual animals are valuable, labor-intensive strategies may be justified. Many husbandry systems, however, will support only low-input solutions and treatments may only be feasible when animals are handled for other management procedures. Epidemiologic patterns differ for each worm species and vary considerably from region to region, with subtle variations often occurring from locality to locality. It is therefore beyond the scope of this book to make specific recommendations for control, but it is possible to describe general principles that can be adapted to local needs.

**Knowledge of local epidemiology** is a necessary prerequisite for designing a control program. In particular, the animals providing the major source of contamination should be identified and the period of development from egg to infective larvae and the availability of infective larvae throughout the year known. It is essential to formulate clear and precise control objectives, otherwise, much time and expense can be wasted. Management may have to be adjusted to aid control. On organic farms, where anthelmintic usage is greatly restricted, worm control may be a major factor in determining stocking density and grazing management. Often, control measures are aimed primarily at protecting the most susceptible group, that is, young animals up to 18 months of age exposed to infestation for the first time.

**Anthelmintic resistance** is an important consideration influencing the choice and intensity of control measures. Even if economically justified, frequent routine treatments impose strong selection pressure on worm populations and encourage the development of resistant strains. As only three major chemical groups are currently available for the treatment of gastrointestinal and pulmonary nematodes, it is imperative that their usefulness be conserved for as long as possible. Many anecdotal field reports of resistance are erroneous, and the problem is one of reinfestation or incorrect anthelmintic usage. Nevertheless, resistant and multiresistant strains are already prevalent in many sheep-rearing areas. In cattle, resistance of *Cooperia* spp. to MLs, BZDs, and levamisole have been observed in Australia and New Zealand.27-29 Additionally, there are reports of *Ostertagia* and *Trichostrongylus* spp. resistance to BZDs, levamisole, and ivermectin.30 The following recommendations have been made to slow the onset of resistance:

1. Use an effective drug in the most efficient manner:
   - Check fecal egg counts regularly to confirm that chosen products remain effective.
   - If a worm population is already partly resistant to a compound, continued use of products based on that chemical group will endanger the health of the animals and reinforce the resistance.
2. Do not overdose (this may encourage resistance):
   - Weigh each animal or the heaviest individuals in a group.
   - Comply with all label recommendations.
   - Ensure good maintenance and calibration of dosing equipment.
3. Use the minimum number of doses needed to maintain health:
   - Strike a balance between encouraging resistance by treating too intensively and allowing pasture contamination to rise to unacceptable levels.
4. Use sound epidemiologic principles:
   - Use an integrated approach to worm control, which maximizes the potential of management techniques and minimizes reliance on anthelmintics.
5. Rotate the chemical group annually (to ensure that worms are exposed to compounds with a different mode of action each year):
   - Remember there is no benefit in rotating compounds within a chemical group or in using a group already rendered ineffective by anthelmintic resistance.
6. Avoid introducing resistant worms onto a property (obvious, but often overlooked):
   - Place all new stock into quarantine and treat with an effective compound.
   - Do not graze goats on sheep pastures (as caprine worm populations often have a higher prevalence of resistance genes).
7. Make sure that the farmer is aware of the problem and the consequences of anthelmintic resistance.

**The concept of maintaining parasite refugia** is assuming greater prominence as a means of conserving anthelmintic efficacy in modern control strategies. The theoretical
into three categories: 31-33

Methods for detection of resistance to BZDs include egg-hatch assays for BZDs and obtained with levamisole (if large numbers sterilized but not killed) and false positives obtained with BZDs (if female worms are by 95% or more, but false negatives may be produced by susceptible worms. Similarly, dose and move systems encourage resistance as all eggs dropped onto the pasture are produced by susceptible worms. In contrast, a high proportion of the total Haemonchus population is exposed to the drug (as there are few larvae in refugia on the pasture) and, consequently, there is an enhanced risk of anthelmintic resistance developing. From this viewpoint, it could be beneficial in the longer term to withhold the winter treatment from some ewes. This would ensure that the majority of eggs subsequently dropped onto the pasture are produced by susceptible worms. In cooler temperate climates, infective Ostertagia larvae overwinter on grass in large numbers but most Haemonchus larvae succumb to the cold. If ewes are dosed during the winter to eliminate the periparturient egg rise, only a small proportion of the Ostertagia population (those in the animal) are exposed to the anthelmintic, whereas the remainder (those on the pasture) are in refugia. In contrast, a high proportion of the total Ostertagia population is exposed to the drug (as there are few larvae in refugia on the pasture) and, consequently, there is an enhanced risk of anthelmintic resistance developing. From this viewpoint, it could be beneficial in the longer term to withhold the winter treatment from some ewes. This would ensure that the majority of eggs subsequently dropped onto the pasture are produced by susceptible worms. Similarly, dose and move systems encourage resistance as all eggs dropped onto the new pasture are from worms that have survived treatment. It could therefore be advantageous to use a short-acting drug and to delay the move. This would ensure that the animals acquire a small burden of susceptible worms before the move. These strategies involve obvious inherent risks, and all aspects of a particular situation must be carefully considered before implementation.

Protocols for detecting anthelmintic resistance in a herd or flock are available. The fecal egg count reduction test can be performed easily without sophisticated equipment. The epg value should be reduced by 95% or more, but false negatives may be obtained with BZDs (if female worms are sterilized but not killed) and false positives obtained with levamisole (if large numbers of mucosal larvae present at the time of dosing survive treatment). Laboratory tests include egg-hatch assays for BZDs and larval development tests for avermectins and levamisole. Experimental genetic-based methods for detection of resistance to BZDs using pyrosequencing and PCR assays, targeting isotype-1 \( \beta \)-tubulin gene SNPs, have been developed and demonstrated to be more robust, specific, and cost-effective than the fecal egg count reduction test.1-33

The principles of control generally fall into three categories:

1. Preventive
2. Evasive
3. Diluting

Preventive measures are those that place livestock on clean pasture or that use early season chemoprophyaxis to ensure clean grazing later in the season.

Evasive strategies are those in which pasture contamination is allowed to build up naturally but susceptible stock are moved onto clean grazing before pathogenic numbers of infective larvae have accumulated. An anthelmintic dose can be given at the time of the move. This "dose and move" system is effective and reduces anthelmintic dosage considerably. It may, however, encourage resistance, as discussed earlier.

Diluting systems reduce the effective stocking density of susceptible animals by grazing them alongside nonsusceptibles (older immune stock or alternative species). In cow–calf systems, for example, adults produce at least four times as much feces as their calves, but their average egg count is typically no more than 15 epg. The number of trichostrongylid eggs and the subsequent accumulation of infective larvae on the herbage will therefore be considerably smaller than if the pasture was fully utilized by calves alone.

In cool temperate regions, control measures can take advantage of the fact that overwintered larvae die away in early summer. Hay or silage pastures therefore provide safe grazing after the grass has been cropped. Alternatively, suppressive anthelmintic therapy over the first 90 to 100 days of the grazing season will prevent overwintered larvae from establishing in the host, stopping the subsequent accumulation of infective larvae on the herbage. This strategy is very effective on set-stocked permanent calf paddocks provided that no untreated animals are introduced. The required effect can be obtained by use of an intraruminal anthelmintic device administered around the time of spring turnout or by giving two or more doses of an anthelmintic with prolonged activity against incoming larvae. Because the goal is to prevent egg excretion, the required treatment interval is calculated by adding the length of the protective effect (which varies with the product) and the prepatent period of the worms (about 3 weeks). Ivermectin given 3, 8, and 13 weeks after turnout and doramectin given at turnout and 8 weeks later are very effective for this purpose, as are the intraruminal boluses listed earlier.

Controlled field studies have demonstrated significant weight-gain advantages from this approach but, as with cattle lungworm, there is concern that the level of immunity acquired during the first grazing season may be reduced. Usually this is of no clinical consequence, but results from an epidemiologic survey of 87 farms in Holland suggest a beneficial relationship between immunity to nematodes gained during the first grazing season and the growth rate of cattle during their second grazing season. It seems that optimal protection has to balance the risk of production losses in first and subsequent grazing seasons, but there is currently no objective way of doing this. One suggestion is that rumen boluses would be more effective if used to provide anthelmintic cover in the second half of the grazing season when pasture contamination is high ("metaphylaxis"). Good immunity would be ensured but the growth rate advantage may be inferior to that obtained with the early season prophylaxis described earlier. If cattle have been exposed to high pasture challenge in the autumn, they should be dosed with a product active against hypobiotic larvae at housing or during the winter to prevent type II ostertagiosis. In countries in which Dictyocaulus viviparus is a problem, control of PGE and lungworm must be integrated.

Elimination of the PPER is the most important feature of worm control in sheep. Ideally, ewes should be dosed toward the end of gestation and again 1 month after parturition with a product active against hypobiotic larvae. Lambs should be dosed at weaning and if possible moved to clean pasture. In most cases, further treatments will be necessary to maintain health until marketing but these should be kept to a minimum. The number will depend on the stocking density, initial pasture contamination, and weather. A compromise has to be struck between an acceptable level of disease control and the risk of inducing anthelmintic resistance. Fecal egg counts can be used to check the adequacy of the dosing interval and the efficacy of the treatments.

Control of Nematodirus differs from that of other forms of PGE because the ewe is not a source of contamination. The simplest form of control is to avoid putting the new lamb crop onto pasture contaminated by the previous year's lambs. Often, however, this is not feasible and prophylactic anthelmintic doses at 3-week intervals are necessary to cover the limited period of risk (May to early June, for example, in Scotland). Waiting for the first clinical signs before starting treatments is not recommended because deaths can occur very quickly. The precise timing of the egg hatch varies from year to year according to prevailing weather conditions, but forecasting systems are in operation in some countries.

In warm temperate regions, PGE control strategies are more difficult to design because animals graze all year round. The main transmission period is late winter and early spring. Treatment of beef cattle at weaning and once or twice at locally determined intervals thereafter is often sufficient to reduce pasture contamination. In sheep, an effective program is to dose lambs at weaning and move them onto safe pasture. Two or three subsequent treatments at 8-week intervals may be needed. In summer rainfall areas, Haemonchus is an additional hazard and
systems have to be designed to combat this as well as other gastrointestinal worms. In regions with a prolonged dry season, larvae will be killed on the ground and, providing there are no foci of infection around water holes, etc., a single strategic anthelmintic dose at this time with a product active against hypobiotic larvae may be more effective at maintaining low pasture contamination around the year than repeated dosing throughout the wet season. This single dose may, however, apply greater selection pressure for resistance, because the whole parasite population is exposed to the drug and survivors are likely to carry resistance genes.

Reduced reliance on anthelmintics can be achieved in a number of ways. For example, alternate grazing with sheep and cattle can be used to good effect. In Australia, the number of anthelmintic drenches can be substantially reduced by alternation at 2- to 6-month intervals. In northern Britain annual stock rotations, sometimes with an arable crop grown in the third year, have been successfully evaluated. Host specificity, however, is not absolute and calves can become infected with *N. battus*. If this happens, they may drop sufficient numbers of eggs to cause clinical problems in lambs the following year. Lambs have also been known to succumb to *T. axei* on calf paddocks. An exciting future prospect is the use of nematophagous fungi. Orally administered fungal spores produce hyphae in the feces that trap and kill nematode larvae. Field experiments show that pasture contamination can be substantially reduced in this way. Feed supplementation to enhance host resilience and resistance to infection, vaccination, and future prospects for breeding lines of sheep with innate host resistance are described under *Haemonchus*.

Breakdowns in control programs are usually caused by the following:

- **Failure to prevent worm egg output at times critical to the accumulation of infective larvae on the pasture**
- **Failure, after treatment, to move animals on an already contaminated pasture to a clean environment**
- **Use of an insufficient dose or incorrect anthelmintic**
- **Failure to repeat treatment or repeating treatment at overlong intervals at times of high risk**
- **Failure to appreciate that not all anthelmintics kill all immature stages, particularly hypobiotic forms**
- **Introduction of susceptible sheep from a worm-free environment into a high risk area**
- **Failure to protect young animals adequately.**

**REFERENCES**

**HEMONCHOSIS IN RUMINANTS**

**ETOLOGY**

Sheep, cattle, and goats are all affected by species of the nematode genus *Haemonchus*, which is closely related to the other trichostrongylids of ruminants. *H. contortus* is the species most commonly found in sheep and goats, but *H. placei* is the usual species in cattle. Molecular studies have confirmed that these are distinct taxa. Even so, cross-infection may occur when small ruminants and cattle graze together but the infestations are usually of lesser severity. Another abomasal trichostrongylid, *Mecistocirrus digitatus*, occurs in sheep, cattle, and buffalo in Asia and in Central America, causing a disease very similar to hemonchosis.

**SYNOPSIS**

**Etiology**

The nematode parasite *Haemonchus contortus* in sheep and goats and *H. placei* in cattle.

**Epidemiology**

Female worms produce large numbers of eggs; infective larvae develop rapidly in warm wet conditions; dangerous levels of pasture contamination can therefore accumulate rapidly.

**Signs**

- **Acute**: Sudden death, anemia.
- **Chronic**: Wasting, anemia, anasarca.

**Clinical pathology**

Anemia, hypoproteinemia; often high fecal egg count.

**Lesions**

Anemic carcass; abomasal mucosa hyperemic with many red-colored worms.

**Diagnostic confirmation**

“Barber’s pole” appearance of female worms (if fresh).

**Treatment**

All modern broad-spectrum anthelmintics; also, closantel, rafoxanide, nitroxynil, disophenol, and some organophosphates; care needed in selection as resistant and multiresistant strains of *H. contortus* occur.

**Control**

Strategic dosing schemes using broad-spectrum anthelmintics; closantel or disophenol can be used to reduce dependence on broad-spectrum products.

**LIFE CYCLE**

*H. contortus* inhabits the abomasum. It is easily seen because it is 1 to 2.5 cm long and a little stouter than most other trichostrongylids. Adult males are homogeneously red but the females have a spiral red and white appearance as the intestine and uterus intertwine. Adult *H. contortus* are prolific egg layers. Egg production increases until maximum output is reached 25 to 30 days after infection, after which individual females lay up to 10,000 eggs per day for several months. The egg hatches and passes through two noninfective larval stages in 4 days under optimal conditions, but in less suitable environments this period may be prolonged. For example, in Scotland the shortest time required for development from egg to third-stage larva is 2 weeks, but development takes a great deal longer over most of the year. Infective larvae migrate away from fecal pellets, some traveling 90 cm in 24 hours.
More than 90%, however, are found within 10 cm of the fecal mass, and this number decreases logarithmically as the distance increases. Mortality is greatest in hot, moist conditions. Larvae are susceptible to desiccation and do not withstand cold temperatures well. Hostile external conditions occur regularly, such as winter in temperate regions or the dry season in some tropical climates, *H. contortus* larvae on pasture are conditioned at the appropriate time to become hypobiotic after uptake by a host. Transmission occurs when the host ingests infective larvae while grazing. After developing through the fourth larval stage in the abomasal glands, the adult worms emerge to commence egg laying in about 18 days after infection. Hypobiotic larvae resume their development so that egg laying is coordinated with the start of spring or the wet season. The life cycle of *H. placei* is similar except that the first eggs do not appear in the feces of cattle until the 26th day after infection. Hypobiotic larvae resume their development so that egg laying is coordinated with the start of spring or the wet season.

**EPIDEMIOLOGY**

The epidemiology of hemonchosis is largely determined by the high fecundity of the female worms and the speed with which infective larvae can develop in warm, humid conditions. Thus when conditions are favorable, large numbers of infective larvae can accumulate very rapidly on pasture. Opportunities for transmission are, however, restricted by the susceptibility of the larvae to desiccation and cold.

Hemonchosis is an important disease of sheep, goats, and cattle in all but the coldest regions. The greatest economic impact is seen in sheep in tropical and warmer temperate countries, especially where there is good summer rainfall. It is not uncommon for serious outbreaks to occur in cooler climates during periods of high humidity in summer. The disease is uncommon in semiarid regions unless there are opportunities for transmission to occur, for example, in irrigation schemes. In sheep, losses occur mostly in lambs, especially those recently weaned, but yearlings and mature sheep may also be affected. Goats of any age are susceptible but their browsing habit may protect them from the heaviest sources of contamination. Dairy calves are the most commonly involved group among cattle but steers and other young cattle up to 3 years of age may also be affected.

Predisposing causes for hemonchosis include overcrowding, lush pasture, hot and humid climatic conditions, and a low plane of nutrition. Disease can be precipitated in several ways. An important causal mechanism in sheep is when lambs, which may be in excellent condition on good grazing, are overcome by a sudden massive wave of pasture contamination. Sheep in poor condition may be clinically affected by worm burdens too small to harm an otherwise healthy animal. Outbreaks of disease may occur in sheep overwintered indoors if large numbers of hypobiotic larvae mature simultaneously. Cattle harboring subclinical infestations while on a good plane of nutrition may show clinical signs if the pasture subsequently fails because of drought or overgrazing. In goats, *Trypanosoma congoense* infection has been shown to increase the susceptibility to *H. contortus*.

The climatological conditions that permit the development of hemonchosis in sheep have been the subject of a great deal of research. Bioclimatographs have been produced for many different geographic areas. In regions with narrow diurnal temperature fluctuations, outbreaks are likely during months with a mean maximum temperature of 18°C (64°F) and more than 5.25 cm of rain. In areas with regular summer rainfall, larval availability increases from late spring to reach maximum levels by late summer to early autumn and quickly declines in winter. A similar trend, but with fluctuating larval numbers, occurs in areas with more variable rainfall patterns.

The self-cure phenomenon is a sudden naturally occurring expulsion of adult *H. contortus* which may also, although not invariably, eliminate incoming larvae (reviewed in Alba-Hurtado and Munoz-Guzman 2013 in the Further Reading section). In some areas, this may be associated with changes in the pasture but more often it occurs in sheep when a large uptake of infective larvae is superimposed on an established worm burden in a sensitized animal. Self-cure may also expel existing *O. circumcincta* and *T. axei* from the abomasum and *Trichostrongylus* spp. from the small intestine. Strain or breed differences occur, and a genetic resistance operating primarily against worm establishment and probably controlled by the immune response has been reported. There is no complete self-cure with *H. placei* in calves, but after an initial infection there is a rapid decline in egg laying, adults are expelled, and subsequent larval development is retarded. Immunity is much stronger in calves than in sheep.

**PATHOGENESIS**

Vigorous bloodsucking by both fourth-stage larvae and adults is the main factor differentiating the pathogenesis of *H. contortus* from that of other abomasal nematodes. The histologic changes and biochemical sequelae associated with *Ostertagia* infections also occur in hemonchosis, but additionally a hemorrhagic anemia evolves that is caused by the daily loss of around 0.05 mL of whole blood per worm. The course of the disease depends on the numbers of worms present and the ability of the animal to compensate for acute or chronic losses of plasma proteins, hemoglobin, and other blood constituents. In continuing infections, the increased rate of red cell production is maintained at the expense of the animals’ iron stores and a state of iron deficiency occurs. Death may be acute and result purely from blood loss or may be more gradual and accompanied by weight loss, anemia, and hypoproteinemia. Poor growth in young lambs can result from a reduction in the ewes’ milk production. Susceptibility to hemonchosis varies with breed. Those with superior resistance include the Scottish Blackface, Red Maasai, Florida Native, St Croix, and Barbados Blackbelly, whereas the Hampshire Down is relatively susceptible. Individuals within a flock also vary in vulnerability. This natural resistance to infection is heritable.

The role of nutrition in modifying the pathogenesis of hemonchosis in lambs is undergoing intense investigation. There is experimental evidence that lambs on a high-protein diet are better able to withstand *H. contortus* infestation. There are considerable breed differences; in some cases, animals with a higher protein intake mount a more effective immune response, in other cases they are better able to tolerate and compensate for the blood losses associated with the infection.

**CLINICAL FINDINGS**

Hemonchosis causes heavy losses because of animal deaths and reduced production. Lambs and young sheep are commonly affected by the acute form of the disease. Often only a few individuals will be seriously affected, but in very severe outbreaks a large proportion of the flock may suffer if not treated. Animals may be found dead without premonitory signs. The mucosae and conjunctivae of such sheep are always extremely pale. More chronic cases show lethargy and muscular weakness, pallor of the mucosae and conjunctivae, and anasarca, particularly under the jaw and to a lesser extent along the ventral abdomen. Affected sheep are often noticed for the first time when the flock is being driven: they lag behind, breathe faster, have a staggering gait, and often go down. Some sheep may die as a result of exercise but most can rise and walk a little further after rest. Grazing animals lie down a good deal of the time, often around the water troughs; the energy needed to walk and eat appears to be lacking. Most affected sheep show constipation rather than diarrhea. There is a loss of BW and a detrimental effect on wool growth and quality. In sheep with the chronic condition, there may be extreme weight loss during the dry season, even though larval uptake is negligible at this time. Sheep not fatally affected develop a break in the wool and the fleece may be lost at a later date.

In calves, the disease is characterized clinically by severe anemia and anasarca.
Heavy infestations occurring in summer may not manifest clinically until winter when the plane of nutrition declines.

**CLINICAL PATHOLOGY**

As *Haemonchus* is a prolific egg layer, fecal egg counts tend to be high (10,000 epg in severe cases), but it must be remembered that low egg counts may be encountered in the early part of the evolution of the disease when the bulk of the pathogenic worms are in the larval stage. There is a significant rise of abomasal pH soon after infection accompanied by increased plasma pepsinogen and gastrin concentrations. Worm counts and hemoglobin levels are correlated.

**NECROPSY FINDINGS**

Gross necropsy findings include severe anemia, gelatinization of fat deposits, general anasarca, and the presence of large numbers of readily visible *H. contortus* or *H. placei* in the abomasum. If the cadaver is fresh, the worms may still be attached or swimming actively in the ingesta, but a careful search may be necessary if the animal has been dead for some time. The abomasal wall is hyperemic and blood clots may be present in the mucosa. Small ulcerations may be present in which adult worms have been attached. The abomasal contents usually have a distinct brownish color caused by the presence of free blood.

**DIAGNOSTIC CONFIRMATION**

In mixed infections, eggs of *Haemonchus* spp. cannot be easily differentiated from those of many other gastrointestinal nematodes. Identification and quantification therefore depend on counting larvae in fecal cultures, which is a procedure not readily applicable in routine diagnosis. The number of worms required to depress hemoglobin levels varies with the weight of the sheep. In Merino sheep up to 20 kg, a hemoglobin level of 10.5 g/dl has been associated with 112 worms and 8.0 g/dl with 355 worms. However, in sheep over 50 kg, 355 and 1259 worms were required to give similar values. At necropsy, counts of 3000 *H. contortus* in lambs and 9000 in adult sheep are usually associated with heavy mortalities. Highly sensitive and species-specific experimental PCR and loop-mediated isothermal amplification assays for detection of *Haemonchus* in fecal samples, targeting the amplification of the internal transcribed spacer (ITS-1) region of ribosomal DNA (rDNA), have been developed.

- Fasciolosis.
- Eperythrozoonosis.
- Nutritional deficiencies of copper and cobalt.
- Diarrhea is a much more prominent sign in other parasitic infestations, particularly trichostrongylosis and coccidiosis.

**Control**

Local geographic factors have a large influence on optimal control programs; consult local authorities (R-1)

FAMACHA scoring system used to identify heavily infected animals (R-1)

PO, orally; SQ, subcutaneously; TOPp, topical pour on.

All the broad-spectrum ruminant anthelmintics are effective against *Haemonchus* provided that resistance has not developed to that chemical group. Ivermectin given by injection provides up to 14 days' protection against reinfection with *H. placei* in cattle and up to 10 days' protection with *H. contortus* in sheep. Moxidectin, by mouth or by injection, gives up to 35 days' persistent activity against *H. contortus*. Some compounds active against *F. hepatica* that bind to plasma proteins are also active against blood-sucking nematodes, such as *Haemonchus*, and are useful where resistance to broad-spectrum products is a problem; these include closantel, rafaxonide, and nitroxynil. Closantel and disophenol, another narrow-spectrum product, exert a persistent protective effect in sheep for up to 4 weeks. With closantel, this period can be extended by reducing feed intake for 24 hours before treatment to enhance the uptake of the drug. Organophosphate anthelmintics are available in some localities for use against resistant strains. *H. contortus* strains resistant to benzimidazoles (BZDs), levamisole, morantel, naphthalophos, ivermectin, moxidectin, and closantel have been reported, and strains with multiple resistance to two or more of these chemicals are common in some areas. There are recent reports of *H. placei* resistance to ivermectin and benzimidazoles in cattle.

**CONTROL**

In sheep flocks, a late winter treatment will remove hypobiotic larvae before they resume development and start to shed eggs onto the pasture. Where winters are severe enough to kill most of the free-living stages, this single drench will considerably reduce subsequent pasture contamination but may also expose the parasite population to a high level of selection pressure, encouraging the onset of resistance. In areas in which larvae overwinter on pasture and infest lambs in early spring, further treatments may be needed in spring and early summer to prevent an accumulation of infection in the sheep and a subsequent buildup of pasture contamination.

If no routine control is practiced and pasture contamination becomes high, stock should be dosed and moved to clean grazing areas. If this is not possible, anthelmintic cover must be provided by using a sustained acting compound such as closantel,
Susceptible strain onto pasture at different temperatures. Small ruminants are grazed sequentially for up to 4 days on a series of small plots, each of which is rested for at least 30 days before use. Where fencing is not feasible, a similar rotation can be based on a planned tethering system. This approach is not effective in temperate areas, however, because under these conditions infective larvae have a prolonged life span and substantial numbers will still be present when the grass needs to be regrazed.

Frequent treatments with broad-spectrum anthelmintics can lead to the development of anthelmintic resistance. Control programs have therefore been devised that reduce dependence on broad-spectrum products by using the sustained action of closantel against *H. contortus*. Treatment with closantel in late winter kills hypobiotic larvae and, subsequently, overwintering larvae from the pasture as they are ingested. In the case of ewes, which lamb in early spring, further treatments in late spring and late summer can provide excellent cover. Because closantel has no effect against *O. circumcincta* or *Trichostrongylus spp.*, strategic treatments with a broad-spectrum compound must also be incorporated into the scheme. Lambs can be treated with closantel and a broad-spectrum compound when they are about 12 weeks of age and again 12 weeks later. This procedure has been designated the “Wormkill” program and variations on the theme, tailor-made for particular localities, are about 12 weeks of age and again 12 weeks later. This procedure has been designated the “Wormkill” program and variations on the theme, tailor-made for particular localities.

A BZD-resistant *H. contortus* population on a farm is unlikely to revert to susceptibility even if this class of compound is withheld from use for a protracted period, which is because of the genetic mechanisms involved in the selection process. In a novel approach, however, raises obvious ethical questions.

**BUNOSTOMOSIS (HOOKWORM DISEASE) IN RUMINANTS**

**SYNOPSIS**

*Etiology* Nematodes of the genus *Bunostomum* and related hookworms.

**Epidemiology** Transmission is generally by skin penetration and is favored by warm, humid conditions.

**Signs** Anemia, diarrhea, and anasarca.

Continued
**Clinical pathology** Eggs and occult blood in feces, anemia, hypoproteinemia; none of these signs is specific.

**Lesions** Red worms attached to mucosa of small intestine, nearby ingesta often bloodstained.

**Diagnostic confirmation** Necropsy is only certain method.

**Treatment** Most modern broad-spectrum ruminant anthelmintics are effective as well as those narrow-spectrum compounds that bind to plasma protein.

**Control** General preventive programs for parasitic gastroenteritis are also effective against hookworm.

**ETIOLOGY**

All farm animals other than horses harbor hookworms. The main species are the following:

- **Cattle**: *Bunostomum phlebotomum* is the most widespread but *Agrostomum vryburgi* may occur in cattle in Asia and South America.
- **Sheep**: *B. trigonocephalum* is found worldwide, whereas *Gaigeria pachyscelis* occurs in India, Indonesia, South America, and Africa.

Additionally, *Globocephalus* spp. occur in pigs but are rarely of clinical importance.

**LIFE CYCLE**

Hookworms are reddish-colored nematodes, 1 to 2.5 cm long, and inhabit the small intestine of their hosts. The females are prolific egg layers and the life cycle is direct. The eggs hatch and two free-living, nonparasitic larval stages follow, which are very susceptible to migration. In *B. trigonocephalum* infestations, the fourth-stage larvae reach the intestine in about 11 days and egg-laying adults may occur about 7 weeks after infestation. The prepatent period in *B. phlebotomum* infestations is about 8 weeks and in *G. pachyscelis* it is about 10 weeks.

**EPIDEMIOLOGY**

The chances of infestation occurring by percutaneous entry are greatly enhanced when the surroundings are wet, and this, together with the susceptibility of the larvae to desiccation, leads to a higher incidence of the disease in humid subtropical or warm temperate countries such as the southern United States, Mexico, Africa, Asia, northern Australia, and parts of Europe. Heavy infestations of sheep or cattle are uncommon in cooler temperate countries but do occur occasionally when animals are winter housed in dirty surroundings with insufficient bedding. Immunity to *B. phlebotomum* in cattle appears to develop with age, and animals affected after 1 year appear to be completely immune the next year. Calves 4 to 12 months of age are most commonly affected, and the degree of infestation is always greatest in the winter months.

**PATHOGENESIS**

Hookworms are active bloodsuckers and cause severe anemia in all animal species. Total worm numbers as low as 100 may cause clinical illness and 2000 may cause death in young cattle. There is a loss of whole blood and hypoproteinemic edema may result. Some irritation to the intestinal mucosa is inevitable and mild or intermittent diarrhea follows. Penetration of the skin by larvae may cause signs of irritation and lead to the introduction of pathogenic bacteria.

**CLINICAL FINDINGS**

In mild infestations in stabled cattle, fidgeting, stamping, and licking of the feet may be observed. Constipation, accompanied by mild abdominal pain, is seen in the early stages and is followed by bouts of diarrhea. The cattle are unthrifty and anemic. In severe infestations there is obvious pallor of mucosa, weakness, anasarca under the jaw and along the belly, prostration, and death in 2 to 3 days. The signs in sheep are similar to those in cattle. The convalescent period, even after treatment, is prolonged unless the diet is supplemented to stimulate erythrocyte production.

**CLINICAL PATHOLOGY**

The eggs in feces are similar in appearance to many other gastrointestinal nematodes. Hookworm egg counts of 400 to 500 epg are usually associated with fatal infestations. Because both larvae and adult worms are avid bloodsuckers, clinical signs are often evident before eggs appear in the feces. The degree of anemia and the presence of occult blood in the feces can be used as a measure of the severity of the infestation.

**NECROPSY FINDINGS**

Hookworms attached to the mucosa are easily found but they may be few in number. In calves, total worm counts of 100 or more suggest a significant level of infestation; counts of over 2000 worms indicate a degree of infestation likely to be fatal. In sheep and goats, 24 adult *G. pachyscelis* have been reported to be fatal, but the usual fatal figure is probably closer to 100. Most of the worms are found in the first few feet of the small intestine, and the intestinal contents nearby are often deeply bloodstained. *B. trigonocephalum* in sheep has been observed to be localized predominantly in jejunum and ileum. Hookworms often form part of a mixed infection comprising several or many gastrointestinal nematodes.

**DIAGNOSTIC CONFIRMATION**

Anemia, diarrhea, and anasarca are signs common to several diseases so necropsy is the only certain method of diagnosis. Experimental PCR assays, targeting the amplification of parasite internal transcribed spacers (ITS-1, 5.8S, and ITS-2) of nuclear rDNA, have been developed for identification of *Bunostomum* spp. in animal fecal samples.

**DIFFERENTIAL DIAGNOSIS**

- Hepatic fascioliosis
- Hemonchosis
- Coccidiosis
- Mycoplasma ovis
- Dietary deficiency of cobalt or copper and chronic molybdenosis

**TREATMENT**

**TREATMENT AND CONTROL**

**Sheep**

- Ivermectin, doramectin, or moxidectin (0.2 mg/kg SQ; 0.5 mg/kg TOPp) (R-1)
- Eprinomectin (0.5 mg/kg TOPp) (R-2)
- Albendazole (10 mg/kg PO) (R-2)
- Febantel (7.5 mg/kg PO) (R-2)
- Fenbendazole (5 mg/kg PO) (R-3)
- Oxfendazole (4.5 mg/kg PO) (R-2)
- Levamisole (7.5 mg/kg PO; 10 mg/kg TOPp) (R-2)

**Cattle**

- Ivermectin, doramectin, or moxidectin (0.2 mg/kg SQ or PO) (R-1)
- Albendazole (7.5 mg/kg PO) (R-2)
- Febantel (5 mg/kg PO) (R-2)
- Fenbendazole (5 mg/kg PO) (R-2)
- Oxfendazole (5 mg/kg PO) (R-2)
- Mebendazole (15 mg/kg PO) (R-2)
- Levamisole (7.5 mg/kg PO) (R-2)

**Control**

Local geographic factors have a large influence on optimal control programs; consult local authorities (R-1)

PO, orally; SQ, subcutaneously; TOPp, topical pour on.

Most newer broad-spectrum anthelmintics including the benzimidazoles, avermectin/milbemycins, levamisole, and morantel are effective against adult *Bunostomum* spp. in...
sheep and cattle, but not all products have label claims against larval stages. Eprinomectin extended-release formulation is effective against larvae of *B. phlebotomum* in cattle and provides protection for up to 150 days. Moxidectin by injection gives 4 weeks residual protection in sheep against *Gaigeria*. Nitroxynil and rafoxanide, which bind to blood protein and are ingested by bloodsucking worms, are effective. Doramectin has a label claim for *G. pachyscelis*, and moxidectin has been shown to protect sheep from reinfection for at least 35 days.

**Supportive treatment** is essential in this disease because of severe anemia. The provision of a mineral mixture containing iron, copper, and cobalt is recommended and a supple diet of free-choice feed for at least 35 days. Horses infected for at least 35 days.

**Nitroxynil** and **rafoxanide**, which bind to blood protein, have been shown to protect sheep from reinfection for at least 35 days.

**Control**

Preventive programs to protect against *Hae-

monchus* or *Ostertagia* infections will usually give adequate protection against hookworms. Wet surroundings such as in pastures, in yards, and in barns should be avoided to reduce the chances of percutaneous infestation and reduce the viability of the free-living larvae. Pens should be cleaned frequently and ample bedding provided. Heavy stocking of sheep or calves in small pens should be avoided. Under conditions of heavy risk, periodic treatment should be administered. The hookworm of cattle will not infect sheep and vice versa, so alternate grazing may be advantageous although it has been suggested that some species of deer may act as a source of infection for *B. phlebotomum*.

**REFERENCES**

**OESOPHAGOSTOMINOSIS (NODEL WORM DISEASE) IN RUMINANTS AND PIGS**

**SYNOPSIS**

**Etiology** Nematodes of the genus *Oesophagostomum*.

**Epidemiology** In sheep, disease is mostly confined to warmer summer rainfall regions; pigs of all ages are susceptible but sub-tropical climates with summer rainfall. If sufficient larvae are ingested, acute disease may occur during the summer months. Lighter infestations or exposure of older animals to infection may give rise to a chronic condition that presents clinically in the following winter when animals are on a low plane of nutrition. Disease in cattle is similarly most common in warmer summer rainfall areas. Nevertheless, the more chronic form of the disease is quite common in ruminants in eastern Canada and the New England states of the United States.

In pigs, *Oesophagostomum* infections are cosmopolitan. The female worms produce large numbers of eggs and in pig houses only the highest standards of hygiene will prevent infections from persisting. Outdoors, the larvae thrive best when sheltered by thick vegetation. Numbers decline markedly during dry summers on bare soil or during the winter. Some larvae, however, can over-winter even in Scandinavia, but cold Cana-
dian winters kill all free-living stages. A periparturient rise in fecal egg counts has been described in sows but it is not as con-
stant a feature as the similar phenomenon in ewes. The periparturient egg rise is closely related to lactation and terminates when the piglets are weaned. When it occurs, it can be an important source of contamination in the farrowing house. *Oesophagostomum* has been associated with the thin sow syndrome, in which sows rapidly lose condition late in pregnancy and while they are lactating. Fecal egg counts may be very high but parasitism is only a contributory factor. The primary cause is inadequate nutrition. In group-fed animals, timid sows not able to secure an adequate share of the ration satisfy their hunger by eating bedding, increasing their intake of infective larvae.

**PATHOGENESIS**

The size of the nodules in the intestinal wall, and hence their pathogenicity and economic importance to the meat industry, varies with the worm species and immunity of the host. In ruminants, for example, *O. columbianum* provokes a massive host response, whereas *O. venulosum* does not produce visible lesions. In pigs, *O. quadrispinulatum* nodules are larger than those of *O. dentatum*. *O. columbianum* larvae in young sheep exposed for the first time stay in the wall of the anterior small intestine for about 5 days. Some subsequently enter the mucosa a second time in the large intestine, whereas others develop directly to adults. In second and subsequent infections, few larvae develop directly to adults and most are arrested in either the first or second mucosal phases. Persistence of larvae in the intestinal wall for long periods is thought to indicate host immunity; thus in older sheep, nodules develop in the intestinal wall at any level and may occasionally be present in nearby organs. Larvae may remain alive in these...
nODULES FOR PERIODS OF UP TO 1 YEAR BUT MANY ARE DESTROYED BY THE HOST RESPONSE. WHEN THE RESISTANCE OF THE ANIMAL IS LOWERED, FOR EXAMPLE, BECAUSE OF POOR NUTRITION, LARVAE LEAVE THE NODULES, REENTER THE INTESTINAL LUMEN, AND PASS DOWN TO THE COLON TO BECOME ADULTS. THIS IS THE PROBABLE EXPLANATION FOR THE COMMON FINDINGS AT NECROPSY:

1. Young sheep with many adult worms and no nodules
2. Adult sheep with many nodules and no adult worms
3. Adults with both

Oesophagostomosis is sometimes implicated as a primary cause of intussusception in young sheep.

Young susceptible ruminants generally suffer as a result of the emergence of larvae from the mucosa, which provokes a catarrhal colitis, and the feeding activities of the adults, which produce small ulcers and some mucosal bleeding. In older, immune animals the nodular reaction plays a more important role. *O. radiatum* and *O. columbianum* cause the following:

- Anorexia
- Severe and persistent mucoid diarrhea
- Loss of weight
- Anemia
- Hydropsyrenimia
- Death

The hydropsyrenimia follows edema of the mucosa and colon and is caused by loss of albumin into the lumen. Anemia results from blood loss when mucosal larvae reenter the lumen. The fall in platelet factor levels and platelet numbers observed 6 to 7 days after primary infection of calves probably aggravates this loss. Nodules eventually caseate and calcify and may cause interference with intestinal motility or local peritonitis and adhesion formation, which leads to intussusception or stenosis. In sheep the nodules can cause considerable pain and result in an arched back (“humpy back”) and a stilled gait. The nodules in pigs are much smaller, although edema and thickening of the colon and cecum can develop in the case of heavy infestation. Outbreaks of necrotic enteritis may be activated in pigs carrying *Salmonella* spp. populations.

**CLINICAL FINDINGS**

In heavily infested sheep, severe persistent diarrhea may occur in young animals. More commonly, older sheep in the winter months will show an intermittent passage of semisolid droppings that contain excessive amounts of mucus and occasionally blood. There is rapid loss of condition, hollowing of the back, stiffness of gait, and elevation of the tail. Nodules may be palpated on rectal examination. Anemia is not characteristic and is never marked.

Young calves may show anorexia, diarrhea, emaciation, and anemia. Initially the diarrhea may alternate with constipation, but later it is continuous and is dark and fetid.

In pigs, clinical signs are less severe. Loss of condition and diarrhea in weaners and growers have been attributed to heavy infection, but deleterious effects, if any, are normally found at a subclinical level. In the thin sow syndrome, lactating sows become thin or in severe cases emaciated, even though they have a good appetite, but there is usually no diarrhea.

**CLINICAL PATHOLOGY**

There are no specific laboratory tests. The eggs in feces are similar in appearance to those of many other gastrointestinal nematodes. Also, the severity of the disease may bear no relation to the number of eggs in the feces; counts vary widely with the season and the stage of development of the disease. In the early stages of a massive infestation, signs may be evident but there may be no eggs in the droppings. After the prepatent period in young sheep, eggs are usually present in large numbers and may be accompanied by living adult worms. In chronic cases, however, very few eggs may be passed. Serum albumin concentrations are low in severe cases and anemia may be detected in cattle.

**NECROPSY FINDINGS**

In early acute cases there is a mild catarrhal enteritis and larvae may be detectable in scrapings of intestinal mucosa. In the later more chronic stage, adult worms are easily visible in the colon. They are usually lying in thick mucus overlying a chronic catarrhal colitis. *O. columbianum* is very pathogenic and 200 adult females is considered a heavy infection. Nodules, when they are present, may be found at all levels of the intestine; they measure up to 6 mm in diameter and, depending on their age, contain green, pasty or yellow-brown, crumbly, partly calcified material. There may be a great deal of thickening of the intestinal wall and local peritonitis.

**DIAGNOSTIC CONFIRMATION**

A definite diagnosis of oesophagostomosis can only be made by necropsy examination or identification of larvae from a fecal culture. Experimental coproantigen-based ELISA and PCR-based assays for the detection of *Oesophagostomum* infection from animal fecal samples have been developed. 1-3

**DIFFERENTIAL DIAGNOSIS**

- Trichostrongylosis in sheep is also at its peak during the winter but diarrhea is more evident.
- Hysteromyiasis also causes emaciation in lactating sows but is confined to outdoor herds.
- Malnutrition, especially when sheep are housed and poorly fed.

PO, orally; q.d., four time a day; SQ, subcutaneously; TOPp, topical pour on.

All modern broad-spectrum compounds are effective against adult *Oesophagostomum*. Moxidectin provides up to 4 weeks’ protection from reinfection with *O. columbianum* in sheep. *Oesophagostomum* spp. strains resistant to pyrantel have been detected on some pig farms in Denmark. Low efficacy (52%) of ivermectin against larval *O. dentatum* in pigs and against *O. radiatum* in cattle has been observed.

**CONTROL**

In sheep and cattle, the principles of control described under PGE in ruminants apply also to *Oesophagostomum* infections. In pigs, the thin sow syndrome is unlikely to be cured or prevented by anthelmintic
Infective larvae are relatively resistant to cold and heavy infestations may occur in mild winters. After ingestion, larvae undergo a period of development in the wall of the small intestine before passing to the cecum and then to the colon. Unlike Oesophagostomum, the larvae do not cause any significant damage. The infection becomes patent in about 7 weeks.

Clinical signs are first seen when immature adults start to attach to the mucosa about 26 days after infection. Soft blood-flecked feces with excess mucus are passed. A protein-losing enteropathy occurs with lowered blood albumin and weight loss. Death may occur in heavy infections. Fecal egg counts do not always correlate well with clinical signs because these may occur before the worms mature. Immunity can also reduce the fecundity of adult Chabertia.

Changes at necropsy include thickening, edema, and petechiation of the wall of the colon with blood sometimes present in the intestinal contents. The worms, which are easily recognized by their large buccal cavities, are usually confined to the first 25 to 30 cm of the colon, except in very heavy infections. The number of worms present is often surprisingly small, and severe morphologic changes may be evident with only five to 10 worms. More than 100 worms is considered to be a heavy infestation. All the newer broad-spectrum anthelmintics are effective against C. ovina.

REFERENCES

STOMACH FLUKE DISEASE (INTESTINAL AMPHISTOMOSIS)

**SYNOPSIS**

**Etiology** Paramphistomum cervi, P. microbothrioides, and related flukes.

**Epidemiology** Infection by ingestion of metacercariae on herbage; geographic distribution, seasonality, and disease risk determined by occurrence of intermediate hosts (aquatic planorbid snails).

**Signs** Severe enteritis, fetid diarrhea.

**Clinical pathology** Hypoaalbuminemia; immature flukes may be passed in feces.

**Lesions** Duodenal mucosa thickened, mucus blood stained with large numbers of small, flesh-colored flukes.

**Diagnostic confirmation** Demonstration of immature flukes in feces.

**Treatment** Oxyclozanide, closantel, hexachlorephene.

**Control** Avoidance or drainage of snail habitats; anthelmintic treatments to prevent contamination of pastures with eggs.

**ETIOLOGY**

Intestinal amphistomosis is associated with paramphistome flukes in the duodenum migrating toward the forestomachs. Cattle and, to a lesser extent, sheep are at risk of infection. The paramphistomes are cosmopolitan but disease is most common in warmer regions, particularly Australasia, Africa, and India. However, there are recent reports of increasing prevalence of paramphistomosis in Europe. Commonly recorded paramphistome species include Paramphistomum cervi, P. microbothrioides, P. lorchis, P. ichikawai, P. microbothrium, Calicophoron calicophorum, Ceylonocotyle streptocoelium, Calicophoron ijimai, and Cotylophoron catylophorum.

**LIFE CYCLE**

The life cycle is similar to that of F. hepatica except that the intermediate hosts are planorbid snails and the immature flukes migrate proximally along the duodenum and through the abomasum to reach their predilection site in the rumen and reticulum. The period required for maturation varies from 6 weeks to 4 months.

**EPIDEMIOLOGY**

Planorbid snails are aquatic. They are more adaptable and occupy more diverse habitats than lymnaeid snails. Thus zones of endemicity for intestinal amphistomosis and hepatic fasciolosis do not necessarily coincide. Most outbreaks of disease occur during the late summer, autumn, and early winter when pastures are heavily contaminated with encysted cercariae. Planorbid snails multiply very rapidly in warm, watery environments but can subsequently survive dry conditions. Metacercariae are therefore found on pastures prone to flooding as well as on herbage in and around ponds, streams, and other water sources. All ages of cattle, sheep, goats, and wild ruminants grazing near water or on land liable to flooding may be affected, but young cattle in the yearling class are the usual subjects. It is possible that some degree of immunity develops.

**PATHOGENESIS**

The immature flukes excyst in the duodenum or mid to proximal jejunum. As they migrate, they attach firmly to the mucosa and may penetrate as far as the muscularis mucosa. Damage is related to the numbers of migrating flukes and increases in intensity from localized enteritis through patches of villous atrophy to severe destruction of the mucosa. Clinical and production effects are dependent on the extent of the lesions because some compensation for functional deficiency can take place in the undamaged lower small intestine. The presence of mature flukes in the rumen does not usually elicit any significant response but in massive infections papillae are short and red, becoming fused into aggregations.
with ruminal contents adhering firmly to the surface.

**CLINICAL FINDINGS**

Severe enteritis associated with enormous numbers of migrating flukes in the duodenum seems to be the only manifestation of disease. A characteristic and persistent fetid diarrhea is accompanied by weakness, depression, dehydration, and anorexia. There may also be submaxillary edema and obvious pallor of the mucosa. Death usually occurs 15 to 20 days after the first signs appear. The mortality rate in heavily infested animals may be high. Mature flukes in the forestomachs of animals normally cause little harm, although loss of weight, anemia, a rough dry coat, and a drop in production have been ascribed to heavy infestations.\(^{10}\)

**CLINICAL PATHOLOGY**

A sedimentation and decanting technique may be used to find immature flukes passed in feces. The larvae are round with prominent anterior and posterior suckers. Because the disease is caused by immature forms, eggs are not usually present in the feces, although they may be detectable in older animals in the same herd. Paramphistome eggs are dense structures so sedimentation methods for detection are preferred to flotation. The eggs have a distinct operculum and resemble those of *F. hepatica*, but the shell is colorless. Blood biochemistry reveals a marked drop in TP due largely to a fall in plasma albumin.

**NECROPSY FINDINGS**

There is muscular atrophy, subcutaneous edema, and accumulations of fluid in the body cavities, and the fat deposits are gelatinous. In the upper part of the duodenum the mucosa is thickened and covered with bloodstained mucus, and there are patches of hemorrhage under the serosa. Large numbers of small, flesh-colored flukes (3–4 mm long and 1–2 mm wide) are present in this area but decrease in number toward the ileum. There may be none in the abomasum and forestomachs. There may be a few in the peritoneal cavity and on histologic examination the young flukes are present not only on the mucosal surface but are also embedded in the mucosa and deeper layers.\(^{11}\)

**DIAGNOSTIC CONFIRMATION**

The occurrence in yearling cattle of a severe enteritis, unaccompanied by fever, in environmental conditions suitable for the propagation of flukes and where host snails can be found should arouse suspicion of intestinal amphistomosis. Confirmation depends on demonstration of immature flukes in feces or at necropsy. A coprological assay, mini-FLOTAC, has been demonstrated to be reliable in detecting the presence of adult rumen fluke infection in cattle.\(^{12}\) Experimental PCR assays targeting the amplification of mitochondrial or rDNA have been demonstrated to be sensitive and species specific in detecting paramphistomes.\(^{12,14}\) Care is needed because the small parasites are easily missed.

**DIFFERENTIAL DIAGNOSIS**

- Nutritional deficiency of copper
- Infestation intestinal roundworms
- Infectious enteritides, but these are usually accompanied by fever
- Johne’s disease in adult animals, but this is a much more chronic disease
- Poisonings, including many weeds, inorganic arsenic and lead

**TREATMENT**

**TREATMENT AND CONTROL**

<table>

</tbody>
</table>

Few drugs are oral highly effective. Two doses of oxyclonazide 18.7 mg/kg 2 days apart, or a single oral dose of hexachlorophene 20 mg/kg, give consistent results against immature paramphistomes in cattle, but hexachlorophene may show toxicity at this dose rate and is therefore not preferred as a treatment. In goats, oral oxyclonazide at 22.5 mg/kg orally has 95.9% efficacy against adult *C. daubneyi*.\(^{11}\) This dosage protocol is higher than the recommended dose rate for oxyclonazide of 10–15 mg/kg once orally for cattle and 15 mg/kg once orally for sheep and goats. Niclosamide 160 mg/kg as a single oral dose or as two oral doses 3 days apart is effective but somewhat variable; however, it has good activity at 100 mg/kg against immature paramphistomes in sheep. Closantel used at orally 10 mg/kg has up to 99% efficacy against rumen flukes in cattle.\(^{10}\) Bithionol has been used in Asia and Africa.

**CONTROL**

Animals should, where possible, be denied access to contaminated areas. Otherwise, regular treatments will be needed. Snails quickly repopulate pastures once they become wet and stock should be removed before the intermediate hosts start to shed large numbers of cercariae (1–2 months from infection of the snail depending on temperature). Meta-cercariae may persist on pasture for up to 2 or 3 months after floodwater has dried out.

In areas where paramphistomes are a regular problem, knowledge of the local epidemiologic cycle will help determine optimum times for prophylactic treatments. These are aimed at killing migrating immature flukes before they cause disease and at reducing egg output by adult worms, minimizing opportunity for snails to become infected. Drainage of low-lying areas and destruction of host snails by the use of molluscicides could be considered.

ETIOLOGY
Urea is a common, inexpensive, and readily available form of nonprotein nitrogen (NPN) used in ruminant rations and as a fertilizer.2,3 Most other diseases. Urea needs to be gradually introduced into the diet over several days to allow the rumen bacteria time to become accustomed to the ammonia source.

- Cattle: In cattle starved beforehand, dose levels up to 0.33 g/kg BW are associated with increases in blood levels of ammonia. Dose levels in cattle of 0.44–0.56 g/kg BW produce signs of poisoning within 10 minutes of dosing, and dose rates of 1 to 1.5 g/kg BW are associated with death. Cows unaccustomed to urea may show clinical signs of toxicosis when fed 0.4 g/kg BW, but by gradually increasing the quantity fed this amount can be tolerated. Most rations contain 3% urea in the grain mixture or 1% in the total ration but as much as 6% has been produced experimentally.

- Sheep: They can eat 6% of their total ration throughout the day as urea provided it is well mixed with roughage, preferably by spraying the urea mixed with molasses onto the roughage. Much more urea is tolerated if provided to sheep in molasses (18 g) than if given as a drench (8 g). Prior feeding on lucerne further increases the tolerance; fasting for 24 hours reduces it. A dose rate of 1 g/kg BW to sheep appears to be nontoxic, but 2 g/kg BW is quickly fatal.

- Horses: They appear to be tolerant of relatively large doses of urea and poisoning rarely occurs. The disease has been produced experimentally in ponies by administering 450 g by stomach tube. The clinical picture is similar to that seen in cattle. There is a sharp increase in blood ammonia levels after ingestion of the urea, and it is assumed that hydrolysis of the urea occurs in the cecum.

- Pigs: They are quite unaffected by very large doses of urea unless they are deprived of water or have developed a cecal flora that produces urease.

PATHOGENESIS
Under normal circumstances, urea in the rumen is broken down by urease to ammonia, which is then used by rumen bacteria to synthesize proteins. Excess ammonia remains in the rumen as the ionized ammonium ion. The sudden introduction of large amounts of urea upsets this reaction and toxicosis occurs. Excess quantities of ammonia produced are rapidly absorbed across the rumen into the systemic circulation. Rumen pH is elevated and more ammonia remains in the ionized form and is absorbed.1,2 The onset of signs occurs in 10 to 30 minutes after feeding. The severity of signs is directly related to blood ammonia levels and not to ammonia levels in the rumen.2 Excess blood ammonia interferes with energy metabolism, inhibits the citric acid cycle, and results in systemic lactic acidosis.6 Hyperkalemia, associated with systemic metabolic acidosis, may cause cardiac arrhythmias and arrest.6

CLINICAL FINDINGS
Cattle and Sheep
Signs of toxicosis occur as early as 10 minutes after the urea is eaten and include severe abdominal pain, frothing at the mouth and nose, bellowing, hypersensitivity to sound, movement to the point of being aggressive, muscle tremors, incoordination, weakness, dyspnea, bloat, and violent struggling. Less severe cases are drowsy and recumbent. In severe cases death occurs in a few minutes, but more commonly, animals die about 4 hours after ingestion. The case–fatality rate in affected animals is high.

CLINICAL PATHOLOGY
Cattle
Signs are visible when rumen ingesta levels of ammonia are 1000 mg/L, serum levels of ammonia nitrogen (NH3-N) are 10 to 13 mmol/L, and when blood ammonia nitrogen concentrations reach 0.7 to 0.8 mg/dL. The higher the serum ammonia levels (up to 1719 µmol/L), the higher the blood lactate levels (up to 26.01 µmol/L) were in a group of poisoned steers.4 Blood pH (7.24) in this group was consistent with metabolic acidosis.4

Sheep
Deaths occur at blood ammonia nitrogen levels of 33 µg/mL of blood, when the rumen contents are alkaline (pH elevated from 6.94–7.90), and rumen ammonia levels rise from 6 to 50 mg/dL.

NECROPSY FINDINGS
There are no characteristic lesions at necropsy, but most animals show generalized congestion, hemorrhages, and pulmonary edema. Death is thought to result from respiratory or cardiac arrest caused by ammonia intoxication. In pigs, encephalomalacia has been produced by feeding a ration containing 15% urea. The clinical picture and histopathological findings were similar to those of salt poisoning except that no eosinophilic aggregations are present in the cerebral lesions.

DIFFERENTIAL DIAGNOSIS
Outbreaks of this poisoning are usually closely linked to known exposure to urea or nonprotein nitrogen source and are confirmed by high serum levels of ammonia. In dead animals, fluid from the rumen, abomasum, or eye may be used. Without the historical link to a source of urea the differential list is very

Continued
long because of the similarity of the syndrome to other diseases. 

**Differential diagnosis list:**
- Acute 4-methylimidazole poisoning from ammoniated forages (bovine bonkers syndrome)
- Acute bovine pulmonary emphysema and edema
- Acute hepatic insufficiency
- Acute salt toxicosis
- Anaphylaxis
- *Clavibacter toxicus* toxicosis
- Cyanobacteria toxicosis
- Encephalitis, encephalomalacia
- Hypomagnesemia

---

**TREATMENT**

**TREATMENT AND CONTROL**

- **Formaldehyde diet:** 5% acetic acid (v/v) (0.5–1 L orally to a sheep, 4 L orally to a cow) (R-2)
- **Cold water:** (10–30 L PO for adult cattle, repeat as needed). (R-2)
- **L-alanine:** 20 g/kg of body weight for dairy cows (R-2)
- **L-alanine:** 20 g/kg of body weight for dairy cows (R-2)

No primary treatment is likely to be effective, especially in large herd situations, because the mortality rate is high and death occurs before treatment can be instituted. In single ruminants or small groups, the oral administration of a 5% acetic acid solution such as vinegar (0.5–1 L to a sheep, 4 L to a cow) is recommended to lower the rumen pH. Cold water (10–30 L for adult cattle) will dilute excess urea, temporarily lower rumen pH, and slow NPN metabolism by urease enzymes. This may reduce the amount of ammonia absorbed, but it must be administered as soon as the first clinical signs appear and treatment repeated because clinical signs tend to recur about 30 minutes after treatment. The only really effective treatment is prompt and efficient emptying of the rumen, either via a large-bore stomach tube or by rumenotomy, but the results are variable because serum ammonia levels may already be high.

**CONTROL**

Urea is highly toxic and care is essential when handling it in the vicinity of animals. Feed manufacturers’ recommendations about maximum concentration of urea in prepared rations and acclimatization to the diet with inclusion of adequate readily available carbohydrates should be adhered to. In dairy cows, urea should be fed at 1% of the concentrate, 135 g per animal per day, and not more than 20% of the total crude protein (including other NPN sources). Other sources of NPN cause similar clinical signs, but toxicosis is much less frequently reported with them. Nevertheless, if they are incorporated into the diet all of the issues with control of urea should be followed.

**REFERENCES**

**CHEMICALLY TREATED NATURAL FEEDS**

**Formaldehyde-Treated Grain**

This is a special diet fed to dairy cows to produce dairy products containing an increased proportion of polynsaturated fats for special human diets. Fats in the grain are protected against hydrogenation in the rumen by coating the grains with formaldehyde. If the formalin and the grain are not properly mixed, the free formalin left as a residue is associated with rumenitis and severe diarrhea.

**Caustic-Treated Grain**

Grain treated with caustic to improve its digestibility is recorded as causing focal interstitial nephritis, rumenitis, and abomasal ulceration in feedlot steers. The lesions have been produced experimentally. They may not be detected until the animals are slaughtered.

**Ammoniated Forage**

Anhydrous ammonia is added to hay to improve its digestibility and nitrogen content. Environmental risk factors enhancing the production are low dry matter content of the feed, high environmental temperature, and high concentrations of ammonia in the treatment mixture. If the forage is high quality and has a high carbohydrate content, it may undergo chemical change, possibly with the formation of a substituted imidazole, 4-methylimidazole (MeI), which is associated with hysteria (bovine bonkers) in the cattle eating it. Calves sucking cows fed ammoniated hay may also be affected by this same syndrome. Experimental feeding with MeI produces the same syndrome but it is not the sole cause; other substances are also involved. Clinical signs include hyperexcitability, hyperesthesia, restlessness, rapid blinking, pupillary dilatation, ear flicking, frequent urination and defecation, dyspnea, frothing at the mouth, bellowing, charging, circling, and convulsions. Tremors, beginning at the head and opisthotonus are obvious early signs. Between convulsions, affected sheep walk in circles and have a stiff gait. Nursing calves may show signs even though their dams are unaffected. No clinicopathologic abnormalities occur, blood ammonia levels are normal, and no specific necropsy lesions have been identified.

Treatment consists of sedation, but many patients do not respond to agents such as acepromazine. Dilution of toxic forage with normal feed is not recommended because the toxin may be cumulative. The maximum rate of ammoniation to avoid toxicity for poor forage is 3% and 1% for high-moisture forage.

**Newspaper**

Newspaper is fed commercially to ruminants as alternative roughage. Toxicologic hazards of the material in sheep fed colored magazines for 6 months and comprising 23% of their ration included a significant deposition of lead in tissues and an increase in enzyme activity in liver, but there were no clinical signs and no histopathological lesions. Feeding for periods of several weeks has no detectable clinicopathologic effects, and there is evidence that the known toxins are not secreted in cows’ milk.

**Sewage Sludge**

Urban sewage sludge is incorporated into the soil when used as top-dressing for pasture and grazing lands and may be associated with the spread of infectious disease as well as goiter. Sewage sludge may also be fed directly to animals, but may lead to dissemination of lead, cadmium, and polybrominated and polychlorinated biphenyls to animals and the food products derived from them. Potential damage caused by illness or contamination of animal-produced feed can be minimized by leaving treated pasture exposed to weather for a period of several weeks before allowing animals access to it.

Diseases of the Ruminant Alimentary Tract of Unknown Cause

**CHRONIC INFLAMMATORY BOWEL DISEASE OF SHEEP**

This syndrome of unknown etiology manifests with wasting, ill-thrift and mortality, or culling for poor production, and is reported in England and Canada. It affects both housed and pastured sheep predominantly in their first year of life, but cases up to 3 years of age have been seen. Affected sheep are dull and anorectic with pale mucous membranes and have fecal staining of the perineum. The rumen fill is reduced, and the feces are soft and malodorous. Blood examination shows hypoalbuminemia, an elevated blood urea nitrogen, and leukocytosis with neutrophilia. On postmortem there is lymphocytic enteritis with gross thickening of segments or the entire or distal part of the small intestine. There is no evidence for Johne’s disease or parasitic gastroenteritis, and the syndrome has similarities to the proliferative enteropathies of swine and horses.

**FURTHER READING**

**SALIVARY ABOMASUM DISEASE**

This was first reported in lambs and kids aged 3 to 17 days old Greece in 2008. Affected lambs are lethargic, weak, and not suckling with increased abdominal distension, but did not have clinical evidence of profuse salivation, septicemia, or umbilical infection. Some lambs had mild uremia on serum biochemical analysis. At necropsy, the abomasum was distended with gas or saliva, with multiple small mucosal and serosal hemorrhages and associated blood clots. Histologic examination of the abomasal lesions indicated the presence of a mild to moderate inflammatory cell infiltrate and acute tubular necrosis. Bacteriologic culture results were unremarkable. Salivary abomasum disease has an unknown pathogenesis but appears to have a different presentation of *watery mouth disease* from lambs reported from the UK and elsewhere and *abomasal tympany* in lambs from Norway.

Early treatment of affected lambs with oral erythromycin or sodium bicarbonate solution has been successful in some lambs, in combination with general nursing care. Erythromycin might be effective because it promotes abomasal emptying.

Diseases of the Liver: Introduction

Liver disease in farm animals can have a variety of etiologies including toxicities, parasitism, metabolic disorders, infectious diseases, or biliary obstructive disorders. A classification of hepatic diseases into primary and secondary liver disease is sometimes used in the literature. In primary hepatic disease the clinical manifestations are caused solely by liver disease, whereas with secondary liver disease symptoms arise as part of a generalized disease process, or they are spread from another organ.

This chapter is devoted to a consideration of primary diseases of the liver and to those aspects of other diseases in which manifestations of hepatic involvement occur.

Principles of Hepatic Dysfunction

DIFFUSE AND FOCAL HEPATIC DISEASE

The liver has a large reserve of function and approximately three-quarters of its parenchyma must be rendered inactive before clinical signs of hepatic dysfunction appear. Diffuse diseases of the liver are usually accompanied by signs of insufficiency than are focal diseases, which produce their effects either by the toxins formed in the lesions or by pressure on other organs, including the biliary system. The origin of a toxemia is often difficult to localize to the liver because of the physical difficulty of examining the organ.

Diffuse diseases of the liver can be classified as hepatitis and hepatosis according to the pathologic change that occurs, and the classification also corresponds roughly with the type of causative agent. Hepatitis is defined as inflammation of the liver occurring in response to a causative factor and characterized by a series of mesenchymal reactions such as proliferation of bile ducts and Kupffer cells or fibrotic processes. The classical symptoms of inflammation, such as increased capillary permeability and exudation, are not readily applicable to the liver, because high capillary permeability is a feature of healthy hepatic sinusoids. In contrast, hepatosis is defined as a metabolic disorder of liver cells in the widest sense and is characterized by degenerative, noninflammatory changes of the liver parenchyma. Clinically, the differences between these two diseases are not marked, although some assistance can be obtained from clinicopathologic examination.
HEPATIC DYSFUNCTION

There are no specific modes of hepatic dysfunction. The liver has several important functions and any diffuse disease of the organ interferes with most or all of the functions to the same degree. Variations occur in the acuteness and severity of the damage, but the effects are the same and the clinical manifestations vary in degree only. The major hepatic functions that, when disordered, are responsible for clinical signs include:

- Maintenance of normoglycemia
- Synthesis of plasma proteins including so-called positive and negative acute phase proteins
- Formation and excretion of bile salts as well as conversion and excretion of bilirubin
- Formation of prothrombin
- Detoxification and excretion of toxic substances, including ammonia and photodynamic agents

The clinical signs produced by interference with each of these functions are dealt with under manifestations of hepatic dysfunction. A rather special aspect is the role of the liver in the genesis of primary ketosis of cattle.

PORTAL CIRCULATION

The portal circulation and the liver are mutually interdependent, with the liver depending on the portal vein for its supply of nutrients and the portal flow depending on the patency of the hepatic sinusoids. The portal flow is unusual because blood from the gastrointestinal area and the lower part of the large intestine passes to the left half of the liver and the blood from the two intestines to the right half, without mixing of the two streams in the portal vein. The restriction of toxicopathic hepatitis to one half of the liver and the localization of metastatic abscesses and neoplasms in specific lobes occurs because of the failure of portal vein blood from different gut segments to mix. The localization of toxicopathic hepatitis may be because of selective distribution of the toxin or of protective metabolites. The passage of blood from the portal circuit through the liver to the caudal vena cava is dependent on the patency of the hepatic vascular bed, and obstruction results in the damming of blood in the portal system, portal hypertension, interference with digestion and absorption, and in the final stages the development of ascites.

JAUNDICE (ICTERUS)

Jaundice or icterus is characterized by the yellow discoloration of unpigmented skin, mucosal and conjunctival membranes, as well as membranes over the sclera and is caused by elevated blood bilirubin concentrations. Jaundice often arises in diseases of the liver and biliary system but is not pathognomonic for disturbed function of one of these organ systems. Approximately 10% to 15% of healthy horses are mildly icteric, and jaundice is commonly observed in fasted or anorectic horses. On the other hand, jaundice does not always occur with hepatic or biliary disease and may be conspicuously absent in acute hepatitis.

Jaundice is classified into three categories depending on its etiology: prehepatic or hemolytic, hepatic or hepatocellular, and posthepatic or cholestatic.

PREHEPATIC OR HEMOLYTIC JAUNDICE

Hemolytic jaundice is caused by massive intravascular or extravascular hemolysis resulting in the release of red blood cell hemoglobin. The breakdown of the increased amounts of hemoglobin results in elevated concentrations of unconjugated (or indirect) bilirubin, which needs to be converted into conjugated (or direct) bilirubin by the liver before being excreted through the biliary system.

Hemolytic jaundice is common in animals and may be associated with bacterial toxins, invasion of erythrocytes by protozoa or viruses, inorganic and organic poisons, and immunologic reactions. Diseases in which bacterial toxins cause intravascular hemolysis are bacillary hemoglobinuria of cattle and leptospirosis, although the mechanism by which hemolysis is produced in the latter disease does not seem to have been accurately determined. The common protozoan and viral diseases in which hemolysis occur include babesiosis, anaplasmosis, eperythrozoonosis, and equine infectious anemia. Chronic copper poisoning, selenium poisoning in sheep, phenothiazine poisoning in horses, pastoruring on rape and other cruciferous plants, and bites by snakes are other common causes. Postparturient hemoglobinuria has an uncertain etiology but has been attributed to a deficiency of phosphorus in the diet and the feeding of cruciferous plants. Isoimmunization hemolytic anemia of the newborn is caused by an immunologic reaction between the sensitized cells of the newborn and antibodies in the colostrum of the dam. The occurrence of acute hemolytic anemia and jaundice in calves that drink large quantities of cold water (water intoxication) has been associated with a sudden drop in plasma osmolarity thought to occur after rapid ingestion of large volumes of salt-free water. Lower plasma osmolarity would result in a shift of water into red blood cells and could result in a burst of erythrocytes in severe cases.

Neonatal jaundice is relatively common in babies and is regarded as a benign condition. It is rarely, if ever, observed clinically in newborn animals but may be noticeable at necropsy. Although generally jaundice is hemolytic and results from the destruction of excess erythrocytes when postnatal life begins, it appears more probable that it is caused by retention of bile pigments because of the immaturity of the hepatic excretion mechanism. It does occur in foals and is an important differential diagnosis from isoerythrolysis.

Prehepatic or hemolytic jaundice is characterized by a moderate degree of yellowing of the mucosae. Although both intravascular and extravascular hemolysis can cause hemolytic jaundice, hemoglobinemia and hemoglobinuria are only observed with intravascular hemolysis. An extravascular destruction of erythrocytes in organs of the reticuloendothelial system as it occurs, for instance, with bovine anaplasmosis, does not result in the release of free hemoglobin into plasma or urine. Clinicopathologic findings indicate the presence of regenerative anemia, with normal blood protein concentrations. An increase in urobilinogen and the absence of bilirubin in urine, as well as a preponderance of indirect bilirubin in the serum, are characteristic findings.

In cattle most cases of jaundice are seen with hemolytic disease and are primarily associated with highly elevated levels of unconjugated bilirubin in serum.1

HEPATIC OR HEPATOCELULAR JAUNDICE

Hepatocellular jaundice is the result of impaired capacity of the liver to conjugate indirect to direct bilirubin, which is required for excretion of bilirubin with bile. The cause may be any of those diffuse diseases of the liver that cause degeneration of hepatic cells, which are listed under hepatitis. Swelling and edema in the liver caused by inflammation can result in a mechanical obstruction of the biliary flow within the liver. The degree of obstruction of the intrahepatic bile tree can vary and may result in varying levels of conjugated bilirubin in serum. Clinical experience shows that although both conversion and excretion of bilirubin can be disturbed with hepatic disease, it is the excretion through the biliary tract that is impaired to the greatest extent. As a result, conjugated...
bilirubin is the most elevated with hepatic jaundice. 

Mechanical stasis of the biliary flow can also be caused by fibrous tissue constriction and obliteration of the small biliary canaliculi after hepatitis and in many forms of fibrosis. Cholelithiasis, the formation of biliary calculi, is frequently reported as a cause of cholestasis in humans and has been reported in horses and cattle. Functional stasis is a major problem in hepatic disease in humans but has not been defined in animals. In these instances, the defect is the same as in posthepatic biliary obstruction, and the two conditions cannot be differentiated by laboratory tests.

Serum concentrations of total bilirubin are increased primarily because of retention of direct bilirubin, which also passes in the urine, causing an elevation of urine levels. The urobilinogen levels in the urine also rise.

**POSTHEPATIC JAUNDICE**

Obstruction of the bile ducts or common bile duct by nematodes, flukes, or biliary calculi, as well as compression by tumor masses, is a possible cause of posthepatic jaundice. Inflammation of the bile ducts by extension from enteritis or by infestation with trematodes can also impair the bile flow and result in elevated concentrations of direct bilirubin.

A significant number of pigs die with biliary obstruction and purulent cholangitis secondary to invasion of the ducts by *Ascaris lumbricoides*. Parasitic cholangitis and cholecystitis also occur because of fascioliasis and infestation with *Dicrocoelium dendriticum*. In horses an ascending cholangitis may develop from a parasitic duodenal catarrh and cause signs of biliary obstruction.

Obstruction is usually complete and results in the disappearance of bile pigments from the feces. Serum concentrations of conjugated bilirubin rise, causing a marked elevation of total bilirubin in the serum. Excretion of the conjugated bilirubin in urine occurs on a large scale, but there is no urobilinogen because of the failure of excretion into the alimentary tract. Partial obstruction of the common bile duct or occlusion of a number of major bile ducts may cause variations in serum and urine similar to those observed in complete obstruction, except that the feces do contain bile pigments and urobilinogen appears in the urine. In this circumstance it is difficult to differentiate between partial extrahepatic biliary obstruction and jaundice caused by hepatic cell degeneration.

**CLINICAL FINDINGS**

The staining of jaundice is caused by staining of tissues, especially elastic tissue, and not by accumulation in tissue fluids, which makes it best detected clinically in the sclera.

Jaundice is usually much more severe with impairment of bile flow and when bile pigments are absent from the feces. However, postobstructive jaundice can occur with only partial occlusion of hepatic flow provided at least half the bile flow is obstructed. In such cases jaundice may occur even though bile pigments are still present in the feces. With lesser obstruction the portion of the liver and biliary tract that is functioning normally excretes the extra load of bile pigments.

**CLINICAL PATHOLOGY**

The levels of bilirubin in blood affect the intensity of the jaundice. The obstructive form is often associated with levels of bilirubin that are 10 times higher than those commonly seen in hemolytic anemia.

The only accurate basis for the differentiation between jaundice with impaired bile flow and jaundice without impaired flow is the examination of the urine for the presence of bilirubin and urobilinogen and the determination of the relative amounts of conjugated and unconjugated bilirubin present in the serum. Unconjugated (indirect) bilirubin that has not passed through hepatic cells is not excreted by the kidney, so that in hemolytic jaundice the indirect bilirubin content of serum is increased markedly and, although the urine contains an increased amount of urobilinogen, no bilirubin is present. When jaundice is caused by impairment of bile flow there is a marked increase in the serum level of conjugated (direct) bilirubin, and the bilirubin content of the urine is greatly increased. The amount of urobilinogen varies depending on whether any bilirubin reaches the intestine to be metabolized to urobilinogen and reabsorbed. In complete extrahepatic biliary obstruction urobilinogen is not present in the urine.

**HEPATIC ENCEPHALOPATHY**

Hepatic encephalopathy is defined as the occurrence of neurologic signs caused by neurotoxic substances in the blood that are normally detoxified by the liver. Typical signs include the following:

- Dullness
- Head pressing
- Compulsive walking
- Ataxia
- Muscle tremors and weakness
- Central blindness
- Hyperexcitability
- Convulsions

These signs are common with any severe hepatocellular insufficiency or major circulatory bypass of the liver. Terminally, hepatic coma may occur. The biochemical and anatomic basis for these signs is not well understood. Many factors, including hypoglycemia and failure of normal hepatic detoxification mechanisms, leading to the accumulation of excess amino acids and ammonia, or of acetylcholine, and the liberation of toxic breakdown products of liver parenchyma, have all been suggested as causes, and it is probable that more than one factor is involved.

One of the primary effects of severe, acute liver damage is a precipitate fall in blood glucose. If the hepatic damage occurs more slowly, the hypoglycemia is less marked and less precipitous. With persistent hypoglycemia, structural changes may occur in the brain (hypoglycemic encephalopathy), and these may be the basis for the chronically drowsy animals or dummies. However, hypoglycemia does not always occur in acute hepatitis and cannot be considered to be the only or even the most important factor in producing cerebral signs.

**High blood levels of ammonia** occur in pyrrolizidine poisoning in sheep, and are reflected in the development of spongy degeneration in the brain and the clinical signs of hepatic encephalopathy. The role of ammonia as a cerebrotoxicant can be important in hepatopathies in which the detoxicating function of the liver is lost, and also in congenital defects of hepatic vasculature in which blood is bypassed around the liver. In the latter case ammonia and similar toxic by-products of protein degradation in the large intestine avoid the detoxification filter of the liver. However, the severity of encephalopathy clinically correlates well with the degree of hepatic functional compromise but only poorly with the degree of hyperammonemia, suggesting that hyperammonemia may not be the only factor causing hepatic encephalopathy. On the other hand, *status spongiosus*, a form of spongiform encephalopathy, has been reproduced experimentally in sheep and calves by the intravenous infusion of ammonia.

Other factors, such as hypokalemia, alkalosis, short chain volatile fatty acids, and false and true neurotransmitters, may be important in the pathogenesis of hepatic coma in cattle and horses.

In horses the most common cause of hyperammonemia and encephalopathy is a depression of hepatic function caused by acute or chronic liver disease. In cattle severe hepatic lipidosis (with hepatic lipid concentration of 30% and higher) has been associated with hepatic encephalopathy and liver coma.

**EDEMA AND EMACIATION**

Failure of the liver to anabolize amino acids and protein during hepatic insufficiency is manifested by tissue wasting and a fall in plasma protein. This may be sufficiently severe to cause edema because of the lowered oncotic pressure of the plasma. Hepatic edema is not usually very marked and is manifested most often in the intermandibular space (bottle jaw). If there is obstruction to the portal circulation, as may occur in hepatic fibrosis, the edema is much more severe but is largely limited to the abdominal cavity.
DIARRHEA AND CONSTIPATION

In hepatitis, hepatic fibrosis, and obstruction or stasis of the biliary system, the partial or complete absence of bile salts from the alimentary tract deprives it of the laxative and mildly disinfectant qualities of these salts. This, together with the reflex effects from the distended liver in acute hepatitis, produces an alimentary tract syndrome comprising anorexia, vomiting in some species, and constipation punctuated by attacks of diarrhea. The feces are pale in color and, if there is an appreciable amount of fat in the diet, there is steatorrhea.

Diarrhea can also be the result of impaired blood flow from the portal vein through inflamed liver tissue. Congestion of the portal vein is associated with increased hydrostatic pressure in the capillary system of the digestive tract. This in turn may result in edematous swelling of mucous membranes and hampered absorptive capacity of the digestive tract.

PHOTOSENSITIZATION

Photosensitization is caused by the accumulation of photosensitizing substances in the skin, resulting in the local irritation of unprotected, unpigmented skin after exposure to sunlight. Phylloerythrin, a breakdown product of chlorophyll in the alimentary tract, is excreted in the bile. In hepatic or biliary insufficiency excretion of these substances is retarded and photosensitization occurs (see also Photosensitization in Chapter 16).

HEMORRHAGIC DIATHESIS

In severe diffuse diseases of the liver there is a deficiency in prothrombin formation and a consequent prolongation of the clotting time of the blood. Abnormality of the prothrombin complex is not the only defect, and deficiencies of fibrinogen and thromboplastin also occur. Prothrombin and other factors in the prothrombin complex depend on the presence of vitamin K for their formation, and an absence of bile salts from the intestine retards the absorption of this fat-soluble vitamin. Parenteral administration of vitamin K is advisable before surgery is undertaken in patients with severe hepatic dysfunction.

ABDOMINAL PAIN

Two mechanisms cause the pain in diseases of the liver: distension of the organ with increased tension of the capsule and lesions of the capsule. Acute swelling of the liver occurs as a result of engorgement with blood in congestive heart failure and in acute inflammation. Inflammatory and neoplastic lesions of the capsule or of the liver parenchyma just beneath the capsule cause local irritation to its pain end organs. The pain is usually subacute, causing abnormal posture, particularly arching the back, and disclination to move. Tenseness of the abdominal wall and pain on deep palpation over the liver area may also be detected in the majority of cases.

ALTERATION IN SIZE OF THE LIVER

Great variation in the size of the liver is often seen at necropsy, but clinical detection is not easy unless the liver is grossly enlarged. This is most likely to occur in advanced congestion of the liver caused by congestive heart failure, in some plant poisonings in horses, and when multiple abscesses or neoplastic metastases occur. In acute hepatitis the swelling is not sufficiently large to be detected clinically, and in terminal fibrosis the liver is much smaller than normal.

Atrophy of the right lobe of the liver occurs in the horse and may be related to chronic distension of adjacent segments of the intestinal tract. The normal equine liver is anatomically bisected into two approximately equal halves by the umbilical interlobe fissure; additional interlobular fissures divide the liver into four distinct lobes in the foal: right, left, quadrate, and caudate. In horses with right lobe atrophy, the capsule of the right lobe is wrinkled and thick when atrophy is severe. In clinically normal horses, the right lobe constitutes half of the total liver weight, whereas the right lobe in horses with atrophy ranges from 11.0% to 38.8% of the total liver weight. This is thought to be caused by long-term, insidious compression of this portion of the liver by abnormal distension of the right dorsal colon and base of the cecum.

DISPLACEMENT OF THE LIVER

The liver may be displaced from its normal position and protrude into the thoracic cavity through a diaphragmatic hernia, causing respiratory distress and abnormal findings on percussion of the chest. Torsion of a lobe of the liver has been recorded in aged sows in the early part of lactation. Inappetence, uneasiness, and unwillingness to suckle the young were followed by severe prolonged vomiting, acute abdominal pain, and dyspnea. The twisted lobe was greatly increased in size and in one case the capsule was ruptured, leading to severe internal hemorrhage.

RUPTURE OF THE LIVER

Rupture of the liver is an occasional accident in animals, occurring usually as a result of trauma. In most instances rupture results in death from hemorrhage, although small breaks in the capsule may heal. Horses used for the production of serum frequently develop hepatic amyloidosis, presumably as a reaction to repeated injection of foreign protein, and the death rate from rupture of the liver is relatively high in this group. Amyloidosis is essentially a space-occupying lesion, which results in a liver with a friable texture. The amyloid masses exert pressure on liver cell cords and sinusoids, gradually causing pressure atrophy, ischemic degeneration, and necrosis of hepatic parenchyma.

A high prevalence of liver rupture is recorded in newborn lambs of the North Country Cheviot breed. Losses resulting from this condition were 12.5% of all neonatal deaths in purebred lambs and varied from 6.4% to 24.7% on individual farms. The lambs are stillborn or are born alive but become anemic and weak and die within 12 hours of birth from internal hemorrhage. It is thought that the cause of the fatal anemia is an inherited short sternum, which exposes the liver to compression and rupture of its capsule. Vitamin K deficiency in the ewes and lambs may also be a factor.

BLACK LIVERS OF SHEEP

Dark brown to black pigmentation of the liver and kidneys occurs often in sheep in certain parts of Australia. No illness is associated with the condition, but the livers are not used for human consumption for esthetic reasons and extensive financial loss may result. Commonly referred to as “melanosis,” it has been determined that the pigmentation is the result of deposition of the pigment lipofuscin at various stages of oxidation. Areas in which the disease occurs have many mulga trees (Acacia aneura), the leaves of which are fed to sheep in drought times.

This condition should not be confused with the black livers found in a mutant strain of Corriedales in California. In these mutant sheep there is photosensitization following retention of phylloerythrin. The darkening of the liver is caused by melanin.

Special Examination of the Liver

When disease of the liver is suspected after a general clinical examination, special techniques of palpation, biopsy, and laboratory diagnostic tests can be used to determine further the status of the liver.

PALPATION AND PERCUSSION

In cattle, the liver is well concealed by the rib cage on the right side, and in most cases its edge cannot be palpated. A general impression of the size of the liver can be obtained
by percussion of the area of liver dullness, but accurate definition is not usually attempted. Deep percussion or palpation to detect the presence of hepatic pain can be performed over the area of liver dullness in the posterior thoracic region on the right side. Percussion over the entire area is necessary, because the pain of a discrete lesion may be quite localized. If the liver is grossly enlarged in cattle, its edge can be felt on deep palpation behind the right costal arch. In cattle, the liver may be enlarged and palpable in advanced right-sided congestive heart failure, multiple liver abscesses, hepatic lipodosis, and diffuse hepatitis. This type of palpation is relatively easy in ruminants but is unrewarding in horses and pigs because of the thickness of the abdominal wall and the shortness of the flank.

**BIOPSY**

Biopsy of the liver has been used extensively as a diagnostic procedure in infectious equine anemia, hepatic lipodosis in cattle, poisoning by *Crotalaria* spp. and other species of plants, and experimental work on copper and vitamin A deficiency. The technique is straightforward but requires some anatomic knowledge.

The most satisfactory instrument is a Tru-Cut type biopsy instrument. Tru-Cut needles are either spring-loaded or manually activated cutting devices available with various diameters and lengths. Spring-loaded biopsy guns cut more reliably because of the higher force and speed with which the cutting edge is advanced into the tissue.

Liver biopsies can be performed blind, but with the widespread availability of ultrasonography it is advisable to perform a liver biopsy under ultrasound guidance whenever possible. 1 In horses the anatomic location for biopsy is the right 13th or 14th intercostal space halfway between two imaginary lines, one going from the tuber coxae to the shoulder and one from the tuber coxae to the elbow. 1 In cattle the liver biopsy site is in the right 10th intercostal space between two imaginary lines, one going from the tuber coxae to the elbow and one horizontal line departing from the greater trochanter. 2

Sedation in most cases is not required in cattle but is recommended in horses. The biopsy site must be clipped, prepared aseptically, and infiltrated with a local anesthetic. The skin must be pierced either with a large-bore needle or incised with a scalpel. After confirming proper function of the biopsy instrument, the sharp point of the instrument is inserted into the skin incision and advanced through the intercostal muscles and the diaphragm into the liver. Penetration of the diaphragm can be felt by the movement of the needle that is synchronous with respiration. Once the sharp edge of the instrument has been advanced several centimeters into the liver, the needle is fired and then retracted swiftly. Depending on the intended examination, the sample can be processed immediately and fixed in 10% formaldehyde or frozen. Several biopsies can be obtained through the same skin incision just by slightly changing the direction in which the needle is advanced into the liver. The stab incision can then be stapled or sutured if necessary and covered with wound spray. Details of the technique for cattle and horses are available. 3,4

The principal danger of this procedure is that if the direction of the instrument is at fault it may approach the hilus and damage the large blood vessels or bile ducts. If the liver is shrunken or the approach too caudal, then there is no sample obtained. Fatal hemoperitoneum may result if a hemorrhagic tendency is present, and peritonitis may occur if the liver lesion is an abscess containing viable bacteria. Biliary peritonitis results if a large bile duct is perforated. It seems possible that the technique could precipitate a fatal attack of “black disease,” but many thousands of biopsies are performed without such an incident.

Evidence indicates that liver biopsy is the antemortem test of greatest value, in the absence of noninvasive tests, in reliably distinguishing animals with significant liver disease from those without it. Examination of liver biopsies may establish the presence of liver disease, provide a specific diagnosis, guide therapeutic choice, and help determine prognosis in cases of suspected liver disease.

The major deficiency of this method lies in the small sample that is obtained, and unless the liver change is diffuse the sample may not be representative.

**MEDICAL IMAGING OF THE LIVER**

**ULTRASONOGRAPHY**

Ultrasonography of the liver is now an established technique that is routinely used for the diagnosis of liver disease. Ultrasonographic examination of the liver can provide detailed information about the size, position, and parenchymal pattern of the liver as well as the size and position of the gallbladder and bile ducts. Ultrasonography can be used to guide the collection of liver biopsy and bile samples; furthermore, it is the only practical method for the diagnosis of thrombosis of the caudal vena cava. A systematic approach for the ultrasonographic examination of the liver of cattle and small ruminants has been described. 3,4

Examination of the liver is performed with a 3.5- to 5.0-MHz linear or convex transducer. The hair is clipped and contact gel or alcohol applied onto the skin. In cattle the liver is imaged from caudal to the last rib to the fifth intercostal space of the standing cow. In horses the liver is examined between the 6th and 15th right intercostal space and between the 6th and 9th left intercostal space of the standing horse. Each intercostal space is examined from dorsal to ventral, with the transducer held parallel to the ribs. The texture and the visceral and diaphragmatic surface of the liver are scanned, and the hepatic and portal veins, caudal vena cava, and biliary system are examined. Breed and age of cow does not influence the ultrasonographic appearance of the liver, particularly position, size, and vasculature of the liver and gallbladder. During pregnancy, the diameter of the caudal vena cava increases slightly and that of the portal vein decreases.

Ultrasonography can be used to detect thrombosis of the caudal vena cava in a cow with ascites. Cholestasis in cows can be diagnosed using ultrasonography to visualize dilatation of the extrahepatic and intrahepatic bile ducts and dilatation of the gallbladder. In cattle bile samples can be collected by percutaneous ultrasound-guided cholecystocentesis for demonstration of *Fasciola hepatica* and *D. dendriticum* eggs and for determination of bile acids. The procedure is done on the right side in the 9th, 10th, or 11th intercostal space. In horses cholelithiasis would present ultrasonographically as distended bile ducts and hyperechoic structures causing acoustic shadows located within these ducts.

Ultrasonography and digital analysis can be used for the diagnosis and evaluation of the degree of hepatic lipodosis of cows. 5 Hepatic abscesses in horses and cattle can be visualized using ultrasonography. The abscesses may vary in size and location; because in adult horses and cattle only parts of the liver are accessible for ultrasonographic examination, those abscesses located in the left part of the liver may escape ultrasonographic visualization. Ultrasound-guided catheterization of the portal or a mesenteric vein in cows has been described and is currently used for research purposes. 6

**RADIOGRAPHY**

Lateral abdominal radiography can be used to determine the size and location of the liver in foals. Fluoroscopy and contrast media injected into the mesenteric vein have been used to detect the presence of portosystemic shunts in foals and calves.

**LABORATORY TESTS FOR HEPATIC DISEASE AND FUNCTION**

Hepatic disease is difficult to diagnose based on clinical findings alone because of the unspecific symptoms caused by disturbed liver function. The diagnosis of liver disease therefore heavily relies on serum biochemical analyses. The results and interpretation of such diagnostic tests, however, are complicated by the fact that although several of the used parameters are specific for liver disease, they often do not allow differentiating between different types of liver disease.
Specific tests that identify the exact nature of the lesion are not available, and a combination of tests is usually necessary to make a diagnosis.

The laboratory tests for the diagnosis of hepatic disease and to evaluate hepatic function in farm animals can be divided into those that evaluate hepatobiliary function, the hepatic function tests, and those that are indicative of hepatocellular injury, the serum hepatic enzyme tests.

HEPATIC FUNCTION TESTS

Hepatic function tests determine the serum concentration of compounds produced, converted, or detoxified in the liver. Analytes produced by the liver include glucose, albumin, urea nitrogen, bile acids, and coagulative factors. Compounds detoxified or converted by liver cells include ammonia and unconjugated (indirect) bilirubin that is converted into conjugated (direct) bilirubin in the liver.

Serum Bile Acids

Bile acids are synthesized in the liver from cholesterol and are then secreted into the duodenum. The large majority of the bile acids excreted are reabsorbed from the digestive tract into the portal circulation, returned to the liver, and reexcreted into the biliary system. This recycling circuit is termed enterohepatic circulation.

The concentration of serum bile acids reflects the efficacy of this enterohepatic circulation. Elevated serum bile acid concentrations occur with impaired hepatocyte function, liver cirrhosis, and portosystemic shunts and are observed before jaundice occurs.

The rise in total serum bile acid concentration usually correlates well with the severity of liver disease. In cattle, however, there is extreme variability among all types and ages of animals, and the variation is even greater in beef cattle than in dairy cattle. There are hour-to-hour fluctuations in serum bile acid concentrations in cattle, making interpretation difficult. Feeding practices and stage of lactation can also affect the serum bile acid concentrations. Values of calves and yearlings are significantly lower than those of lactating dairy cows. Elevated serum bile acid concentrations have been reported in cattle with hepatic lipodisosis, liver abscesses, fasciolirosis, and biliary calculi. However, to be specific for liver damage in cattle, the value determined for a single sample would have to be above 126 µmol/L in beef cattle or 88 µmol/L in lactating dairy cattle.

In cattle, the total serum bile acid concentration is considered to be a more specific and sensitive indicator of a wide variety of hepatic disease and is significantly correlated with the degree of illness compared with other tests of hepatic function. In horses, the total serum bile acid concentration is also a sensitive indicator of several hepatic diseases and is most useful when combined with other tests of hepatic disease.

Serum Bilirubin

Bilirubin is a product of the degradation of hemoglobin. In blood unconjugated and thus insoluble bilirubin bound to albumin is transported to the liver to be conjugated with glucuronic acid and excreted into bile. Glucuronidation of bilirubin is required to improve water solubility and allow excretion in bile. Hyperbilirubinemia can occur as a result of increased red blood cell destruction, severe liver disease impairing either the uptake or conversion of unconjugated bilirubin by hepatocytes, or impaired bile flow out of the liver. Serum bilirubin concentration above 17 µmol/L (1.0 mg/dL) will cause a yellow tinge of the serum, and jaundice of mucosal membranes becomes apparent with concentrations above 40 µmol/L (2.3 mg/dL). The ratio of conjugated to unconjugated bilirubin is often used to differentiate between different etiologies of hyperbilirubinemia. Although this concept adopted from the human medical literature may appear as an attractive and straightforward diagnostic approach, more recent evidence indicates that species-specific differences in the elimination kinetics of bilirubin complicate the interpretation of this ratio to differentiate between the different forms of jaundice. In cattle and horses hyperbilirubinemia in most cases is driven by an increase of unconjugated bilirubin even with posthepatic obstruction of the bile flow.

Adult cattle with hepatic disease do not consistently have high serum bilirubin concentrations, and visible jaundice does not occur frequently in cattle with hyperbilirubinemia. The use of high bilirubin concentrations as an indicator of liver disease in calves is unreliable. This is similar to results in adult cattle in which serum bilirubin concentrations are not a specific or a sensitive test for chronic liver disease.

Ammonia

The microbial deamination of amino acids in the intestinal tract is the major source of ammonia, which is absorbed by the intestine into portal venous blood and converted into urea by the liver. The concentration of blood ammonia can be an indication of functional hepatic mass. Generally, plasma ammonia concentration is a sensitive and specific indicator of hepatic disease in the horse, although it may fluctuate widely even on the same day, and the concomitant low plasma urea concentration anticipated because of the liver's reduced synthetic ability is often not apparent.

In cattle with hepatic disease, plasma ammonia levels are significantly elevated compared with normal animals but not
always accompanied by a decline in plasma urea concentrations. In healthy cattle, the plasma ammonia:urea concentration ratio is 9:1 and the plasma ammonia:glucose concentration is 11:1. In hepatic disease, a plasma ammonia:glucose ratio of 40:1 or plasma ammonia:urea ratio 30:1, particularly with a rising total ketone body concentration and a declining glucose concentration, represents a guarded prognosis.

Most cases of portosystemic shunts are accompanied by marked increases in blood ammonia concentrations.

Although the serum ammonia concentration is considered to be a valuable diagnostic parameter to assess liver function, it is rarely included in biochemical diagnostic profiles. Blood samples assayed for ammonia require special handling because of the volatility of this compound, which makes this parameter unsuitable for routine use under field conditions. Samples must be placed on ice and transported to the laboratory immediately to be analyzed within 30 minutes of collection.

Urea Nitrogen
Blood urea nitrogen (BUN) or serum urea nitrogen is the end product of the hepatic detoxification of ammonia. It is this parameter that is sometimes also used to assess liver function. Urea nitrogen concentration in blood may decrease with impaired conversion of ammonia to urea by the liver. Low serum urea concentrations are, however, not specific for liver disease. Low urea nitrogen concentration is also seen in anorectic patients consuming less protein. In ruminants that are anorectic or on a low-protein diet, rumen microbes recur to BUN as a nitrogen source for their own protein synthesis, decreasing the BUN concentration.

Albumin
Albumin in blood is synthesized by the liver and may be decreased with severe and chronic liver disease. Low serum albumin concentrations are, however, not specific for liver disease because they may be the result of excessive loss (e.g., through the kidney) or impaired production that is unrelated to liver disease. Insufficient albumin synthesis that is not attributable to liver disease can be caused by inadequate dietary protein content or disturbed protein digestion or absorption. Low serum albumin concentration in combination with elevated serum globulin concentration is indicative of chronic inflammatory disease and is not suggestive of a primary liver disease.

**SERUM HEPATIC ENZYME TESTS**
The determination of the serum activity of hepatic enzymes is routinely used for the detection and evaluation of hepatocellular injury. Liver cell damage is, however, not necessarily correlated with disturbed liver function because of the redundancy of the functional capacity of the liver. Liver damage, reflected in markedly elevated serum enzyme activities, is only associated with clinical disease when over half of the functional liver tissue is affected.

Serum hepatic enzymes are categorized into enzymes leaking from the cytoplasm of a damaged hepatocyte (so-called leakage enzymes) and enzymes that are increased because of increased synthesis in response to cholestasis. The serum enzyme activity in individuals with liver disease depends on the concentration of the enzyme in question in the hepatocyte, the severity and the duration of liver disease, and the half-life of the enzyme. Enzymes used for the diagnosis of hepatocellular injury ideally have a high enzyme activity within hepatocellular cytoplasm, resulting in a measurable increase of the enzyme activity in serum with liver cell injury. To be specific, the cytoplasmatic activity of the enzyme in question should be higher in the liver than in any other tissue. The following enzyme activities are commonly measured in serum or plasma to diagnose liver disease in farm animals:

- l-glutamyl transpeptidase (formerly glutamyl transpeptidase [GT])
- This enzyme is highly selective as an indicator of acute liver injury. Liver cell damage results in a steep increase in serum enzyme activity followed by a rapid decline because of its short half-life. This parameter is thus less suited for the diagnosis of chronic liver disease. Another inconvenience is the instability of this enzyme in serum or plasma even when refrigerated or frozen. Marked drops in enzyme activity within 24 hours have been reported in chilled samples and within 72 hours in frozen samples.

- Lactate dehydrogenase (LDH) is abundant in liver, kidney, muscle, myocardium, and red blood cells. To differentiate liver disease from muscle cell injury, the analysis of other liver or muscle-specific enzymes is required.

- Aspartate aminotransferase (AST; formerly serum glutamic oxaloacetic transaminase) like LDH is abundant in a variety of tissues including liver and muscle. Elevated serum activities of AST therefore can only be interpreted in conjunction with other more specific liver enzyme to diagnose liver disease.

- Alanine aminotransferase (formerly serum glutamic pyruvate transaminase) is commonly used for the diagnosis of hepatic disease in small animals. In ruminants, horses, and pigs, however, this enzyme is of little diagnostic value because of the low cytoplasmic enzyme activity in hepatocytes of these species.

- γ-Glutamyl transferase (GGT) is an enzyme widely distributed in a variety of equine and bovine tissues. Specific activity of GGT is highest in the kidney, pancreas, and liver, but GGT enzyme activity in serum or plasma almost exclusively originates from hepatocytes, making this enzyme highly specific for disease of the hepatobiliary system in cattle, horses, and sheep. In the horse, increases in serum GGT may be associated with hepatocellular damage and liver necrosis in a variety of natural and experimentally induced liver diseases. These include bile duct ligation, carbon disulfide toxicity, carbon tetrachloride toxicoses, cholestasis, iron hepatotoxicosis, Senecio poisoning, and hyperlipidemia in ponies. GGT is a sensitive indicator of liver damage in horses affected with pyrrolizidine alkaloids (PAs) in the early stages of the disease, but values do not correlate with the increase in the severity of the lesions observed on liver biopsy samples collected later in the chronic phase of the disease. In horses that had consumed hay contaminated with Senecio vulgaris, the GGT values fluctuated widely: some horses with high levels did not die, whereas others had values slightly above reference values at the initial sample collection and died. GGT is a practical routine test for the evaluation of liver amyloidosis status in serum-producing horses. In foals during the first month of life values were 1.5 to 3 times higher than the upper physiologic reference values for healthy adult horses. In neonatal foals, the serum alkaline phosphatase (ALP), GGT, and SDH activities were increased during the first 2 weeks of life.

- In neonatal calves the serum GGT activity is used as an indicator for consumption of colostrum. High serum GGT activity in newborn calves comes from the passive intestinal absorption of this enzyme from colostrum, normally containing large amounts of GGT.

- Glutamate dehydrogenase (GDH or HDH) occurs in high concentration in the serum of ruminants and horses and is considered highly specific for liver disease.

- Ornithine carbamoyl transferase (OCT) activity is also elevated, even in chronic diseases, but only when there is active liver necrosis and not when the lesions are healing. Furthermore, OCT has been proposed as a tool to assist in the diagnosis of hepatic lipodosis in cattle.

- ALP activity is used as a test of hepatic excretory function in the horse and is of value in that species, but variations in normal cattle have such a wide range that results are difficult to interpret. Of the tests available for testing of biliary obstruction, the serum ALP test is preferred. However, there is a similar response to damage in other tissues.
Hepatic Enzyme Profile According to Species

The serum hepatic enzymes considered to be most useful as an aid in the diagnosis of liver disease in the different species are as follows.

Cattle
In adult cattle, GGT, ALP, SDH, AST, and GDH are most useful in identifying animals with chronic hepatic disease. The dehydrogenases (SDH and GDH) have the shortest half-lives in serum and may not increase in cattle with chronic liver disease.

In the early stages of hepatic dysfunction in cattle, SDH is the most efficient and sensitive test. The instability of this enzyme, even when the blood sample is placed on ice, requires analysis within hours of blood collection. In the later stages when tests of biliary excretion are more applicable, estimations of serum bilirubin are more indicated.

Calves
In neonatal calves under 6 weeks of age, none of the common tests for the assessment of liver damage or function in adult cattle are useful for detection of hepatic disease. The serum activity of most enzymes and total bilirubin are significantly higher in newborn calves than in 2-week-old calves. In calves less than 6 weeks of age with suspected liver disease, a combination of parameters should be used to assess liver damage, including GDH activity and total serum bile acid concentration. Percutaneous liver biopsy may provide the most information.

Horses
Total serum bile acids, GGT, GGT, and liver biopsy are helpful in studying different types of hepatic disease in the horse. In one series of primary hepatic disease all horses had high activities of serum GGT, and most had high activities of serum GDH and high concentrations of bile acids. Horses that were euthanized or died had significantly higher concentrations of bile acids. Horses that were hypoglycemic, and none had abnormally high activities of serum GDH and high concentrations of bile acids, and increased total bilirubin. Increased AST and increased GDH were also of good diagnostic value but only when used in combination with the previously mentioned tests. No single combination or sequential test was able to fully discriminate between horses with and without biopsy-confirmed liver disease, and reliance on the use of noninvasive tests for the prediction of the presence or absence of significant liver disease may lead to frequent diagnostic errors. Certain positive results did reliably predict the presence of liver disease, but negative test results were invariably unsatisfactory predictors of absence of liver disease.

In the early stages of hepatic dysfunction, SDH is preferred. Plasma ammonia concentrations may be significantly elevated compared with clinically normal horses but are not always accompanied by a decline in plasma urea concentration. A fall in plasma glucose concentration represents a poor prognosis.

The most useful noninvasive prognostic test in cases of suspected liver disease in adult horses is the severity of clinical signs.

Principles of Treatment in Diseases of the Liver

In diffuse diseases of the liver, no general treatment is satisfactory, and the main aim should be to remove the source of the damaging agent. The most that can be attempted in acute hepatitis is to help the animal over the danger period of acute hepatic insufficiency until the subsidence of the acute change and the normal regeneration of the liver restores its function. Death may occur during this stage because of hypoglycemia, and the blood glucose level must be maintained by oral or intravenous injections of glucose. Because of the danger of guanidine intoxication, an adequate calcium intake should be ensured by oral or parenteral administration of calcium salts.

There is some doubt as to whether protein intake should be maintained at a high level, because incomplete metabolism of the protein may result in toxic effects, particularly in the kidney. However, amino acid mixtures, especially those containing methionine, are used with apparently good results. The same general recommendations apply to prevention in the treatment of acute diffuse liver disease. Diets high in carbohydrate, calcium and protein of high biological value, and a number of specific substances are known to have a protective effect against hepatotoxic agents.

In chronic, diffuse hepatic disease fibrous tissue replacement causes compression of the sinusoids and is irreversible except in the very early stages, when removal of fat from the liver by the administration of lipotropic factors including choline and maintenance on a diet low in fat and protein may reduce the compressive effects of fibrous tissue contraction. A high-protein diet at this stage causes stimulation of the metabolic activity of the liver and an increased deposit of fat, further retarding hepatic function.

Local diseases of the liver require surgical or medical treatment depending on the cause, and specific treatments are discussed under the respective diseases.

Diffuse Diseases of the Liver

HEPATITIS

The differentiation of hepatic diseases into hepatits and hepatitis has not achieved general acceptance, and nomenclature such as hepatic injury have been suggested to avoid the connotation of inflammation associated with the word hepatitis. To facilitate ease of reading, the word hepatitis is used throughout this chapter to include all diffuse, degenerative, and inflammatory diseases that affect the liver. It is used here also to include the common pathologic classification of cirrhosis. Clinically, the syndrome caused by fibrosis of the liver is the same as that caused by hepatitis and the etiology is the same; the only difference is that the onset of the disease is slower and less acute than in hepatitis.

ETIOLOGY AND EPIDEMIOLOGY

Although there is an extensive list of causes of hepatitis there are still a number of unknown factors. At least there are many sporadic cases of hepatic insufficiency, especially in horses, in which the cause is not determined. In most cases the clinical disease has an acute onset and a fatal outcome, but the hepatic lesion is of a much longer duration.
In a case-control study of cases of equine hepatic disease admitted to the Liphook Equine Hospital in the UK, ponies were more likely to develop hepatic disease than light riding horses. Overall, the case fatality rate was low (25.9%); horses with unclassified hepatoepathies had the lowest fatality rate, and horses with cholangiohepatitis, pyrrolizidine alkaloid toxicity, and chronic active hepatitis had significantly higher fatality rates by comparison. Age, breed, or sex had no detectable effect on outcome.

**Toxic Hepatitis**
The common causes of toxic hepatitis in farm animals are:
- Inorganic poisons: Copper, phosphorus, arsenic, and possibly selenium
- Organic poisons: Carbon tetrachloride, hexachloroethane, gossypol, creosols, and coal tar pitch, chloroform, and copper diethylamine quinoline

Ferrous fumarate administered in a digestive inoculate to newborn foals is also recorded as a cause.

**Poisonous Plants, Fungi, and Insects** These include the following:
- Weeds: Senecio, Crotalaria, Heliotropium, Amsinckia, and Tribulus spp.; Ecephalartos lanatus; and Trachyandra spp.
- Pasture and cultivated plants: Panicum effusum, lupins, aslime clover, and water-damaged alfalfa hay
- Trees and shrubs: Lantana (Lantana camara), yellow wood (Terminalia oblongata), ngaio tree (Myoporum laetum), Australian boobialla (M. tetrandrum), and seeds of cycads (Zamia spp.)
- Algae: The slow death factor
- Insects: Ingestion of sawfly larvae (Lophyrotoma interrupta)

**Miscellaneous Farm Chemicals**
Miscellaneous farm chemicals include dried poultry waste, cottonseed cake, and herring meal.

**Toxemia Perfusion Hepatitis**
Moderate degrees of hepaticitis occur in many bacterial infections regardless of their location in the body, and the hepatitis is usually classified as toxic; whether the lesions are caused by bacterial toxins or by shock, anoxia, or vascular insufficiency is unknown. Hepatic failure may occur in dairy cattle following mastitis or metritis. It is thought that the hepatic dysfunction may have been the result of endotoxemia. This also applies to hepatitis associated with extensive tissue damage occurring after burns, injury, and infarction.

**Infectious Hepatitis**
Diffuse hepatic lesions in animals are rarely associated with infectious agents. The significant ones are:
- Rift Valley fever virus
- Bacillus piliformis, associated with Tyzzer’s disease in foals
- Equine herpesvirus-1 of viral rhinopneumonitis as a cause of abortion in horses
- Deltaproteobacterium associated with epizootic abortion of cattle in California
- Postvaccinal hepatitis of horses, also known as serum hepatitis, idiopathic acute hepatic disease, Theiler’s disease, and acute liver atrophy; is the most common cause of acute hepatic failure in the horse. The disease is commonly associated with the administration of biologic of equine origin, usually tetanus antitoxin.

A series of four fatal cases of serum hepatitis associated with the administration of commercial plasma in the horse has been reported. The prevalence in one veterinary teaching hospital has been recorded as 0.4%. A large number of cases of equine hepatic encephalopathy of unknown etiology occurred in France between 1992 and 1997.
- Severe cases of equine viral arteritis manifest signs of hepatitis.
- Systemic myoses, e.g., histoplasmosis, may be accompanied by multiple granulomatous lesions of the liver.
- There are diseases in which hepatic lesions may be common at necropsy, but in which there are no overt signs of clinical disease during life. Some of these are infectious equine anemia, salmonellosis, septicemic listeriosis, and leptospirosis in aborted foals.
- Infectious necrotic hepatitis associated with Clostridium novyi has been described in a 9-year-old mare.

**Parasitic Hepatitis**
- Acute and chronic liver fluke infestation
- Migrating larvae of Ascaris spp.
- Fibrosing granulomas of liver in horses with chronic chistosomiasis
- Hepatic sarcocystosis in horses

**Nutritional Hepatitis (Trophopathic Hepatitis)**
Selenium and vitamin E deficiency are factors in dietary hepatic necrosis in pigs. A multiple dietary deficiency has also been suggested as the cause of a massive hepatic necrosis observed in lambs and adult sheep on trefoil pasture in California. Hepatic lipidosis and hyperlipemia occurs most often in pregnant Shetland pony mares on a falling plane of nutrition. Hepatic lipidosis occurs in cattle during the transition period from late gestation to peak lactation. It is triggered by a negative energy balance occurring in the periparturient period in overconditioned dry cows. Rapid mobilization of large amounts of body fat in states of energy deficiency results in accumulation of nonesterified fatty acids in the liver, where they are reesterified to triglycerides and deposited as fat droplets within the liver cells. This fatty infiltration of the liver is reversible but if severe enough presents a functional impairment of the liver metabolism.

**White liver disease** is a well-identified clinical entity occurring in young sheep in the warmer parts of New Zealand. The cause is unknown but the disease affects only cobalt-deficient sheep. The disease occurs on leafy pastures with lots of leaf litter and in spring and early summer. Affected sheep show photosensitivity, anorexia, weight loss, sometimes jaundice, and blindness. At necropsy there is a greatly enlarged, light-colored, fatty liver. Most deaths occur in a chronic phase after the acute signs have passed. A similar disease, suspected to be caused by a mycotoxin, has been observed in Norway.

**Idiopathic Hepatosis and Cirrhosis**
Hepatic cirrhosis and hemochromatosis in horses has been recorded. There is cirrhosis with increased iron stores in the parenchymal cells of the liver. Hepatic fatty cirrhosis (hard yellow liver) in sheep and cattle has occurred in isolated areas of western and southern Texas during years of maximal rainfall. The cause is unknown, but the high incidence during periods of heavy rainfall suggests the possibility of either a mycotoxin or nutritional deficiency.

**Congestive Hepatopathy**
Increased pressure in the sinusoids of the liver causes anoxia and compression of surrounding hepatic parenchyma. Congestive heart failure is the common cause and leads to centrilobular degeneration.

Inherited hepatic insufficiency occurs in Southdown and Corriedale sheep.

**Portosystemic Vascular Anomaly**
Portosystemic shunts in large animals have been recorded occasionally in foals and calves. There is altered blood flow through the liver and hepatic insufficiency secondary to hepatic atrophy.

**PATHOGENESIS**
Hepatitis may be associated with a number of agents, but the clinical effects are similar in all instances. The usual lesion in toxicopathic hepatitis is centrilobular and varies from cloudy swelling to acute necrosis with a terminal veno-occlusive lesion in some plant poisonings. If the necrosis is severe enough or repeated a sufficient number of times, fibrosis develops. The effects of endotoxin on the liver include multifocal hepatocellular necrosis, impaired hepatic gluconeogenesis, and decreased hepatic blood flow. Endotoxin...
may cause the Kupffer cells to release lysosomal enzymes, prostaglandins, and collagenase, which can damage hepatocytes. Endotoxin not detoxified by the Kupffer cells may interact directly with the hepatocytes, causing lysosomal damage and decreased mitochondrial function, leading to necrosis. In infectious hepatitis the lesions vary from necrosis of isolated cells to diffuse necrosis affecting all or most of the hepatic parenchyma.

**Serum hepatitis in the horse** is characterized by severe central lobular necrosis following the administration of biologics of equine origin such as tetanus antitoxin, commercial equine plasma, and other products.

**In parasitic hepatitis** the changes depend on the number and type of migrating parasites. In massive fluke infestations sufficient damage may occur to cause acute hepatic insufficiency, manifested particularly by submandibular edema. In more chronic cases extension from cholangitis may also cause chronic insufficiency.

**Trophopathic hepatitis** is characterized by passive or submassive necrosis. Hepatic lipidosis is characterized by fatty infiltration of hepatocytes progressing to development of fatty cysts.

**Congestive hepatitis** is characterized by dilatation of central veins and sinusoids with compression of the parenchymal cells.

**Hepatic fibrosis** develops particularly if there is massive hepatic necrosis that destroys entire lobules. Degeneration is not possible, as it is when the necrosis is zonal, and fibrous tissue replacement occurs. Thus fibrosis is a terminal stage of hepatitis that may have developed acutely or chronically and is manifested by the same clinical syndrome as that of hepatitis, except that the signs develop more slowly. Fibrosis may also develop from cholangitis.

The term **cirrhosis** has been avoided because it carries connotations from human medicine that may be misleading when applied to animals. **Hepatic fatty cirrhosis** occurs in sheep and cattle and is characterized at necropsy by ascites, hydropenicardium, and acquired hepatic vascular shunts. There is progressive fatty change of the liver leading to cirrhosis. Fibrosis begins in the periportal zone associated with ruptured fatty cysts and continues until there is widespread bridging periportal fibrosis. No lesions of hepatic encephalopathy occur.

**In portosystemic vascular anomalies** the increased levels of ammonia, short chain fatty acids, and amino acids in the peripheral circulation are the cause of the depression and neurologic abnormalities that are typical of hepatic encephalopathy. These high levels of metabolites are the result of failure of the hepatic metabolism and detoxification of substances absorbed from the intestines, which are normally delivered to the liver via the portal vein before they enter the peripheral circulation.

**Liver Disease and Liver Failure**

The liver has vast reserves of function, an almost embryonic capacity to regenerate itself, and it can perform adequately despite extensive pathologic damage to its integrity. This is best exemplified in liver abscesses in cattle, in which clinical disease is rarely evident, even in the presence of large abscesses.

Liver disease is usually diagnosed by identifying clinical signs produced by failure of some of its functions. There is often liver disease before failure of function, and laboratory tests may detect disease before there is actual failure. The liver has a reserve of about 70% to 80%, and this amount of functional liver tissue must be compromised before some of its functions fail. Some functions fail before others, which explains the progression of clinical signs.

**Intravascular Hemolysis in Equine Liver Disease**

Intravascular hemolysis with prominent hemoglobinuria has occurred in horses with severe and advanced liver disease. Neutrophil hypersegmentation of undetermined cause was present in one horse with liver disease and intravascular hemolysis.

**CLINICAL FINDINGS**

The cardinal signs of hepatitis are anorexia, mental depression (with excitement in some cases), muscular weakness, and jaundice, as well as somnolence, recumbency, and coma with intermittent convulsion in the terminal stages. Hemoglobinuria is a variable sign in horses. The hemolytic crisis with which it is associated is always a precursor to a fatal outcome. Animals that survive the early acute stages may show photosensitization, a break in the wool or hair leading to shedding of the coat, and susceptibility to metabolic strain for up to a year.

The clinical findings of **hepatic disease in the horse** are generally nonspecific, but the most useful noninvasive prognostic test in cases of suspected liver disease in adult horses is the severity of clinical signs. Regardless of the cause, consistent clinical findings include weight loss, anorexia, dullness, and depression. Other findings include jaundice, tachycardia, intermittent fever, abdominal pain, ventral body wall edema, clotting deficiency, muscle fasciculations, and diarrhea or constipation. Jaundice is a constant feature in acute hepatic necrosis. Dysphagia, photosensitization, encephalopathy, and hemorrhages tend to occur terminally, particularly in horses with cirrhosis. In chronic liver disease, the course is several months.

The initial anorexia is often accompanied by constipation and punctuated by attacks of diarrhea. The feces are lighter in color than normal, and if the diet contains much fat then there may be steatorrhea.

In a series of 50 cases of primary hepatic disease in horses, the following occurrence of clinical signs was observed (%): dull demeanor (68), anorexia (56), abdominal pain (50), encephalopathy (50), weight loss (50), jaundice (42), abnormal intestinal motility (42), abnormal fecal consistency (28), dehydration (18), photosensitization (16), bilateral laryngeal paralysis (14), clinical coagulopathy (10), dermatitis and pruritus (8), peripheral edema (6), oral ulceration (6), tenesmus (4), penile prolapse (2), and rectal impaction (2).

The nervous signs are often pronounced and vary from ataxia and lethargy with yawning or coma, to hyperexcitability with muscle tremor, mania including aggressive behavior, and convulsions. A characteristic syndrome is the dummy syndrome, in which affected animals push with the head, do not respond to normal stimuli, and may be blind. There may be subacute abdominal pain, usually manifested by arching of the back, anorexia, and pain on palpation of the liver. The enlargement of the liver is usually not palpable.

Jaundice and edema may or may not be present and are more commonly associated with the less acute stages of the disease. Photosensitization may also occur but only when the animals are on a diet containing green feed and are exposed to sunlight. A tendency to bleed more freely than usual may be observed. In chronic hepatic fibrosis the signs are similar to those of hepatitis but develop more slowly and persist for longer periods, often months. Ascites and the dummy syndrome are more common in hepatitis.

**Serum hepatitis (Theiler’s disease)** is the most common cause of acute hepatic failure in the horse. Typically, clinical findings become apparent several weeks after administration of tetanus antitoxin. Lactating mares appear to be at a higher risk than other horses, but this may be caused by the administration of the antitoxin to mares at the time of parturition. In a group of affected horses, the illness may begin with an unexplained death in a horse after a short illness. Clinical findings include sudden anorexia, marked lethargy, stiff gait, subcutaneous edema of the distal aspects of all four limbs and body wall, blindness, head pressing, circling, bruxism, abdominal pain, tachycardia, icterus, and a marked reduction in gastrointestinal sounds. Death in a few days is common.

Serum hepatitis following the transfusion of commercial plasma into horses may cause severe unresponsive colic, lethargy, and sudden death 41 to 60 days later. Severe encephalopathy has also been described.

Hepatic disease in cattle is characterized by weight loss, dullness, and depression. Signs of hepatic encephalopathy include blindness, head pressing, excitement, ataxia, and weakness. The presence of fever and jaundice represents a poor prognosis.

Hepatic fatty cirrhosis in ruminants in Texas is characterized by failure to gain
weight, progressive emaciation, loss of wool crimp, ascites, depression, head pressing, and walking with the head held high. In the terminal stages, animals become immobile and die in a state of coma. Morbidity may reach 80% to 100%, and mortality varies from 10% to 60%. Mortality increases during each succeeding month following October, climaxes in January and February, and then decreases in the months thereafter.

**Portosystemic Shunts**

In young animals with portosystemic shunts the clinical findings include stunted growth, ascites, and variable neurologic abnormalities resulting from hepatic encephalopathy. Calves and foals may be a few weeks to a few months of age before they are presented for examination. Apparent cortical blindness, circling, and dementia are common. Persistent tenesmus is common in calves. Recurrent episodes of unexplained neurologic clinical findings in a young foal suggest the presence of a portosystemic shunt. A tentative diagnosis may be made using clinicopathologic results, but a definitive diagnosis requires portovenography. Blood ammonia levels are markedly increased and serum bile acids are also increased, but the serum levels of hepatic-derived enzymes may be normal.

**CLINICAL PATHOLOGY**

The clinicopathologic features of primary liver disease are summarized in the section dealing with laboratory tests for hepatic disease and function.

Scoring liver biopsies of the horse with suspected liver disease is highly predictive of the severity of the lesion and of prognosis. In a series of 82 cases in horses, 61 were confirmed to have significant liver disease and 12 were not confirmed. Only serum activities of GGT and ALP and serum globulin concentration were found to be significantly different between the two groups of horses.

Clinical and ultrasonographic data were found, when present, to be good indicators of the presence of liver disease. The single positive test results of greatest diagnostic value in horses were the presence of hepatic encephalopathy, elevated serum GGT and ALP activity, hypoalbuminemia, increased total bile acids, and increased total bilirubin concentration. Increased serum AST and GDH were also good diagnostic values but only when used in combination with the previously mentioned tests. No single combination or sequential test was able to fully discriminate between horses with and without biopsy-confirmed liver disease. Reliance on the use of noninvasive tests for the prediction of the presence or absence of significant liver disease may lead to frequent diagnostic errors. Certain positive results did reliably predict the presence of liver disease, but negative test results were invariably unsatisfactory predictors of absence of liver disease.

The most useful noninvasive **prognostic** test in cases of suspected liver disease in adult horses is the severity of clinical signs. A significantly poorer prognosis was found in association with clinical signs suggestive of liver disease, the presence of hepatic encephalopathy, ultrasonographic abnormalities, increased globulins, increased total bile acids, increased serum ALP and GGT activity, erythrocytosis, leukocytosis, low serum albumin, and low serum urea concentrations.

**NECROPSY FINDINGS**

The liver in hepatitis is usually enlarged and the edges swollen, but the appearance of the hepatic surface and cross section varies with the cause. In acute toxic and trophopathic hepatitis the lobulation is more pronounced, and the liver is paler and redder in color. The accentuation of the lobular appearance is caused by engorgement of the centriloculuar vessels or centriloculuar necrosis. There may be accompanying lesions of jaundice, edema, and photosensitization. In infectious hepatitis the lesions are inclined to be patchy and even focal in their distribution. Parasitic hepatitis is traumatic, with focal hemorrhages under the capsule and the necrosis and traumatic injury definable as tracks. Congestive hepatitis is marked by severe enlargement of the liver, a greatly increased content of blood, and marked accentuation of the lobular pattern caused by vascular engorgement and fatty infiltration of the parenchyma. In hepatic fibrosis the necropsy findings vary widely depending on the causative agent, on the duration of its action, and on its severity. The liver may be grossly enlarged or be greatly reduced in size with marked lobulation of the surface.

**Hepatic encephalopathy** associated with portosystemic shunt is characterized by spongiform changes and gliosis of white matter in all levels of the brain. The liver may be of normal size or small and firm, with a prominent reticular pattern visible on the capsular and cut surfaces, and the portal veins may be absent.

**TREATMENT**

Protein and protein hydrolysates are probably best avoided because of the danger of ammonia intoxication. The diet should be high in carbohydrate and calcium and low in protein and fat, but affected animals are usually completely anorectic. Because of the failure of detoxification of ammonia and other nitrogenous substances by the damaged liver and their importance in the production of nervous signs, the oral administration of broad-spectrum antibiotics has been introduced in humans to control protein digestion and putrefaction. The results have been excellent with neomycin and chlortetracycline, with the disappearance of hepatic coma coinciding with depression of blood ammonia levels. Purgation and enemas have also been used in combination with oral administration of antimicrobials, but mild purgation is recommended to avoid unnecessary fluid loss. Supplementation of the feed or periodic injections of the water-soluble vitamins are desirable. Hepatic fibrosis is considered to be a final stage in hepatitis and treatment is not usually undertaken.

**DIFFERENTIAL DIAGNOSIS**

Hepatitis is easily misdiagnosed as an encephalopathy unless jaundice or photosensitization is present. The nervous signs are suggestive of the following:

- Encephalomyelitis
- Encephalomalacia
- Cerebral edema

Congestive hepatitis is usually not manifested by nervous signs and, being a secondary lesion in congestive heart failure, is usually accompanied by ascites and edema in other regions and by signs of cardiac involvement. Hepatic fibrosis may produce ascites without evidence of cardiac disease.

Acute diseases affecting the alimentary tract, particularly engorgement on grain in cattle and horses, may be manifested by signs of nervous derangement resembling those of acute hepatic dysfunction, but the history and clinical examination usually suggest a primary involvement with the alimentary tract. Anorectic hepatic insufficiency may be mirrored by an adenocarcinoma of the pancreas, which is unlikely to be diagnosed during life.

**FURTHER READING**

**Liver Abscess and Necrobacillosis of the Liver**

**SYNOPSIS**

**Etiology** *Fusobacterium necrophorum* subsp. *necrophorum* is the most common isolate present in pure culture. *F. necrophorum* subsp. *funduliforme* is less common and isolated as a mixed infection with *Trueperella* (formerly *Arcanobacterium*) pyogenes.

**Epidemiology** Greatest importance in grain-fed cattle where it occurs secondary to rumenitis.
Although the terms liver necrobacillosis and liver abscess are often used synonymously, the term liver abscess refers to a morphologic diagnosis, whereas liver necrobacillosis in the strict sense of the term is an etiologic diagnosis referring to those abscesses caused by Fusobacterium necrophorum.1 Although F. necrophorum is by far the most commonly isolated pathogen from liver abscesses in cattle, strictly speaking a liver abscess can be referred to as necrobacillosis of the liver only after isolation of F. necrophorum.

**Etiology**

F. necrophorum is a gram-negative, non-spore-forming, rod-shaped anaerobic but aerotolerant organism. It is a normal inhabitant of the ruminant oral cavity and upper digestive and respiratory tract and an opportunistic pathogen generally associated with abscesses and various necrotic infections.1 In addition to hepatic necrobacillosis, this bacterium is also the causative agent of digital necrobacillosis of calves.

Historically, a subdivision of F. necrophorum into four different biotypes (A, B, AB, and C) was used. Biotypes A and B, which are considered to be most relevant in the etiology of F. necrophorum–associated diseases in cattle, have been renamed F. necrophorum subsp. necrophorum (formerly biotype A) and F. necrophorum subsp. funduliforme (formerly type B). F. necrophorum is often found in hepatic abscesses in ruminants, and subspecies necrophorum is the more common type isolated and is usually present in pure culture. F. necrophorum subsp. funduliforme is less prevalent and usually isolated with other bacteria, such as Trueperella (formerly Arcanobacterium) pyogenes, Bacteroides spp., Streptococcus spp., and Staphylococcus spp.1

T. pyogenes, a gram-positive, rod-shaped, facultative anaerobe, is the second most common pathogen isolated from liver abscesses in cattle; it acts synergistically to promote growth of F. necrophorum by using oxygen to create an anaerobic environment and provide iron for growth through its hemo lytic activity. In most cases T. pyogenes is cultured as a mixed culture with F. necrophorum, which has led to the widely held assumption that there is a synergism between these pathogens. The leukotoxin (LT) of F. necrophorum is thought to protect T. pyogenes against phagocytosis, suggesting that T. pyogenes is an opportunistic pathogen contributing to the development of liver abscesses and not the primary invader.3

Hepatic abscesses in goats have been described. The organisms isolated included Corynebacterium pseudotuberculosis (58.9%), Escherichia coli (11.8%), Corynebacterium spp. (11.8%), Mannheimia haemolytica (5.0%), Proteus sp. (5.9%), and Staphylococcus aureus (5.9%).

Clostridium sordellii is associated with hepatic abscesses in neonatal lambs and bacillary hemoglobinuria by a toxin from C. haemolyticum with focal hepatic necroses. A focal bacterial hepatitis in horses, identified as Tyzzer’s disease and associated with Bacillus piliformis, and yersiniosis associated with Yersinia pseudotuberculosis are listed elsewhere. Occasional cases of strangles that develop bacteremic spread may also develop hepatic abscesses, as may septicemia in lambs associated with Histophilus somni. In most cases hepatic abscesses in horses have an unknown etiology and pathogenesis. The fungus Mortierella wolffi has been isolated from a liver abscess in a cow in Australia. The liver abscess was grossly indistinguishable from other common bacterial abscesses, such as those associated with T. pyogenes or F. necrophorum.

**Epidemiology**

**Occurrence**

The disease occurs in all ages and types of cattle and sheep but achieves the greatest economic significance in grain-fed cattle where it occurs secondary to rumenitis. In feedlots in the United States the prevalence varies widely between feedlots but ranges from 12% to 32% in most; equivalent rates occur in “barley beef” cattle in the UK. In a series of recent slaughter plant surveys conducted in the United States, the incidence rate of condemnation of the liver for either minor or major abscesses was determined to be 13.7%.4

Sporadic cases or occasional outbreaks of liver abscess occur in the neonate from umbilical infection or in individuals as a complication of an episode of acute rumen acidosis (grain overload).

**Pathogen Risk Factors**

F. necrophorum is a common inhabitant of the upper digestive and respiratory tract of ruminants and a common inhabitant of the environment of farm animals. It uses lactate as the major sugar substrate, and its numbers in the rumen increase with a change from roughage to high grain diets. F. necrophorum is not capable of prolonged survival outside the animal body; 1 month is the probable maximum period under favorable conditions. Infection to the liver requires a predisposing injury at a primary site of infection. The disease can be reproduced experimentally by intraportal inoculation of F. necrophorum.

F. necrophorum possesses a number of virulence factors such as endotoxin lipopolysaccharide (LPS), LT hemolysin, hemagglutinin, and others that are considered to be of critical importance for the anaerobic pathogen to penetrate, colonize, and proliferate in nonsuperficial tissue.6 Of these factors LT and LPS have been studied in the greatest detail and are considered the primary virulence factors. The LT is cytotoxic specifically to ruminant neutrophils, macrophages, hepatocytes, and possibly also to rumen epithelial cells, possibly facilitating the penetration of the damaged rumen mucosa. The importance of LT to the virulence of F. necrophorum is corroborated by the correlation between toxin production and the ability to induce abscesses observed in laboratory animals.7 F. necrophorum subsp. necrophorum was found to produce larger amounts of LT than F. necrophorum subsp. funduliforme, which may contribute to the obvious difference in virulence between the two subspecies. F. necrophorum subsp. necrophorum is isolated from 71% to 95% of all bovine liver abscesses (in 75% as pure culture), whereas F. necrophorum subsp. funduliforme is commonly isolated from 5% to 29% of all abscesses (in over 75% of cases as mixed culture).

**Risk Factors in Grain-Fed Cattle**

Rumenitis, resulting from rumen acidosis, is the primary site of infection in grain-fed cattle. The risk for liver abscess is increased by factors that predispose rumenitis, such as low roughage and high-energy diets, and the incidence increases as roughage in the diet decreases.

**Management**

Introducing hungry cattle to high-energy diets, rapidly increasing dietary energy, and poor feed bunk management with irregular periods and amounts of feeding are associated with higher rates of liver abscess.

**Diet**

The type of grain and the use of processed, including gelatinized, grain can influence risk of abscess, as can the physical nature of the diet if it allows feed sorting by the animal during feeding.

**Breed**

Holstein Friesian cattle are at greater risk than beef breeds, presumably because they are fed longer and have higher feed intakes. The prevalence of steers is marginally higher than in heifers, probably also related to higher feed intake.

**Risk Factors in Other Farm Animals**

In lambs and calves infection usually occurs through the navel at birth or through ruminal ulcers; the infection originates from infected bedding grounds or barn
Neutrophils are the predominant phagocyte in lesions of 8 hours or less, and macrophages are the predominant phagocyte in lesions of 12 hours’ duration or more. The LT is responsible for allowing the bacteria to withstand the phagocyte cell response and enable the infection to persist. If there is sufficient hepatic involvement, then a toxemia develops from the bacterial infection and causes a chronic or acute illness.

In most infections, the lesions are too small to produce clinical signs. Hematogenous spread from hepatic lesions, including rupture into the caudal vena cava, may result in multiple lesions in many organs, severe pulmonary disease with hemoptysis, and rapidly fatal termination (caudal vena cava syndrome).

**CLINICAL FINDINGS**

In the majority of cases of hepatic abscessation in feeder cattle there are no clinical signs of illness. Abscesses that are very large may result in an acute or chronic illness.

In acute cases in dairy cattle there is fever, anorexia, depression, drop in milk production, and weakness. Abdominal pain is evidenced on percussion over the posterior ribs on the right side, and affected cattle show arching of the back and reluctance to move or lie down. The liver may be so enlarged that it is readily palpable behind the costal arch. The abdominal pain may be sufficiently severe to cause grunting with each breath. In chronic cases, there are no localizing signs but anorexia, emaciation, and intermittent diarrhea and constipation occur. Animals infected through the navel show signs at about 7 days of age, and omphalophlebitis is usually present.

**Hepatic abscesses in horses** are characterized clinically by a history of weight loss, fever, inappetence, and depression. The prognosis is very unsatisfactory, in spite of intensive antibiotic and supportive therapy, and euthanasia is recommended.

**CLINICAL PATHOLOGY**

Leukocytosis with marked neutrophilia may be present with large or multiple abscesses. Clinical chemistry and liver function tests have been found to be poor indicators and of little diagnostic value in predicting the presence of liver abscesses, but hepatic dysfunction can be detected by these means in the acute stage of hepatic injury. Ultrasound may aid in diagnosis. In horses clinicopathologic abnormalities are consistent with a diagnosis of chronic bacterial infection such as leukocytosis with a mature neutrophilia, thrombocytosis, hyperglobulinemia, hypoalbuminemia, and a markedly decreased albumin-to-globulin concentrations ratio.

**NECROPSY FINDINGS**

Usually, multiple hepatic abscesses are present. The hepatic lesions may be deep in the parenchyma or under the capsule, especially on the diaphragmatic surface. Extension to the diaphragm or perirenal tissues is not unusual.

In bovine ruminitis cases, the anterior ventral sac is most commonly affected. There are local or diffuse mucosal lesions with thickening of the wall, superficial necrosis, and the subsequent development of ulcers. In lambs there may be lesions at the cardinal end of the esophagus. The histologic appearance of acute to subacute necrobiocilosis lesions consists of a zone of necrosis bordered on one edge by mats of filamentous rods and on the other by a band of karyorrhectic leukocytes.

**Samples for Confirmation of Diagnosis**

- **Bacteriology:** Swab of abscess or tissue sample from deep edge of lesion (anaerobic culture).

**Differential Diagnosis**

| Acute cases in cattle resemble cases of traumatic reticuloperitonitis, and differentiation can only be made on localization of the pain, ultrasonography, and by exploratory rumenotomy. The latter is essential if traumatic hepatitis is a possible diagnosis. |

**Treatment**

- **F. necrophorum** is susceptible in vitro to β-lactam antibiotics, tetracyclines, macrolides, and lincomycins but is resistant to amnoglycosides and tonophore antibiotics. The apparent sensitivity of this gram-negative pathogen to penicillin and cephalosporins is peculiar even based on its cell wall structure.

Liver abscess in feedlot cattle is not clinical and not routinely treated as a clinical disease. In clinical disease associated with liver abscess, prolonged treatment with high doses of antimicrobials is required if therapeutic concentrations are to be achieved at the site of infection. Relapse is common because of incomplete control of the localized infection.

CONTROL
Control procedures in feedlot cattle include prevention of rumenitis by feed management and the use of prophylactic antimicrobials.

Feed Management
Feed management aims to prevent the occurrence of rumen acidosis and rumenitis and requires controlled dietary energy step up, attention to the grain type and content of the diet, and correct feed bunk management. The control of rumen acidosis is discussed in Acute Ruminal Acidosis in chapter 8.

Prophylactic Antimicrobial Therapy
The addition of antimicrobials to the feed can significantly reduce the incidence of liver abscesses and is a routine practice in over 70% of all feedlots in the United States. Adding antimicrobials to feed as disease prophylaxis is not permitted in many countries, including member countries of the European Union.

In the United States bacitracin, methylene disalicylate, chlorotetracycline, oxytetracycline, tylosin, and virginiamycin are approved for feed inclusion for the control of liver abscess in feedlot cattle. Tylosin is the most commonly used compound and appears highly effective. A summary of trials feeding tylosin at 11 g/tonne of feed or 90 mg per animal per day showed a 73% reduction in the occurrence of liver abscesses. Antimicrobial feed additives also increase average daily gain and feed conversion efficiency, but the inclusion level for these effects and prevention of liver abscess is not necessarily the same.

The site of action may be in rumen or the liver or possibly in both, but is probably the rumen because tylosin and virginiamycin, which are both effective in prevention, are not absorbed into the circulation. Tylosin has been shown to inhibit the increase in ruminal F. necrophorum numbers that occur in association with feeding high-grain diets.

Vaccination
Vaccination with leukotoxoid vaccines has shown some protection against intraportal challenge and has reduced the abscess rates in a study of naturally occurring disease in a feedlot. A trial of the efficacy of a high antigenic-mass-combined T. pyogenes–F. necrophorum bacterin-toxoid in preventing naturally occurring liver abscesses in feedlot cattle showed a significant effect of vaccination with a reduction of the prevalence and severity of abscesses that was equivalent to that achieved by the incorporation of tylosin in the feed. The reduction in prevalence in two trials comparing vaccinated and nonvaccinated cattle was 48.4% (31% of controls and 16% of vaccines with liver abscess) and 37.5% (48% of controls and 30% of vaccines with liver abscesses). An additive effect when combining vaccination and preventive treatment with oral tylosin could not be observed.

Control in Young Lambs
In young lambs, the disease can be controlled by disinfecting the navel at birth and providing clean bedding or bedding grounds.

FURTHER READING

REFERENCES
The disease is spread from infected to noninfected areas by flooding, natural drainage, contaminated hay from infected areas, or carrier animals. The carriage of bones or meat by dogs or other carnivores could also affect spread of the infection. Contamination of pasture may occur from feces or from decomposing cadavers.

**PATHOGENESIS**

Although attempts to produce the disease by feeding the organism have been unsuccessful, it is probable that under natural conditions in endemic areas invasion occurs from the alimentary tract after ingestion of contaminated material. As in black disease of sheep, the bacteria are carried to the liver and lodge there until damage to the parenchyma of the liver and the resulting hypoxia create conditions suitable for their proliferation. Migrating flukes are thought to be predisposed to clinical disease by leading to liver necrosis and the establishment of anaerobic conditions in the liver that will lead to the multiplication of the causative organism. Invasion of the liver by *Cysticercus tenuicollis* and other causes of liver damage can also lead to the disease. Once *C. haemolyticum* returns to its vegetative state in an anaerobic environment and replicates, it also produces phospholipase C (β-toxin). This β-toxin causes hemolysis, necrosis of hepatocytes, and damage to capillary endothelium, all of which lead to hemoglobinuria and loss of vascular fluid into tissues and serous cavities.

The development of an organized thrombus in a subterminal branch of the portal vein produces the large anemic infarct that is characteristic of the disease. Most of the bacteria are to be found in this infarct and, under the anaerobic conditions, the necrotoxic and hemolytic β-toxin is released systemically to result in toxemia, generalized vascular damage, and intravascular hemolysis.

**CLINICAL FINDINGS**

Animals brought into contact with the infection in endemic areas seldom develop disease until 7 to 10 days later. The illness is of short duration, and cattle at pasture may be found dead without obvious signs of the disease. More often there is a sudden onset, with complete cessation of rumination, feeding, lactation, and defecation. Abdominal pain is evidenced by reluctance to move and an arched-back posture. Grunting may be evident on walking. Respiration is shallow and labored and the pulse is weak and rapid. Fever (39.5–41°C, 103–106°F) is evident in the early stages, but the temperature subsides to subnormal before death. Edema of the brisket is a common finding. The feces are dark brown; there may be diarrhea with a great deal of mucus and some blood. The urine is dark red. Jaundice is present but may not be very obvious. The duration of the illness varies from 12 hours in dairy cows in advanced pregnancy to 4 days in dry stock. Pregnant cows often abort. Severe dyspnea is evident just before death. The disease in sheep presents with similar signs.

**CLINICAL PATHOLOGY**

The red color of the urine is caused by the presence of hemoglobin; there are no free red cells. In the later stages there is anemia, characterized by a marked decline of packed cell volume and red blood cell counts. Leukocyte counts tend to be markedly elevated with the presence of toxic granulocytes. Most prominent changes in blood biochemistry analysis are elevated enzyme activity of AST and GGT, as well as mild to moderate elevation of serum bilirubin concentrations, which are reflective of liver damage.

Blood cultures during the acute stages of the disease may be positive. Serum agglutinins against *C. haemolyticum* may be detectable at low levels (1:25 to 1:50) during the clinical illness and, if the animal recovers, rise to appreciable levels (1:50–1:800) a week later. Titters greater than 1:400 are usual at this time. A positive agglutination test is not conclusive evidence of the presence of the disease.

**NECROPSY FINDINGS**

Rigor mortis develops quickly. The peritoneum is soiled with bloodstained urine and feces. Subcutaneous, gelatinous edema, which tends to become crepitant in a few hours, and extensive petechial or diffuse hemorrhages in subcutaneous tissue are characteristic. There is a variable degree of jaundice. Excessive amounts of fluid, varying from clear to bloodstained and turbid, are present in the pleural, pericardial, and peritoneal cavities. Generalized subserous hemorrhages are also present. Similar hemorrhages appear under the endocardium. Hemorrhagic abomasitis and enteritis are accompanied by the presence of bloodstained ingesta or free blood. The characteristic lesion of bacillary hemoglobinuria is an ischemic infarct in the liver. One or more may be present in any part of the organ and vary from 5 to 20 cm in diameter. The infarct is pale, surrounded by a zone of hyperemia, and has the general appearance of local necrosis. Red urine is present in the kidneys and bladder, and petechiation is evident throughout the kidney.

*C. haemolyticum* can be isolated from the liver infarct and many other organs from a fresh carcass, but postmortem invaders quickly obscure its presence. A positive fluorescent antibody test (FAT) on impression smears taken from the hyperemic zone around the liver infarct and stained with fluorescein isothiocyanate–labeled rabbit antiserum to *C. novyi* antisera will confirm the presence of *C. novyi*–type organisms but cannot differentiate type B from type D. A polymerase chain reaction (PCR) test to identify toxin-producing genotypes of *Clostridium* spp. may assist in the identification of isolates.

**Samples for Confirmation of Diagnosis**

- Bacteriology: Tissue from edge of liver infarct, placed in an airtight container; four air-dried impression smears from lesion border [anaerobic culture, FAT]
- Histology: Fixed liver lesion, kidney

**DIFFERENTIAL DIAGNOSIS**

The diagnosis of bacillary hemoglobinuria is largely a question of differentiation from other diseases in which hemoglobinuria, myoglobinuria, and hematuria are cardial signs. In an animal found dead, differentiation from other clostridial diseases and anthrax may be required. Differentiating between hemoglobinuria and hematuria by spinning urine will allow the discrimination of those differentials not associated with intravascular hemolysis.

- Acute leptospirosis
- Postparturient hemoglobinuria
- Hemolytic anemia caused by cruciferous plants
- Babesiosis and anaplasmosis
- Enzootic hematuria
- Chronic copper poisoning (sheep)

**TREATMENT**

Specific treatment includes the immediate use of penicillin or tetracyclines at high doses and antidotal serum if available. Prompt treatment is essential. If the serum is administered in the early stages of the disease, then hemoglobinuria may disappear within 12 hours. If the serum is administered too late, it may be of some value.

Supportive treatment, including blood transfusion, parenteral fluid, and electrolyte solutions, is of considerable importance. Care is required during treatment and examination, because undue excitement or exercise may cause sudden death. Bulls should not be used for service until at least 3 weeks after recovery because of the danger of liver rupture. Convalescence is often prolonged, and animals should be protected from nutritional and climatic stress until they are fully recovered.
REFERENCES
The carcasses of animals dying of the disease and need to be administered twice a year. These local reactions lack immunogenicity. Modern vaccines prepared to avoid injections are likely to produce severe reactions, because intradermal and intramuscular inoculum may be administered at several locations of extreme risk. A second vaccination during the grazing season is recommended. To obviate the local reaction that occurs at the site of injection, the inoculum may be administered at several sites and distributed under the skin by massage. The injection must be subcutaneous, because intradermal and intramuscular injections are likely to produce severe reactions. Modern vaccines prepared to avoid these local reactions lack immunogenicity and need to be administered twice a year. The carcasses of animals dying of the disease should be disposed of by burning or deep burial.

FURTHER READING

CLINICAL FINDINGS
Sheep have a rapid clinical course and are usually found dead. Short clinical course in cattle and horses with profound depression and toxemia, abdominal pain, and peritonitis.

CLINICAL PATHOLOGY
None described.

NECROPSY FINDINGS
Rapid autolysis, engorgement of subcutaneous vessels with edema; liver has small areas of yellow-colored necrosis surrounded by a zone of hyperemia.

DIAGNOSTIC CONFIRMATION
Isolation of Clostridium novyi in the typical liver lesion; fluorescent antibody staining identifies C. novyi but not the type.

TREATMENT
Parenteral penicillin may be attempted but high case fatality.

CONTROL
Vaccination

ETIOLOGY
The etiologic agent of infectious necrotic hepatitis affecting sheep and cattle and rarely pigs and horses is Clostridium novyi, type B. Spores of C. novyi are resident in soil and may be present in the liver of normal animals. Clinical disease is triggered by a primary necrotic process in the liver, which causes the organism to proliferate and produce lethal amounts of toxin. C. novyi types A and C are also resident in soil and may invade a carcass postmortem but do not cause infectious necrotic hepatitis. The disease has been produced experimentally in sheep by the administration of spores of C. novyi after prior infection with fluke metacercaria. Although field outbreaks of the disease are usually precipitated by invasion of the liver by immature liver flukes, it is possible that other causes of local hepatic injury, e.g., invasion by cysts of Cysticercus tenuicollis, and trauma from liver biopsy may precipitate the disease. Thysanosoma actinoides is thought to be a predisposing infection in South America. Cases are reported in which no specific precipitating lesions are detected and have been advanced as an explanation of sudden deaths in feedlot cattle. C. novyi types A and B have been incriminated as a cause of sudden death in sows.

EPIDEMIOLOGY
Occurrence
The disease is worldwide in distribution but is of particular importance in Australia and New Zealand and to a lesser extent in the UK, the United States, and Europe. In sheep, the incidence rate in a given year is usually about 5% in affected flocks but may be as high as 10% to 30% and in rare cases up to 50%. The disease is practically always fatal in both sheep and cattle. Details of the incidence in cattle are scanty, but the disease is becoming more common in some areas where fluke is being introduced. The disease is rare in horses.

Risk Factors
Animal Risk Factors
Well-nourished adult sheep in the 2- to 4-year age group are particularly susceptible, and lambs and yearlings rarely are affected.

Environmental Risk Factors
The epidemiologic association between liver flukes and C. novyi has been supported by the observation that both are more prevalent in the soil in areas where black disease occurs than in other areas, and the survival of both the bacteria and the fluke is favored by the same type of soil environment. In temperate climates, a seasonal occurrence is obvious presumably because of fluctuation in the liver fluke and host snail population. Outbreaks are most common in the summer or autumn months and cease within a few weeks after frosts occur because of destruction of encysted metacercaria. Exposure to fluke infestation, as occurs when sheep graze on marshy ground during dry summers and drought, is commonly associated with outbreaks of black disease, although they can occur in winter. Sheep removed from a black disease farm may die of the disease up to 6 weeks later because of the time lag required for migration of the flukes.

Heavy irrigation of pastures creates favorable conditions for the development of flukes and may predispose disease. Outbreaks in cattle commonly occur on irrigated farms.

Source of infection
Infection occurs through fecal–oral transmission of C. novyi. Fecal contamination of the pasture by carrier animals results in ingestion of clostridial spores by herdmates; the cadavers of sheep dead of the disease may cause heavy contamination. Many normal animals in flocks in which the disease occurs carry C. novyi in their livers, because not all strains are pathogenic. The spread of infection from farm to farm occurs via these sheep and probably also by infected wild animals and birds and by the carriage of contaminated soil during flooding.

Other Species
There is little information about the epidemiology of the disease in the horse, although prior administration of an anthelmintic may be a risk factor. C. novyi can be a significant cause of sudden death of adult pigs. In some herds the disease is more common in older sows (average parity 5.6 litters) with the highest prevalence in the spring months.

PATHOGENESIS
Spores of C. novyi are ingested and carried to the liver in the lymphatic system; the organism can be isolated from the liver of normal animals. Under local anaerobic conditions, such as occur in the liver when migrating flukes cause severe tissue destruction, the organisms already present in the liver proliferate, liberating α-toxin, which is

CONTROL
A formalin-killed whole culture adsorbed on aluminum hydroxide gives good protection for a year in cattle. Vaccination is performed 4 to 6 weeks before the expected occurrence of the disease. Annual revaccination of all animals over 6 months of age is necessary in enzootic areas. In some locations of extreme risk a second vaccination during the grazing season is recommended. To obviate the local reaction that occurs at the site of injection, the inoculum may be administered at several sites and distributed under the skin by massage. The injection must be subcutaneous, because intradermal and intramuscular injections are likely to produce severe reactions. Modern vaccines prepared to avoid these local reactions lack immunogenicity and need to be administered twice a year. The carcasses of animals dying of the disease should be disposed of by burning or deep burial.

Infected Necrotic Hepatitis (Black Disease)

SYNOPSIS
Etiology An acute toxemia of sheep, cattle, and sometimes pigs and horses caused by the toxin of Clostridium novyi type B produced in damaged liver tissue. Outbreaks usually associated with fasciolosis.

Epidemiology Adult sheep in good condition; seasonal prevalence related to the migration of immature liver fluke in the liver.

Infectious Necrotic Hepatitis (Black Disease)

TREATMENT AND CONTROL

Treatment
Penicillin G sodium/potassium (15,000 IU/kg IV every 6–8 h) (R-2)
Oxytetracycline (15–20 mg/kg IV every 24 h) (R-2)
Supportive therapy

Control
Clostridium haemolyticum bacterin vaccine

IV, intravenously.
necrotic and causes local liver necrosis and more diffuse damage to the vascular system. The nervous signs observed may be caused by this general vascular disturbance or by a specific neurotoxin.

**CLINICAL FINDINGS**

**Sheep**

Affected sheep commonly die during the night and are found dead without having exhibited any previous signs of illness. When observation is possible, clinically affected sheep are seen to segregate from the rest of the flock, lag behind, and fall down if driven. There is fever (40–42°C, 105–107°F), which subsides to a premortal (subnormal) level, and some hyperesthesia; respiration is rapid and shallow; and the sheep remains in sternal recumbency and often dies within a few minutes while still in this position. The course from first illness to death is never more than a few hours and death usually occurs quietly, without evidence of struggling.

**Cattle**

Clinical findings are the same in cattle as in sheep but the course is longer, with the illness lasting for 1 to 2 days. Outstanding clinical findings in cattle include a sudden severe depression, reluctance to move, coldness of the skin, absence of rumen sounds, a low or normal temperature, and weakness and muffling of the heart sounds. There is abdominal pain, especially on deep palpation of the liver, and the feces are semifluid. Periorbital edema may also develop.

**Horses**

In the horse the syndrome presents as a peritonitis accompanied by severe and progressive toxemia and manifests with depression, reluctance to walk, pain on palpation of the abdomen, frequent straining, and recumbency. Fluid from abdominal paracentesis has a profound increase in nucleated cells and protein. Death occurs within 72 hours of onset of the disease.

**CLINICAL PATHOLOGY**

Antemortem laboratory examinations are not usually possible because of the peracute nature of the disease, and there is no body of information for this disease.

**NECROPSY FINDINGS**

Bloodstained froth may exude from the nostrils. The carcass undergoes rapid putrefaction. There is pronounced engorgement of the subcutaneous vessels and a variable degree of subcutaneous edema. The dark appearance of the inside of the skin, particularly noticeable on drying, has given rise to the name **black disease**. Gelatinous exudate may be present in moderate quantities in the visceral planes of the abdominal musculature. Bloodstained serous fluid is always present in abnormally large amounts in the pericardial, pleural, and peritoneal cavities. Subendocardial and subepicardial hemorrhages are frequent.

The **liver** is swollen, gray-brown, and exhibits characteristic areas of necrosis. These are yellow areas 1 to 2 cm in diameter and are surrounded by a zone of bright red hyperemia. They occur mostly under the capsule of the diaphragmatic surface of the organ but may be more deeply seated and can easily be missed unless the liver is sliced carefully. In cattle they are often linear in shape and may be difficult to find. There is usually evidence of recent invasion by liver fluke, with channels of damaged liver tissue evident on the cut surface of the liver. These may be mistaken for subcapsular hemorrhages when viewed from the surface. Mature flukes are not ordinarily observed. **Histologically**, the liver lesion consists of a central tract of eosinophilic inflammation (caused by fluke migration) surrounded by a zone of coagulation necrosis and an outer rim of infiltrating neutrophils. Gram-positive bacilli can easily be demonstrated within the lesion.

A diagnosis of infectious necrotic hepatitis requires the culture of *C. novyi* from the typical liver lesion and the demonstration of preformed toxin in the peritoneal fluid and/or the liver lesion from a fresh carcass. Autolysis rapidly clouds the postmortem findings and false-positive diagnoses are likely if toxin assays are performed on carcasses more than 24 hours old. Another problem is the relatively common occurrence of nonpathogenic strains of *C. novyi B*. These strains are detected in livers by fluorescent antibody technique, and this may lead to a false-positive identification of black disease.

Fluorescent antibody techniques are almost as accurate and much less time-consuming than traditional anaerobic culture methods. An enzyme-linked immunoassay (ELISA) for β-toxin in intestinal contents has been described, and PCR techniques for better identification of toxin-producing strains of clostridia are available.

Unusual lesions, such as a large area of inflammation in the wall of the abomasum and congestion of the subcutaneous tissue and muscle in the shoulder and withers, have been observed in some cattle dying of the disease.

**Samples for Confirmation of Diagnosis**

- **Bacteriology**: Liver in air-tight container; four impression smears from periphery of lesion (anaerobic culture, FAT)
- **Histology**: Fixed liver

**DIFFERENTIAL DIAGNOSIS**

- **Acute fasciolosis** in sheep can cause heavy mortality caused by massive liver destruction at the same time and under the same conditions as does black disease.
- **Other clostridial disease** includes blackleg and malignant edema.
- ** Anthrax**

**TREATMENT**

No effective treatment is available. Although *C. novyi* is susceptible to penicillin in sheep, parenteral treatment with antimicrobials generally comes too late once clinical signs are apparent because of the peracute course of the disease. In cattle and horses, the longer course of the disease suggests the possibility of controlling the clostridial infection by the parenteral use of penicillin or broad-spectrum antibiotics, but reported cases have high case fatality.

**CONTROL**

**Vaccination** with an alum-precipitated toxoid is highly effective and can be performed during the course of an outbreak. The mortality begins to subside within 2 weeks. On an affected farm the initial vaccination is followed by a second vaccination 4 to 6 weeks later and subsequently by annual vaccinations. To provide maximum immunity at the time when the disease is most likely to occur, vaccination as a prophylactic measure should be performed in early summer.

Control of the disease should also be attempted by **control of the liver fluke**. The host snail must be destroyed in streams and marshes by the use of a molluscicide and the flukes eliminated from the sheep by treatment with flukicides. Pasture contamination from cadavers should be minimized by burning the carcasses.

**FURTHER READING**

**Clostridium novyi** Infection

*C. novyi* type B infection in finishing pigs and sows causes unexplained sudden death.

**ETIOLOGY**

The cause is *C. novyi* type B, although recently, type A has also been found in some
cases. It is a large Clostridium with oval, central, or subterminal spores and is a fastidious anaerobe that is difficult to cultivate and sometimes may be mistaken for Bacillus anthracis. The toxic factor may be the α-toxin.

PATHOGENESIS AND EPIDEMIOLOGY

Very little is known about either, but the former may be related to stress causing a reduction of liver oxygenation facilitating clostridial invasion.

CLINICAL SIGNS

Usually you discover this condition at sudden death. An outbreak in two Iberian sows has recently been described.1

PATHOLOGY

The characteristic pathologic finding is rapid decomposition of the carcass. The subject is usually a well-conditioned pig. They may show submandibular swelling, pulmonary edema, and tracheal froth. Fluid exudation in the pericardium, pleural sacs, and peritoneum are also a relatively common finding and the exudation may be bloodstained. A specific finding is the presence of large numbers of frothy gas-filled spaces.

DIAGNOSIS

Accurate diagnosis depends on the recognition of sudden death in weanled pigs, and the classic postmortem findings. Confirmation is by culture of the organism on egg yolk agar under anaerobic conditions, the use of fluorescent antibody techniques, and PCR tests.

TREATMENT

Rarely is there time to see the condition clinically.

PREVENTION

Prevention may involve feeding bacitracin zinc at 225 to 260 g/tonne of feed.

The use of clostridial vaccines for sheep has been helpful when the condition has become endemic, and C. oedematiens Type B vaccine has also proved useful.

REFERENCE

Diseases Characterized by Systemic Involvement

ACUTE HEPATITIS (POSTVACCINIAL HEPATITIS) OF HORSES (THELER’S DISEASE, SERUM HEPATITIS)

Acute hepatitis is an acute hepatopathy of horses associated with administration of equine biological products such as tetanus antitoxin.

ETIOLOGY

The disease appears to be associated with infection by “Theiler’s disease-associated virus” (TDAV), a recently recognized virus in the Pegivirus genus of Flaviviridae.1 The virus is capable of parenteral transmission and infection can be subclinical.1 Infection can be chronic, persisting for over a year in some clinically normal horses. Infection of horses with another pegivirus (equine pegivirus [EPgV]) causes persistent viremia usually, but not invariably, without apparent clinical signs.23 Given the frequency of viremia in healthy horses, the importance of detection of EPgV RNA in horses with signs of liver disease is unclear. Approximately 50% of 326 horses sampled, some which had evidence of liver disease, had antibodies to EPgV, although the frequency with which antibodies, or RNA, were detected in healthy and ill horses did not differ.2

Horses have recently been demonstrated to be infected with viruses, named Nonprimate hepacivirus (NPHV), from the closely related hepativirus group (which included human hepatitis C virus).3 The clinical importance of infection by this virus, if any, is unclear, although it appears to be minimal despite approximately 50% of horses having serum antibodies to the virus.3 Antibodies, RNA of NPHV, or EPgV were not detected in 100 donkeys sampled.3 One of 113 dogs sampled had antibodies to NPHV and that dog was from a stable with a viremic horse, although any causal connection was not established.3 There is evidence of infection of horses by human hepatitis E virus (HEV) in China and Egypt, but the clinical or human public health aspects of this observation are uncertain.3

EPIDEMIOLOGY

Hepatitis occurs in horses administered equine serum or tissue products. The first reports of the disease were in 1919 in horses in South Africa administered equine serum as prophylaxis for Africa horse sickness. Outbreaks of the disease have occurred in horses in Africa, Europe, and North America administered equine serum as prophylaxis for a variety of diseases including African horse sickness, encephalomyelitis, botulism, Streptococcus equi infection, tetanus, and influenza, and in mares given pregnant mare serum. Most sporadic cases of the disease appear to be associated with administration of tetanus antitoxin.3

Administration of equine antitoxin positive for TDAV to 17 horses resulted in clinically overt disease in two horses and biochemical evidence of liver damage in eight horses.1 Fifteen of the 17 horses had TDAV detected in blood by quantitative reverse transcriptase (qRT)-PCR, and the virus was detected in blood samples from the antitoxin donor horse. Horses from the same farm as the affected horses that were not administered the incriminated antitoxin did not have evidence of liver disease, and TDAV also was not isolated from them.3 Of the 17 horses administered contaminated antitoxin, 16 were sampled 1 year later. Of these, 4 were positive for TDAV, whereas the remaining 12, including the 2 horses that had clinical disease soon after administration of antitoxin, did not have detectable virus in their blood.

Experimental inoculation of four horses revealed diversity of viral dynamics among the horses, with most horses having high viral loads 4 weeks after inoculation, with persistence of detectable virus for at least 14 weeks in one horse and 10 weeks (the latest time point examined) in three horses.

The disease is reported only from adult horses (>1-year age), and most cases are reported in the summer and autumn. There is a suspicion that pregnant mares are at increased risk.

The morbidity rate in outbreaks among horses administered equine serum ranges between 2% and 18%, although the rate among horses administered tetanus antitoxin as prophylaxis following injuries is clearly much lower. Acute hepatitis developed in 4 (0.4%) of 1260 horses >1-year of age administered commercial equine plasma at one institution in the United States over a 6-year period. The disease can occur after intrauterine infusion of equine serum to mares.

The case-fatality rate is between 50% and 90%.

The disease occurs sporadically in horses that have not been administered equine biological products. There are reports of in-contact, nontreated horses developing the disease, but such transmission, if indeed it occurs, is inefficient and uncommon.1

PATHOGENESIS

Experimental induction of the disease by administration of serum from TDAV-positive horses reveals viremia that precedes biochemical evidence of liver damage and/or clinical disease by several weeks.1 Destruction of hepatocytes results in hepatic dysfunction. Hepatoencephalopathy develops in severely affected horses.

CLINICAL FINDINGS

The disease usually occurs after an incubation period of 40 to 70 days (range 27–165 days). Depression, anorexia, and icterus are evident in mildly affected cases. There can be mild to moderate colic. Body temperature and heart rate are usually normal. Acutely affected, or horses observed infrequently, can die unexpectedly. Signs of hepatoencephalopathy include restlessness, excitement, compulsive walking and head pressing, abnormal head position, seizures, apparent blindness, muscle tremors, and ataxia. Affected horses often injure themselves by walking into fences and troughs.
**CLINICAL PATHOLOGY**

Leukocytosis with neutrophilia and mild lymphocytopenia is common. The hematocrit and plasma total protein concentrations may be mildly increased. Hyperbilirubinemia and an increase in direct (conjugated) bilirubin concentration are present and serum bile acid concentration is increased, as is serum activity of liver-specific enzymes AST, GGT, and SDH. Increases in serum GGT activity is often less than expected for the increases in serum AST, SDH, and bile acid concentrations, likely reflecting the primary insult to hepatocytes.

Hypoglycemia (<2 mmol/L, 40 mg/dL) and hyperammonemia (>150 μmol/L) may be severe. Clotting time, especially the on-stage prothrombin time, can be prolonged.

A qRT-PCR test is available to identify virus genome in blood or plasma.

**NECROPSY FINDINGS**

The liver may be enlarged, normal, or shrunk and discolored slightly yellow to green. There is severe centrilobular necrosis of hepatocytes with mild infiltration of lymphocytes and plasma cells. Alzheimer type II astrocytes are present in the brains of horses with encephalopathy.

**Hepatitis E Virus (HEV)**

HEV is the cause of acute hepatitis in humans, causing 1% to 4% mortality in the normal population but 25% in pregnant women. It therefore can be considered a serious public health risk. It is also a serious risk in immuno-compromised patients. It is possible but not yet proven that the pig may act as a reservoir for infection. There is a high prevalence in pig liver. Although the consumption of pig meat by humans is quite high, the consumption of pig liver is generally much lower, which may explain the low prevalence in humans. The consumption of raw pig liver sausage is considered a risk. The consumption of certain pork products may also be a source of exposure. Those people who have a high occupational contact with swine and swine excrement, such as veterinarians, farmers, and slaughterhouse workers, have a high seroprevalence. Swine farm workers in one study in Japan had a 16.7% prevalence. Pig farmers in Inner Mongolia are frequently infected with a markedly divergent genotype 4 virus. It has also been found in deer.

**REFERENCES**

**DIFFERENTIAL DIAGNOSIS**

Diagnostic confirmation antemortem is achieved by examination of a liver biopsy, although this should be performed with caution in animals with coagulation abnormalities. Differential diagnosis list:

- Acute aflatoxicosis
- Rubratoxicosis (*Penicillium rubrum*)
- Pyrolizidine alkaloid intoxication
- Dioxin intoxication
- Idiopathic hyperammonemia
- Fluphenazine toxicosis
- Congenital abnormalities (Gilbert's syndrome)

**TREATMENT**

Treatment is essentially supportive and consists of correction of metabolic and acid-base abnormalities, reduction of plasma ammonia concentration, and preventing horses with hepatocencephalopathy from injuring themselves.

Hypoglycemia and dehydration can be corrected by intravenous administration of 5% dextrose and isotonic electrolyte solutions. Metabolic acidosis can be corrected by infusion of sodium bicarbonate. Plasma transfusions might be necessary to correct coagulation abnormalities.

Hyperammonemia can be treated by giving neomycin (20 mg/kg, orally, every 6 hours for four doses) or lactulose (0.25 mL/kg, orally every 8 hours) to decrease absorption of ammonia from the gastrointestinal tract.

**Sedation** with xylazine or similar compounds may be necessary to prevent the animal from injuring itself. The affected horse should be housed in an area where it has the least opportunity to injure itself and might need to be fitted with a padded helmet.

**CONTROL**

Minimal use of biologics, including plasma, of equine origin is prudent.

**ETIOLOGY**

The virus is a small nonenveloped single-stranded positive sense RNA virus. It is the sole member of the genus *Hepavirus* in the family *Hepaviridae*. There are considered to be four genotypes: genotypes 1 and 2 are found in humans. Human HEV 1 is particularly common in Asia and Africa and HEV 2 in Mexico and Western Africa. Types 3 and 4 are found in both pigs and humans and thus considered potentially zoonotic. The seroprevalence has increased recently, but this may be lower than in previous decades. Isolates of human and porcine HEVs are phylogenetically closely related with nucleotide sequences, sometimes up to 100% similar. In one study the prevalence in the pigs and humans was similar. Recently, novel heparaviruses was identified in Japanese wild boars.

**EPIDEMILOGY**

HEV has been widespread in Spain since 1985. A high prevalence of HEV and HEV-specific antibodies in pigs has been observed in a number of European countries and in Portugal, Denmark, Italy, Spain, England, France, and Switzerland. Generally, these results revealed a high farm prevalence of HEV and infected animals on the farms, although there is considerable variation among farms, suggesting the existence of specific on-farm factors.

Pigs shed the virus for 10 days on average in experimental infections of specific pathogen-free pigs but for much longer in natural infections.

Although no evidence was found in Italy for porcine circovirus type 2 (PCV2)/HEV infections, there was in Spain, especially in pigs with hepatitis lesions.

Many human infections arise with HEV type 3, which is found in a variety of species including the wild boar and domestic pigs. In Asia and Belgium, HEV 4 is found in domestic pigs and wild boars.

Recent studies in Europe suggest that type 3 is the most common, and certainly this was found to be true in a recent Danish study. In another Danish study, 49.5% of the pigs were seropositive, which was much higher than the Spanish studies (17.4%). This is similar to levels found in the United States and Italy. In Germany, the seroprevalence ranged from 34.9% to 60%. A recent study has shown that the seroprevalence of HEV depends on the pig's age and herd origin.

The seroprevalence results also still depend on the test assay used. In Portugal, the prevalence varies from 10% to 30%. Studies in the Netherlands showed an increase in prevalence from 22% in 1999 to 55% in 2006. In France, a high prevalence on the farm of 65% and 31% of slaughter pigs had antibodies all of genotype 3, and the same genotype was found in Czechoslovakia. In Italy, HEV is widespread and might be endemic on most farms (one study revealed 97% of farms were affected and 50% of the pigs).

Genotypes 3 and 4 are found in a wide variety of countries, including the United States, Europe, Argentina, Japan, and Australia. Genotype 4 is mainly Asian (Japan, China, India, and Indonesia).

Transmission is largely oral–fecal through infected water, and it seems it is particularly associated with heavy rain and flooding in unhygienic conditions.

It has also been found in wild boar in Japan and Sweden where there was found to be a close association between the prevalence in the domestic population and wild boar in
the same county. Types 3 and 4 have also been found in swine livers in Japan. It has been transmitted through the consumption of uncooked or undercooked pork and viscera. Pork liver sausage in France (Figatelli) seems particularly suspect. It has been found in livers purchased from grocery stores in the Netherlands, the United States, and Japan, and some of the livers were found to have infective virus.

The virus has also been found in the liver of aborted fetuses and in fecal and serum samples of their mothers. The results suggested that the piglets were infected by transplacental spread.

Pork consumption and HEV positivity have been suggested, but the source of infection often remains unknown, and is not consistently related, but in many cases it is.

Direct contact and environmental contamination are responsible for HEV transmission in pigs. Domestic pigs are considered the main reservoir for human HEV. Direct transmission from infected to naive pigs is responsible for most of the transmission and for persistence of the infection within a population. The quantity of the virus in the environment was found to play an essential role in the transmission process. Direct and within-pen environmental transmissions were essential components to explain the transmission process. Environmental transmission between pens remained a rare event. HEV propagation within a pig population is therefore highly dependent on pig management and hygiene procedures.

In a study of healthy people directly exposed or unexposed to pigs, a cross-sectional study HEV infection in a rural community in Thailand was described. The prevalence of antibodies was 23%. The presence of frequent hand washing was associated with a lower prevalence. Humans living in an area with frequent flooding or regularly eating internal pig organs more than twice a week are found to be associated with a higher seroprevalence of antibodies. There was no association with direct occupational pig contact.

In a study in Serbia in pigs referred to a clinic 29/50 livers (58%) had mild to moderate hepatitis, 37/50 (74%) had PCR-positive titers for transmission-transmitted viruses (TTVs), 28/50 (56%) had PCR positives for PCV2, and 13/50 (26%) had an RT-PCR for HEV. There was an association between TTVs and infectious hepatitis of pigs in concomitant infections with PCV2 and HEV.

PATHOGENESIS
It is thought most pigs become infected early on in life between 8 and 12 weeks, have a transient viremia for 1 to 2 weeks, and shed virus for about 3 to 7 weeks. In a Spanish study of viremia it was found in 7% of the pigs at 1 week of age and decreased to 2% at 6 weeks before rising again at 9 weeks.

In a Canadian study, HEV prevalence in fecal samples increased from 11.8% at 2 weeks to 52.9% at 8 weeks of age. Most nursery and finishing pigs are positive. At slaughter most pigs are not shedding virus in the feces and have detectable IgG levels in the serum. However, 6% and 12% of pigs may harbor virus in the liver at slaughter. In a study in Yorkshire in the UK, 9% of the pigs were excreting HEV in the slaughterhouse. Experimentally infected pigs can shed the virus for several weeks. Pigs orally inoculated with swine HEV were able to infect by contact sentinel pigs.

CLINICAL SIGNS
Infection in pigs is nearly always asymptomatic, but occasionally pigs may show evidence of hepatitis. Occasionally they will also abort.

PATHOLOGY
There are no gross lesions in the pig. Histologically, there may be mild to moderate multifocal and periporal lymphoplasmacytic hepatitis with mild focal hepatic cell necrosis.

DIAGNOSIS
Diagnosis relies entirely on laboratory tests. A nested RT-PCR was developed in Korea. A home-produced IgG ELISA has high specificity and sensitivity and was found to be comparable with commercial kits, and an RT-loop-mediated isothermal amplification has also been developed.

An immunofluorescence technique for tissues has been described. A new technique is the development of fluorescent microbead immunoassay (FMIA) for the detection of HEV IgG antibodies. It was compared with an ELISA and both were found to be 100% specific, but the FMIA had a higher sensitivity of 92.3% compared with an ELISA.

A recent study of handling and storage conditions and stabilizing agents on the recovery of viral RNA from oral fluid of pigs has shown that it is not necessary to stabilize oral fluid from swine for the detection of viral RNA provided the samples are stored at 4°C or frozen at −20°C.

TREATMENT AND CONTROL
No treatment of pigs is necessary. Most pigs are probably protected by maternal antibody. General biosecurity measures and cleaning, disinfection, and drying will reduce the level of contaminated feces.

Hepatic Diseases Associated With Trematodes
FASCIOLOSIS (LIVER FLUKE DISEASE)

SYNOPSIS
Etiology Fasciola hepatica and, in warmer climates, F. gigantica
Epidemiology Infection by ingestion of metacercariae on herbage; geographic

Continued
ETIOLOGY

*Fasciola hepatica* is the most common and important liver fluke and has a cosmopolitan distribution in cooler climates. Lymnaea mud snails are intermediate hosts and release the infective form, the metacercaria, onto herbage. Hepatic fasciolosis is mainly of economic importance in sheep or cattle, but other species may provide a reservoir of infection. *F. hepatica* may infest all domestic animals, including Equidae and many wild species, but chronically infected sheep are the most important source of pasture contamination. Human cases are usually associated with the ingestion of marsh plants such as watercress. A similar but larger fluke, *F. gigantica*, is restricted to warmer regions including parts of Africa and Asia.

LIFE CYCLE

Adult *Fasciola* live in bile ducts producing eggs that are excreted with the feces. Hatch occurs in moist conditions only after the first larval stage, the miracidium, has formed and when ambient temperatures rise above 5°C to 6°C (41-43°F). Miracidia must find and invade the tissues of a suitable host snail within 24 to 30 hours. After several cycles of asexual multiplication, the flukes leave the snail as cercariae. These attach to herbage and transform into metacercariae by secreting a tough protective cyst wall. After ingestion by the final host, each metacercaria releases an immature fluke that crosses the intestinal wall and migrates across the peritoneal cavity to the liver. The migration is sometimes misdirected and ectopic flukes can be found in the lungs, particularly in cattle. The young *F. hepatica* migrate through the hepatic parenchyma for about 4 to 5 weeks, growing from 0.1 to 10 mm. After entering the bile ducts, they more than double in size before egg laying starts at about 10 to 12 weeks after infestation. Adult sheep and cattle may remain carriers for many years because of the longevity of the adult flukes.

EPIDEMIOLOGY

The risk of hepatic fasciolosis is determined by the numbers of infected lymnaea snails in the grazing area. The disease has a predictable seasonal pattern in regions where snails are active for only part of the year. Some lymnaea snails have a more aquatic habit than others, but all are restricted to damp or wet environments. Generally, they prefer nonacidic low-lying swampy areas with slow-moving water, but land with small streams, springs, blocked drainage, or spillages from, for example, water troughs may also be potentially hazardous for grazing stock. Land frequently irrigated is also highly suitable for infection to take place. Snails burrow into the soil to survive dry periods and release cercariae when free water is present. Snail habitats may be permanent or temporary. The latter expand and contract depending on water availability. Construction works, such as road building, may alter drainage patterns and disease risk. Improvement of peaty pastures by lime application may increase risk by reducing soil acidity and allowing snail colonization.

Important host snails for *F. hepatica* include *Lymnaea truncatula* in the UK and Europe and *Stagnicola bulimoides*, *Stagnicola bulimoides techella*, and others in the United States. *L. columella* has been identified as an intermediate host in Canada and more recently in Brazil. In New Zealand, *L. torrentosa* and *L. truncatula* have occurred without fasciolosis becoming a major problem, but the introduction of *L. columella* markedly increased the range and severity of the disease. *L. torrentosa* is the major host snail in Australia, although *L. columella* has been reported to be present in nonfarming areas, and *L. viridis* has also been found.

The main factors determining the timing and severity of hepatic fasciolosis are those that influence the number of metacercariae accumulating on herbage. In particular, temperature and rainfall affect both the spatial and temporal abundance of snail hosts and the rate of development of fluke eggs and larvae. Temperatures above 10°C (50°F) are necessary before the snail hosts will breed or before *F. hepatica* can develop within the snail. Therefore no development takes place during the winter in most countries.

The “summer infection of the snail” by miracidia hatching from eggs in spring and early summer results in the emergence of cercariae and the consequent contamination of herbage some 5 to 8 weeks later. For any climatic region, cercarial shedding is a fairly regular occurrence with minor differences in timing determined by year-to-year variations in weather patterns.

The “winter infection of the snail” is a separate cycle occurring when snails are exposed to miracidia in the autumn. Fluke development ceases in the snail during winter but resumes as temperatures rise the following spring. The relative importance of this cycle depends on the mortality rate of the snails during the winter, which varies from region to region and from year to year.

The availability of metacercariae is generally greatest in the late summer and autumn. Massive numbers can accumulate in wetter parts of the British Isles and Europe. *Metacercariae may overwinter in milder climates to infect stock in spring, but they do not survive under severe winter conditions. In hot, dry regions, metacercariae die quickly, so in Australia, for example, infections are usually caused by a recent release of cercariae. Stock are also vulnerable in dry conditions if forced to feed in swampy areas to obtain green feed. Metacercariae are normally killed during the preparation of hay or silage, but can remain infective for up to 8 months if hay is harvested in moist conditions and not properly dried.

The clinical outcome of infection depends largely on the density of metacercariae on the herbage. This will be greatest when weather conditions have been favorable for snail reproduction and survival. A high intake of metacercariae over a short time will produce acute disease; lower numbers over a longer period lead to chronic disease. The degree to which immunity influences the course of infection differs with species. Sheep and goats do not develop a strong protective immune response to *F. hepatica* and remain vulnerable throughout their lives. Cattle eventually expel most but not all of their fluke burden and gain partial but not complete protection against reinfection. *F. hepatica* has a number of survival mechanisms for evading host immune responses, including changing its surface antigen during migration, releasing a proteolytic enzyme that can cleave immunoglobulins, and modulating the host immune response.

PATHOGENESIS

Acute hepatic fasciolosis is caused by the passage of young *F. hepatica* through the liver parenchyma. Clinical signs occur 5 to 6 weeks after the ingestion of large numbers of metacercariae. By this time, the migrating flukes are large enough to do substantial
mechanical damage to the liver. Acute hepatic insufficiency and hemorrhage result. 

P. quiescent spores of C. novyi may become activated by the anaerobic necrotic conditions created in the liver parenchyma by migrating F. hepatica, causing infectious necrotic hepatitis (“black disease”) in sheep and cattle. This migration has also been thought to stimulate the development of occasional cases of bacillary hemoglobinuria in cattle.

Chronic hepatic fasciolosis develops only after the adult flukes are established in the bile ducts. Here they cause cholangitis, biliary obstruction, fibrosis, and a leakage of plasma protein across the epithelium. Although this protein can be reabsorbed in the intestine, there is poor utilization and retention of nitrogen leading to hypoalbuminemia. There is also a loss of whole blood caused by the feeding activities of the flukes. This exacerbates the hypoalbuminemia and eventually gives rise to anemia. It places a continuous drain on iron reserves so that the anemia, which is initially normochromic, becomes hypochromic. These changes are more severe in sheep on a low plane of nutrition. Chronic infection may limit growth rate and feed conversion in growing heifers and growth rate in beef cattle. F. hepatica infection has been reported to increase the susceptibility of cattle to Salmonella Dublin and predispose to prolonged infection and fecal excretion. Infected ewes may have reduced fertility, growth rate, and wool production. Food intake is reduced and this leads to a reduction in efficiency of utilization of metabolizable energy and a reduction in calcium and protein deposition in the carcass.

The fibrotic response of the liver to fluke-induced damage varies with the host and may partially account for differing species susceptibilities. The severe reaction in cattle, which includes calcification of the bile ducts, appears to hinder the establishment and feeding of challenge infections, reinforcing immune responses. Both horses and pigs are generally highly resistant to infection with F. hepatica but differ in their mode of resistance. Horses overcome the migrating fluke at an early stage so that few reach the liver, whereas in the pig the resistance mechanism operates in the liver parenchyma.

CLINICAL FINDINGS

Acute Fasciolosis

Acute fasciolosis in sheep most often occurs as sudden death without other apparent clinical abnormality. It is usually seen in the summer and autumn but may occur at any time when sheep have the opportunity to graze heavily contaminated herbage. If the disease is observed clinically in sheep it is manifested by the following:

- Pallor and edema of mucosae and conjunctivae
- Pain when pressure is exerted over the area of the liver. Death occurs quickly and may be accompanied by the passage of bloodstained discharges from the nostrils and anus. Outbreaks are usually of relatively short duration; most deaths occur within a period of 2 to 3 weeks. Acute fasciolosis rarely occurs in cattle.

Subacute Fasciolosis

Acute and chronic fasciolosis are opposite ends of the clinical spectrum. Intermediate forms occur, and a subacute syndrome has been described in sheep. The major clinical signs are weight loss and pallor of the mucous membranes. Submandibular edema will be seen in only a few cases, but many animals will resent palpation over the region of the liver.

Chronic Fasciolosis

Chronic fasciolosis does not become apparent until several weeks after the danger of acute disease has receded. Affected sheep lose weight and develop submandibular edema (bottle jaw) and pallor of the mucous membranes. Submandibular edema will be seen in only a few cases, but many animals will resent palpation over the region of the liver. Chronic fasciolosis develops in sheep only when the young flukes are migrating as far as 2 to 3 months in those that die; many survive but may remain in poor condition for longer periods. Cattle also lose weight, especially if lactating; milk production falls; and anemia may develop.

CLINICAL PATHOLOGY

In acute fasciolosis there is a severe normochromic anemia, eosinophilia, and a severe hypoalbuminemia. Blood concentrations of a number of serum enzymes indicating liver damage are elevated. GDH is of particular value when the young flukes are migrating through the liver parenchyma, but concentrations fall after they enter the bile ducts. Increases in AST can be measured from 4 weeks and are useful as a measure of immure infection. Eggs will not be present in the feces because the flukes are still juvenile.

In subacute and chronic disease weight loss is associated with a severe hypochromic, macrocytic anemia, hypoalbuminemia, and hyperglobulinemia. Submandibular edema and ascites occur only occasionally in the subacute condition but more frequently in the chronic disease. Serum γ-glutamyl transpeptidase concentrations are raised by the activities of adult F. hepatica in the bile ducts. Other liver function tests are not significantly affected. A diagnosis of chronic hepatic fasciolosis can be confirmed by the detection of large numbers of characteristic, operculated fluke eggs in the feces. These eggs are thin walled and stained yellow-brown by bileary pigments. They are dense and do not rise satisfactorily in all flotation solutions. Zinc sulfate solution (specific gravity 1.36) is recommended. Sedimentation tests are more accurate. Operculated fluke eggs are also characteristic of paramphistome infections, and care is needed to differentiate the two.

NECROPSY FINDINGS

Acute Hepatic Fasciolosis

Acute hepatic fasciolosis is characterized by a badly damaged, swollen liver. The peritoneal cavity may contain an excess of bloodstained serum. The liver capsule has many small perforations and subcapsular hemorrhages. The parenchyma shows tracts of damaged tissue and is more friable than normal. The immature flukes are often so small that they are not readily discernible. They are most easily demonstrated by slicing a piece of liver thinly and shaking in water, permitting the flukes to settle to the bottom. The size of the flukes may allow estimation of the duration of the infection and this may help to determine which pastures are hazardous.

Chronic Hepatic Fasciolosis

Leaf-like flukes, measuring about 3.5 × 1 cm, are present in grossly enlarged and thickened bile ducts, particularly in the ventral lobe of the liver. The bile ducts may protrude above the surface of the liver, and cysts may be present because of blockage of ducts with flukes and desquamated epithelial cells. Calcification of the bile duct walls is a common finding in cattle but not in sheep. The hepatic parenchyma is extensively fibrosed, and the hepatic lymph nodes are dark brown in color. Anemia, edema, and emaciation are attendant abnormalities.

DIAGNOSTIC CONFIRMATION

In fluke-endemic areas, fasciolosis must be considered as a possible factor in any outbreak of chronic ill health in sheep, either as the main cause or as a contributory factor along with other debilitating disease processes. To support a diagnosis, grazing history and the seasonality of fasciolosis in that locality should be taken into account. There should be fluke eggs in the feces and characteristic hepatic lesions at necropsy. As these may be ubiquitous findings in endemic areas, a judgment is necessary to determine whether the severity of the lesions is sufficient to incriminate the fluke as the sole or major contributory etiologic factor. ELISAs are available for use with blood or milk and are particularly useful for the diagnosis of infection in cattle on an individual or herd basis. 1,2 A rise in antibody can be detected by 2 weeks after infection and keeps rising until week 6. A commercially available coproantigen ELISA (BIOK 201, Bio-X Diagnostics, Belgium) has been developed for use in cattle 9,12 that has the ability to indicate the intensity of fluke infestations in cattle. 10 Experimentally, PCR methods for species-specific diagnosis of Fasciola species targeting the nuclear and/or
mitochondrial DNA of the parasite have been developed. Acute disease can only be confirmed at necropsy.

DIFFERENTIAL DIAGNOSIS

Acute fasciolosis
- Hemorrhosis
- Infectious necrotic hepatitis
- Eperythrozoonosis
- Anthrax
- Enterotoxemia

Chronic fasciolosis
- Nutritional deficiencies of copper or cobalt
- Other internal parasitisms, including parasitic gastroenteritis (particularly hemorrhosis) in sheep and ostertagiosis in cattle
- Johne’s disease

PO, orally; SC, subcutaneously.

Not all compounds are equally effective against all stages of development of *F. hepatica* in the body. Oral triclabendazole comes closest to this ideal. For treatment of acute fasciolosis, it is essential to choose a product highly effective against the juveniles that damage the liver parenchyma. For chronic disease, a compound active against the adult fluke is required. Product safety is an important consideration, as hepatic detoxicating mechanisms are already impaired. Flukicides can be used therapeutically for treating disease or prophylactically to prevent outbreaks. Some bind to plasma proteins (e.g., closantel) or erythrocytes (clorsulon), extending their period of protection. All flukicides either have milk-withholding periods or are prohibited from use in animals providing milk for human consumption, so the best time to treat dairy cattle is at the drying off stage. Many products combine a flukicide with a nematicide, but these should only be used when there is simultaneous risk from the two types of parasite.

Triclabendazole is an orally compound specifically for use against *F. hepatica* in sheep (10 mg/kg) and cattle (12 mg/kg). Higher doses are required for the control of *F. gigantica* in buffalo. It is highly effective against all stages of fluke from 2 days old in sheep and 2 weeks in cattle, and is the drug of choice in outbreaks of acute fluke disease. An 8- to 10-week dosing interval is recommended for use in control programs. Fluke populations resistant to triclabendazole have developed following intensive control regimens in Australia, UK, Europe, and South America. Combining compounds has been shown to increase efficacy against immature stages of flukes. An example of a combination is SC clorsulon (2 mg/kg) and nitroxynil (10.2 mg/kg), which increases efficiency up to 99%. Oral triclabendazole has been used with success in horses and donkeys (12 mg/kg) but is not licensed for this purpose.

Albendazole is a broad-spectrum compound also active against nematodes and cestodes. It is effective against adult *F. hepatica* at an oral dose rate of 7.5 mg/kg in sheep and 10 mg/kg in cattle. It is oxicidal and will kill any *F. hepatica* eggs present in bile ducts or the alimentary tract at the time of treatment. Nitrobin (20 mg/kg, PO) is metabolized to albendazole in the body and has similar activity against *F. hepatica*.

Closantel will kill the majority of flukes older than 4 weeks in sheep at an oral dose rate of 10 mg/kg PO and will delay fluke egg output by animals grazing contaminated pasture for up to 12 weeks. It also has a residual effect against *Haemonchus contortus*. Clorsulon is supplied in combination with ivermectin for combined fluke and roundworm control in cattle. At the recommended dose rate of 2 mg/kg by subcutaneous injection, clorsulon is effective against adult and 12- to 14-week-old immature flukes, but activity against 8-week-old *F. hepatica* is variable.

Nitroxynil is given subcutaneously at 10 mg/kg and has good efficiency against the adult fluke, but the dose has to be increased by up to 50% to obtain adequate control of acute disease. In sheep, spillage stains the fleece yellow. It cannot be given orally because the rumen microflora reduce the compound to an inactive metabolite.

Oxyclzanide used in cattle (10 mg/kg, PO) has a shorter milk-withholding period than most other flukicides. It has a significant effect against adult fluke but is inactive against immature forms. It may cause transient softening of feces. This compound has been combined with levamisole to provide activity against fluke and gastrointestinal nematodes.

CONTROL

Preventive measures are required in endemic areas because fasciolosis can cause death without warning or significant production losses. An integrated strategic approach is more cost beneficial than reliance on routine dosing and is less likely to induce anthelmintic resistance, but it requires detailed knowledge of the local epidemiologic cycle. In some countries in which risk varies from year to year, predictions of likely disease levels are issued based on analysis of meteorologic data and field observations. This enables control measures to be intensified when necessary. Computer models have been devised to assist this process.

Segregation of stock from sources of infection is the ideal method of control but is not always feasible in practice. Identification and mapping of snail habitats may enable grazing plans to be devised that avoid danger areas at times of high risk. Where habitats are restricted in size and clearly defined, it may be possible to exclude stock by fencing.

Stock on heavily contaminated land may be protected from acute fasciolosis by taking advantage of the interval between the ingestion of metacercariae and the onset of disease. Treatment during this period with a product effective against young flukes will eliminate the migrating parasites before they cause serious liver damage. A further dose may be necessary depending on the duration of metacercarial intake and residual activity of the chosen product. Some metacercariae will continue to be ingested after the main danger period has passed, so treatment with a product active against adult *F. hepatica* will be needed some weeks later to ensure against possible losses from chronic fasciolosis. Additional strategic doses may be required in regions where the winter infection of the snail is of significance. The precise timing of each of these doses depends on the local epidemiologic pattern.

Reduction of pasture contamination with metacercariae will reduce future risk. This can be done by preventing the snails from becoming infected with *F. hepatica* or by diminishing the size of the snail population. To achieve the first objective, adult flukes should be eliminated from the bile ducts of all grazing stock in spring and early summer. This prevents egg excretion and minimizes the numbers of snail-seeking miracidia at this crucial stage in the epidemiologic cycle. There may, however, be wildlife sources of *F. hepatica* eggs that cannot be controlled in this way. Snail numbers can be reduced by restricting the size of their habitat. This can be done, where feasible, by draining boggy areas and by making sure that ditches, land drains, water troughs, and so forth, are well maintained.

With stall-fed buffaloes in the tropics advantage can be taken of the fact that the metacercariae of *F. gigantica* concentrate on the lower part of forage plants, for example, rice straw. This can be cut off and used for other purposes, and the upper, uninfected, part can be fed to the farm stock.

Chemical snail control was widely practiced before reliable animal treatments became available. Lymnaeid snails have an
enormous reproductive capacity and can quickly recolonize wet land. Therefore application has to be thorough to have a significant season-long effect, and there must be no possibility of invasion from neighboring land. Chemicals can be applied in spring for maximum impact on the snail population before breeding starts, or later in the season when snails are plentiful, but before cercariae start to emerge. Efficacy is reduced if luxuriant plant growth hinders penetration to soil level. Inorganic compounds such as copper sulfate or sodium chlorophenate are effective but may be potentially hazardous to humans, stock, and the environment. Safer and more selective low-volume mollusicides such as n-trityl morpholine have been developed but are not commercially available.

Vaccines for *F. hepatica* are under development. One of these that uses recombinant fluke calpeshin L proteins has produced up to 79% protection against infection in cattle and sheep. Successful vaccination strategies elicit T-helper-1 (Th1) rather than Th2 immune responses induced by natural infection.

**Fascioloides magna**

*Fascioloides magna* is a large liver fluke found mainly in North America but also occurs in some European countries. It is a parasite of moose and deer but can also infect other animals grazing the same pastures. Sheep and goats are particularly susceptible to infection. The prevalence of infestation in cattle may be high in endemic areas, but they are seldom affected clinically.

The life cycle in normal hosts is similar to that of *F. hepatica*, except that it grows up to 10 cm long and 3 cm broad in thick-walled cysts in the liver parenchyma. Connections between the cysts and the bile ducts allow the passage of eggs with the feces. *Lymnaea* snails, particularly *G. trunculata* and *Radix* (syn. *Lymnaea*) peregra, act as intermediate hosts, and the final host is infected by ingesting metacercariae encysted on herbage. The fluke enters the liver after spending 3 to 4 weeks in the peritoneal cavity. In sheep and goats, the fluke continually migrates, never becoming encapsulated but forming large, black tracts. Hepatic damage and hemorrhage are so severe that one or two flukes can be fatal. In cattle, necrotic tracts are seen in the parenchyma as well as dark, thick-walled cysts 4 cm in diameter that have no connection to the bile ducts. Clinical signs in sheep and goats are similar to acute hepatic fasciolosis, and infected animals can die without warning. Infestations in cattle are usually inapparent but may cause signs similar to chronic hepatic fasciolosis. Eggs may be found in the feces. These resemble *F. hepatica* eggs but are larger and have a small appendage at the blunter end.

Most anthelmintics effective against *F. hepatica* are also active against *F. magna*, but few confirmatory reports have been published. Albendazole 10 mg/kg removed 74% of *F. magna* in naturally infected cattle, and 15 mg/kg had good efficacy in sheep 8 weeks after infection, dorsulion gave variable results in cattle at 21 mg/kg, whereas triclabendazole 20 mg/kg was 98% effective in sheep when given 12 weeks postinfestation.

**PYRROLIZIDINE ALKALOID TOXICOSIS**

**SYNOPSIS**

Etiology Pyrrolizidine alkaloids (PAs) are present, e.g., in *Crotalaria*, *Echium*, *Heliotropium*, *Senecio*, and other plants

Epidemiology Sporadic outbreaks (mainly in cattle and horses) occur worldwide; many herb outbreaks are enzootic to large areas in which toxic plants dominate pasture. PA-containing seeds in feed grains or dry plants in hay also lead to poisoning. A wide range of syndromes is associated with primary cumulative toxicosis and the effect of metabolites.

Clinical pathology Liver function tests and blood levels of hepatic enzymes indicate hepatic insufficiency.
**Lesions**
Hepatic encephalopathy with blindness, head pressing, bouts of frenzy, jaundice, photosensitization, and intravascular hemolysis; chronic wasting; necropsy lesion of hepatic megalocytosis, fibrosis, and biliary hyperplasia

**Diagnostic confirmation**
Histopathology of liver. Assay of plants for PAs. Assay of whole blood or liver for pyrrolic metabolites

**Treatment**
None

**Control**
Avoidance of significant exposure to plants. Biological control of plants

---

**ETIOLOGY**

Most hepatotoxic PAs are esters of two amino alcohols, retronecine and heliotridine, and occur in three groups—monoesters, noncyclic (open) diesters, and cyclic diesters—in ascending order of toxicity.1 Nontoxic N-oxides of PAs may be converted to the toxic-free base in the alimentary tract. A complete list of known PAs would be too long to be useful; for example, *Echium plantagineum* contains at least 10 of them known to be toxic to grazing animals. Most PA-containing plants are classified in the plant families Boraginaceae (*Heliotropium, Cynoglossum, Amsinckia, ceae*), Compositae (*Senecio* spp.), Fabaceae (*Lithospermum arvense, Crotalaria spp.,* and Asteraeae (*Compositae; *Senecio* spp.).

The recorded plant sources of hepatotoxic PAs (common names and toxins when known) include the following:

- *Amsinckia intermedia* (tarweed, fiddleneck, ironweed; contains intermedine, lycopsamine, and echiunime)
- *Arnebia hispidissima* (contains monocrotaline and echimidine)
- *Crotalaria anagyroides*
- *C. crispa* (Kimberley horse poison)
- *C. dura* (wild lucerne)
- *C. cremaea* (bluebush pea)
- *C. globifera* (wild lucerne, jaagsiektebossie)
- *C. goreensis* (Gambia pea; contains monocrotaline)
- *C. incana* (woolly rattlepod; contains fulvine)
- *C. juncea* (sunn hemp; contains retusine)
- *C. mauensis* (contains juncine)
- *C. mesoponcita*
- *C. medicaginosa* (trefoil rattlepod)
- *C. mitchelli*
- *C. novae-hollandiae* (New Holland rattlepod)
- *C. ramosissima* (Kimberley horse poison)
- *C. retusa* (wedge-leafed rattlepod; contains monocrotaline and retusine)
- *C. spectabilis* (showy rattlepod; contains monocrotaline and spectabiline)
- *Cynoglossum officinale* (hound’s tongue; contains heliotridine, heliosupine, and echimidine)
- *Echium plantagineum* (E. lycopsis; Patterson’s curse, Salvation Jane; contains echimidine and echimidine)
- *E. sericeum* (contains echimidine)
- *E. vulgare* (viper’s bugloss; contains echimidine)
- *Heliotropium europaeum* (common heliotrope, potato weed; contains indicine, heliotrine, lasiocarpine, eurpope, supinine, and heuleurine)
- *H. amplexicaule* (blue heliotrope; contains lasiocarpine and echimidine)
- *H. ovalifolium*
- *Ligularia amplexicaulis* (dola)
- *L. mortonii* (bong dok pu)
- *Lithospermum arvense* (Buglossoides arvensis; corn gromwell)
- *Senecio absyssinicus*
- *S. alpinus*
- *S. aquaticus* (marsh ragwort)
- *S. brasiliensis*
- *S. burchelli* (geelgifbossie)
- *S. cineraria* (dusty miller)
- *S. cisplatinus*
- *S. cunninghamii*
- *S. erraticus* (corn gromwell)
- *S. globifera, C. juncea, C. mitchelli, and C. spar
tioides.* Some additional effects on the lungs are produced by *C. ramosissima/C. crispata.* In addition to the dominant hepatotoxic effect, *C. retusa* is associated with nephrosis in affected pigs and hepatic damage in goats.

**EPIDEMIOLOGY**

**Occurrence**

Diseases associated with PAs occur in most animal species in most countries, causing syndromes such as “Molteno straining disease” of cattle, “walking disease,” “Winton disease” of horses and cattle, and “Kimberley horse disease” (walkabout disease), “jaagsiekte” (panting disease), and “dunsiekte” (thin disease), or stomach stagers of horses. Poisoning of humans causing hepatic veno-occlusive disease also occurs.4

Clinical manifestations of poisoning may be delayed for up to 18 months after ingestion of a toxic dose of PAs; the reason for this is unknown.

**Risk Factors**

**Animal Risk Factors**

Cows and horses are 30 to 40 times more susceptible to PA poisoning than other species, followed by goats and sheep, respectively.3,5 The difference appears to be related to the animal’s ability to detoxify the PAs in the liver, probably related to the diet consumed before domestication.1 Small herbivores are more likely to be browsers and to develop resistance to the toxins. It is possible that detoxification of the PAs may occur in the rumen as a result of microbial activity, but there are opposing opinions about this. Poisoning from several PAs has been reported in pigs.7

**Environmental Risk Factors**

**Plant Factors**

The plants associated with PA poisoning are not very palatable and are usually eaten in sufficient quantity to be associated with poisoning only when other feed is in short supply or when they are included accidentally in conserved feed, such as hay, or when their seeds contaminate feed grains. The toxicity of plants containing PAs is not significantly reduced by conversion of the plants to hay or straw, but a significant reduction occurs when made into silage.1 Hot air drying of the plants considerably reduces their toxicity. Flowers are more toxic than herbage.2 Mature plants are avoided; the largest intake by animals is when the plants are sending out...
new shoots. With Senecio spp., the foliage is the source of poisoning. With Crotalaria, Heliotropium, and Amsinckia spp. the seeds are a common source, either as contaminants of grain crops harvested for animal feed or in the cake made from the seeds after the extraction of oils. This is usually the way in which pigs are poisoned.7

Environmental stress, including drought and high temperatures and especially spraying with herbicide, appears to increase the plants’ content of PAs.10 The differences in PA concentration in different samples of the same plant species invalidates the evaluation of the toxicity of the plant on the basis of intake by the animal. Fertilization with NPK products reduces the PA concentrations in Senecio plants.

**Human Risk Factors**

PAs and their metabolites are excreted in cows’ milk and incorporated into products such as yogurt and cheese. The human implication of this is unknown but may be important because some of the PAs are genotoxic, carcinogenic, and teratogenic.1,11 Experimental feeding of goats’ milk containing PA metabolites has produced hepatic lesions in rats. Concentrations of these substances in the meat of animals eating the plants are currently not thought to be dangerous to humans.

**Transmission**

Although most field cases of poisoning occur in animals grazing pasture infested with the toxic plants, the disease may result from the feeding of contaminated, stored feeds, especially hay, or the use of the plants in bedding.12,13 The effects of the intoxication are cumulative, and fatal intoxication may develop over a period of years. Mass mortalities are possible among intensively housed livestock such as pigs, poultry, and feedlot cattle.

**PATHOGENESIS**

**Hepatic Injury**

PAs themselves are not poisonous, but their pyrrolic metabolites produced in the liver by cytochrome P450 are serious, cumulative hepatotoxins.9,14 These toxic pyrroles react with cellular proteins and cross-link DNA and RNA, ultimately causing hepatic cell dysfunction or death, mitotic abnormalities, megalocytosis, and tissue necrosis.1,9,12 Most of the pyrroles remain in the liver, although small amounts may enter the systemic circulation.1 The relative resistance of sheep to PA toxicity may be related to the relatively low capacity of the sheep’s liver to produce pyrroles. In cattle there is damage to the centrilobular and hepatic veins leading to occlusion of the vessels as well as megalocytosis.

**Hepatic Encephalopathy**

One of the consequences of liver insufficiency is the systemic accumulation of metabolites such as ammonia, which is associated with cerebral edema. This results in the nervous signs of depression, aimless walking, and head pressing. The spongy degeneration (status spongiosus) produced in the central nervous system is characteristic of hyperammonemia. Other metabolites may also be significantly involved, but ammonia is best studied.

**Toxemic Jaundice**

Liver damage caused by ingestion of PAs, commonly H. europaeum, results in the accumulation of copper in the liver, but only if the copper intake in the diet is above normal. This may be associated with clinical cases of chronic copper poisoning in sheep, leading to the development of one of the forms of “toxemic jaundice.” E. plantagineum has the double disadvantage of containing PAs and a high copper:molybdenum ratio, so that copper accumulation occurs readily in the plant. Similar accumulations of zinc and iron also occur. There is some evidence for an impairment of storage of vitamins A and E by PAs, but there are no field occurrences of resulting wastage.

Some of the reactive metabolites of hepatic pyrrolizidine escape into the general circulation and are associated with damage to other tissues, including interstitial pneumonia and nephrosis (pigs), which occur in some poisonings.6,5,10 They also react with erythrocytes, and the pyrrolic esters formed there are bound to hemoglobin so that they could be used as markers of past intake of the PAs. The usefulness of the technique is limited by the short life span of erythrocytes. Along with the incidental escape of toxic metabolites into the circulation and the subsequent damage to pulmonary tissue, the PAs from some plants, e.g., some southern African Crotalaria spp., exert their major effect on lung tissue and produce pulmonary as well as hepatic signs.4

**SECONDARY PHOTOSENSITIZATION**

Photosensitization occurs secondary to liver damage. Phylloerythrin, the degradation product of chlorophyll, is a photoreactive agent associated with hepatoxicogenic (secondary) photosensitization. Under normal circumstances the liver conjugates phylloerythrin and excretes it in the bile. When the liver is impaired phylloerythrin accumulates in the liver, blood, and ultimately the skin, resulting in a range of signs varying from irritation with pruritus to necrosis with serum leakage and skin sloughing.13

**CLINICAL FINDINGS**

Although the hepatic lesions develop slowly in most cases, the onset of clinical signs is usually sudden. The onset of illness may occur many months after the animals have been removed from the toxic pasture.14 The prominent signs are hyposensitivity to external stimuli, anorexia, ill-thrift, aberrant or odd behavior, precipitate drop in milk yield and, in cases surviving for more than 2 days, there is often jaundice and photosensitive dermatitis.10,14 Sheep may have serious liver damage, but the effects may be limited to loss of body weight and reduction in wool yield. Most animals poisoned with PAs develop hepatic syndrome; however, some cases will have signs of uremia or interstitial pneumonia.

**Cattle**

In poisoning caused by Senecio spp. there is a sudden onset of depression and poor sensitivity to external stimuli. This hyposensitivity is sometimes punctuated by short outbursts of excitability and frenzy and often by aggressive behavior. During these episodes there is usually severe diarrhea and straining to defecate. This may result in a high incidence of rectal prolapse. Other signs include abdominal pain, staggering gait, dragging of the hooves, walking in circles, and partial blindness. Such cases usually die within 2 to 3 days of the onset of signs.

Some cases may linger on for several weeks. There are no excitable episodes, the animal remains hyposensitive, becomes anorexic, loses weight, and is afflicted with diarrhea and tenesmus, and usually develops jaundice, mucosal pallor, and, rarely, photosensitive dermatitis.

**Horses**

Horses poisoned by S. jacobaea or C. crispata/C. ramosissima/C. medicagoe lose weight, are mildly jaundiced, and profoundly hyposensitive to external stimuli, often standing with the head down.14 They may stop eating halfway through a mouthful of hay or grass. Muscle tremors, especially of the head and neck, frequent yawning, and difficulty in swallowing occurs. The latter may be sufficiently severe to cause aspiration of food into the lungs or regurgitation through the nasal cavity. Affected horses appear to be blind. They walk in circles or straight ahead, bumping into objects and becoming wedged in places from which they cannot back out; they also walk into streams, houses, or outbuildings. Death by misadventure is a frequent outcome. Head pressing is common and there may be attacks of frenzy and violent, uncontrollable galloping. Multiple skin abrasions of the head and chest are indicators of this deranged behavior. The disease is usually fatal, the course lasting from a week to several months. An unusual outcome to pyrrolizidine toxicosis of horses is the development of gastric impaction with the dried stools of the plant, causing colic with nasal regurgitation and, in some cases, a fatal gastric rupture.

Paralysis of the pharynx and larynx are thought to be associated with an unusual occurrence of inspiratory dyspnea in ponies with severe pyrrolizidine toxicosis. A further effect in horses may be intravascular
hemolysis, manifested as hemoglobinuria. Pseudoneoplastic proliferation of bronchiolar epithelium is the basis of jaagsiekte of horses, manifesting as progressive severe dyspnea associated with pneumotoxic pyrrolizidine alkaloids such as dicrotalein, monocrotaline, fulvine, and crispatine in some *Crotalaria* spp., including *C. dura*, *C. globifera*, *C. juncea*, and *C. spartioides* in southern Africa, and *C. ramosissima*, *C. crispatia*, *C. medicaginea*, and *C. mitchelli* in Australia.4,3

The progress of the disease in horses may be in one of two patterns. In the chronic disease there is a gradual worsening of signs until death at 6 to 22 weeks. In the chronic-delayed form the lesions progress, as measured by biopsy, but there are no clinical signs until a sudden onset of illness at 38 to 58 weeks. Similarly, the signs of the disease may not occur until several months after the last ingestion of the toxic material, with death occurring soon afterward.

**Pigs**
Pigs poisoned with *Crotalaria* spp. show anasarca, pale mucosae and conjunctiva, Ruffled bristles, emaciation, and apathy. The disease is chronic and progressive, and the mortality rate is high. Pigs poisoned with the seeds from *C. spectabilis* had lesions consistent with hepatic damage as well as submucosal edema, hemopericardium, and petechial hemorrhages.3

**CLINICAL PATHOLOGY**
Diagnosis is based on presence of a toxic PA in the feed or animal. Methods for identifying and quantitating the presence in feed products using gas or liquid chromatography, and mass spectrometry have been described for many of the toxins.5,16 It is far more difficult to determine the presence of PAs in the blood, primarily because they are quickly excerted and because poisoning precedes the onset of signs by many months.7 Liver function tests such as serum levels of bilirubin and bile acids and bromsulphalein (BSP) clearance are useful in determining the degree of liver damage. Contributory evidence is the presence of hyperammonemia, hyperbilirubinemia, and hyperalbuminemia. Levels of serum enzymes are transiently elevated. For the prediction of early hepatic damage in cattle grazing on *Senecio* spp., measurements of serum γ-glutamyl transpeptidase and glutamyl dehydrogenase are recommended. In horses, GGT and ALP estimations are favored, especially the former, which is recommended as a screening test to identify subclinical cases in horse herds. The changes in serum liver enzymes precede the changes detectable histologically in liver biopsy specimens. For assessment of the degree of damage to the liver in chronic cases, a combination of BSP clearance test and liver biopsy is regarded as most useful in cattle and horses.

**NECROPSY FINDINGS**
Hepatic megacystosis; fibrosis, which may be veno-occlusive; and biliary hyperplasia are the common histopathological findings. In cases of sufficient duration there is jaundice, general edema, and ascites. Secondary histopathological changes occur in intestinal mucosal cells and may be responsible for impaired absorption of nutrients. In some poisonings associated with PA-bearing plants, necropsy findings will be dominated by lesions of nephrosis, particularly in pigs,5 or interstitial pneumonia, particularly in horses.4,5

**DIFFERENTIAL DIAGNOSIS**
Diagnostic confirmation depends on positive identification of pyrrolic metabolites in blood or liver. Presumptive diagnosis is provided by hepatic histopathology detecting megacystosis, which needs to be differentiated from that seen in aflatoxicosis. Cases in which exposure to toxic plants occurred some time ago can only be diagnosed presumptively.

**NECROPSY FINDINGS**
Hepatic megacystosis, fibrosis, which may be veno-occlusive, and biliary hyperplasia are the common histopathological findings. In cases of sufficient duration there is jaundice, general edema, and ascites. Secondary histopathological changes occur in intestinal mucosal cells and may be responsible for impaired absorption of nutrients. In some poisonings associated with PA-bearing plants, necropsy findings will be dominated by lesions of nephrosis, particularly in pigs,5 or interstitial pneumonia, particularly in horses.4,5

**DIFFERENTIAL DIAGNOSIS**

Presumptive diagnosis is provided by hepatic histopathology detecting megacystosis, which needs to be differentiated from that seen in aflatoxicosis. Cases in which exposure to toxic plants occurred some time ago can only be diagnosed presumptively.

**Differential diagnosis lists**
Cattle hepatopathies caused by the following:

- Phytotoxins, e.g., in *Lantana* spp. *(Myoporum)*
- Mycotoxins as in *Aspergillus* spp. *(Phomopsis, Diaporthe toxica, and Myrothecium spp.)*
- Tunicaminyricil poisoning as in *Clavibacter toxica*
- Cyanobacteria *(blue-green algae)*
- Zootoxins as in *Lophyrotoma, Arge* spp.
- Encephalopathies such as the following:
  - Rabies
  - Lead toxicity
  - Polioencephalomalacia
  - Other causes of jaundice also need to be taken into account; special attention needs to be given to chronic copper poisoning in sheep because sheep poisoned by PAs are much more inclined to develop high levels of copper in the liver than are other sheep

**Horses:**
- Equine viral encephalomyelitis
- Nigropicodal encephalomalacia
- Leukoencephalomalacia

**TREATMENT**
Primary treatment of the hepatic lesion is unlikely to be attempted. Supportive treatment requires provision of a high nutrient diet during the convalescent period plus symptomatic treatment for photosensitization and dehydration. Horses that have recovered clinically may never regain their former physical fitness, and any exertion will lead to rapid exhaustion.

**CONTROL**

Populations of these plants undergo cyclic changes, and the diseases associated with them tend to wax and wane. Artificial reduction of plant numbers using herbicides is attempted. Because of the comparative resistance of sheep to PA poisoning, they may also be used to keep infested pasture under control by having them graze it only intermittently, for example, for a 1-month period once a year, or for only one season during their lifetime.17 Biological control, using insects such as the cinnabar moth *(Tyria jacobea)*, which feeds only on plants that contain PAs, may be an effective control procedure for their specific host plants.16 A concerted effort at biological control of *H. europaeum* and *E. plantagineum* is currently underway in Australia using several insect herbivores and fungal pathogens in combination. Attempts to control *H. europaeum* poisoning by administration of cobalt or an antimethenogen have been unsuccessful. Attempts at immunization against PAs, manipulation of ruminal flora, manipulation of hepatic metabolism, protection by thiol compounds, and selection for heritable resistance, have all failed to date. The use of sesame oil and peanut oil against monocrotaline, a PA present in several species of *Crotalaria*, has been studied in a rat model and may be effective in cattle and other animals.17

Plants Causing Hepatic Injury (Unidentified Toxin)

Ingestion of some plants with unidentified or unknown toxin(s) may result in hepatic injury. Several different syndromes have been identified and are listed next.

**HEPATIC INJURY-DUMMY SYNDROME (CIRCLING, HEAD PRESSING, COMPULSIVE WALKING, AND BLINDNESS)**

In many cases, an expression of hepatic encephalopathy with hepatic necrosis and status spongiosus in the brain, e.g., *Helichrysum argyroserbaceum*, which is associated with blindness, paresis, and spongy degeneration of the brain in sheep and cattle, and *H. blandowskianum* (woolly daisy) has caused death and similar brain lesions in cattle. *Oxystenia acerosa* (copperweed), *Phyllanthus spp.* (spurge), and *Riedelliclla graciliflora* are associated with hepatic injury. *Tremata tomentosa* (syn. *T. aspera*) is associated with acute hepatic necrosis in cattle and horses. In *Matricaria nigellifolia* poisoning, affected cattle become clumsy and docile and head push against fixed objects, hence, the common name “pushing disease.” Sheep are not affected.

**HEPATIC INJURY: JAUNDICE AND/OR PHOTOSENSITIZATION**

*Acanthospermum hispidum* (star burr)
*Antherasia trifurcata*
*Callicarpa longifolia*
*Capparis tomentosa*
*Chrozophora plicata* (terba)
*Enterolobium spp.*
*Fallopia convolvulus* (black bindweed)
*Ficus tsiela*
*Galeopsis spp.* (hedge nettle)
*Hertia pallens* (springbokbush)
*Heterophylla pustulata* (cegadera)
*Kochia scoparia* (summer cypress)
*Lythrums hyssopifolia*
*Nidorella foetida*
*Nolina texana* (sacahuiste)
*Persicaria lapathifolia* (syn. *Polygonum lapathifolium*; pale willow weed)
*Pongamia glabra* (Indian beech)
*Psathyrotes annua*
*Pteronia pallens* (Scholtz bush)
*Sartwellia flaversiae* (sartwell)
*Sesca brasiliensis*
*Stryphnodendron coriaceum*
*Tridactyla canescens* (spineless horsebrush)
*Trifolium hybridum* (abise clover)

*The Polygonum spp.* (= *Persicaria spp.*) listed next also are associated with photosensitive dermatitis but are credited with causing a primary hepatic injury. Many of the findings about these plants are equivocal:

*P. convolvulus*
*P. orientale* (smartweeds)
*P. sagittatum*

Poisoning by Mycotoxins

**POISONING BY AFLATOXINS (AFLATOXICOsis)**

**SYNOPSIS**

Etiology Aflatoxins are mycotoxins that contaminate food and foodstuffs.

Epidemiology All species are affected; toxin is excreted in milk and eggs.

Clinical pathology Acute elevations in serum hepatic enzymes (specially γ-glutamyl transpeptidase, aspartate amino transferase, and sorbitol dehydrogenase); increases in prothrombin time and serum bilirubin; changes in hematological parameters

Lesions Primarily hepatic: jaundice, hepatocyte necrosis, megalocytosis, and fibrosis

Diagnostic confirmation Positive assay of aflatoxin in tissue and fluids

Treatment Symptomatic only

Control Preventive assay of large quantities of feedstock. Detoxification of contaminated feed currently being attempted by various means

**ETIOLOGY**

Aflatoxins (AFs) are metabolites produced by fungi growing on spoiled feeds. Elevated relative humidity (95%–97%) levels and warm temperatures (25°C–37°C) are associated with fungal growth.1,2 Eighteen AFs have been isolated with AFB1, AFB2, AFG1, AFG2, and the second-generation metabolites M1 and M2 are the most widely studied.3-4 AFB is generally recognized as one of the most potent hepatic carcinogens in the world. It is related chemically and structurally to dicoumarin compounds.5 The most important toxicosis, aflatoxicosis, is associated with the ingestion of Aspergillus spp. and AFs, but other important toxins produced by the fungi are ochratoxin, patulin, and sterigmatocystin. Aspergillus flavus, A. nomius, and A. parasiticus are the most commonly recognized species that produce AFs.6 Other less common AF-producing species include *A. niger, A. ruber, A. wentii, Penicil­lium citrinum, and P. frequentans*.7

Levels of AFs attained in feed may be as high as 3500 ng/kg for all AFs, 2000 ng/kg for AFB1, and 1000 ng/kg for AFB2. In sheep, the oral LD50 is 5 mg/kg; a dose rate of 4 mg/kg is associated with death at 15 to 18 hours caused by acute hepatic insufficiency; at dose rates of 2 mg/kg there is increased respiratory rate, a rise in temperature of 1.5°C (34°F), and diarrhea with blood and mucus; at a dose rate of 0.2 mg/kg there is anorexia and diarrhea. Similar dose relationships have been established for calves and for pigs. A great deal of AF ingested in the feed by cattle is physically bound to ruminal contents, and as little as 2% to 5% reaches the intestine.8 Levels of AFB1 in excess of 100 μg/kg of feed are considered to be poisonous for cattle. The estimated LD50 for AFB1 in calves is estimated to be 0.5 to 1.5 mg/kg. Information regarding toxic ingestions in horses is sparse, but ingestions of 500 to 1000 mcg/kg have resulted in liver damage, with signs related to the duration of exposure. The oral LD50 of AFB1 is species dependent but for most species is in the range of 0.03 to 18 mg/kg.9

**EPIDEMIOLOGY**

**Occurrence**

Aflatoxicosis has been reported in most countries and on many spoiled feeds, especially harvested peanuts, peanuts in shells, cottonseed meal, sorghum grain, corn, moldy bread, green chop sorghum, or rarely on a standing crop, e.g., ears of sweet corn.10 The mycotoxin is not destroyed by milling of the grain.

**Animal Risk Factors**

All animal species are susceptible, but outbreaks occur mostly in pigs, sheep, and cattle; beef and dairy cattle are more susceptible than sheep or horses. Young animals of any species are more susceptible than adults, and nursing animals may be at increased risk because AFs are excreted in the milk.14-16 Therapeutic administration of *A. oryzae* to newborn foals as a digestive inoculant to promote fast development of digestion is suspected of producing mycotoxins and being associated with acute hepatic insufficiency, including encephalopathy.

**Human Risk Factors**

AF is an important consideration in the etiology of human hepatocellular carcinoma. Because the toxin is excreted in cows’ milk it has public health importance. The concentration of AF in cows’ milk may be as high as 0.33 μg/L and may continue to be as high for 1 to 3 days after ingestion of the feed.9,12 In dairy goats treated with a single dose of AF, a maximum concentration of AFM1 was reached at 3 to 6 hours and was no longer detectable at 72 to 84 hours.9,10 AFs can also be present in the meat from animals eating contaminated feed, but the risks to humans eating the meat are thought to be small.8

**PATHOGENESIS**

AFs are rapidly absorbed from the gastrointestinal tract, entering the portal blood system in a short period of time and concentrating in the liver. In the liver AFs undergo biotransformation, producing a range of metabolites.24 Cytochrome P450 is actively involved with the transformation of AFB1 to the toxic metabolite AFB2,-8,9-epoxide, which forms adducts with DNA, RNA, and proteins.1 AFs, 8-9-epoxide is detoxified by conjugation with glutathione.25 About 1% to 2% of ingested AFB1 is metabolized to AFM1 and secreted into the milk.13 Excretion
occurs primarily through the urine, bile, and feces, but also to some extent in the milk, eggs, and semen. The toxic effects of AFs are most pronounced in the liver where the metabolism of carbohydrates, lipids, and proteins is impaired. The effects of AFB1, 8-9-epoxide include inhibition of RNA and protein synthesis and resistance of DNA to repair. Hepatosis and hepatic insufficiency are the principal effects, but mutagenic and teratogenic effects are recorded in laboratory animals and suspected in humans on epidemiologic grounds.

**CLINICAL FINDINGS**

**Cattle**

Clinical signs include blindness, walking in circles, ear twitching, teeth grinding, frothing at the mouth, photosensitve dermatitis and keratoconjunctivitis, diarrhea, severe tenesmus, abortion, and anal prolapse. Recumbency is followed by terminal convulsions. The appetite is normal. Afflicted animals usually die within 48 hours, and calves in the 3- to 6-month group are the most susceptible. Aflatoxicosis is also reputed to interfere with clotting of the blood in cattle, leading to the development of hematomas. Amounts of toxin insufficient to cause overt disease in cows may be sufficient to reduce food intake, weight gains, and milk production, and to be associated with diarrhea.

**Pigs**

In pigs, the period between when the toxin is ingested and when signs appear is thought to be quite long, at least 6 weeks, and varies with the toxicity of the batch of feed. The mortality rate is often 20%, but may be as high as 90% (including euthanasia). Feeder pigs are more susceptible than adults. The clinical syndrome includes a rough coat, depression, anorexia, weight loss, muscle tremors, staggering gait, walking in a daze, and recumbency. Some pigs have intermittent or hemorrhagic diarrhea and some have seizures just before death. The course of the disease may be as short as 6 to 12 hours. Abortion is a commonly reported sequela, but there is doubt about the relationship. At necropsy there is icterus, ascites, swelling of the liver, and mesenteric edema.

**Horses**

Reports of aflatoxicosis are less common probably because horses are less likely to be fed damaged feed. Clinical signs are nonspecific but include depression, anorexia, fever, tremors, ataxia, icterus, and hemorrhage. A link between inhaled A. fumigatus and the development of chronic obstructive pulmonary disease has been proposed. Necropsy lesions include encephalomalacia, hepatocyte necrosis and hepatic fibrosis, bile duct hyperplasia, hemorrhagic enteritis, and myocardial degeneration. The experimental disease is characterized by depression, inappetence, tremor, and prostration, with death following in 2 to 6 weeks.

**CLINICAL PATHOLOGY**

Acute elevations in serum hepatic enzymes with γ-glutamyl transpeptidase, AST, and SDH are most often reported. Elevations in prothrombin time and serum bilirubin are common as are changes in hematological parameters.

Analysis and quantification of AFs in feed materials, urine, blood, and tissues are standard practice. Laboratory assay methods include chromatography/mass spectrometry and immunoassays.

**NECROPSY FINDINGS**

Necropsy findings in all species are those of hepatosis, including megalocytosis, multiple foci of necrosis and fibrosis, portal round cell infiltration, and bile duct hyperplasia. Jaundice and serous exudates in body cavities may occur in some animals. In pigs a pronounced lower enterocolitis with diarrhea and dysentery is common, but not constant. Other reported lesions include equine cardiac fiber degeneration, focal cerebral malacia, and the presence of protein in the glomerulus and renal proximal tubules; pneumonia in calves; and photosensitization.

Diagnosis confirmation depends on the detection of AF in the feed and blood serum, and the characteristic gross and histopathological findings in the liver.

**DIFFERENTIAL DIAGNOSIS**

**Differential diagnosis list:**

- Aflatoxin intoxication
- Cyanobacteria (blue-green algae) intoxicosis
- Fascioliasis
- Lantadene intoxicosis
- Phomopsin intoxicosis
- Primary hepatic disease (neoplasia, bile duct obstruction)
- Pyrrolizidine alkaloid intoxicosis
- Sporidesmin intoxicosis
- Steroidal saponin intoxicosis
- Theiler’s disease

**TREATMENT**

Symptomatic treatment of hepatic insufficiency is all that can be attempted.

**CONTROL**

Because of the advent of reliable and accurate methods of assaying AF in feeds there has been a notable tendency for feed to be less contaminated. Supplementation of the diet with zinc, selenium, and vitamin E is not effective in preventing aflatoxicosis, and those procedures that have shown promise in experimental trials have not been translated into practicable, cost-effective techniques. Binding of AF in the gastrointestinal tract has been useful. Studies have included smectites such as hydrated sodium calcium aluminosilicate (several formulations of the compound are already used as anticaking agents in the animal feed industry) and sodium bentonite in the form of clay. Agronomic methods to reduce AF contamination of peanuts have recently been successful. Ammoniation of feed has been useful in reducing contamination. Modified yeast cell wall extracts (Saccharomyces cerevisiae) have been successful in some species.

**Phomopsins Toxicosis (Lupinosis)**

**SYNOPSIS**

**Etiology** Family of mycotoxins produced by Fungi Diaportha toxica growing on Lupinus (lupin) plant stubble or to a lesser extent seeds

**Epidemiology** Worldwide with cases in Europe, Australia, New Zealand, South Africa, and other countries. Primarily cattle and sheep grazing lupin stubble or fed seeds in ration; horses and pigs are affected less often
ETIOLOGY
Phomopsins are a family of mycotoxins produced by the saprophytic fungus Diaporthe toxica (anamorph Phomopsis spp.). The fungus infects lupin crops and seeds and causes lupinosis in cattle and sheep ingesting contaminated feed. Phomopsins A, B, C, D, and E, all cyclic hexapeptide mycotoxins, are the specific cause. Phomopsin A is the main toxic metabolite and is two to five times as toxic as Phomopsin B. D. woodi (anamorph Phomopsis leptostromiformis) was originally, and erroneously, considered to be the source of these toxins. P. emesis, a saprophyte of Emex australis, produces phomopsins in vitro, but is not associated with natural disease incidents.

EPIDEMIOLOGY
Occurrence
The disease is common in Europe, Australia, New Zealand, and South Africa. It is rarely reported in the United States. Sheep, goats, and cattle are most commonly affected, probably because of their greater exposure. Poisoning of pigs and horses rarely occurs.

Risk Factors
Animal Risk Factors
Naturally occurring cases are seen far more often in sheep, followed by goats, and then cattle. Although lupinosis rarely occurs in horses, they may be the most susceptible because sudden death is the normal finding. Most occurrences are in animals grazing lupin stubble in which there is dry foliage, seed pods, and/or seeds. Poisoning occurs rarely in sheep ingesting only seeds; it has also occurred in pigs fed ground lupin seeds.

Environmental Risk Factors
Factors increasing the chances of poisoning associated with fungal infection of the seenscent plants include summer rain, which is conducive but not essential to fungal growth; the time lapse since rain, during which toxic lupins remain poisonous for several months; and the provision of alternative feed or the presence of other plants, including weeds, in a crop, both of which may reduce lupin intake and hence its toxicity. Some varieties of lupins are much more susceptible to fungal infections than others. The mature stalks are the most poisonous so that a heavy stocking rate, which encourages the ingestion of all parts of the plants, increases its prevalence. Stubble from which lupin seeds have been harvested is the most common cause of lupinosis.

PATHOGENESIS
The liver is the primary target organ for phomopsins in all species, with the kidney a secondary target. Ruminants develop hepatoxicosis, whereas horses and pigs are more susceptible to renal insult and nephrotoxicosis. Phomopsins exert their toxicity by binding to tubulin isotypes and altering microtubular functions.

Phomopsins injected intramuscularly have variable effects depending on dose and duration of administration. Subcutaneous dosing results in anorexia, weight loss, lethargy, jaundice, elevation of serum levels of liver enzymes, recumbency, and death in 90% of sheep. Clinical biochemistry findings suggest that the hepatosis is accompanied by injury to muscle, kidney, and adrenal cortex.

Affected sheep have a higher hepatic concentration of copper and selenium and a lower concentration of zinc, which is caused by necrosis of liver cells. The affinity for copper may lead to the development of a complicating chronic copper poisoning in affected sheep.

CLINICAL FINDINGS
In sheep, signs include anorexia, constipation, hepatomegaly, stumbling gait, recumency, and a variable degree of jaundice. Affected sheep have a stiff gait, walk reluctantly, and stand with their back humped and their feet under the body, and have difficulty getting to their feet. Experimental phomopsin poisoning at mating time is associated with reduced reproductive efficiency in ewes.

In cattle, three syndromes may be encountered. Most common is ketosis, precipitated by inappetence, and found in pregnant or freshly calved cows. Less common is hepatic cirrhosis, found in cattle several weeks after they are removed from lupin stubble. The course of the disease is 1 to 3 days, and signs include anorexia, depression, staggering gait, jaundice, and bleeding from orifices. Photosensitization occurs in cases that survive for more than a few days. Death may occur within a few days of first illness or be delayed for months, with affected animals standing immobile for long periods or wandering aimlessly, often dying from misadventure. More chronic cases exhibit ill-thrift and photosensitization. Recovery may occur if animals in the early stages of the disease are taken off the dangerous pasture, but severely affected animals usually die.

Animals that regain their appetite will completely recover.

Phomopsin ingestion in pigs results in a profound anorexia, vomiting, lethargy, jaundice, and stunted growth. Larger doses cause more gait abnormalities, including incoordination, dog sitting, and hind end paralysis.

Lupinosis in horses is often associated with sudden, acute death. Affected horses are depressed, weak, uncoordinated, jaundiced, and pass dark reddish-brown urine. The duration of clinical signs is generally only 2 days.

CLINICAL PATHOLOGY
In the early stages of lupinosis, serum liver enzyme tests are the best aids to diagnosis. The γ-glutamyl transpeptidase test is preferred in the early subacute stages and ascertain transaminase when the disease is more severe. In the late stages of the disease liver function tests are preferred.

NECROPSY LESIONS
There are jaundice and either a swollen, mottled bright yellow or pale orange, firm, friable liver in acute cases, or a small and fibrotic one in chronic cases, plus extensive hemorrhages under the skin and serous membranes. Spongy transformation of the brain has been recorded in naturally occurring cases and has also been produced experimentally. Histologically, mitotic figures are found in many hepatocytes as well as necrosis of individual hepatocytes, biliary hyperplasia, and diffuse hepatic fibrosis.

DIFFERENTIAL DIAGNOSIS
Diagnosis confirmation depends on liver histopathology and detection of phomopsins in rumen contents and feed by immunoassay or chromatography/mass spectrometry.

Differential diagnosis list
The differential diagnosis list contains many cases of illness in pregnant and recently calved cows in lupin country that are diagnosed as lupinosis but are actually cases of pregnancy toxemia or fat cow syndrome. Other fungal or plant hepatopathies will need to be differentiated.

TREATMENT
There is no treatment other than removing the animal(s) from contaminated fields and providing supportive care.

CONTROL
Lupin crops should be grazed after seed harvest in early summer and not in late autumn. Sheep stocking rates should be less than 30 per hectare. It is an advantage to train sheep to eat lupin seed before they are exposed to crops, thus reducing the intake of stubble because the sheep will forage for seed on the ground. The intake of lupin can be decreased during summer grazing by...
establishing crop mixtures with wheat, oats, or barley.

Prevention is assisted by restricting grazing on mature, standing, dry plants during warm, humid weather that favors fungal growth, avoiding copper supplementation near danger periods, and encouraging the administration of cobalt. Hay made from lupins appears to be free of toxicity, and this may be a useful technique in the prevention of the disease. Fungicidal agents, such as benomyl, are also sprayed onto lupins to reduce fungal growth, but no specific recommendations have been made. Additional protection may be gained by the optimal administration of zinc, which has been shown to reduce the severity of liver damage associated with lupins/fungal poisoning, but commercial application of this knowledge is not yet possible, partly because of the toxicity of the administered zinc. It is advisable to be wary at all times when grazing mature lupin crops. If they are used, the crops should be inspected regularly for evidence of fungal infection. If this does occur, livestock should be permitted to have access for short periods only, and alternate and supplementary feed should be available.

A satisfactory measure of prevention has been achieved by the development of a phomopsin-resistant strain of Lupinus angustifolius, which is capable of reducing the mortality rate from 57% to 8%. A phomopsin-conjugate vaccine has been successfully tested under field conditions but is not yet commercially available.

Risk Factors
Animal Factors
Sheep, cattle, goats, New World cameldids, and kangaroos are affected. Experimental production of the disease in Saanen goats requires two to four times the sheep dose, and feral goats need four to eight times the sheep dose.

Plant Factors
The environmental factors, which encourage the growth of the fungus and the production of sporidesmin, include the type of plants in the pasture and the climatic conditions. Pithomyctoxicosis is commonly associated with ryegrass pastures, but the causative fungus is capable of growing on all kinds of dead leaf material, including cereal hay, and causing facial eczema. In South Africa the ingestion of P. chartarum is thought to enhance the toxicity of Tribulus terrestris.

Pithomyctoxicosis occurs extensively only when pasture is short and contains abundant dead, recently killed plant material, and during warm (grass minimum temperature >12°C), humid weather, which favors growth of the fungus. This is most likely to be a problem in autumn when the summer has been hot and dry, the pasture well eaten back, and good rains fall when the ground is still warm. In such circumstances the grass and the fungus grow rapidly. It is predicted that the disease will increase in range in New Zealand with global warming (Fig. 9-3).

PATHOGENESIS
Sporidesmin is associated with severe damage to biliary epithelium, leading to acute biliary obstruction and a resulting severe hepatic insufficiency manifested by loss of condition, obstructive jaundice, and secondary (hepatogenous) photosensitization. Sporidesmin administered by mouth is excreted unchanged in high concentrations in urine and bile, especially the latter where it reaches 100 times the concentration in serum. Sporidesmin undergoes autoxidation in bile resulting in free radical formation in biliary epithelium and associated biliary epithelial injury. The resulting inflammation of the bile ducts and progressive obliterative cholangiolitis slows down the rate of bile flow to negligible levels over a period of about 14 days. The photodynamic agent is phytoporphyrin (formerly called phylloerythrin), the first porphyrin metabolite of chlorophyll, which is produced by anaerobic microbial fermentation in the ruminant forestomach and retained in tissues because of failure of its excretion through the damaged liver and bile ducts. In nonpigmented areas of the skin and hide, phytoporphyrin absorbs ultraviolet radiation and becomes reactive, with local cell death and inflammation manifested as photosensitization. The frequent observation that only part of the liver is involved is probably explained by the deposition of toxin in the liver in mononuclear hepatocytes.

Pithomyctoxicosis (Sporidesmin Toxicity and Facial Eczema)

SYNOPSIS
Etiology Toxin metabolites of fungus Pithomyces chartarum growing on litter from pasture plants, particularly ryegrass
Epidemiology Outbreaks only at pasture are most common in sheep in warm moist climates when pasture is short and grazing animals consume the dead plant litter.
Clinical findings Pithomyctoxicosis findings include acute hepatic injury characterized by dullness, anorexia, jaundice, and photosensitization. High case-fatality rate, long chronic course in survivors
Clinical pathology Elevated serum activities of liver enzymes in early stages
Necropsy findings Liver swollen, discolored early, and later tough, and contracted; obliterative cholangitis
Diagnosis confirmation High spore count on pasture; elevated concentrations of sporidesmin in serum
Treatment Change to rough, mature pasture.
Control Monitor pasture spore counts, destroy fungus on pasture with fungicide, and restrict access to dangerous pasture; daily oral dosing with zinc preparation

ETIOLOGY
Sporidesmins are metabolites of the fungus Pithomyces chartarum (Sporidesmin bakeri) infesting dead plant material in standing pasture. The sporidesmins A–H are pyrrolines and are associated with pithomycotoxicosis (facial eczema), a major disease of sheep and cattle in selected regions of the world. The term facial eczema is misleading, and the continued use of this name is discouraged because the major pathogenic effect is liver dysfunction, and the main toxin is sporidesmin A. The term facial describes only a small part of the clinical picture, and eczema is a poorly defined term describing one clinical manifestation, in which photosensitization provides a more encompassing term. In 1973, the name pithomyctoxicosis was proposed; this word combines the pitho of Pithomyces chartarum, the causative fungus, with mycotoxicosis, which is a widely used term describing diseases caused by fungal toxins. The occurrence of nontoxicogenic strains of P. chartarum probably accounts for the wide variation in disease occurrence between countries.

EPIDEMIOLOGY
Occurrence
Pithomyctoxicosis was first reported in sheep in 1887 and has been recorded most often in northern New Zealand where it is of major economic importance. The disease occurs to a limited extent in coastal regions of Europe, Turkey, Australia, South Africa, and in irrigated perennial ryegrass fields in the United States (Oregon). The incidence varies widely depending on climatic conditions; in some years the disease does not occur, in others the morbidity rate in affected flocks of sheep may be 70% to 80%, and 5% to 50% of these may die. Of the survivors, many are unthrifty and make less than normal weight gains. In cattle, the morbidity rate is much lower and rarely exceeds 50%. In spite of the obvious weight loss associated with the nonfatal form of the disease, there is no appreciable effect on the palatability of the carcass meat.
predisposition.

CLINICAL FINDINGS

In cattle and sheep the disease starts suddenly with the appearance of lethargy, dullness, anorexia, jaundice, and photosensitive dermatitis (Fig. 9-4). The skin lesion and jaundice are both variable in occurrence, and sheep may die without either having been observed. Many animals die during this acute stage, but some survive and pass into a state of chronic ill-health manifested by poor bodily condition and a susceptibility to minor environmental stresses. Many others show no clinical signs but have significant changes in serum enzyme systems indicative of an acute hepatic injury and measurable reductions in reproductive efficiency and lamb weights. Occasional animals develop the syndrome of hepatic encephalopathy manifested by dullness and depression progressing to tremor and lateral recumbency. Spongy vacuolation of brain tissue is observed. Many animals die during this acute phase there is extensive hepatic fibrosis, the liver is tough and contracted, and the left lobe is almost completely atrophic. Areas of regeneration are usually apparent macroscopically. Histologically, there is perilobular fibrosis with obliteration of the bile ducts and pressure atrophy of hepatic cells. The changes are much more marked in the left lobe and the medium- to large-sized bile ducts.

NECROPSY FINDINGS

In the acute stages of pithomycotoxicosis there is jaundice and a swollen, mottled liver with thickened bile duct walls. In the chronic phase there is extensive hepatic fibrosis, the liver is tough and contracted, and the left lobe is almost completely atrophic. Areas of regeneration are usually apparent macroscopically. Histologically, there is perilobular fibrosis with obliteration of the bile ducts and pressure atrophy of hepatic cells. The changes are much more marked in the left lobe and the medium- to large-sized bile ducts.

CLINICAL PATHOLOGY

Tests of hepatic function, especially the BSP clearance test, should be of value in determining the presence of liver damage. In the very early stages, serum enzyme estimations should also be of value. Serum GGT activity is regarded as the best indicator of hepatic damage in cattle and remains elevated for at least several months after an attack of pithomycotoxicosis; in cows serum GGT activities frequently range from 500 to 2000 U/L (reference range <36 U/L). Serum GDH activity and phylloerythrin concentrations are also increased in sheep with pithomycotoxicosis.1

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation depends on a positive assay of sporidesmin in fluids and tissues of affected animals. High spore counts on pasture are circumstantial evidence.

Pithomycotoxicosis must be differentiated from those other diseases in which photosensitization and hepatitis occur.

Differential diagnosis list
- Pyrrolizidine alkaloid poisoning
- Aflatoxin poisoning
- Steroidal saponin poisoning
- Lantadene poisoning
- Cyanophyte (cyanobacterial) poisoning
- Fasciolasis
- Phomopsis poisoning
- A disease of cattle in the southern United States thought to be associated with the ingestion of dead forage on which a Periconia spp. fungus is growing

TREATMENT

There is no primary treatment, except to change animals to new pasture. Supportive treatment for hepatitis and photosensitization, as outlined under those headings, and the administration of antibiotics and antihistamines to control secondary infection and shock, may be applicable in animals of sufficient economic value.

The provision of drinking water containing 6 g of zinc sulfate per 100 L for 28 days is claimed to hasten recovery of affected sheep and cattle.7 Zinc provides protection against sporidesmin toxicity through an
unknown mechanism, but efficacy appears to be associated with an increased serum zinc concentration.

**CONTROL**

Research into practical control methods for pithomyctotoxicosis has focused on monitoring pasture fungal spore counts to guide grazing practice, development of pastures different to ryegrass that do not promote fungal growth, fungicide and biological control of the saprophytic fungus, and the use of zinc prophylaxis on animals. One of the major difficulties in the control of the disease is that of predicting the occurrence of an outbreak so that the flock can be changed to nondangerous pasture. Meteorologic observation can be of value, but the counting of spores by a mobile spore catcher is now routinely used in danger areas.

In a comparison of fungicides used to control the growth of *P. chartarum*, carbendazim was most effective at 0.15 and at 0.30 kg/ha of active ingredient, whereas benzomyl and thiophanate methyl were effective only at 0.30 kg/ha. The original methods of applying fungistatic agents to pasture included thiabendazole or benomyl (Benlate) sprayed on at the rate of 272 g/ha in January. The growth of *P. chartarum* was controlled and the development of pithomyctotoxicosis prevented.

The discovery of nontoxic strains of *P. chartarum* in New Zealand and South Africa, which sporulate profusely but produce no sporesdmin, and compete aggressively with sporesdmin-producing strains, raises the question of controlling pithomyctotoxicosis by dominating the pastoral fungal population with the sporesdmin-negative strain. The daily oral administration of zinc (15–30 mg of zinc per kilogram bodyweight per day) as zinc oxide to sheep and lactating cattle ingesting excess zinc as a control measure for pithomyctotoxicosis, which runs the risk of inducing copper toxicity and decreasing the absorption of zinc. Iron salts, including ferric ammonium citrate, and ferric and ferrous sulfates, have the same protective effect as zinc, but the volume required makes their application impractical. Supplementing cows with up to 1.44 g zinc per day (equivalent to 3.6 mg of zinc per kilogram bodyweight per day) in a zinc amino acid complex was not effective in preventing pithomyctotoxicosis.

Finnish Landrace sheep are significantly more resistant to *P. chartarum* poisoning than Romneys, with crossbreeds in an intermediate position. Resistance to sporesdmin is strongly inherited (heritability estimate 0.45), but flocks containing increased numbers of resistant animals do not have superior productivity. Eight putative resistance loci have been identified on different chromosomes. A diagnostic DNA test has been developed for use in sheep with an accuracy of 0.38 for identifying pithomyctotoxicosis resistance. The test accuracy is much lower than that provided by a commercially available artificial challenge test (Ramguard), in which the ram is orally dosed with sporesdmin and the serum GGT activity measured 21 days later. Attempted vaccination against sporesdmin has not been successful in protecting sheep against pithomyctotoxicosis.

**Rubratoxin Toxicosis**

*R. rubrum* and *P. purpurogenum* produce rubratoxins suspected of causing hepatic and hemorrhagic diseases. Rubratoxin administered experimentally to calves has produced mild liver damage. Naturally occurring cases of *P. purpurogenum* poisoning in horses fed cornmeal and cottonseed cake are associated with an acute illness. Clinical signs include anorexia; depression; vomitting; profuse, foul-smelling, bloody diarrhea; recumbency on day 4 or 5; and terminal convulsions. Necropsy lesions include icterus, liver damage, and severe hemorrhagic enteritis.

**Miscellaneous Fungi Causing Hepatic Damage (Unidentified Toxin)**

*Helminthosporium ravenelii* growing on esparto grass is credited with producing a syndrome of excitement, dyspnea, tachycardia, hypersalivation, tremor, jaundice, and some deaths in Argentinian cattle. *Drechslera campanulata* (synonym *Helminthosporium* spp.) occurs as brown-red spots on the leaves of cereal oat plants and is associated with diarrhea, milk yield reduction, and death in some cows. Similar syndromes are found in sheep and goats, except that photosensitivity is also apparent in goats. At necropsy there is ulceration of the forestomach mucosa.

A fungus, *Periconia* spp., which grows on forage in the field, is suspected of being associated with hepatic damage and photosensitization in cattle in the southern United States. There is a close resemblance in clinical signs and circumstances of occurrence to myrotheciosis (*Myrothecium* genus).

**SAWFLY LARVAE (LOPHYRTOMIN AND PERGIDIN) TOXICOSIS**

**ETIOLOGY**

Ingestion of larvae of the sawflies *Lophyrtoma interrupta* (Australian sawfly) in Australia, *Arge pullata* (birch sawfly) in Denmark, and *Perreyia flavipes* in South America is associated with acute hepatotoxicosis.

**EPIDEMIOLOGY**

Large piles of larvae accumulate on the pasture under the infested trees and are eaten by cattle, sheep, goats, or pigs. Lophyrtomin is the primary toxin in Australian and Danish larvae and pergidin in the South American larvae. Sheep are more susceptible to sawfly poisoning than cattle, developing signs at 7.5 g larvae per kilogram body weight versus 40 g larvae per kilogram body weight for cattle.
CLINICAL SIGNS
The onset is very rapid and in many cases animals are just found dead. Most signs are associated with severe liver necrosis, and neurologic signs are attributed to hepatic encephalopathy. Clinically, animals may develop weakness, stupor, muscle tremors, depression or agitation, recumbency, convulsions, and death in 2 to 7 days. Less acute cases show hyposensitivity, jaundice, photosensitization, diarrhea, and dysentery.

NECROSIS LESIONS
These include periarterial or panacinar hepatic necrosis, some nephrosis, extensive hemorrhages in the alimentary tract, and fluid transudates in serous cavities in longer surviving cases.

Coal Tar Pitch Poisoning in Pigs

ETIOLOGY
Pigs may be exposed to coal tar pitch and its toxic cresols when housed in pens with tarred walls or floors, which they nibble, or when they have access at pasture to fragments of “clay pigeons” used as targets by gun clubs. Bitumen and asphalt appear to be nontoxic. Young pigs 6 to 20 weeks of age are most often affected.

CLINICAL FINDINGS
Clinical findings include an acute illness of a few days or a chronic course of some weeks. In the acute illness there are nonspecific signs of inappetence, rough coat, tuck-up abdomen, weakness, and depression. The chronic illness is characterized by anorexia, depression, weakness, anemia, and jaundice. A subclinical syndrome includes a reduction in growth rate of up to 20% to 30%, a severe reduction in hemoglobin concentration and erythrocyte count, and reduced vitamin A storage.

NECROSIS FINDINGS
These include jaundice, ascites, and anemia, but the characteristic finding is a red and yellow mottling of the hepatic surfaces, and histologically a hepatic lesion of severe centrilobular necrosis. Cresols can be detected in the ingesta and liver of affected pigs.

Focal Diseases of the Liver

Focal Diseases of the Liver

TUMORS OF THE LIVER
Metastatic lesions of lymphomatosis in calves are the most common neoplasms encountered in the liver of animals, although primary adenoma, adenocarcinoma, and metastases of other neoplasms in the area drained by the portal tract are not uncommon, especially in ruminants. For the most part, they produce no signs of hepatic dysfunction, but they may cause sufficient swelling to be palpable and some abdominal pain by stretching of the liver capsule. Primary tumors of the gallbladder and bile ducts also are rare and do not generally cause clinical signs. A primary hepatic fibrosarcoma in a goat has caused loss of body weight, although appetite was maintained, as well as anemia and jaundice. Hepatic biliary cystadenoma has been described in a 10-year-old horse. It is regarded as a morphologic variant of biliary cystadenoma of domestic animals.

A series of 66 primary hepatic tumors of cattle has been examined and classified using modern criteria. Fifty hepatocellular tumors (10 adenomas and 40 carcinomas), 10 cholangiocellular tumors, 2 cavernous hemangiomas, 2 hemangioendothelial sarcomas, 1 fibroma, and 1 schwannoma were diagnosed. An association with cirrhosis was not found. A bile duct hamartoma in a calf has been reported.

DISEASES OF THE BILIARY SYSTEM
Cases of biliary tract disease with clinical manifestations are uncommon in food animals and horses. Occasional cases of cholangitis occur in cattle and horses. Associated clinical signs include jaundice, photosensitization, fever, and pain over the liver. There is usually an accompanying leukocytosis. In horses a sequela to cholangitis may be a diffuse bacterial hepatitis with signs of hepatic insufficiency.

Concretions in the biliary system of cattle are usually a sequela to fascioliasis. Mild cases show anorexia and pain over the liver. Severe cases show recurrent attacks of severe abdominal pain, alimentary tract stasis, and pain on percussion over the liver. Jaundice occurs only in the terminal stages of fatal cases and is accompanied by recumbency, depression, and coma. The frequency of pigmented gallstones is high in sheep and associated with high total bilirubin concentration in the bile. Other causes of biliary tract disease include gallbladder empyema and a bile duct carcinoma. In the latter case there was severe loss of body weight and signs referable to metastases in other organs, but there were no clinical or postmortem signs of biliary malfunction. Biliary atresia in young foals is manifested by an early period of normality for 2 to 3 weeks after birth followed by the development of listlessness; anorexia; the passage of gray, pasty feces; and jaundice. Death occurs about one week later. Obstructive cholelithiasis in horses that do not have a gallbladder may cause intermittent colic or continuous pain and sometimes jaundice. Clinical findings include fever, icterus, mild intermittent colic, and weight loss. Laboratory findings include leukocytosis, hyperproteinemia, and hyperbilirubinemia. Serum activity of GGT and LDH may also be elevated.

Cholangiohepatitis in Horses
A series of nine cases was reported of cholangiohepatitis and cholelithiasis in mature horses with a median age of 13 and a range of 4 to 18 years. Clinical signs that prompted referral to a veterinary teaching hospital included anorexia, depression, weight loss, colic, intermittent fever, and icterus. In all horses, the serum activity of GGT and ALP were elevated, and there was hyperbilirubinemia. Transabdominal ultrasonography was used to evaluate the size and nature of the liver and to obtain liver biopsy for histopathology and culture. The ultrasonographic findings included increased hepatic echogenicity, hepatomegaly, enlarged distended bile ducts, and occasional calculi as the salient features. Neutrophilic cholangiohepatitis consistent with an infectious cause was a feature of biopsy material from each horse.

The etiology and pathogenesis of cholangiohepatitis and cholelithiasis in horses are uncertain. Retrograde bacterial infection from the small intestine is considered probable. Culture of liver biopsy material yielded Escherichia coli and Bacteroides vulgatus from only a small number of affected animals. Long-term parenteral antimicrobial therapy with antibiotics with a gram-negative spectrum for a median of 51 days (range 17–124) was associated with survival in 7/9 horses. Supportive intravenous fluid therapy is recommended. Progress can be monitored by evidence of clinical improvement and declining levels of GGT.

Cholangiohepatitis in a 2-month-old calf was characterized clinically by depression, fever, and diarrhea. There was marked leukocytosis and neutrophilia. The serum activity of GGT and ALP as well as the total serum bilirubin concentration were markedly elevated. Ultrasonographic examination of the liver revealed gross abnormality, and liver biopsy results indicated neutrophilic hepatitis and multifocal hyperplasia of the biliary epithelium suggesting cholangiohepatitis. Culture of liver tissue yielded E. coli.

Suppurative cholangiohepatitis and cholelithiasis associated with enteritis has been described in adult horses. Clinical findings included nonresponsive colic, fever, depression, severe abdominal pain, tachycardia, dehydration, gastric fluid accumulation, and absence of abdominal sounds over all four quadrants. Distended loops of small intestine...
were palpable on rectal examination, and the peritoneal fluid was serosanguinous. Azotemia, hyperbilirubinemia, and increased serum activity of ALP and GGT were determined and persisted for several days. Cases were associated with severe inflammation of the small intestine and hypovolemic shock.

Cholangiohepatitis and pancreatitis secondary to gastroduodenal ulceration in a 2-month-old foal was characterized clinically by colic unresponsive to surgical treatment. At necropsy, gastric ulceration, segmental duodenal stenosis, severe chronic cholangiohepatitis, and pancreatitis were present.

Choledocholithiasis attributable to a foreign body in a horse is recorded. Clinical signs suggestive of biliary disease in adult horses may be caused by neoplasia of the pancreas. A case of congenital hepatic fibrosis in a newborn calf has been reported.

**Diseases of the Pancreas**

Pancreatic disease in large animals is extremely rare and, consequently, only a few comments are offered here.

**PANCREATITIS**

Pancreatitis is rare in farm animals. Inflammatory and degenerative changes are detected postmortem in some cattle but are rarely diagnosed clinically because of a lack of clinical and laboratory findings. Ultrasonographic imaging of experimentally induced pancreatitis in cattle has been described.

**DIABETES MELLITUS**

Lesions of the pancreas resulting in diabetes mellitus, which is characterized by a lack of adequate pancreatic insulin secretion, has been described in cows, horses, and donkeys. The clinical syndrome in horses includes weight loss, polydipsia, polyuria, intense hyperlipidemia, and high plasma concentrations of cholesterol, triglycerides, and glucose. Clinical observations suggest that the disease is most likely to occur in old horses and may be caused by pancreatic injury related to migration of strongyle larvae. Diabetes mellitus resulting from pancreatic β-cell failure is rare in the horse but has been reported in a domesticated Spanish Mustang. In cows there is afebrile emaciation, polydipsia, ketonuria, glucosuria, and hyperglycemia.

**PANCREATIC ADENOMA**

Convulsions caused by hypoglycemia have been recorded in a pony with a pancreatic adenoma. It is assumed that the hypoglycemia resulted from hyperinsulinism generated by the β-cell adenoma.

**PANCREATIC ADENOCARCINOMA**

The pancreatic duct of the horse is anatomically close to the common bile duct, and it is not unexpected that a tumor mass should cause a syndrome of biliary duct pathology, although there is a surprising absence of jaundice at some stages of the disease. There is emaciation, concomitant moderate abdominal pain, and variable fecal texture up to diarrhea. Serum GGT activity and blood ammonia levels are greatly increased.
Diseases of the Cardiovascular System

Principles of Circulatory Failure

The primary function of the cardiovascular system is to ensure an adequate circulation of blood so that nutrients are delivered, waste products are removed, and a homeostatic milieu is maintained at the organ and cellular level. An inadequate circulation interferes with nutrient delivery and waste product removal, ultimately leading to circulatory failure, the primary concept in diseases of the cardiovascular system.

The two functional units of the cardiovascular system are the heart and the blood vessels; these two units are best characterized as a pump (the heart) and a circuit (the blood vessels and blood). The pump and circuit may fail independently of each other, giving rise to two forms of circulatory failure, heart failure and circuit failure. In heart failure the primary problem is inadequate pump performance, whereas in circuit failure the deficiency is in the vascular system, which fails to return an adequate volume of blood to the heart. Circuit failure can also result from decreased circulating blood volume or redistributed blood volume.

Heart Failure

The failure of the heart as a pump can result from a filling defect of the heart, an abnormality in the generation or conduction of the electrical wave of depolarization, an abnormality in contractile function, excessive workload, anatomic abnormalities, or a combination of one or more abnormalities.

CAUSES OF CARDIOVASCULAR DYSFUNCTION

- Cardiac arrhythmia
- Obstructed flow
- Regurgitant flow
- Contractile dysfunction (systolic failure)
- Inadequate filling (diastolic failure)
- Anatomic abnormalities

It is usual to divide heart failure into two types, acute and chronic (congestive) heart failure. However, a complete range of syndromes occurs and some of them do not fit neatly into either category. Circulatory equilibrium is not maintained when cardiac output is deficient. If inadequate cardiac output develops sufficiently slowly, compensatory mechanisms, plus the failure of the heart itself as a pump, result in an increase in venous pressure and congestive heart failure. If, on the other hand, there is an acute reduction of cardiac output, as is caused by sudden cessation of the heartbeat, the effect is to deprive tissues of their oxygen supplies and the syndrome of acute heart failure develops.

Heart failure can be left-sided, right-sided, or both left-sided and right-sided. Left-sided heart failure causes an increase in left ventricular end-diastolic pressure, mean left atrial pressure, and pulmonary venous pressure. Depending on the magnitude and rate of the increase in pressure, left-sided heart failure results in interstitial edema in the lungs and, if severe enough, pulmonary edema, dyspnea, and death. Right-sided heart failure causes an increase in right ventricular end-diastolic pressure, mean right atrial pressure, and jugular venous pressure. Depending on the magnitude and rate of the
increase in pressure, right-sided heart failure results in symmetric venous distension (most readily detected in the jugular veins); an increase in pleural, pericardial, and abdominal fluid (ascites); and hepatomegaly.

CIRCUIT FAILURE
In circuit failure the effective blood volume is decreased because of loss of fluid from the vascular system (hypovolemic shock) or by pooling of blood in peripheral vessels and increased capillary permeability (maldistributive shock, which is commonly seen in endotoxemia). The failure of venous return results in incomplete filling of the heart and a reduction in cardiac output, although the pump performance may be normal. The effects of circuit failure are the same as those of chronic (congestive) heart failure because the supply of nutrients to the tissues and the removal of waste products from the tissues are reduced.

CARDIAC RESERVE AND COMPENSATORY MECHANISMS IN HEART FAILURE

The normal heart has the capacity to increase its output severalfold in response to normal physiologic demands created by exercise and to a lesser extent by pregnancy, lactation, digestion, and hot ambient temperatures. Collectively, these compensatory responses comprise the cardiac reserve. Similar compensatory responses are used by the failing heart in an attempt to maintain cardiac output. Cardiac reserve and its response in heart failure have not been studied extensively in large domestic animals; consequently, its description must rely heavily on studies on cardiac failure in small domestic animals and studies of the effect of exercise on cardiovascular performance in the horse. Clinical observations on cardiac insufficiency and cardiac failure in large animals suggest that the processes are very similar to those in small animals and humans.

The major mechanisms in which the blood flow to an organ can be increased are
- Increase in heart rate
- Increase in stroke volume
- Redistribution of blood flow to vital organs, or organs with particularly high metabolic requirements

All of these mechanisms act synergistically and are interrelated. Heart rate and stroke volume are the determinants of cardiac output (cardiac output is the product of heart rate and stroke volume).

CARDIAC RESERVE AND HEART RATE

There is a great deal of cardiac reserve in the heart rate, and an elevation of heart rate alone is a significant factor in increasing cardiac output in the exercising horse. There is a limitation to heart rate reserve because with increasing heart rates there is a decrease in diastolic filling time, and stroke volume falls at excessive heart rates. Effective heart rate reserve can be increased with exercise training, and maximum heart rate in trained exercising horses is six to seven times the resting value. This large increase in heart rate reflects the metabolic scope of trained horses. In contrast, cattle can only increase their heart rate to two to four times their resting values. An increase in heart rate is also used to maintain cardiac output by the failing heart. With cardiac insufficiency in the horse and the cow it is rare for the heart rate to exceed 120 beats/min at rest, and rates higher than this are frequently caused by tachyarrhythmias that require immediate treatment.

CARDIAC RESERVE AND STROKE VOLUME

Stroke volume is variable and depends on the amount of shortening that the myocardial fibers can attain when working against arterial pressure. It is determined by the interplay of four factors:
- Ventricular distending or filling pressure (preload)
- Contractility of the myocardium (inotropic state)
- The tension that the ventricular myocardium must develop during contraction and early ejection (afterload)
- The sequence of atrial and ventricular depolarization

An increase in ventricular distending pressure (end-diastolic pressure or volume) will increase ventricular end-diastolic fiber length, which, by the Frank–Starling mechanism and stretch-dependent calcium sensitization, will result in increased stroke work and a larger stroke volume. Ventricular distending pressure is influenced by atrial contraction and is greatly augmented by increased venous return associated with exercise and increased sympathetic activity. Contractility is most influenced by adrenergic activity and circulating catecholamines. An increase in stroke volume is achieved primarily by an increase in the ejection fraction and a reduction in the end-systolic volume but can also be achieved by a decrease in afterload, which is primarily a function of aortic or pulmonary impedance (the resistance and reactance of the vasculature to ejection).

CARDIAC RESERVE AND MIXED VENOUS OXYGEN TENSION

In normal animals at rest, the oxygen tension of mixed venous blood is above 40 mm Hg (5.3 kPa), which represents a considerable reserve. Increased extraction of oxygen from the blood by various tissues, with a subsequent decrease in mixed venous oxygen tension and a corresponding increase in arterial venous oxygen difference, occurs during exercise and in pump and circuit failure. In uncompensated heart failure, in which stroke volume is reduced, the mixed venous oxygen tension falls below 40 mm Hg, reaching 15 to 25 mm Hg in severe shock states, and the arterial venous oxygen difference is large. There is also a redistribution of blood flow to vital organs. In the horse the splenic storage capacity for erythrocytes is large and the spleen may contain one-third of the total red cell volume. Maximal emptying of the spleen under adrenergic activity can significantly influence the oxygen-transporting capacity of the blood, and in the horse, the splenic reservoir contributes significantly to cardiovascular reserve.

CARDIAC RESERVE AND AUTONOMIC NERVE ACTIVITY

It is evident that increased sympathetic nerve activity also plays a significant role in compensating for the failing ventricle, but one that is not readily determined clinically. An increase in sympathetic activity acts to augment cardiac output by increasing the heart rate, by improving the contractility of the myocardium, and by augmenting venous return to the heart. Autonomic nerve activity also regulates blood flow to more essential organs, even when faced with insufficient cardiac output.

CARDIAC RESERVE IN CARDIAC INSUFFICIENCY

In cardiac insufficiency the principal defect is in the contractile state of the myocardium, and ventricular performance at any given end-diastolic volume or pressure is diminished. In early failure, cardiac output may still be maintained in the normal range by an increase in filling pressure and, through utilization of stretch-dependent calcium sensitization and the Frank–Starling principle, the ventricles can eject a normal stroke volume despite the depression in contractility. Thus early in the course of cardiac failure, the end-diastolic pressure may be elevated only during periods with heavy demands on the heart, such as during exercise. However, as myocardial function becomes increasingly impaired, this mechanism is increasingly used for lesser work demands until end-diastolic pressure is elevated even at rest or with normal activity.

Ventricular filling pressure is augmented by increased venous return associated with contraction of the venous capacitance vessels under increased sympathetic tone, and by an increase in blood volume as the result of salt and water retention by the kidney. Decreased renal perfusion results in the release of renin by the juxtaglomerular cells in the kidney and the activation of the renin-angiotensin-aldosterone system. Renin causes the conversion of angiotensinogen to angiotensin I, and angiotensin I in turn is converted to angiotensin II in the lungs. Angiotensin II is a powerful vasoconstrictor that promotes the effect of norepinephrine. Angiotensin II also stimulates the release of aldosterone from the adrenal cortex, which acts to increase
sodium retention by the kidney with consequent expansion of the interstitial fluid and blood volumes.

Although the increase in ventricular end-diastolic pressure acts to maintain cardiac output, it is associated with a marked increase in systemic or pulmonary venous pressure, producing secondary effects that result in many of the clinical abnormalities associated with congestive heart failure. Where the contractile state of the heart is markedly reduced, the increased end-diastolic pressure is unable to maintain normal stroke volume, even at normal activity, and cardiac output is reduced even at rest—the state of uncompensated heart failure, which is clinically manifested as pump failure.

**MEASUREMENT OF CARDIAC RESERVE**

From a clinical standpoint it would be desirable to be able to detect incipient cardiac insufficiency at a very early stage. A clinical estimation of cardiac reserve based on physical examination is important when a prognosis is to be made for an animal with heart disease. Some of the important criteria used in making this assessment include the heart rate, the intensity of the heart sounds, the size of the heart, the characteristics of the pulse, and the tolerance of the animal to exercise. A resting heart rate above normal indicates loss of cardiac reserve. The absolute intensity of the heart sounds suggests the strength of the ventricular contraction, soft sounds suggesting weak contractions, and sounds that are louder than normal suggesting cardiac dilatation and possibly hypertrophy, although this is a very crude and insensitive measure. The interpretation of variation in intensity must be modified by recognition of other factors, such as pleural and pericardial effusion, that interfere with audibility of the heart sounds.

Pulse characteristics are of value in determining the cardiac reserve, but they are greatly affected by factors other than cardiac activity. An increased pulse amplitude occurs when the cardiac stroke volume is increased, but a decreased pulse amplitude may result from reduced venous return as well as from reduced contractile power of cardiac muscle.

Exercise tolerance is an excellent guide to cardiac reserve and the least expensive and most practical method for quantifying cardiovascular reserve. Exercise tolerance is best assessed by measuring the maximum heart rate attained after a standard exercise test, and the time required for the heart rate to return to normal.

**CARDIAC ENLARGEMENT**

The ratio of heart weight to body weight (BW) is greater in athletic animals than in nonathletic animals, and the heart:weight ratio in horses can be modestly increased during training as a result of physiologic hypertrophy. Cardiac enlargement is also a compensatory response to persistent increased workloads that are associated with cardiovascular disease. The heart may respond by dilatation, hypertrophy, or a combination of both; with endurance training there is both cardiac hypertrophy and cardiac enlargement.¹

Cardiac hypertrophy (concentric hypertrophy) is the usual response to an increased pressure load, and there is hypertrophy of individual fibers with an increase in the number of contractile units (sarcomeres) and an increase in total muscle mass.² However, cardiac hypertrophy is usually accompanied by decreased capillary density and increased intercapillary distance and, in states of cardiac insufficiency, coronary blood flow reserve places limitations on this compensatory mechanism.

Cardiac dilatation (eccentric hypertrophy) is the usual response to an increased volume load and probably results from fiber rearrangement. Contractions occurring in a dilated chamber can eject a larger volume of blood per unit of myocardial shortening. However, the limitation to this compensatory mechanism is evident in the law of Laplace, which shows that in the dilated chamber greater myocardial wall tension is required to produce an equivalent elevation of intrachamber pressure during ejection.

The significance of finding cardiac enlargement on clinical examination is that it indicates the presence of a significant volume or flow load on the heart, or the presence of myocardial disease and a reduction of cardiac reserve. The detection of cardiac enlargement on physical examination is aided by careful auscultation of the heart and palpation of the apex beat. Cardiac size can be accurately detected by thoracic percussion in the horse, and percussion is an underutilized part of the routine physical examination.³ A palpable and audible increase in the apex beat and area of audibility, backward displacement of the apex beat, increased visibility of the cardiac impulse at the base of the neck and behind the elbow, and increased area for the cardiac shadow during thoracic percussion are all suggestive of cardiac enlargement. Care must be taken that the abnormalities observed are not caused by displacement of the heart by a space-occupying lesion of the thorax, such as thymic lymphosarcoma, or to collapse of the ventral part of the lung and withdrawal of lung tissue from the costal aspects of the heart. Echocardiography should be used to quantify the magnitude of the enlargement whenever the results of physical examination suspect the presence of cardiac enlargement.¹

**REFERENCES**

**SYNOPSIS**

**ETIOLOGY**

Diseases of the endocardium, myocardium, and pericardium that interfere with the flow of blood into or away from the heart, or that impair myocardial function, may result in congestive heart failure.

**Clinical findings**

Generalized venous distension and edema in right-sided failure; pulmonary edema and respiratory distress in left-sided failure.

**Clinical pathology**

Increased plasma or serum concentration of cardiac troponin I, a cardiac-specific enzyme.

**Necropsy findings**

Subcutaneous edema, ascites, hydrothorax, and hydropericardium; enlargement and engorgement of the liver with right-sided failure; pulmonary edema with left-sided failure.

**Diagnostic confirmation**

Clinical

**Treatment**

Treatment of specific cause, often unsuccessful; diuretics, salt restriction, minimize activity, possibly digoxin.

**MANIFESTATIONS OF CIRCULATORY FAILURE**

The manifestations of circulatory failure depend on the rapidity of its onset, the magnitude of its severity, and the length of its duration. Chronic (congestive) heart failure and acute heart failure are discussed in the following sections.

**CHRONIC (CONGESTIVE) HEART FAILURE**

**ETIOLOGY**

Causes of chronic (congestive) heart failure can be broadly characterized as follows.

**Valvular Disease**

- Endocarditis resulting in either valvular stenosis or valvular insufficiency
- Congenital valvular defects, most commonly valvular stenosis
- Rupture of valve or valve chordae

**Myocardial Disease**

- Myocarditis: bacterial, viral, parasitic, or toxic
- Myocardial degeneration: nutritional or toxic
- Congenital or hereditary cardiomyopathy
- Toxins affecting cardiac conduction

**Congenital Anatomic Defects Producing Shunts**

- Cardiac defects, such as ventricular or atrial septal defects, tetralogy of Fallot
- Vascular abnormalities producing shunts, such as patent ductus arteriosus
Hypertension
- Pulmonary hypertension: high altitude disease, cor pulmonale
- Systemic hypertension: undocumented cause of congestive heart failure in large animals

Pressure Load
Pressure loads occur with lesions that produce an obstruction to outflow, such as aortic or pulmonary valve stenosis, during which the heart is required to perform more work to eject an equivalent amount of blood. Pressure loads are not necessarily associated with lesions in the heart. For example, pulmonary hypertension, such as occurs in high altitude disease of cattle because of an increase in pulmonary vascular resistance, may result in cardiac insufficiency. Generally, the left ventricle can tolerate a pressure load to a much greater extent than the right ventricle without overt signs of cardiac insufficiency.

Volume Load
Volume loads (flow loads) are common with both acquired and congenital heart defects. In aortic valve and mitral valve insufficiency the volume of blood delivered to the tissues does not differ significantly from normal. However, to achieve a normal cardiac output, the forward stroke volume of the ventricle is markedly increased and the heart is much more inefficient for the same amount of effective work. In a similar manner a patent ductus arteriosus or an interventricular septal defect with a large left-to-right shunt of blood can place a considerable flow load on the left ventricle. Generally, the right ventricle is more capable of sustaining a flow load than the left ventricle.

Pumping Defects (Systolic Failure)
Cardiac insufficiency may occur without any increase in workload if there is a primary weakness in the myocardium or defect in its rhythmic and coordinated contraction. Myocarditis, cardiomyopathy, and neoplasms of the heart, especially bovine viral leukosis lesions of the right atrium, are common causes. Arrhythmias are a rare cause of congestive heart failure but a common cause of acute heart failure.

Filling Defects (Diastolic Failure)
Pericardial diseases such as pericarditis and pericardial tamponade can result in cardiac insufficiency by interfering with diastolic filling. Filling of the ventricle is determined by the complex interaction of a number of factors, including mean circulatory filling pressure, mean right atrial pressure, stiffness of the ventricular chamber (which is determined, in part, by mean arterial blood pressure), and the pressure gradient across the ventricular wall. The latter is markedly affected by increases in pericardial fluid pressure that are present in pericarditis and pericardial tamponade.

PATHOGENESIS
Cardiac reserve and compensatory mechanisms in heart failure were described in the preceding section. In the early stages of cardiac disease circulatory equilibrium may be maintained. However, cardiac reserve is reduced and the animal is not able to cope with circulatory emergencies as well as a normal animal. This is the stage of waning cardiac reserve in which the animal is comparatively normal at rest but is incapable of performing exercise (the phase of poor exercise tolerance) or responding appropriately to a physiologic stressor such as late gestation or being housed in hot ambient temperatures. Congestive heart failure develops when these compensatory mechanisms reach their physiologic limit and the heart is unable to cope with the circulatory requirement at rest.

Failure may manifest as primarily being right-sided, left-sided, or both left-sided and right-sided. Many of the clinical signs that appear during the development of cardiac insufficiency, as well as those associated with decompensated heart failure, are the consequence of congestion or edema caused by increased venous hydrostatic pressure. A decreased cardiac output also contributes to the clinical signs by the production of tissue hypoxia.

Right-Sided Congestive Heart Failure
Venous congestion is manifested in the systemic circulation. The increase in mean right atrial pressure increases the mean capillary pressure, and the net force for filtration of fluid across the capillary bed is therefore greatly increased. This results in the production of edema in dependent subcutaneous body areas and in body cavities. In the kidneys the increase in hydrostatic pressure is offset by the reduced flow of blood and urine output is reduced. The increased back pressure to the glomeruli causes increased permeability and escape of plasma protein into the urine. Venous congestion in the portal system is an inevitable sequel of hepatic congestion and is accompanied by impaired digestion and absorption and terminally by diarrhea.

Left-Sided Congestive Heart Failure
Increased pulmonary venous pressure causes venous congestion, decreased compliance of the lung and an increase in respiratory rate, an increase in the work of breathing, and exercise intolerance. Similarly, bronchial capillary congestion and edema result in encroachment on airways and a decrease in ventilatory efficiency. When venous hydrostatic pressure is exceptionally high, the net force for filtration of fluid across the pulmonary capillary bed is greatly increased. This can result in pulmonary edema, with the presence of fluid around the septal vessels and in the alveolar spaces accompanied by marked impairment of gas exchange. The development of clinically detectable pulmonary edema depends to some extent on the rapidity of the onset of cardiac failure. In chronic failure syndromes, the development of a capacious lymphatic drainage system limits the occurrence of clinical pulmonary edema and, in large animals, pulmonary edema is usually limited to acute heart failure when there is a relatively sudden onset of volume load on the left ventricle.

CLINICAL FINDINGS
The specific findings on auscultation and other examinations were described earlier. In the very early stages when cardiac reserve is reduced but decompensation has not yet occurred, there is respiratory distress on light exertion. The time required for return to the normal respiratory and pulse rates is prolonged. In affected animals there may be evidence of cardiac enlargement and the resting heart rate is moderately increased. There may be a loss of BW. Clinical signs of heart failure are predominantly right-sided in large animals, with the exception of heart failure caused by mitral valve disease in horses and pulmonary edema in pigs caused by fumonisin mycotoxicosis.

Right-Sided Congestive Heart Failure
In right-sided congestive heart failure the heart rate is almost always increased and there is venous distension and subcutaneous edema. The superficial veins are engorged and this is most easily detected by the presence of bilateral jugular vein distension. In ruminants there is subcutaneous edema occurring primarily in the brisket region (brisket edema) and less frequently under the jaw (submandibular edema) and along the ventral midline (Fig. 10-1 A and B). In advanced cases ascites is present and can occasionally be detected by the presence of an abdominal fluid wave on ballottement with palpation, the presence of excess abdominal fluid on palpation per rectum, and in rare cases by the presence of abdominal distension with a pear-shaped abdomen. Ascites needs to be differentiated from other causes of abdominal distension, and the detection by palpation per rectum of viscera floating in a fluid medium and the presence of a fluid wave on abdominal ballottement are highly suggestive of ascites. Care must be taken to differentiate ascites from uroabdomen and hydrops conditions of the uterus. Hydrothorax and hydropericardium may also be clinically detected in animals with ascites. Noncardiac causes for ascites, such as abdominal mesothelioma or caudal vena caval thrombosis that interfere with removal of peritoneal fluid, need to be ruled out.1

In horses, edema is initially more prominent in the pectoral region between the front...
limbs, the ventral abdominal wall, the prepuce, and the limbs. Ruminants and camels do not get edema in their legs in right-sided heart failure because their comparatively thicker skin acts as an antigravity suit (G suit), minimizing the extent of hydrostatic pooling of blood in the limbs.

The liver is enlarged, and, in cattle, may be palpable, protruding beyond the right costal arch with a thickened and rounded edge. In both horses and cattle liver enlargement may be detected by ultrasound examination. The respiration is deeper than normal and the rate may be slightly increased. Urine flow is usually reduced and the urine is concentrated and contains a small amount of protein. The feces are usually normal at first, but in the late stages diarrhea may be evident. BW may increase because of edema, but the appetite is poor and condition is lost rapidly. Epistaxis may occur in the horse but is rare in other species. The attitude and behavior of the animal is one of listlessness and depression; exercise is undertaken reluctantly and the gait is shuffling and staggery through weakness.

Left-Sided Congestive Heart Failure
The heart rate is increased and there is an increase in the rate and depth of respiration at rest with cough, the presence of crackles (discontinuous sounds) at the base of the lungs, and increased dullness on percussion of the ventral borders of the lungs. Terminally there is severe dyspnea and cyanosis. A "cardiac" cough associated with pulmonary edema formation is rarely observed in large animals, with reports confined to horses with mitral valve regurgitation.

The prognosis in congestive heart failure varies to a certain extent with the cause, but in most cases in large animals it is poor to grave. The possibility of recovery exists with an arrhythmia, pericardial tamponade, or pericarditis, but when the epicardium, myocardium, or endocardium is involved, complete recovery rarely if ever occurs, although the animal may survive with a permanently reduced cardiac reserve. Uncomplicated defects of rhythm are common in the horse, and these defects are more compatible with life than are extensive anatomic lesions.

CLINICAL PATHOLOGY
Clinicopathologic examinations are usually of value only when differentiating the causes of congestive heart failure and in differentiating it from other diseases. Aspiration of fluid from accumulations in any of the cavities may be thought necessary if the origin of the fluid is in doubt. The fluid is an edematous transudate except in pericardial tamponade (serosanguinous) or pericarditis (effusion), when it may be septic or nonseptic. In most cases protein is present in large amounts because of leakage of plasma from damaged capillary walls. Proteinuria is often present because of pressure-induced damage to the glomerulus. The serum or plasma concentration of cardiac troponin I (cTnI) provides an excellent cardiac biomarker in large animals, providing a sensitive and persistent indicator of myocardial injury.

NECROPSY FINDINGS
On necropsy, lesions characteristic of the specific cause are present and may comprise abnormalities of the endocardium, myocardium, pericardium, lungs, or large vessels. Space-occupying lesions of the thorax may constrict the cranial vena cava and interfer e with venous return. The lesions that occur in all cases of congestive heart failure, irrespective of cause, are pulmonary congestion and edema (if the failure is left-sided) and anasarca, ascites, hydrothorax and hydropericardium, and enlargement and engorgement of the liver with a "nutmeg" pattern of congested red centers of liver lobules surrounded by paler fatty peripheral regions (if the failure is right-sided). It is important to characterize the heart failure as being left-sided, right-sided, or both left-sided and right-sided at necropsy, because this information will help prioritize the likely cause.

DIFFERENTIAL DIAGNOSIS
- Causes of edema
- Causes of dyspnea

TREATMENT
The treatment of animals with clinical signs of congestive heart failure caused by pericarditis or pericardial tamponade focuses on removing the pericardial fluid and preventing its return. In animals with pump failure, the treatment of congestive heart failure initially focuses on the reduction of the effects of increased preload by administering diuretic agents, angiotensin-converting enzyme (ACE) inhibitors, and restricting sodium intake, reducing the demands on cardiac output by restricting activity, and improving contractility by the administration of positive inotropic agents such as cardiac glycosides and dobutamine.

Diuretics
Diuretic treatment (furosemide, acetazolamide, or chlorothiazide) is an important component of treatment because it mobilizes and eliminates excess body fluids. Furosemide is most often used because it is the most potent diuretic available, is inexpensive, and pharmacokinetic parameters have been determined for large animals. Furosemide should be administered at an initial intravenous (IV) dose of 0.25 to 1 mg/kg for horses and 2.5 to 5 mg/kg for cattle for the treatment of congestive heart failure. Multiple doses of furosemide will induce a hypokalemic, hypochloremic metabolic alkalosis, so it is important to monitor serum potassium and chloride concentrations during treatment. Access to free salt should be stopped, although it is usually impractical to formulate a salt-restricted diet.

Angiotensin-Converting Enzyme Inhibitors
ACE inhibitors have been recommended widely for the treatment of congestive heart disease caused by valvular dysfunction in...
horses, but efficacy data is lacking. Theoretically, ACE inhibitors should be beneficial in addressing the activation of the renin-angiotensin-aldosterone system that results in sodium and fluid retention and vasoconstriction. Single oral doses of benazepril (0.5 mg/kg) was a more effective ACE inhibitor in healthy adult horses than single oral doses of ramipril (0.3 mg/kg), quinapril (0.25 mg/kg), or perindopril (0.1 mg/kg). A daily dosage protocol for benazepril has not been developed. Enalapril has low oral bioavailability and has not been formally evaluated in the horse.

**Stall Rest**
Stall rest in a thermoneutral environment is also an important treatment requirement. Parturition may be electively induced in late gestation to prevent in utero fetal hypoxia and abortion as well as to decrease the additional demand placed by placental blood flow on the cardiac output.

**Positive Inotropic Agents (Dobutamine, Calcium, Cardiac Glycosides)**

**Dobutamine** is a synthetic catecholamine and is the most commonly used positive inotropic agent in horses, particularly in anesthetized horses in which short-term cardiovascular support is required. At low IV doses (1 µg/kg/min) the major change is a small increase in mean arterial blood pressure. At intermediate IV doses (2.5–7.5 µg/kg/min) the major effect of dobutamine is increased cardiac contractility, and this should be the target dose range for animals needing inotropic support. Other sympathomimetics have been used in large animals (such as adrenaline, dopamine, dopexamine, and ephedrine) but none have the triple attractiveness of efficacy, minimal proarrhythmic activity, and safety that dobutamine possesses.

**Calcium gluconate**, calcium borogluconate, and calcium chloride provide a low-cost, widely available dose-dependent IV positive inotropic agent that has been used in conscious and anesthetized large animals. The major disadvantage of IV calcium as an inotropic agent is a dose-dependent increase in left ventricular end-diastolic pressure that may predispose to acute left-sided heart failure.

**Digoxin** is the most commonly used cardiac glycoside. In horses it can be administered either intravenously or orally, but in ruminants it must be given intravenously or orally after induction of esophageal groove closure because digoxin is destroyed in the rumen. Digoxin should not be given intramuscularly in any species because it causes severe muscular necrosis. This is also reflected in erratic plasma digoxin concentrations following intramuscular administration. Treatment with digoxin results in an increase in cardiac contractility and a decrease in heart rate with increased myocardial oxygen consumption, increased cardiac output, and a decrease in cardiac size. The improvement in cardiac output promotes diuresis and the reduction and elimination of edema.

The half-life of digoxin in the horse is 17 to 23 hours and a plasma therapeutic range for digoxin of 0.5 to 2.0 ng/mL has been suggested. Pharmacokinetic studies suggest that therapeutic but nontoxic plasma concentrations of digoxin in the horse will be achieved by an initial IV loading dose of 0.01 to 0.015 mg/kg BW followed by a maintenance IV dose of 0.005 to 0.0075 mg/kg BW every 24 hours. In horses the bioavailability of powdered digoxin given orally is low, being less than 20% of the administered dose. An oral loading dose of 0.07 mg/kg, followed by a daily oral maintenance dose of 0.035 mg/kg is suggested by pharmacokinetic studies. The half-life of digoxin in cattle is 5.5 to 7.2 hours, requiring more frequent dosing than in horses, and an initial IV loading dose of 0.022 mg/kg BW followed by 0.0034 mg/kg BW every 4 hours has been suggested. An alternative is to give digoxin as a continual infusion at 0.86 (µg/kg BW)/hour. There is no established dose for digoxin administration in sheep, but the half-life is similar to that in cattle.

No dosing regimen is absolute, and the dose may need adjustment based on clinical response, evidence of toxicity, or by measuring the plasma digoxin concentration. Dose rates other than those given earlier have been used successfully. Toxicity with digoxin treatment is reported and may occur because the clearance of digoxin in some animals with congestive heart failure differs from that of normal animals on which the suggested doses have been based.

If treated animals are not eating, the daily oral administration of KCl (cattle 100 g, horses 30 g) is recommended as well as monitoring serum potassium concentrations, because the toxic effects of digoxin are affected by the serum potassium concentration. Because of the necessity for frequent dosing in cattle and the ineffectiveness of oral treatment, digoxin therapy has major limitations in ruminants, especially since the primary pathology that leads to congestive heart failure in cattle is usually not correctable. Unless myocardial damage is transient, administration of the digoxin in all species will probably have to be continued for life, and this is rarely practical. Calcium sensitizing agents could theoretically be beneficial in providing long-term positive inotropic support, but clinical studies are not available.

**REFERENCES**

**ACUTE HEART FAILURE**

**ETIOLOGY**
Acute heart failure can occur when there is a severe defect in filling; when there is failure of the heart as a pump, caused by severe tachycardia, bradycardia, or arrhythmia; and where there is a sudden increase in workload. The sudden occurrence of tachyarrhythmias in association with excitement that is severe enough to cause acute heart failure presumably results from the exacerbating influence of catecholamines. These are released in association with episodes of excitement and act to heighten the discharge potential of ectopic excitatory foci associated with myocardial disease.

**SYNOPSIS**

**Etiology** Sudden onset of a severe arrhythmia, rupture of a heart valve or vessel, pericardial tamponade

**Clinical findings** Sudden loss of consciousness, falling with or without convulsions, severe pallor of the mucosae and either death or complete recovery from the episode

**Clinical pathology** Increased serum cardiac troponin I concentrations, but clinical course usually too short for examination

**Diagnostic confirmation** Clinical

**Necropsy findings** Pulmonary congestion and edema; findings related to specific cause

**Treatment** Treatment of specific cause, often unsuccessful

Acute heart failure can also occur in the absence of primary cardiac disease under the influence of pharmacologic agents that affect cardiac conduction. These are associated with the ingestion of certain poisonous plants.

The many causes of acute heart failure are listed in greater detail later. Some examples are as follows:

**Disorders of filling**
• Pericardial tamponade: atrial and ventricular rupture
• Aortic and pulmonary artery rupture
• Tachyarrhythmia
• Myocarditis, e.g., encephalomyocarditis virus, foot-and-mouth disease
• Nutritional deficiency myopathy, e.g., copper or selenium deficiency
• Plant poisoning, e.g., Phalatris spp., white snake root
• Electrocut and lightning strike

Bradycardia
• Iatrogenic, e.g., IV calcium gluconate or borogluconate administration, xylazine, tolazoline, concentrated solutions of potassium chloride
• Plant poisoning, e.g., Taxus spp.

Increase in workload
• Rupture of aortic valve
• Acute anaphylaxis

Arrhythmias and cardiac arrest may occur during the induction of anesthesia with barbiturates in the horse and may also occur without premonitory signs in horses under halothane anesthesia.

PATHOGENESIS
With excessive tachycardia the diastolic period is so short that filling of the ventricles is impaired and cardiac output is grossly reduced. In ventricular fibrillation no co-ordinated contractions occur and no blood is ejected from the heart. The cardiac output is also seriously reduced when the heart rate slows to beyond a critical point because cardiac output is the product of heart rate and stroke volume and stroke volume cannot be markedly increased. In all these circumstances there is a precipitous fall in cardiac output and a severe degree of tissue ischemia. In peracute cases the most sensitive organ, the brain, is affected first, and the clinical signs are principally neurologic. Pallor is also a prominent sign in acute heart failure because of the reduction in blood flow.

In less acute cases respiratory distress is more obvious because of pulmonary edema and, although these can be classified as acute heart failure, they are more accurately described as acute congestive heart failure.

CLINICAL FINDINGS
The acute syndrome may occur while the animal is at rest but is most common during periods of excitement or activity. The animal usually shows dyspnea, staggering, and falling, and death often follows within seconds or minutes of the first appearance of signs. There is marked pallor of the mucosae. Although clonic convulsions may occur, they are never severe and consist mainly of sporadic incoordinated movements of the limbs. Death is usually preceded by deep, asphyxial gasps. If there is time for physical examination, weakness or absence of a palpable pulse and bradycardia, tachycardia, or absence of heart sounds are observed. The specific findings in the heart and vascular system depend on the arrhythmia and are detailed later in this chapter.

Horses with sudden onset of tachyarrhythmias caused by atrial fibrillation or multiple ventricular extrasystoles, or with rupture of the aortic or mitral valve chordae show a syndrome in which sudden onset of respiratory distress is the prominent manifestation. However, examination of the heart will allow a diagnosis of the underlying cause.

Acute heart failure is cause of death in a significant proportion of horses that die suddenly and unexpectedly during training or racing. The diagnosis is based primarily on the findings of significant pulmonary hemorrhage and edema, although myocardial pathology is absent in most cases. Severe arrhythmic disturbances secondary to preexisting myocardial injury and the concurrent presence of catecholamines, hyperkalemia, and metabolic acidosis are likely causes.

CLINICAL PATHOLOGY
Generally there is insufficient time available in which to conduct laboratory tests before the animal dies. The demonstration of elevated serum troponin I concentrations, a sensitive and specific marker of myocardial damage, strongly supports the presence of myocardial disease. Laboratory tests may also be used to elucidate the specific etiology.

NECROPSY FINDINGS
In typical acute cases engorgement of visceral veins may be present if the attack has lasted for a few minutes, but there may be no gross lesions characteristic of acute heart failure. Microscopic examination may show evidence of pulmonary congestion and early pulmonary edema. In more prolonged cases, venous engorgement with pulmonary congestion and edema are evident along with hydrothorax, but these are more accurately described as acute congestive heart failure. The primary cause may be evidenced by macroscopic or microscopic lesions of the myocardium. Animals dying from electrocution have visible hemorrhages in the epicardium and endocardium that are more numerous and larger in size than those typically seen in animals that are slaughtered. Electrocuted animals also have histologic evidence of myocardial hemorrhage and fragmentation of myocardial cells.

DIFFERENTIAL DIAGNOSIS
Acute heart failure should always be a major consideration as a cause of sudden and unexpected death in large animals, especially when death is associated with exertion or excitement. Acute heart failure may be mistaken for primary disease of the nervous system but is characterized by excessive bradycardia or tachycardia, pallor of mucosae, weakness or absence of the pulse, and mild convulsions. Epilepsy and narcolepsy are usually transient and repetitive and have a characteristic pattern of development.

TREATMENT
Treatment of acute heart failure is not usually possible or practical in large animals because of the short course of the disease. Deaths caused by sudden cardiac arrest or ventricular fibrillation while under anesthesia can be avoided to a limited extent in animals by external or internal cardiac compression or electrical conversion stimulation, but these techniques are generally restricted to sophisticated institutional surgical units. Also, the electrical energy required for defibrillation of animals larger than a sheep or goat or neonatal calf is beyond the capabilities of conventional defibrillators unless the paddles are placed directly across the pericardium or transvenous electrodes are used. Intracardiac injections of very small doses of epinephrine in conjunction with external cardiac compression by jumping up and down on the thorax with the knees can be tried, with occasional success.

REFERENCES
with closure of the mitral and tricuspid valves. The area for maximal audibility of the mitral valve in the horse is on the left fifth intercostal space, at a level midway between a horizontal line drawn through the point of the shoulder and one drawn at the sternum at the caudal edge of the triceps muscle. With cattle, sheep, goats, and swine the sound is located at a similar level but at the fourth intercostal space. The area for maximal audibility of the tricuspid valve is on the right side of the chest slightly ventral to the equivalent level for the mitral valve and at the fourth intercostal space in the horse, and at the level of the costochondral junction at the third intercostal space for the other species.

**Second Heart Sound**
The second heart sound (S2) is associated with aortic and pulmonic valve closure and is synchronous with the end of systole and the beginning of cardiac diastole. The aortic component is most audible just ventral to a horizontal line drawn through the point of the shoulder and in the left fourth intercostal space in horses and the left third in the other species. The pulmonic component is most audible ventral and anterior to the aortic valve area in the left third intercostal space in horses and the left second or third intercostal space close to the costochondral junction in other species. These two components of the second heart sound have the same temporal occurrence on auscultation, but tonal differences can frequently be detected at the two areas of maximal audibility. Splitting of the second sound in the horse can be detected on phonocardiographic examination but cannot be detected on auscultation, and there is no respiratory-associated splitting, as occurs with some other species.

**Third Heart Sound**
The third heart sound (S3) is associated with rapid filling of the ventricle in early diastole and is heard as a dull thudding sound occurring immediately after the second sound. It is usually most audible on the left side just posterior to the area of maximal audibility of the first heart sound. However, it is frequently heard over the base and also over the area of cardiac auscultation on the right side. Phonocardiographically there are two components to this heart sound, but these are not usually detectable on clinical auscultation. The third heart sound is very common in horses and can be detected in the majority of fit racing animals. It is more audible at heart rates slightly above resting normal. The third heart sound is very common in slightly excited cattle (heart rates 70–90 beats/min) but becomes much more difficult to hear when the heart rate exceeds 100 beats/min.1

**Fourth Heart Sound**
The fourth heart sound (S4) is associated with atrial contraction. It is also called the “a” sound. It occurs immediately before the first heart sound and is a soft sound most audible over the base of the heart on the left and right side. It is also common in horses but its clear separation from the first heart sound is dependent on the length of the PR interval, which varies between horses. At resting heart rates the S4 sound is detectable on clinical examination in at least 60% of horses. At heart rates <90 beats/min S4 is detectable in approximately 40% of cattle.1 The interval between the S4 and S1 frequently varies in the same horse at rest in association with variation in the PQ interval and results in a clear separation in some beats with slurring of the two sounds together in other beats. The fourth heart sound or a split S1 is also commonly heard in young cattle, but phonocardiographic studies have not been undertaken.

**Sequence of Heart Sounds**
The sequence of heart sound occurrence is thus 4-1-2-3. The intensity of the third and fourth sounds is less than that of the first and second and the complex can be described as du LUBB DUP boo. In some horses, the third or fourth sound may be inaudible so that 1-2, 4-1-2, and 1-2-3 variations occur. The name gallop rhythm is frequently applied when these extra sounds occur. Gallop rhythms also occur in cattle and may be caused by the occurrence of a fourth or third sound or to true splitting of the components of the first heart sound. In sheep, goats, and pigs only two heart sounds are normally heard. The occurrence of a third or fourth heart sound in horses and cattle is not an indication of cardiovascular abnormality, as it is in other species.

**Variation in Heart Sound Intensity**
Change in the intensity of the generation of sound by the heart or change in the transmission of the sounds between the heart and the stethoscope can result in variation in the intensity of heart sounds normally heard on auscultation.

- A decrease in the intensity of heart sound generation occurs in disease where there is poor venous return and decreased strength of cardiac contractility, such as in terminal heart failure; in hypocalcemia in cattle; or in circulatory failure in all species.

Conversely the intensity of the heart sounds may increase with anemia, cardiac hypertrophy, and metabolic diseases such as hypomagnesemia. However, the intensity of the heart sounds is most often increased by sympathetic activation as a result of exercise, fear, and excitement. Muffling of the heart sounds suggests an increase in tissue and tissue interfaces between the heart and the stethoscope. This can be caused by a shift in the heart due to displacement by a mass, changes in the pericardium (increased fluid or fibrous tissue), change in the pleural space, or increased subcutaneous fat. Heart sounds are detectable by auscultation on the left side in animals of all condition scores, but heart sounds may become inaudible on the right side in which the condition score approaches 5/5.

**Heart Rate**
The relative temporal occurrence and the intensity of the third and fourth heart sound change with the heart rate. At moderately elevated heart rates the third heart sound becomes more audible. At faster heart rates the third sound may merge and sum with the fourth sound, or the fourth sound may merge with the first sound if the PR interval decreases. During periods of a rapid change in heart rate, such as during the increase in rate that occurs following sudden noise or similar stimuli in excitable horses or the subsequent decrease in rate, the variation in the relative temporal occurrence and the intensity of the third and fourth sound coupled with the variation in intensity of the first and second sound during this change can give the impression of a gross arrhythmia. Such impressions should be ignored if they occur only during a rapid change of rate obviously induced by external influences and if there is no arrhythmia at the resting rate or the intervening stable elevated rate. Examination of the pulse during these periods of rapid change is also of value.

Variations in the intensity of the individual heart sounds or complete absence of some of them can occur in conduction disturbances and arrhythmic heart disease and can provide valuable clinical information. In several of these disturbances there is variation in the intensity of the first and third heart sounds associated with variation in the time of the preceding diastolic period and variations in diastolic filling. The intensity of the first heart sound may also vary with variations in the PR interval or where there is complete atrioventricular (AV) dissociation. In several of the arrhythmias there is absence of one or more of the heart sounds. These findings are detailed later.

**EXAMINATION OF THE ARTERIAL PULSE**
In arrhythmic heart disease the arterial pulse should be examined in more detail than that applied during routine clinical examination.

**Pulse Rate**
The pulse rate should be examined over a period to determine whether there is any sudden change in rate such as can occur with a shift in pacemaker to an irritable myocardial focus. At some stage during the examination of animals with tachyarrhythmias the heart rate and pulse rate should be taken synchronously to determine the presence of a pulse deficit (auscultation of S1 but a weak or absent S2 accompanied by a weak or absent pulse). A convenient artery for this purpose is located on the posterior medial
aspect of the radius and carpus in the horse and cow. However, the best artery to determine the pulse rate, rhythm, and amplitude is the descending aorta; this artery should be palpated during rectal examination in horses and cattle.

**Pulse Rhythm**

Pulse rhythm is carefully examined. When a "dropped pulse" or arrhythmia is detectable in the pulse, the basic underlying rhythm should be established to determine whether the heart is under regular pacemaker influence. This is best done by mentally or physically tapping out the basic rhythm of the heart and continuing this rhythm when irregularity occurs. With conditions such as second-degree heart block in which there is a basic underlying rhythm initiated by the sinoatrial (SA) node, it is possible to tap through the irregularity and reestablish synchrony with the pulse. However, in conditions such as atrial fibrillation, where there is no regular pacemaker, it is not possible to establish any basic rhythm. This examination of rhythm can alternatively be conducted by auscultation and allows an immediate categorization of the arrhythmia into one of the two basic groups: those superimposed on a regular pacemaker influence (occasionally irregular) and those in which there is no regular pacemaker (irregularly irregular).

**Amplitude**

The amplitude of the pulse should also be carefully examined. Variations in pulse amplitude are associated with those arrhythmias that produce a variation in diastolic filling period within the heart. The extreme of this is a pulse deficit (decrease in intensity or absence of a pulse associated with heart sounds).

**EXAMINATION OF THE JUGULAR VEIN**

In the normal adult horse and cow, the jugular vein will be distended with blood about 5 to 8 cm above the level of the base of the heart when the animal is standing with its head in a normal, nonfeeding alert position. There is a rapid but minor fall in the level of jugular distension associated with the fall of blood into the ventricle during the period of rapid filling in ventricular diastole followed by a slower rise in the level of jugular distension to its original point. Superimposed on this, and immediately preceding the fall, is a slow wave or retrograde distension associated with atrial contraction (a wave) and a second smaller retrograde wave ("c" wave) associated with bulging of the AV valves into the atrium during ventricular systole. These pulsations can be observed in most horses and cattle by careful observation of the jugular vein at its entrance into the thorax and can be timed in conjunction with auscultation of the heart.

Observation of the presence or absence of the atrial a wave is an aid in the clinical differentiation of first- and second-degree heart block. Cannon atrial waves occur periodically in complete heart block when atrial contractions occur against a closed AV valve. An accentuated c wave occurs with tricuspid valve insufficiency.

**PERCUSSION OF THE THORAX TO IDENTIFY THE CARDIAC DULLNESS AREA**

The size of the heart can be estimated by percussion of the thorax to identify the cardiac dullness area. Horses have absolute cardiac dullness on percussion, which means that the percussion sound is completely dull; this should be compared with relative dullness, which reflects a dull sound on percussion. The technique requires a metal percussion hammer with a soft rubber tip and a pleximeter (horn). Percussion focuses on placing the pleximeter in the intercostal space, with the hammer striking the pleximeter to generate a sound. The dimensions of absolute dullness are identified and compared with those of similarly sized horses.

Percussion was widely practiced many decades ago, but echocardiographic determination of cardiac dimensions has now replaced percussion as the preferred diagnostic method for determining relative cardiac size. This is principally because percussion can only identify the presence of a normal or enlarged heart; percussion does not provide additional information on chamber dimensions or contractile performance, which is usually provided by echocardiography.

**MEASUREMENT OF JUGULAR VEIN PRESSURE**

The jugular veins are symmetrically distended in chronic (congestive) right-sided heart failure. This distension is accompanied by an increased jugular venous pressure that can be subjectively assessed by palpation or objectively determined by measuring jugular venous pressure. This underutilized technique can be easily and rapidly performed. The equipment required is a 14- to 16-gauge needle attached to a three-way stopcock. A 20-mL syringe containing heparinized 0.9% NaCl is attached opposite the needle, and a flexible rigid wall fluid administration line is attached to the remaining port on the three-way stopcock. The stopcock is turned so that the needle is in the off position, the needle is threaded down the jugular vein toward the heart, the syringe is pushed to fill the first 10 cm of the flexible fluid line with heparinized 0.9% NaCl, and the stopcock is turned so that the syringe is in the off position. Blood will flow into the flexible tube and the vertical distance (in centimeters) between the top of the column of 0.9% NaCl supported by the jugular venous pressure and the point of the shoulder (scapulohumeral joint), which approximates the position of the right atrium, is a direct measure of jugular venous pressure.

**REFERENCES**

**MEASUREMENT OF CENTRAL VENOUS PRESSURE**

Central venous pressure (CVP) is the pressure in the great veins inside the thorax, but most often this is the pressure measured in the cranial vena cava. The measurement technique is identical to that described for jugular venous pressure, except that the catheter is sufficiently long to reach the thoracic cavity (70 cm in the adult horse), in which negative pressures can be measured (this is an index of jugular venous pressure, which can never be negative). As a consequence, CVP provides a more sensitive index of cardiac function and hydration status than jugular venous pressure and has its greatest clinical utility in monitoring for fluid overload during the rapid resuscitation of hypovolemic animals that may have depressed cardiac function, such as septicemic animals, or animals with oliguric renal insufficiency. In the healthy adult horse, CVP is normally 7 to 12 cmH₂O and decreases by 2.2 cmH₂O for every percentage point decrease in BW caused by dehydration.

Fluid resuscitation of critically ill horses uses a CVP of 8 to 12 cmH₂O as a therapeutic target (the reference range for CVP), but this target has come under criticism. In healthy adult ruminants, mean CVP is 2.3 cmH₂O in cattle, 3.4 cmH₂O in sheep, and 1.3 cmH₂O in goats. Mean CVP in three cattle with traumatic reticulopericarditis was 9 to 21 cmH₂O, and mean CVP in two calves with diarrhea and dehydration was ~3.5 to 0.7 cmH₂O. Similar values for CVP were obtained when goats and sheep were standing or placed in left lateral recumbency.

Pressure transducers can produce pressure readings that differ by up to 2 cmH₂O from that provided by a column of fluid (0.9% NaCl) in a flexible fluid line. An important technical issue when measuring CVP is that head position must be standardized (in a neutral, alert position); an elevated head decreases CVP by 2.0 cmH₂O in adult horses, and a lowered head position increased CVP by 3.7 cmH₂O. The catheter should be advanced at least 40 cm in the horse, 20 to 30 cm in sheep and goats, and 60 cm in adult cattle when the site of insertion in the jugular vein is in the midcervical region. A low-cost method for measuring CVP in the horse uses a 3.5-French, 55-cm polypropylene urinary catheter that is threaded through a 14-gauge needle placed in the jugular vein. CVP should be measured at end-expiration when intrathoracic pressure approximates atmospheric pressure.

EXERCISE TOLERANCE

Dyspnea, fatigue, and a prolonged elevation in heart rate following exercise are signs suggestive of cardiac insufficiency. Frequently, animals with suspected cardiac disease are exercised in an attempt to elicit these signs and to get an estimate of exercise tolerance. In most practice situations, the assessment of exercise tolerance is subjective. There is obviously a considerable difference in the amount of exercise that a beef bull and a trained racehorse can tolerate under normal conditions, and the amount of exercise given to any one animal is determined by the clinician’s judgment. The rate of fall in heart rate following exercise and the time required to reach resting levels depend on the severity of the exercise, even in fit horses. Heart rate falls rapidly over the first minute and then more slowly over the ensuing 10- to 15-minute period.

More objective tests have been developed for the horse, including evaluation by means of telemetry from horses timed over a measured distance on race tracks or the use of a treadmill to provide a defined amount of exercise. The amount and intensity of exercise can be varied by the speed and incline of the treadmill and by the duration of the exercise period. The treadmill allows the recording of a variety of cardiorespiratory measurements in the exercising horse and can be used for evaluating the significance of cardiopulmonary disease and for establishing the cause of poor racing performance.

There are many noncardiac causes of exercise intolerance and, in a report on the evaluation of 275 horses, 84% were found to have more than one problem leading to poor athletic performance.

Criteria for cardiovascular performance in endurance rides have been investigated and the rapidity of heart rate decline following completion of each section of the ride can be used for field assessment of this function.

Electrocardiography

The electrocardiogram (ECG) provides a record and measure of the time-varying potential difference that occurs over the surface of the body as the result of electrical activity within the heart. This is associated with depolarization and repolarization of the myocardium. At any one instant during depolarization and repolarization there are generally several fronts of electrical activity within the heart. However, at the body surface the potential difference is generally the sum of this activity and at any one instant the electrical activity in the heart registers as a single dipole vector that has polarity, magnitude, and direction.

The polarity is determined by the charge on the surface of the cells while the magnitude and direction is determined by the mass of muscle being depolarized or repolarized and the sum of the instantaneous vectors. Thus a wave of depolarization or repolarization over a muscle mass such as the atria or the ventricles is presented at the body surface as a sequence of instantaneous vectors with changing magnitude and direction.

ELECTROCARDIOGRAPH

The electrocardiogram is used to detect these characters. In simple terms it can be considered as a voltmeter consisting of two input terminals, an amplifier to allow the recording of low input signals, and a galvanometer with an attached recording device such as a heated stylus on heat-sensitive paper or an ink pen or ink squirter. When a potential difference exists across the input terminals (electrodes), current flows through the coils of the electromagnet suspended between the poles of the permanent magnet to cause a deflection of the recording pen.

The electrocardiograph can therefore detect the polarity of the cardiac electrical vectors, and by calibration of the machine and appropriate placement of electrodes on the body surface it can detect their magnitude and direction.

Calibration of most electrocardiographs is such that an input of 1 mV produces a 1-cm deflection of the recording pen. Recording speeds are generally 25 mm/s, although 50 mm/s is occasionally used. In recording an ECG, certain standard electrode positions are used for recording.

A lead is the recording or circuit between two recording points. Depending on the wiring within the electrocardiograph, the same potential difference across a lead could result in an upward or downward deflection of the recording pen.

• To allow standard recording and comparison between recordings the polarity of the electrodes for standard leads has been established by convention, and the leads are always recorded at these polarities
• The electrodes of a lead are commonly called positive or negative.

A positive electrode in a lead is one that, when electrically positive relative to the other, caused by a potential difference between them, yields an upward or positive deflection of the recording pen.

The electrodes are usually placed using alligator clips and a 70% isopropyl alcohol or gel contact. Disposable human stick-on type electrodes can be used in horses after cleaning the skin with alcohol before application of the gel; however, specific equine self-adhesive electrodes are preferred to human stick-on electrodes because they contain more gel, which improves electrode contact with the skin and a stronger glue that helps keep the electrode in place during exercise.

Clipping of the hair coat is not recommended in horses because this permits electrodes to fall off more easily during sweating. The ECG is recorded with the animal in a standing position with minimal restraint.

DEPOLARIZATION AND REPOLARIZATION

In the normal heart, depolarization and repolarization of the myocardium occurs in a definite pattern and sequence and the electrocardiography can be used to measure and time these events. Thus discharge of the SA node results in a wave of depolarization over the atria to produce a P wave in the ECG. The delay in conduction at the AV node is registered by no electrical activity at the body surface and an isoelectric PR interval on the ECG (isoelectric means zero voltage difference between the two leads). Depolarization of the ventricles occurs with several sequential fronts to produce the QRS complex, which is followed by another isoelectric period before repolarization represented by the T wave. Important durations to measure on the ECG of large animals are the P wave duration, the duration of the PR interval (which represents the start of the P wave to the start of the QRS complex), the QRS duration, and the QT interval (which represents the start of ventricular depolarization to the end of ventricular repolarization; Fig. 10-2). The QT interval is markedly dependent on heart rate and is shorter in tachycardia and longer in bradycardia. Although there is no universally accepted method to correct the QT interval for heart rate, the most widely used method to calculate a corrected QT interval (QTc) is Bazett’s method, in which QTc (in seconds) = QT/(preceding RR interval in seconds)3. Some investigators use Fridericia correction method (QTcF), in which QTcF (in seconds) = QT/(preceding RR interval in seconds)14. The ST segment represents the end of the QRS complex (ventricular depolarization) and the start of the T wave (ventricular repolarization). The ST segment is usually isoelectric (amplitude = 0 mV), but movement in the ST segment above or below the isoelectric line may reflect the presence of myocardial ischemia, and is most common in critically ill animals with tachycardia and systemic arterial hypotension.

The ECG can also be used as a screening test for electrolyte abnormalities, particularly...
**Fig. 10-2** Typical base–apex lead electrocardiogram (ECG) from a healthy Holstein-Friesian cow. The waves, segments, and intervals are identified. The morphology is similar for the base–apex lead recording of the ECG in sheep, goats, horses, and pigs. Recorded at 25 mm/s. (Reprinted with permission from DeRoth L. Can Vet J 1980;21:271-277.)

**Fig. 10-3** Typical base–apex lead electrocardiogram (ECG) from a healthy Holstein-Friesian cow. The ST peak interval is the interval between the apex of the S wave and the apex of the T wave in seconds. The SS interval is the interval between consecutive S waves in seconds. The corrected ST peak interval (STc) is calculated by dividing the ST peak interval in seconds by the square root of the SS interval in seconds. (Reprinted with permission from Itoh M, Sakurai Y, Nakajima Y, Kawamoto S. J Vet Med Sci 2016;77(12):1655-7.)

The presence of moderate to severe hyperkalemia or moderate to severe hypocalcemia. Progressive increases in plasma potassium concentration result in decreased P wave amplitude until the P wave is not visible, widened QRS duration, and a symmetric T wave (also called a “tented” T wave; both terms emphasize that ventricular repolarization becomes more homogeneous). Progressive decreases in plasma calcium concentration result in prolongation in the QT interval, which in cattle is highly correlated with the ST peak interval (the time interval between the peak of the S wave and the peak of the T-wave; Fig. 10-3).

In dogs, cats, and humans the ECG can be used to assess the cardiac rhythm and the size of the cardiac chambers. However, the order of ventricular activation in horses, cattle, sheep, and swine differs from that of humans and dogs in that ventricular depolarization is represented by only two fronts of activity. Depolarization of a large proportion of the myocardial mass in large animals is not recognized by the surface ECG. This is because the Purkinje fibers penetrate much more deeply in these species and depolarization occurs over multiple minor fronts that tend to cancel out rather than over a single front as in dogs. For this reason, the detection of chamber enlargement by vector analysis of the ECG is generally not possible in large animals. Consequently, electrocardiography is confined to a simple base–apex lead system to examine for conduction disturbances and arrhythmias, which are detected by measurement of the various waveforms and intervals in the ECG that represent depolarization and repolarization in the heart, and by observation of their absence or abnormality.

A decrease in ventricular filling is associated with decreased amplitude of the QRS complex, whereas an increase in ventricular filling causes increased amplitude of the QRS complex. The effect of ventricular volume on QRS amplitude is called the Brody effect and results from the net effect of blood in the ventricle augmenting radial electric potentials while decreasing tangential electric potentials. The Brody effect explains why QRS amplitudes are decreased in animals experiencing hemorrhagic shock.

**Lead Systems**

The base–apex lead system provides the best method for electrocardiography in large animals, with the only exception being fetal electrocardiography. All other lead systems are clinically superfluous or inferior, or have only a research application.

Traditional lead systems are based on Einthoven's triangle as used in humans, and the standard bipolar limb leads (I, II, and III).
Chapter 10  Diseases of the Cardiovascular System

The ECG signal can be recorded and stored using a small battery-powered device and a digital card that is large enough to permit 24-hour recording (Holter monitoring, which is a continuous recording of the ECG while the animal undergoes its normal activities). Commercial systems are available with computer analysis that assists in the identification of artifacts. The software programs also automatically identify each R wave and, consequently, can be used for the evaluation of heart rate variability (HRV); however, concerns have been raised about the ability of some systems to accurately measure the interbeat interval (IBI) in moving horses. Telemetered ECG tracings obtained during exercise contain motion artifacts and can be difficult to interpret, with levels of agreement between observers varying inversely with level of exercise intensity.  

### FETAL ELECTROCARDIOGRAPHY

The fetal ECG may be recorded, and can be of value in determining whether the fetus is alive, the presence of a singleton or twins, and as a monitor for fetal distress during difficult or prolonged parturition. A modified bipolar lead system is required, with the right atrial electrode placed on the right ventral abdomen and the left atrial electrode below placed on the ventral midline in front of the udder. The ground lead can be situated anywhere. The bipolar lead should be recorded using increased sensitivity with meticulous attention to obtaining the best electrical connection to the skin. The animal needs to be electrically isolated (standing on a rubber mat) and muscular activity must be minimized.  

Fetal electrocardiography has been used in cattle to monitor fetal viability, but the fetal ECG signal is very weak and suffers from interference from the maternal ECG, the electromyogram, and motion artifacts caused by gastrointestinal movement. For these reasons, the position of the bipolar recording leads on the abdomen should be moved to provide the optimal recording site for each cow. Digital processing of the fetal ECG signal can assist in detection of the fetal heart rate at more than 157 days’ gestation. Fetal heart rates for calves tend to decrease with advancing gestation, approximating 140 beats/min from 160 to 190 days of gestation and 120 beats/minute at 250 to 280 days of gestation.  

The foal’s fetal heart rate can be detected as early as day 121 of gestation and decreases logarithmically from approximately 110 beats/min at 150 days before term to 75 beats/min near to term. Continued monitoring traces may be needed to assess fetal distress, which is manifested as a decrease in HRV and bradycardia. Fetal heart rate and HRV have also been measured as an indicator of hypoxia and fetal distress during parturition in cattle. Cardiac arrhythmia is common at the time of birth and is thought to

Values are obtained from 600 healthy Holstein-Friesian female cattle aged 1 or more years (Rezaian H et al. Vet Arch 2004; 74:351), 17 healthy male and female horses aged 6 months to 8 years (P Constable, personal communication), and 467 healthy sows (Takemura N et al. J Jpn Vet Med Assoc 1988; 41:398).

The base-apex lead system is the most common system used because it records the major electrical forces in the heart of large animals with consistently clear and large-amplitude waveforms. Animal movement also has minimal effect on the quality of the ECG. The most common bipolar lead placement in horses, ruminants, and swine consists of two electrodes, one positive and one negative, in a format called the base-apex lead. The positive electrode of lead I (left arm) is attached to the skin of the left thorax in the vicinity of the apex beat at the 5th–6th intercostal space immediately caudal to the olecranon, and the negative electrode (right arm) is placed on the skin over the jugular furrow in the caudal third of the right neck. This is by far the most common lead placement, although a small number of investigators place the negative electrode on the left side of the neck instead of the right side. With sheep, where wool interferes with placement on the neck, the negative electrode can be placed on the midline of the poll. When using the base-apex lead system, the ground electrode is placed remotely from the heart, and the location of the ground is not important. Normal values for cattle, horses, and pigs are summarized in Table 10-1.

**TELEMOMETRY**

Telemetry is being increasingly used to examine whether arrhythmias are preset during exercise and the nature of the arrhythmia and their association with exercise intensity. Recording an ECG in an exercising horse is challenging because of the presence of artifacts caused by muscular activity. As a result, the base-apex lead should not be used and a different lead system is used with increased attention paid to the method of fixation of the electrodes to the skin. Usually, best results are obtained by placing ECG electrodes that contain an electrode liquid and adhesive in such a manner that they can be tightly fixed under a girth. For horses exercised on a treadmill or by lunging, the positive (green) electrode is usually placed on the thorax immediately caudal to the elbow joint (over the apex beat), and the negative (red) electrode is placed on the right side of the withers. A third (yellow) electrode is placed approximately 10 cm dorsal to the green electrode, and the reference electrode is placed anywhere under the girth. A different electrode system is needed for horses being ridden; in this case the electrodes should not be placed under the surcingle to minimize artifacts.
result from the transient physiologic hypoxemia that occurs during the birth process. Following birth and during early growth of the foal, there are age-dependent increases in the electrocardiographic intervals and changes in the orientation of the mean electrical axis.

**HEART RATE VARIABILITY**

HRV has received recent interest as a research method to evaluate the relative contributions of sympathetic and parasympathetic tone to the cardiovascular system. Consequently, HRV potentially provides insight into the degree of stress experienced by the animal and therefore has great potential in investigating interventions in animal welfare studies. HRV is assessed using time domain, frequency domain, and nonlinear indices. Interesting findings of HRV analysis are that the equine heart in healthy animals is predominantly under vagal control, and low HRV in horses with colic is associated with increased mortality.

A major drawback with HRV is that measured parameters are heavily influenced by measurement errors, particularly the presence of artifacts and loss of signal.

Time domain indices of HRV are the standard deviation of the normal-to-normal intervals (SDNNs) and the square root of the mean squared differences of successive normal-to-normal intervals (RMSSD); the latter is the best time domain index of vagal tone. These indices usually require that the ECG is recorded for minutes to hours. In comparison, an ECG record digitized at a sufficiently fast rate (at a minimum of 500–1000 Hz) and with accurately detected R waves for at least 512 beats can have sequential RR intervals undergo fast Fourier transform to at least 512 beats can have sequential RR intervals undergo fast Fourier transform to provide frequency domain indices of HRV, such as total power, low frequency power (LF, defined between 0.01 and 0.15 Hz or 0.07–0.60 Hz), and the ratio of LF to HF. Of these indices, HF power corresponds to the respiratory frequency and is positively and strongly associated with parasympathetic tone, whereas LF/HF ratio is thought to reflect changes in sympathovagal balance, whereas SDNN and RMSSD are associated with total power and HF power.

Accurate cut points for LF and HF power have yet to be identified for many large-animal species and species differences in the cut points are required based on normal respiratory rates. For instance, LF power in the pig is measured from 0.0 to 0.09 Hz and HF power from 0.09 to 2.0 Hz. HF power in adult cattle is defined as 0.20 to 0.58 Hz (equivalent to respiratory rates of 12–35 breaths/min), whereas HF power in calves is defined as 0.5 to 0.83 Hz (equivalent to a respiratory rate of 30–50 breaths/min). Recommended frequency bands for HRV interpretation in horses are LF (0.01–0.07 Hz) and HF (0.07–0.6 Hz). Many HRV studies have ignored the effect of respiratory rate on the frequency cut point for HF power and, consequently, the results of these studies are difficult to interpret.

Nonlinear analysis of HRV uses a variety of approaches. A useful graphical depiction of HRV is provided by the Poincaré plot, in which the duration of an IBI in milliseconds is plotted against the duration of the preceding IBI in milliseconds. An ellipse is then fitted along the line of identity that summarizes the variability perpendicular to the line of identity (SD1) and along the line of identity (SD2). An ellipse is then fitted along the line of identity that summarizes the variability perpendicular to the line of identity (SD1) and along the line of identity (SD2).

**Fig. 10-4 The Poincaré plot from an adult cow. The duration of an interbeat interval (IBI) in milliseconds is plotted against the duration of the preceding IBI in milliseconds. An ellipse is then fitted along the line of identity that summarizes the variability perpendicular to the line of identity (SD1) and along the line of identity (SD2). **OTHER USES OF THE ELECTROCARDIOGRAM**

- Changes in the ECG occur with some electrolyte imbalances in large-animal species.
- There is an approximately linear correlation between the heart-rate-corrected QT interval and plasma-ionized calcium concentration in cattle, with elongation of the interval in hypocalcemic and shortening in hypercalcemic states.
- Decreased amplitude and flattening of the P wave, widening of the QRS complex, and an increased symmetry and amplitude of the T wave are seen with hyperkalemia.
- Estimates of heart size of the horse have been made from measurements of the QRS duration on the ECG and the resultant heart score is used to assess potential racing performance.
- Exercise and postexercise ECGs frequently deliver information additional to that of the resting ECG and can be recorded by radiotelemetry or Holter monitoring systems.

**BIOMARKERS OF MYOCARDIAL INJURY**

The serum concentration of cTnI and cardiac troponin T (cTnT) are excellent biomarkers of myocardial injury in large animals because they provide a sensitive and specific indicator of cardiac injury. Troponins I, T, and C are myofibrillar proteins in cardiac and skeletal muscle that regulate the calcium-mediated interaction between actin and myosin, with cTnI and cTnT having different amino acid sequences at their N-terminal end compared with skeletal muscle troponin I and T. This means that an immunoassay directed at the N-terminal end of cTnI or cTnT differentiates between cardiac and skeletal muscle isoforms and therefore the site of injury. Myocardial tissue from horses, cattle, sheep, and pigs has high reactivity for cTnI and cTnT when tested using human immunonoassays, and this reactivity is selective for the myocardium, because it is more than 1000-fold higher in cardiac tissue than in skeletal muscle.

The cTnT is preferred in human medicine as a biomarker for cardiac disease because high-sensitivity methodology is available and the results are consistent between laboratories because only one manufacturer makes the analytical equipment.11 In contrast, cTnI is preferred for detecting and quantifying myocardial injury in animals because it has greater myocardial selectivity than cTnT and because qualitative point-of-care devices using a disposable cartridge are widely available that have clinical utility for the on-farm diagnosis of myocardial disease.14,15 However, results differ between different cTnI assays because the analytical methods often target different amino acids of the cTnI molecule. The magnitude of the increase in serum cTnI is associated with the severity of myocardial injury, as assessed by cardiac function indices and histopathologic changes.2 Damage to the myocardial cell membrane causes the rapid release of cytosolic troponin I into the interstitial fluid, increasing serum cTnI concentrations. Much larger amounts of cTnI are bound to structural proteins within myocardial cells, and release from this larger pool of troponin I is responsible for persistent elevation of serum cTnI concentration after acute myocardial injury. The half-life of serum cTnI in horses is 28 minutes,1 indicating that increased serum cTnI concentrations reflect the presence of ongoing or recent myocardial injury. In other words, serum cTnI concentration provides an excellent guide to the severity of myocardial damage, and serial measurement is clinically helpful in monitoring the progression of cardiac disease.2,8 Generally, healthy horses have serum cTnI concentrations below 0.04 ng/mL when more sensitive assays are used; serum cTnT concentrations are slightly increased after exercise in some horses.2 Larger increases in serum or plasma cTnI concentrations occur in horses with myocarditis, snake envenomation, cantharidin toxicosis, monosodium glutamate, histoplasmosis, and experimental induced endotoxemia.12,13 Increased serum cTnI concentration is associated with the occurrence of ventricular arrhythmias in horses, and in horses with colic it is attributed to endotoxemia, inadequate oxygen delivery, myocardial damage, and a systemic inflammatory response.14 Healthy neonatal foals have serum cTnI concentrations below 0.49 ng/mL, and slight elevations in serum cTnI occur in calves with experimentally induced endotoxemia.19 Healthy goats have serum cTnI concentrations below 0.04 ng/mL when more sensitive assays are used; serum cTnI concentrations are transiently increased at parturition but markedly increased in goats severely affected with pregnancy toxemia.20 Sheep are reported to have serum cTnI concentrations below 0.4 ng/mL, with values increasing in experimentally induced acute ruminal acidosis21 and myocardial ischemia22 and increasing fourfold during experimentally induced endotoxemia.

Serum activities of cardiac isoenzymes of creatine kinase (creatine kinase isoenzyme MB, CK-MB) and lactate dehydrogenase (LDH; isoenzymes 1 and 2) have been used in the past as indices of cardiac disease, but both are inferior as biomarkers to cTnI and are no longer recommended. Only 1.5% of the total CK activity in the equine heart is attributable to CK-MB (compared with 20% in the human heart); therefore CK-MB is an insensitive indicator of cardiac disease in the horse. Isoenzymes of LDH suffer from a similar lack of specificity for cardiac disease. Large animals with cardiac disease associated with inflammation, such as endocarditis in horses and cattle or traumatic reticulo- peritonitis in cattle, may have increases in the serum concentration of serum amyloid A and haptoglobin that reflect an acute phase response; however, the predictive ability of acute phase biomarkers to predict the presence of cardiac disease appears to be limited.21

There is no doubt that cTnI is a clinically useful biomarker of the presence of cardiac injury in large animals. However, cardiac dysfunction may result from a variety of cardiac diseases, such as valvular incompetence, congenital heart disease, or cardiomyopathy that may not have active injury. In these animals, functional biomarkers of chamber enlargement would be clinically helpful. Plasma atrial natriuretic peptide (ANP) concentration may therefore have utility as a biomarker of cardiac disease, although it is unlikely to provide similar sensitivity and specificity as a diagnostic test as cTnI. ANP is produced and released from atrial myocardial cells in response to atrial distension; increased plasma ANP concentration results in natriuresis, inhibition of the renin-angiotensin-aldosterone system, and vasodilation.22 Large animals with disturbed atria caused by incompetent valves, cardiomyopathy, or volume overload would therefore be expected to have increased plasma ANP concentrations, and this has been demonstrated in calves with congenital cardiac disease25 and horses with mitral regurgitation26 and Human immunoassays appear to be accurate for use in large animals for ANP determination because interspecies sequence homology is high. However, plasma ANP concentrations change with age, making interpretation difficult.27 In
animals with cardiac disease, plasma ANP concentration appears to be clinically valuable only in the monitoring of disease progression in adult animals with mitral valve or tricuspid valve regurgitation.

Plasma aldosterone concentration may have some utility as a biomarker of cardiac disease, although it is unlikely to provide similar sensitivity and specificity as a diagnostic test as cTnI or even ANP. Healthy warmblood horses had plasma aldosterone concentrations between 14 and 39 pg/mL, and plasma aldosterone concentrations increased in horses with enlargement of the left atrium and ventricle.27

**MEASUREMENT OF ARTERIAL BLOOD PRESSURE**

Blood pressure may be determined directly by arterial puncture and pressure measurement, but this is impractical in clinical cases. The development of simple methods for the indirect determination of arterial blood pressure has proved difficult in large animals because of the paucity of suitably located arteriae in which a pressure cuff can be applied and because there are problems in detecting pulse return by simple auscultatory or palpatory methods.

In the horse a simple and relatively inexpensive method uses oscillometric sphygmomanometry to detect arterial pulsations and therefore simultaneously determine heart rate and systolic, diastolic, and mean arterial pressure. For adult horses, the optimal cuff width for the oscillometric method is approximately 20% to 35% of the tail circumference, when the cuff is applied snugly to the base of the tail and the ventral coccygeal artery pressure is monitored. The mean tail circumference of an adult horse is 22 cm, therefore the optimal cuff width for horses is 5 to 8 cm for oscillometric pressure measurement. Because the oscillometric units were designed for use in humans, the software programs often have difficulty in measuring arterial pressure when the heart rate is less than 40 beats/min and when arrhythmias or arterial hypotension are present, which minimizes the clinical utility of these units in trained or sick horses. The units are also susceptible to motion of the tail, therefore, it is preferable to keep the tail still during recording. For foals, the oscillometric technique can be used on the tail (coccygeal artery) or the dorsal metatarsus (dorsal metatarsal artery). Other methods of indirect pressure measurement in the horse (modified auscultatory technique, ultrasonic Doppler methodology) appear less accurate than the oscillometric sphygmomanometry. Moreover, oscillometric techniques offer the advantage of providing systolic, diastolic, and mean arterial blood pressures, whereas other indirect methods do not provide mean arterial pressure.

Systolic and diastolic blood pressures of a large series of trained Thoroughbred horses were 112 ± 16 mm Hg (14.9 ± 2.1 kPa) and 77 ± 14 mm Hg (10.2 ± 1.9 kPa), respectively. Equivalent values have been recorded in other breeds. These values are coccygeal uncorrected values and can be corrected to the correct reference level (scapulohumeral joint, which is equivalent to the right atrium) by adding 0.7 mm Hg (0.09 kPa) for every centimeter in height between the scapulohumeral joint and the tail if the coccygeal artery was the recording site for indirect pressure measurement. Posture of the horse is important, because lowering the head significantly lowers systolic, diastolic, and pulse pressures.

Hypertension has been found in association with epistaxis, laminitis in horses, and painful fractures of the distal bones of the limb. Systolic blood pressure is often also elevated in obstruction of the large intestine in horses. Blood pressure measurements are of value in the assessment of the degree of shock and possibly may prove of value in the differential diagnosis of conditions such as acute salmonellosis and in assessing the prognosis of colic. Mean arterial pressure is considered the true driving pressure for blood flow and organ perfusion, therefore, determination of mean arterial pressure provides one index of perfusion. However, it is important to recognize that mean arterial pressure is poorly correlated with cardiac output.

Blood pressure readings can be obtained by equivalent techniques from the tail of cattle. However, because of anatomic differences these do not always correlate well with true blood pressure. Pressures have been observed to be 100 to 140 mm Hg (13.3–18.6 kPa) systolic and 50 to 85 mm Hg (6.7–11.3 kPa) diastolic.

**MEASUREMENT OF PULMONARY ARTERY BLOOD PRESSURE**

Pulmonary artery pressure is increased in all cattle raised in high-altitude regions (>1500 m) because of chronic alveolar hypoxia. Sustained periods of time at high altitude lead to pulmonary hypertension caused by medial hypertrophy of pulmonary arterioles and right-sided heart failure (high mountain disease). Cattle vary in their genetic susceptibility to high mountain disease and, consequently, measurement of pulmonary artery pressure of bulls intended for breeding in herds that graze at high altitude has become commonplace in parts of the United States.

To measure pulmonary artery blood pressure, bulls are restrained in a cattle chute with moderate squeeze to minimize movement. A halter is placed and the head tied level with the shoulder to expose the jugular furrow. The skin over the jugular vein is aseptically cleaned and the jugular vein occluded at the thoracic inlet. The distended jugular vein is then punctured with a 13-gauge 8-cm needle that is advanced down the jugular vein while ensuring a free flow of blood until 1 cm is protruding from the skin to permit control of the needle. A polyethylene catheter (outside diameter, 1.7 mm; length, 120 cm) filled with sterile 0.9% NaCl and attached to a three-way stopcock and connected to a pressure transducer is advanced to the right atrium, through the tricuspid valve to the right ventricle, and then through the pulmonary valve to the pulmonary artery. The location of the catheter tip is identified by the characteristic waveforms on an invasive blood pressure monitor. The mean pulmonary artery pressure measured using the scapulohumeral joint is the reference point for 0 pressure (equivalent to the right atrium in a standing animal). After pressure measurement the polyethylene catheter is removed by first pulling the needle and catheter from the neck, and once the needle is out of the animal the catheter is grasped and removed. This process minimizes the potential for severing the pulmonary catheter.1

Mean pulmonary artery pressures at 1500 to 1800, range from 34 to 44 mm Hg; cattle with pulmonary hypertension have pressures ranging from 48 to 213 mm Hg.1 When breeding stock are evaluated at more than 12
months of age at elevations >1500 m, it is preferable that pulmonary artery pressure is <41 mm Hg. When testing cattle at different altitudes, a rough rule of thumb is an additional increase in mean pulmonary artery pressure of 1 to 2 mm Hg for every 330-m increase in altitude above 1500 m. Use of pulse oximetry and blood gas analysis has been investigated in cattle for predicting mean pulmonary artery pressure, but associations were not sufficiently strong for clinical use.4

ECHOCARDIOGRAPHY
Echocardiography has provided a relatively simple and noninvasive method for the examination of the heart that can give considerable information on cardiac function and detect structural heart disease; however, it cannot reliably detect focal myocardial disease. In echocardiography, high-frequency sound waves are pulsed through tissues at known velocities. When the sound waves encounter an acoustic tissue interface, echoes are reflected back to a transducer and recorded in a number of different modalities. The modalities have become increasingly sophisticated and they have largely replaced traditional invasive evaluations of cardiac function such as cardiac catheterization. The newer technologies that accompany standard echocardiography, such as Doppler measurement of blood flow velocity, tissue Doppler imaging, and two-dimensional (2D) speckle tracking are becoming less and less expensive and high-quality portable units are now available.

Echocardiography allows the measurement of cardiac chamber size, wall thickness, global and regional wall movement, and valve structure and function. A complete echocardiographic study addresses the following: (1) presence of morphologic lesions, (2) motion abnormalities (global or regional), (3) cardiac chamber and great vessel size, (4) cardiac valve function, (5) blood flow disturbances, (6) global and regional ventricular systolic function, (7) hemodynamic measurements, and (8) ventricular diastolic function. Accomplishing this requires the application of complementary 2D, M-mode, and Doppler modalities.

Standard 2D and M-mode (motion mode) views are initially obtained from the right side of the thorax using an approximately 3-MHz transducer for adult horses and cattle and an approximately 5-MHz transducer for neonatal calves, foals, and adult sheep and goats. A small phased array (pencil-like probe) is preferred in ruminants because of the narrow intercostal space. It is also very helpful to tie a soft rope around the distal right limb and have an assistant gently move the rope and right leg forward and outward to facilitate echocardiographic examination of standing adult horses and cattle, because this makes it easier to visualize the heart. A right parasternal short-axis view at the level of the chordae tendinae (papillary muscle level) is used to determine the left ventricular internal diameter at end-diastole (LVIDd) and end-systole (LVIDs) and determine wall thickness of the left ventricular free wall and ventricular septum.1 Three right parasternal long-axis views are then used: the long-axis four-chambers view, the left ventricular outflow tract view, and the right ventricular outflow tract view. Different formula can be used to calculate left ventricular volumes at end-diastole and end-systole and ejection fraction from echocardiographic measurements. Left ventricular fractional shortening (FS) is calculated as:

\[ FS = \frac{LVIDd - LVIDs}{LVIDd} \times 100% \]

FS ranges in healthy adult horses from 28% to 50%.2 Volumetric measurements and Doppler measurement of right ventricular outflow tract velocity may have clinical utility for the noninvasive measurement of cardiac output in horses; however, pulsed-wave Doppler is difficult to perform because of the need to have the ultrasound beam parallel to the blood flow and the small cardiac window for echocardiography.3 A new technique has been developed for ultrasonographic measurement of the right ventricle of the adult horse that offers promise in detecting the presence of right ventricular dysfunction.4 An M-mode short-axis view of the aorta is obtained to calculate left ventricular ejection time from the time interval between opening and closure of the aortic valve; a value >338 ms is normal for healthy adult horses.5 All these echocardiographic indices are load-dependent measures of cardiac function.

Quantitative studies are available for the horse,1 sheep, pigs, and cattle. Measurements of cardiac and individual chamber dimensions, vessel diameters, and flow rates can be used to assess normality, indexes of contractility, and effects of cardiac lesions on cardiac response and function. They can also be used to predict the type of lesion likely to result in these changes.

Valvular defects and endocarditis may be diagnosed by imaging abnormal valve motion, incompetent valve orifices, or vegetative masses associated with the valves, and tumor masses in the heart can be detected. Similarly, the severity of valvular regurgitation can be quantified. Focal areas of myocardial echogenicity and asynchrony of ventricular wall motion is indicative of myocardial disease.6

Echocardiography can be of considerable value in the diagnosis of congenital cardiovascular defects and the injection of echo-genic materials such as microbubble-laden saline may aid in the detection of shunts. Echocardiography can also be used to determine the presence and extent of pleural and pericardial effusion. Combined IV administration of dobutamine (7.5 µg/kg/min) and atropine (5 µg/kg) has been used to cause a sustained increase in heart rate in horses to approximately 140 beats/min in an attempt to perform echocardiography on horses undergoing a pharmaco logically induced cardiac stress test.1 In the examination of the vascular system, ultrasound is capable of the early detection of iliac thrombosis in horses and is more sensitive than manual palpation per rectum.

There is a long-held belief that horses with a large heart relative to their body size have greater athletic capacity. An accurate and noninvasive method for determining heart weight therefore has potential utility as one method for predicting racing success. Echocardiography provides a useful estimate of heart weight that may complement elect rocardiographically determined heart score (calculated from the QRS duration) in the prediction of athletic performance. The thickness of the interventricular septum in diastole provides an accurate prediction of heart weight; the predictive accuracy was such that echocardiography using this measurement has utility as an index of subsequent athletic performance and has been used in North America, Europe, and Australia in such a manner. Significant cardiac enlargement has been observed in Standard-breds between 2.0 and 3.5 years of age, with echocardiographic changes characteristic for endurance trained athletes.5

Fetal Echocardiography
The fetal ECG may be recorded in late gestation using transabdominal ultrasonography and can be of value in determining whether the fetus is alive and as a monitor for fetal distress during difficult or prolonged parturition. The abdomen is clipped and ultrasonic coupling gel is applied liberally to the skin. The fetal heart is detected using a 3-MHz or 5-MHz linear-array probe; however, the technique is challenging and it may take at least 10 minutes to identify the fetal heartbeat, which must be located within 12 cm of the transducer.9

PHONOCARDIOGRAPHY

Phonocardiography allows the recording and measurement of heart sounds. A special microphone is placed directly over the various areas of the thorax used for heart auscultation, and the heart sounds are recorded graphically on moving paper or on an oscilloscope. Before recording, the heart sounds are usually passed through high-pass, low-pass, or band-pass filters to allow better discrimination of the individual sounds and to allow a crude frequency examination. 1 Phonocardiograms are usually recorded in conjunction with an ECG and chamber pressure measurements, which permit timing of their occurrence in relationship to the electrical activity within the heart.

Phonocardiograms can provide considerable information on heart sounds additional to that acquired by stethoscopic examination. In the horse, up to 11 sound events can be detected in each cardiac cycle and figures of the occurrence and duration of normal heart sounds in large animals are available. In conjunction with an ECG, the phonocardiogram can be used to measure systolic time intervals, which may be altered in congenital and acquired cardiovascular abnormalities.

Phonocardiograms have been infrequently used for the characterization and timing of murmurs in animals with cardiovascular disease, especially at fast heart rates when simple stethoscopic examination may not allow this. However, phonocardiography has been rarely used as a clinical diagnostic tool, and the widespread availability of echocardiographs make the clinical application of phonocardiography less likely in the future.

CARDIAC OUTPUT

There are several techniques available for the measurement of cardiac output, but the one almost universally applied in large animals is the indicator dilution technique using thermodilution (injection of iced 5% dextrose) or indicator dyes such as Evans blue, indocyanine green, or lithium chloride. With dye dilution, an exact amount of dye is injected into the jugular vein or pulmonary artery via a catheter and the serial collection of blood samples is performed from a suitable proximally located artery that has been cathetered. Cardiac output is most commonly measured using thermodilution but can also be calculated from a dye dilution curve by determining the mean concentration of the dye and the time taken for one circulation through the heart. Automated cardiodensitometers are also available for this estimation. Cardiac output is expressed as liters per minute and is usually corrected to cardiac index on the basis of weight or body surface area.

Most domestic animals have a cardiac index of 100 (mL/kg BW)/min at rest. The cardiac index for horses, sheep, and cattle at rest has been determined as 86 ± 13, 131 ± 39, and 113 ± 11 (mL/kg)/min, respectively. Stroke volume can also be calculated from the measured cardiac output and simultaneously determined heart rate, in which stroke volume = cardiac output/heart rate. Generally, the normal variation between animals in indexes of cardiac output is too great to allow it to be used as a diagnostic measure in individual animals suspected to have cardiac disease. Measures of cardiac output are used in experimental studies, where the effects of certain procedures can be followed within the same animal. Indicator dilution curves using dyes or thermodilution methodology can be used to detect the presence of intracardiac defects such as septal defects and to quantify their significance.

Doppler echocardiography and the direct or indirect Fick method 2 can be used to estimate cardiac output and gives values equivalent to those obtained by thermodilution techniques.

CARDIAC CATHETERIZATION

The measurement of pressure within the various chambers of the heart and in the inflow and outflow vessels can provide diagnostic information in both acquired and congenital heart disease in large animals. Generally, pressure is determined by means of fluid-filled catheters introduced into these areas and connected to an external pressure transducer. These systems are generally satisfactory for the measurement of pressure and the detection of changes with abnormality. However, because of their transmission characteristics, they are less suitable for the precise timing of pressure events, and high-fidelity catheter tip manometers should be used for this purpose.

Catheterization of the right side of the heart is a comparatively simple procedure in large animals but is not without risk to the animal. Catheterization is done in the standing position, and descriptions are available for horses and cattle. Flow-directed catheters are used and can be introduced through a needle inserted into the jugular vein.
Balloon-tipped catheters aid the flow of the catheter into the pulmonary artery. Catheterization of the left side of the heart is more complicated and performed less often. Left heart catheterization is usually performed under general anesthesia and requires the use of a stiff catheter introduced into the carotid or femoral artery by surgical methods and subsequently manipulated to the left ventricle.

The systematic determination of the pressure within each area of the heart and in the inflow and outflow vessels can allow a determination of the type of abnormality that is present. Valvular stenosis or incompetence is associated with abnormal pressure differences across the affected valve during systole or diastole. Cardiac hypertrophy is generally accompanied by an increase in pressure during systole of the affected chamber. With high-fidelity equipment, pressure waveforms can also have diagnostic value.

The right atrium is usually used as the reference point for pressure comparison and is arbitrarily assigned a reference pressure of zero when recording using a fluid-filled catheter system. The scapulohumeral joint (point of the shoulder) is taken as the anatomic equivalent reference height in the standing animal. A simultaneously recorded base–apex ECG assists in interpretation of the pressure tracings. Numerous publications have reported cardiovascular values for conscious awake horses and adult cattle and calves, and representative values are presented in Table 10-2.

During catheterization blood may be withdrawn through the catheter and subjected to blood gas analysis. In right-sided catheterization, an increase in oxygen saturation in the right ventricle or pulmonary artery can be diagnostic for the presence of a left-to-right shunt caused by an atrial septal defect, a ventricular septal defect, or a patent ductus arteriosus. The normal maximum deflection, a ventricular septal defect, or a patent ductus arteriosus. The normal maximum deflection, a ventricular septal defect, or a patent ductus arteriosus. The normal maximum deflection, a ventricular septal defect, or a patent ductus arteriosus.

blood gas analysis of sequential blood samples obtained from a fluid-filled catheter during a pullback from the pulmonary artery through the right ventricle into the right atrium.

Echocardiography can provide information that, although different, may be of equivalent diagnostic value to that obtained by cardiac catheterization and, because it is noninvasive and technically a much easier procedure, echocardiography has largely supplanted cardiac catheterization in the examination of cardiac disease in large animals.

**Arrhythmias (Dysrhythmias)**

Variations in cardiac rate and rhythm include tachycardia (increased rate), bradycardia (decreased rate), arrhythmia or dysrhythmia (irregularity in rate and rhythm), and gallop rhythms. The rate and rhythm of the heart is influenced primarily by the integrity of the pacemaker, the conducting system, and the myocardium, and also by the influence of the autonomic nervous system. Variation in the rate and rhythm can occur in normal animals because of strong or varying autonomic influences and can also be a reflection of primary myocardial disease. Other factors such as acid-base and electrolyte imbalance can influence rate and rhythm. These factors must be taken into consideration in the assessment of apparent abnormalities detected on clinical examination of the cardiovascular system. The combination of dysautonomia and acid-base and electrolyte abnormalities (particularly hypokalemia and hypocalcemia) are the most likely reasons for the increased prevalence of arrhythmias is horses during recovery from anesthesia. Similarly, ventricular premature complexes are more often present in horses with colic than healthy horses; the increased incidence of ventricular arrhythmias is horses during recovery of dysautonomia and acid-base and electrolyte disturbance and toxicities (particularly hypokalemia, hypocalcemia, and hypomagnesemia), sympathetic nervous system activation, and concurrent endotoxemia. Cardiac arrhythmias are more common in low-producing lactating dairy cattle than high-producing dairy cattle; this is attributed to the presence of concurrent electrolyte disturbances in low-production cattle, particularly hypocalcemia, hypokalemia, and hypomagnesemia.

The majority of arrhythmias and conduction disturbances can be detected on clinical examination. However, some may be unsuspected on clinical examination and be found only on electrocardiographic examination. The occurrence of conduction and myocardial disturbances is probably more common than generally recognized, because an ECG is usually only taken from animals in which there have been prior clinical indications of conduction abnormalities. Because of the importance of electrocardiography in the diagnosis of arrhythmias, the salient electrocardiographic findings are given in the following sections.

The common conduction disturbances and arrhythmias in large animals are listed in Table 10-4. A large-scale cross-sectional study of 952 healthy dairy cattle aged 1 or more years produced the following prevalence of arrhythmias: sinus arrhythmia, 8.5%; first-degree AV block, 1.6%; ventricular premature complexes, 0.6%; atrial premature complexes, 0.4%; sinus bradycardia, 0.2%; and ventricular escape complexes, 0.1%. Atrial fibrillation was not observed in healthy cattle in this study.

The treatment of arrhythmic heart disease generally relies on the treatment of the underlying clinical condition causing the problem. This may vary from electrolyte and acid-base disturbance and toxicities to primary myocardial disease resulting from myocarditis, myocardial ischemia, and changes resulting from heart failure or myopathies resulting from nutritional deficiency. These are detailed in later sections in this text. Racing and work horses should be rested for periods up to 3 months following evidence of myocardial disease. Frequently a course of corticosteroids, or a nonsteroidal antiinflammatory drug (NSAID) such as flunixin meglumine, is given to attempt to reduce the severity of myocarditis if this is not contraindicated by the initiating cause. Specific antiarrhythmic therapy may be applied in certain conditions and is detailed later.

A clinically useful classification system for dysrhythmias is based on the heart rate, as often an ECG is unavailable during the initial physical examination. This is the categorization system used in this text. However, when an ECG record of an arrhythmia is available, it is very helpful to categorize dysrhythmias in large animals into four categories based on their anatomic origin: SA nodal, atrial myocardial, AV nodal, or ventricular myocardial. An alternative system of categorization of cardiac arrhythmias focuses on disorders of impulse formation, disorders of impulse conduction, disorders of both impulse formation and conduction, or escape rhythms.

It is important to be able to recognize those forms of arrhythmia that are not indicative of pathologic heart disease but are normal physiologic variations. These are common in the horse and most can be differentiated on physical examination. It is also important to understand the difference between a premature beat or contraction and a premature complex. A beat or contraction is a mechanical event that can be clinically detected by auscultation, palpation of an artery or visual examination of the jugular venous pulse, or recorded by pressure measurements. A complex is an electrical event that is detected by an electrocardiograph. A beat is always associated with a complex; however, a complex can be accompanied by a beat, particularly in electromechanical dissociation and ventricular tachycardia or ventricular fibrillation. The terms beat or contraction should therefore be used to describe an arrhythmia detected by auscultation, palpation, or recording of the arterial pulse, whereas the term complex should be used when the arrhythmia is detected electrocardiographically.

**FURTHER READING**

**SINUS TACHYCARDIA, SINUS BRADYCARDIA, AND PHYSIOLOGIC DYSRHYTHMIAS**

The heart rate results from the discharge of impulses from the SA node, which has its own intrinsic rate of discharge but which is also modified by external influences, particularly the vagus nerve.

**SINUS TACHYCARDIA**

The term sinus tachycardia or simply tachycardia is used to describe an increase in heart rate caused by detectable influences such as pain, excitement, exercise, hypertension, a fall in arterial blood pressure, or the administration of adrenergic drugs. The heart rate returns to normal when the influence is removed or relieved.

It needs to be stated that sinus tachycardia indicates an increase in heart rate that is initiated by the SA node in the right
atrium (hence the sinus modifier). This means that the term sinus tachycardia should be reserved for use when electrocardiography has been performed and the sinus node has been determined to be the dominant pacemaker. For comparison, the term tachycardia should be used when an increased heart rate is detected by auscultation or palpation of the pulse and the origin of the pacemaker has not been determined. In resting horses and cattle that are used to being handled heart rates are not usually elevated above 48 and 80 beats/min, respectively, and rates above this are usually classified as tachycardia (Fig. 10-5). Fig. 10-6 shows base–apex ECGs of horses with selected arrhythmias, which were recorded at 25 mm/s and 10 mm = 1 mV. In the cow and horse, it is rare for the causes of sinus tachycardia to elevate the heart rate above 120 beats/min in the resting animal, and at heart rates above this an intrinsic pathologic tachycardia should be sought. Sinus tachycardia (heart rate >90 beats/min), with or without sinus arrhythmia, is more common in sheep in the early postpartum period than in late gestation.¹

PHYSIOLOGIC DYSRHYTHMIAS
There are several dysrhythmias that can occur in the absence of heart disease and that appear to result from excess vagal tone. These occur especially in the horse and include the following:
- Sinus arrhythmia
- Wandering pacemaker
- SA block
- First-degree and second-degree AV block (Mobitz type 1).
These physiologic arrhythmias occur in animals at rest and can frequently be induced

SINUS BRADYCARDIA
Sinus bradycardia or simple bradycardia is used to describe a decrease in heart rate caused by a decreased rate of discharge from the SA node. Sinus bradycardia is most commonly associated with highly trained, fit animals and can be differentiated from the pathologic bradycardias by its abolition by exercise or the administration of atropine. Obviously sinus bradycardia, like sinus tachycardia, requires electrocardiographic confirmation that the sinus node is the dominant pacemaker.

Bradycardia may also occur in association with an increase in arterial blood pressure, space-occupying lesions of the cranium and increased intracranial pressure, pituitary abscess, hyperkalemia (see Fig. 8-1), hypothermia, and hypoglycemia and following the administration of α-2-adrenergic agonists such as xylazine or detomidine. Bradycardia is sometimes associated with vagus indigestion and diaphragmatic hernia in cattle and also occurs in cattle deprived of food. Bradycardia has also been reported in cattle with bovine spongiform encephalopathy, although this probably reflects inappetence rather than damage to the vagal nucleus in the brainstem; the latter would be expected to increase, rather than decrease, the heart rate. Bradycardia can be induced in young ruminants by forceful elevation of the tail. Sinus arrhythmia is usually present in animals with sinus bradycardia.

The resting heart rate seldom falls below 22 beats/min in adult horses and 44 beats/min in adult cattle. Rates below this are suggestive of pathologic bradycardias, and hypothermia, hypothyroidism, or an intrinsic cardiac problem should be suspected. However, a general rule is that resting heart rates are inversely proportional to BW, and large, fit horses and cattle have apparently low heart rates.

Fig. 10-5 Base–apex electrocardiograms (ECGs) of large animals with normal sinus rhythm (A and B), supraventricular arrhythmias (C-H), hyperkalemia (H and I), or ventricular arrhythmias (J-L). All ECGs were recorded at 25 mm/s and 10 mm = 1 mV. Base–apex ECGs of large animals with normal sinus rhythm (A and B), supraventricular arrhythmias (C-H), hyperkalemia (H and I), or ventricular arrhythmias (J-L). All ECGs were recorded at 25 mm/s and 10 mm = 1 mV.
Arrhythmias (Dysrhythmias)

by the application of a nose twitch in horses or by forceful elevation of the tail in young ruminants. There is some debate as to the significance of these arrhythmias in animals, but it is generally thought that if they are abolished by exercise or excitement and if there is no evidence of cardiac insufficiency they are not of pathologic significance and do not require further investigation.

Perinodal myocardial fibrosis and microvascular abnormality have been reported in horses with SA and AV block and are considered as an excitatory cause. However, because myocardial fibrosis is common in horses, and is present in 79% of horse hearts examined at random, it remains likely that these arrhythmias are physiologic in horses. All animals with evidence of arrhythmic heart disease should be examined following exercise, as should any animal in which cardiac disease is suspected.

The occurrence of cardiac irregularities following exercise is highly indicative of serious cardiac disease.

A high frequency of arrhythmia has been recorded in newborn foals immediately following birth. Forty-eight of 50 foals had some form of arrhythmia; atrial premature complexes were recorded in 30 foals, atrial fibrillation in 15 foals, and ventricular premature complexes in 10 foals. Other arrhythmias were recorded with less frequency. It was concluded that the arrhythmias resulted from transient hypoxemia during birth and that their occurrence should be considered as part of the normal adaptive process to extrauterine life, as normal sinus rhythm was recorded by 5 minutes following birth and the foals subsequently developed normally.

Cardiac arrhythmias also are commonly associated with gastrointestinal disorders in the dairy cow and less commonly in the horse and resolve without specific antiarrhythmic treatment when the primary gastrointestinal disorder is corrected. Atrial premature complexes, ventricular premature complexes, and atrial fibrillation have been

Fig. 10-6 Base–apex electrocardiograms (ECGs) of horses with selected arrhythmias. All ECGs were recorded at 25 mm/s and 10 mm = 1 mV.
A. An ECG (base–apex configuration) of a horse with atrial fibrillation. The typical characteristics include an irregularly irregular rhythm, absence of P waves, coarse baseline irregularity called fibrillation (“f”) waves, and “QRS” complexes of normal width and morphology. Note that for short RR intervals the T wave (arrow) has opposite polarity to the QRS complexes that follow longer diastolic intervals; the same phenomenon occurs in ECGs recorded during exercise compared with at rest. In the same horse, even in the same ECG trace, coarse and fine fibrillation waves can be present, representing the chaotic nature of the underlying electrical activation of the atria.

Continued
B. Base–apex ECG of atrial fibrillation obtained from a 5-year-old trotter with a 14-day history of reduced athletic performance. The rhythm is irregularly irregular after the 9th QRS complex.

![Third-degree AV block](image)

Fig. 10-6, cont’d  B, Base–apex ECG obtained from a 5-year-old trotter with a 14-day history of reduced athletic performance. The ECG shows atrial flutter with a cycle length of 268 ms (rate 224 beats/min). C, During exercise and during periods of excitement 1:1, 1:2, and 1:3 atrioventricular (AV) conduction of the flutter waves occurred and the horse's heart rate rhythm sounded regular by auscultation. This ECG recording was obtained during and immediately after pulling up from a trot on the lunge. A 1:1 conduction of F waves as parasympathetic tone is withdrawn results in an excessively high heart rate for the work being undertaken, but the horse's cardiac rhythm is now completely regular. The horse was subsequently converted by transvenous electrical cardioversion at the first 125-J shock, after which he returned to his previous level of exercise. D, Junctional ventricular premature depolarization in a horse presented with poor performance. The normal rhythm is broken by a ventricular premature depolarization (VPD) with a morphology that is only slightly different from the normal sinus beats (QRS). Within the QT interval of the VPD a P wave can be identified (P wave indicated by arrow) because the normal sinus rhythm is not interrupted. The P wave does not result in a QRS complex because the ventricle is still refractory. This AV dissociation is a hallmark of ventricular prematurity. Although the complex is not noticeably wider than the sinus beats, it is still ventricular in origin. Its configuration suggests that it originates from the AV junctional, or His-Purkinje system, and has been conducted using (part of) the normal conduction pathways. Note that the T wave preceding the VPD is exactly the same as the other sinus T waves, so that an ectopic P wave could not have been hidden within it. E, Third-degree AV block in a 15-year-old Grand Prix dressage horse. There is complete AV dissociation because of third-degree AV block. PQ interval is highly variable because they have no relation; the fourth QRS complex occurs simultaneously with a P wave. Bifid “P” waves occur at a rapid rate because of associated hypotension. In this case the QRS morphologies are similar but their rate is slow and rhythm is irregular; they are junctional ventricular escape complexes. The gelding presented acutely after multiple episodes of collapse in a single day. The referring veterinarian administered antibiotics and corticosteroids and referred the horse for pacemaker implantation. At presentation, third-degree AV block was present but ventricular escape rhythm was sufficiently high to prevent collapse. Within 48 hours he reverted to normal sinus rhythm. No pacemaker was implanted. The gelding was closely monitored and returned to dressage after 6 months. He was retired 2.5 years later because of chronic tendinitis. ARRHYTHMIAS WITH NORMAL HEART RATES OR BRADYCARDIA

SINUS ARRHYTHMIA

Sinus arrhythmia is a normal physiologic arrhythmia that occurs at slow resting heart rates and is associated with variation in the rate of discharge from the SA node associated with variation in the intensity of vagal stimulation. Sinus arrhythmia is most often correlated with respiration so that the discharge rate and heart rate increase during inspiration and decrease during expiration. In the horse, sinus arrhythmia unassociated with respiration also occurs. In the majority of large animals, sinus arrhythmia is much less overt than in the dog and generally is not detected except on very careful clinical examination or examination of the ECG. Sinus arrhythmia is more clinically obvious in tame sheep and goats and in the young of all species and is correlated with respiration. Sinus arrhythmia is abolished by exercise or by the administration of atropine.

Sinus arrhythmia is detected on the ECG by variations in the PP intervals (often defined as greater than 10% of the mean heart rate but a range of 8–20% has been applied in some studies) with or without variation in the PR interval and is frequently associated with a wandering pacemaker. This is associated with differences in the site of discharge from the SA node with subsequent minor variations in the vector of atrial depolarization with subsequent minor variations in the configuration of the P wave. In the horse there may be an abrupt change in the contour of the P wave so that the normal biphasic positive P wave in lead II, for example, changes to one with an initial negative deflection. There may or may not be a change in PR interval. This is not pathologic and is present in as many as 30% of normal horses at rest. If sinus arrhythmia is not abolished by exercise, it is considered pathologic. Sinus arrhythmia may be induced in the early stages of hypercalcemia during treatment for milk fever in cattle.

SINOATRIAL BLOCK

In SA block the sinus node fails to discharge or its impulse is not transmitted over the atrial myocardium. SA block is associated with the complete absence of heart sounds, of jugular atrial wave, and of an arterial pulse for one beat period. The underlying rhythm is regular unless sinus arrhythmia is present. On the ECG there is complete absence of the P, QRS, and T complex for one beat. The distance between the preblock and postblock P waves is twice the normal PP interval or sometimes slightly shorter. This arrhythmia is not uncommon in fit racing horses at rest and can be induced in horses and cattle by procedures that increase vagal tone. Provided it does not persist during and following exercise, it is considered as a physiologic variant of normal rhythm.

ATRIOVENTRICULAR BLOCK

AV block is divided into three categories (first, second, and third degree) depending on the degree of interference with conduction at the AV node.

First-Degree Atrioventricular Block

First-degree AV block is an electrocardiographic diagnosis and cannot be detected clinically, and it occurs when conduction is delayed at the AV node. The PR interval is prolonged beyond normal limits (conventionally >400 ms in the horse) and the condition may be transient because of waxing and waning vagal tone. First-degree AV block is generally considered to have little significance.

Second-Degree Atrioventricular Block

Also called partial heart block, this occurs when there is periodic interference with conduction at the AV node so that some atrial complexes are not followed by ventricular complexes (see Fig. 10-5H). This may occur at random or in a regular pattern, for example, at every third or fourth complexes. At the blocked complex there is complete absence of the first and second heart sounds and no palpable pulse. The underlying rhythm is still sinus in origin and is thus regular. In horses the presence of a fourth heart sound can be a valuable aid in diagnosis; with careful auscultation it can be heard during the block period in the manner of du LUBB DUPP, du ..., du LUBB DUPP. This is diagnostic for this condition. An atrial jugular impulse can also be detected during the block period. The intensity of the first sound in the immediate postblock beat is usually intensified.

The ECG shows the presence of a P wave but complete absence of the subsequent QRS and T waves at the blocked beat. There may be variations in the PR intervals preceding and following the block. With Mobitz type 1 (Wenckebach) second-degree AV block there is a gradual increase in the PQ interval up to the point of the blocked conduction; however, the PR interval immediately before the blocked conduction does not have to be the longest in the series. With Mobitz type 2 block the PQ interval remains unchanged. In most species, Mobitz type 2 is a normal physiologic response reflecting changes in vagal tone, whereas Mobitz type 2 always indicates the presence of organic heart disease such as myocarditis.

Second-degree AV block is extremely common in horses and occurs as a normal physiologic variation caused by variations in vagal tone. The application of a twitch to the upper lip of a horse will frequently slow the heart rate and allow the expression of second-degree heart block. Second-degree AV block is more common in Thoroughbreds and Standardbreds than in heavy horses and may be detected in approximately 20% of racehorses. Frequency is highest when they are examined in quiet surroundings at rest, at night, or early in the morning. The frequency is also increased when horses are not fed for 24 hours. Second-degree AV block can be abolished by exercise or the administration of atropine.

Second-degree AV block can be associated with myocarditis in the horse and its presence has been associated with decreased racing performance by some clinicians. Second-degree AV block at fast heart rates has also been associated with the syndrome of duodenitis–proximal jejunitis in horses and was correlated with high serum bicarbonate concentrations in this condition. AV conduction disturbances can be associated with electrolyte imbalance in all species, overdosing with calcium salts, digoxin toxicity, cardiomyopathy, and myocarditis associated with nutritional and infectious disease.

Methods for the clinical differentiation of physiologic (Mobitz type 1) versus pathologic (Mobitz type 2) second-degree heart block in the horse have not been established. However, the persistence of the arrhythmia at heart rates above resting normal values should be considered to be abnormal. In all other species the presence of Mobitz type 2 AV block should probably be considered as an indication of myocardial disease.

It is usually not necessary to treat this arrhythmia specifically and treatment is generally directed at the underlying cause. In cases where the block is frequent and syncopal episodes are likely, atropine may alleviate the frequency of the block; however, this is only short-term therapy. Second-degree heart block may progress to third-degree (complete) heart block.

Third-Degree or Complete Heart Block

This occurs rarely in large animals. There is one report on third-degree block in a horse secondary to a rattlesnake bite. In complete heart block there is no conduction at the AV node. The ventricle establishes a pacemaker in the nodal or conducting system and the atria and ventricles beat independently. The ventricular rate is regular but very slow. Bradycardia is the prominent feature and it is unresponsive to exercise or atropine. Atrial contractions are much faster than the ventricle. Atrial contraction sounds are rarely heard on auscultation but evidence of the rate may be detected by examination of the jugular inlet. Periodically, as the atrium
complexes have lower intensity because of lower diastolic filling, and the associated arterial pulse amplitude is decreased. Two main patterns occur. In some instances the sinus node becomes reset from the atrial premature complex so that a regular rhythm is established from this contraction. In this case atrial premature complexes are characterized by the occurrence of periods of regular rhythm interrupted by beats with exceptionally short interbeat periods. In other instances the sinus node is not reset following the atrial premature complexes and if its discharge occurs during the refractory period of the atrium then no atrial or subsequent ventricular contraction will occur. This will be detected electrocardiographically as an early ventricular complex followed by a pause following which normal rhythm is continued. This character is identical to that produced by many ventricular premature complexes.

At slow heart rates the presence of atrial premature complexes is suggested by periodic interruption of an underlying sinus rhythm and by the occurrence of a “dropped pulse.” The prime differentiation is from SA block and second-degree AV block, which have distinguishing electrocardiographic characteristics.

On the ECG the P wave of the premature complex occurs earlier than expected from the basic rhythm and is abnormal in configuration (see Fig. 10-5C). QRS complexes associated with atrial premature complexes are usually normal in configuration because this is a supraventricular arrhythmia and the pathway for ventricular depolarization is not altered.

Junctional Premature Complexes
These are also AV nodal premature complexes that arise from the region of the AV node or conducting tissue. They produce a premature ventricular contraction, which is usually followed by a compensatory pause caused by the following normal discharge from the sinus node that usually falls upon the ventricle during its refractory period. Junctional premature complexes produce QRS configurations that are similar to those of normal complexes, but they may produce a P wave that has a vector opposite to normal.

Ventricular Premature Complexes
Ventricular premature complexes may arise from an irritable process anywhere within the ventricular myocardium. The normal rhythm is interrupted by a beat that occurs earlier than expected, but the initial rhythm is established following a compensatory pause. This can be established by tapping through the arrhythmia as described earlier. The heart sounds associated with the premature beat are usually markedly decreased in amplitude, whereas the first sound following the compensatory pause is usually accentuated. Occasionally, ventricular premature complexes may be interpolated in the normal rhythm and not followed by a compensatory pause. If the diastolic filling period preceding the premature beat is short, the pulse associated with it will be markedly decreased in amplitude or even absent.

On the ECG ventricular premature complexes are characterized by bizarre QRS morphology (see Fig. 10-5K). Conduction over nonspecialized pathways results in a complex of greater duration and amplitude to normal and the complex slurs into a T wave that is also of increased duration and magnitude. The vector orientation depends on the site of the ectopic foci initiating the contraction, but it is invariably different from that of normal contractions. Electrocardiographic examination allows a differentiation of the site of origin of premature complexes and further subclassification within the categories. Premature complexes of all site origins are indicative of myocardial disease; the one exception is the occurrence of atrial premature complexes accompanying cases of gastrointestinal disease in cattle. Atrial premature complexes are common in cattle with gastrointestinal disease, and their presence should be suspected whenever there is a variation in the intensity of the first heart sound with or without an underlying detectable cardiac irregularity. Atrial premature complexes can progress to atrial fibrillation in these cases where there is excessive vagal tone.

Horses in which premature beats are auscultated or suspected should be examined after careful exercise, which will usually increase the occurrence and severity of the arrhythmia. Premature beats are most easily auscultated during the period of slowing of heart rate after exercise.

REFERENCES

ARRHYTHMIAS WITH TACHYCARDIA
An excitable focus within the myocardium may spontaneously discharge and cause depolarization of the remaining myocardium. If the discharge rate approaches or exceeds that of the sinus node, then the focus may transiently take over as the pacemaker of the heart.

ATRIAL FIBRILLATION
In atrial fibrillation atrial depolarization is characterized by numerous independent fronts of excitation that course continuously and haphazardly through the atria. There is no synchronous atrial contraction and AV nodal stimulation occurs in an irregular and random fashion. The effects within the atria cannot be appreciated on auscultation and the clinical detection of this arrhythmia...
occurs through its effects on ventricular function. The random stimulation of the ventricles produces a heart rate and pulse that is irregularly irregular. It is not possible to establish any basic rhythm by tapping out this arrhythmia, and the rate varies from period to period.

Because there is no atrial contraction, filling of the ventricles is entirely passive and very much dependent on diastolic filling time. Some contractions occur very quickly following the preceding contraction with little time for diastolic filling and this produces a marked variation in the intensity of the heart sounds and in the amplitude of the pulse. At fast heart rates there will be a pulse deficit. There is no fourth heart sound (S4) or atrial wave at the jugular inlet because there is no coordinated atrial contraction, but the third heart sound is usually grossly accentuated. The degree of cardiac insufficiency that results from this arrhythmia varies and depends on the general rate at which the ventricles beat at rest. This is determined primarily by vagal activity.

On the ECG there are no P waves discernible but the baseline shows multiple waveforms (f waves) that occur with a frequency of approximately 300 to 600 f waves/min (see Fig. 10-6A,B). QRST complexes are normal in configuration, but there is wide variation and no pattern in the QQ intervals. Atrial fibrillation is one of the more common arrhythmias in large-animal species. The ECG of horses in atrial fibrillation may exhibit modified P waves called F waves (flutter waves) that have a similar sawtooth morphology and polarity with a frequency of approximately 180 to 250 F waves/min.

**Atrial Fibrillation in the Horse**

Horses with atrial fibrillation fall into two categories. In one category, sometimes called "benign fibrillators" or "lone atrial fibrillation," there is no evidence of underlying heart disease, whereas in the second category, called "secondary atrial fibrillation," there is evidence of heart disease.

**Lone Atrial Fibrillation**

In cases that are lone atrial fibrillation, the vagal tone may be high and conduction through the AV node is suppressed to result in heart rates in the region of approximately 26 to 48 beats/min. At this rate there is no cardiac insufficiency at rest, and hemodynamic parameters are normal. The horse can elevate its heart rate with exercise to allow moderate performance, although it will never perform satisfactorily as a racehorse. This is the most common manifestation in this species, and it is typified by a gross irregularity in rate, rhythm, and intensity of the heart sounds and by the occurrence, at rest, of occasional periods lasting for 3 to 6 seconds in which there is no ventricular activity. At very slow rates periodic syncope may occur. The ventricular rate in horses with atrial fibrillation exhibits a high degree of periodicity that is associated with the respiratory rate. A relatively low ventricular rate in horses with atrial fibrillation reflects the dominance of the parasympathetic nervous system. In other words, horses with atrial fibrillation and ventricular response rates exceeding 60 beats/min are sympathetically activated, and concurrent disease processes or stressors should be identified.

The lone form of atrial fibrillation is most common in racehorses and occasionally in draft horses. A survey of 106 cases of atrial fibrillation in horses found that the disease is most common in Standardbred and Thoroughbred horses under 7 years of age, with a high proportion under 4 years of age, which may have been a reflection of the admissions to the clinic rather than real age incidence. There appears to be a genetic predisposition to atrial fibrillation in Standardbreds in Canada with a more complex pattern of inheritance than a simple autosomal recessive disorder.

**Exercise intolerance** was the most common clinical history. All horses had an irregular heart rate and rhythm, and the pulse and intensity of the heart sounds were variable. A separate study of 67 horses showed a significantly higher prevalence in Standardbreds and Thoroughbreds than other breeds of horse and a significant difference in the mean age at diagnosis between Standardbreds (4 years) and Thoroughbreds (9 years). Horses in atrial fibrillation have higher heart rates and much higher pulmonary artery wedge pressures during a standardized treadmill exercise protocol compared with healthy trained horses. It is likely that the marked increase in left atrial pressure in horses in atrial fibrillation will result in loss of pulmonary capillary integrity during exercise and exercise-induced pulmonary hypertension.

**Racehorses** have a history of normality at rest but poor exercise tolerance following a race in which the horse ran well for the first 200 to 300 m but subsequently faded badly and finished a long way behind the field. Paroxysmal atrial fibrillation has also been observed in the horse under these circumstances. Horses with paroxysmal atrial fibrillation show atrial fibrillation when examined immediately following the race, but convert to normal sinus rhythm shortly after and have normal cardiovascular function if the examination for poor racing performance is delayed. A large-scale study of 39,302 racehorses undergoing 404,090 race starts estimated a minimum prevalence of atrial fibrillation of 0.29%. The estimated prevalence was higher (1.39%) in horses that finished slowly or did not finish, and the prevalence increased markedly with age. Atrial fibrillation was paroxysmal in most horses, with 93% of horses with atrial fibrillation spontaneously converting to sinus rhythm within 24 hours of the race. Attempted conversion of horses with atrial fibrillation should therefore be delayed for at least a 1 to 2 days following a race, because most will convert spontaneously without treatment. Serum potassium, magnesium, and calcium concentrations and fractional clearance of potassium should be determined in these horses to identify the presence of electrolyte deficiencies that may have facilitated induction of atrial fibrillation. There is one report of atrial fibrillation of unknown duration in a 9-year-old mare with severe hypokalemia (1.5 mEq/L) and hyponatremia (122 mEq/L) that converted to normal sinus rhythm after the electrolyte abnormalities were corrected with IV fluid administration.

There is debate as to the cause of the lone form of atrial fibrillation and whether myocardial and vascular lesions are present in the atria of a significant proportion of animals with this arrhythmia. However, the high rate at which atrial fibrillation converts spontaneously or by treatment to be followed by successful racing performance suggests that this arrhythmia frequently occurs in young horses in the absence of significant atrial pathology. Lone atrial fibrillation in young racing horses therefore has many similarities to atrial fibrillation in lactating dairy cattle with abdominal disease because it is likely that most cases do not have underlying heart disease. The increased prevalence of atrial fibrillation in race horses with age suggests, however, that underlying heart disease does predispose to developing atrial fibrillation during a race. Increased BW is also a risk factor for atrial fibrillation; this probably reflects an increased atrial size that facilitates sustaining atrial fibrillation, and atrial size is correlated with BW.

**Secondary Atrial Fibrillation**

Horses may develop secondary atrial fibrillation in response to underlying cardiovascular disease, such as mitral valve insufficiency, tricuspid valve insufficiency, or a combination of both, but any acquired or congenital lesion that results in atrial hypertrophy has this risk.

Where there is underlying heart disease, the ventricular rate at rest is much higher and the arrhythmia presents as a tachycardia. It has been suggested that a heart rate greater than 60 beats/min is indicative of underlying cardiac disease in cases of atrial fibrillation. In horses with atrial fibrillation, ventricular filling is impaired at heart rates above 70 beats/min, and at resting heart rates above 80 to 100 beats/min there is severe cardiac insufficiency and the animal rapidly develops signs of cardiac failure. At fast heart rates, atrial fibrillation presents with a syndrome clinically similar to ventricular tachycardia associated with multiple ventricular extrasystoles and electrocardiographic differentiation is required.

Paroxysmal atrial fibrillation has been observed in newborn foals showing signs of respiratory distress and with birth anoxia.
Atrial Fibrillation in the Cow
There may be atrial fibrillation in the cow secondary to myocardial disease or endocarditis resulting in atrial enlargement, but is usually functional in occurrence and traditionally has not been associated with clinically detectable cardiac lesions. However, a histopathologic study in nine Holstein-Friesian cows with atrial fibrillation and 12 healthy controls in sinus rhythm indicated that multifocal or large areas of myocardial fibrosis were present more frequently and with greater severity in cattle with atrial fibrillation than healthy controls. Interestingly, the atrial lesions were largely confined to the dorsal regions of the cranial lateral and medial regions of the right atrium, and it is unknown whether these lesions were the result of sustained atrial fibrillation or played a causative role in the genesis of atrial fibrillation. It is likely that the presence of organic heart disease predisposes cattle to the development of atrial fibrillation because atrial myocardial inflammation is associated with an increased incidence of atrial premature complexes, which are thought to lead to atrial fibrillation when occurring during the vulnerable period for atrial myocytes. An atrial fibrillation prevalence of 2.5% was recorded in apparently healthy lactating dairy cows over an 18-month period. In a large cross-sectional study, atrial fibrillation was not observed during a 3- to 5-minute ECG recording in 952 of dairy cattle aged 1 or more years. There is only one report of atrial fibrillation in cattle less than 1 year of age, and that was a 10-day-old diarrheal calf with profound electrolyte abnormalities (Na, 95 mEq/L; K, 6.9 mEq/L; Ca, 1.7 mmol/L; Mg, 0.4 mmol/L).12 The atrial fibrillation resolved within 1 day of correcting the electrolyte abnormalities.

In sick cattle, atrial fibrillation is most common in association with gastrointestinal disease, abnormalities causing abdominal pain, and metabolic disease. Abnormalities as diverse as acute enteritis, left displacement of the abomasum, and torsion of the uterus may be accompanied by this arrhythmia. Heightened excitation of the atria, in association with electrolyte and acid-base disturbances or change in vagal tone, has been postulated as a cause, and atrial premature complexes are also seen in the same types of clinical case (see Fig. 10-5). The administration of neostigmine to cattle with gastrointestinal disease may precipitate the occurrence of atrial fibrillation. The arrhythmia usually converts spontaneously to sinus rhythm with correction of the abdominal disorder.

Atrial Fibrillation in the Sheep and Goat
This may occur as a result of incompetence of the tricuspid or mitral valves, the presence of myocarditis or, in goats, as a sequel to interstitial pneumonia along with cor pulmonale. The presenting signs are those of respiratory distress and heart failure. Ascites is prominent and there is marked jugular distension with an irregular jugular pulse.

Treatment of Atrial Fibrillation Horses
Horses with atrial fibrillation at sustained high heart rates are generally not treated successfully because serious cardiac pathology is usually present (secondary atrial fibrillation). Digoxin and quinidine sulfate are used. The decision to treat a horse with atrial fibrillation at low heart rates depends on the requirement for the horse to perform work, because horses with this arrhythmia can be retired and will live for several years. They may be used successfully as brood mares. Anticoagulation therapy is not administered to horses in atrial fibrillation because of the absence of reports of thromboembolic events caused by passage of blood clots from the fibrillating atria to the cerebral circulation.6

Horses with lone atrial fibrillation can be converted to normal sinus rhythm with subsequent return to successful racing or other performance. Conversion should be delayed for 48 hours in horses with an initial diagnosis of atrial fibrillation that was associated with poor race performance. This is because normalization of electrolyte and acid-base status after exercise results in some horses reverting to normal sinus rhythm without treatment. Conversion success is higher for horses demonstrating atrial flutter instead of atrial fibrillation, because the atrial rate is slower and depolarization is more organized in atrial flutter.

Oral quinidine sulfate is the initial treatment of choice for correction of atrial fibrillation, whenever quinidine sulfate can be readily obtained at a reasonable cost. The efficacy of quinidine sulfate to achieve cardioversion is 65% to 90%, which is similar to that reported for transvenous electrical cardioversion, and a prospective randomized controlled trial to compare the two methods of cardioversion has not been completed. There is a much greater success rate with conversion of atrial fibrillation in young horses and when it is attempted shortly following the onset of the arrhythmia. If the arrhythmia has been present for more than 4 months, successful conversion is much less common, presumably because of remodeling of atrial myocardial tissue, and side effects with therapy are more common. Following cardioversion, the horse should be rested for at least 2 months. Some clinicians administer corticosteroids (such as oral prednisolone) after conversion on the basis that atrial fibrillation may have been induced by myocarditis, and corticosteroids may decrease inflammatory foci within the myocardium. The efficacy of corticosteroids in preventing new episodes of atrial fibrillation is unknown. In some horses the conditions recur after a period of racing, and repeated conversions with quinidine are possible.

Quinidine is an antiarrhythmic agent of class 1a of the Vaughan Williams classification. It slows intracardiac conduction by blocking the fast sodium channel and prolongs the action potential duration. Several dose regimens have been used, but the administration of an oral quinidine sulfate dose of 22 mg/kg every 2 hours until conversion is achieved or toxicity is manifested has proved effective. In the majority of cases, conversion will occur before the total dose exceeds 40 g. Toxicity is likely when the total dose exceeds 60 g, and the decision to continue with therapy once this dose has been reached should be considered carefully. The plasma quinidine concentration required for cardioversion ranges from 2 to 4 µg/mL and toxicity has been reported at 5 µg/mL. Conversion by IV quinidine glucuronate is reported in the horse using an initial dose of 1.0 to 1.5 mg/kg, given over a period of 1 minute and repeated every 5 to 10 minutes until sinus rhythm is restored or the QRS interval increases 25% over baseline, ventricular rate exceeds 90 beats/min, signs of toxicity occur, or a total dose of 11 mg/kg has been administered. Conversion by concurrent quinidine administration and atrial pacing is also recorded in the horse, but is not routinely needed.

Toxicity common with oral quinidine treatment, and separate studies report 48% and 28% of horses with some form of adverse reaction. Depression, tachycardia, anorexia, urticaria, congestion of the mucous membranes, colic, and death are recorded. Prolongation of the QRS interval to 25% greater than pretreatment values has been considered a monitor for cardiovascular toxicity. The toxic effects of quinidine may be corrected by IV administration of sodium bicarbonate in an attempt to increase the percentage of quinidine bound to protein. Such treatment runs the risk of inducing hypokalemia, which may exacerbate quinidine toxicity. Some prefer to digitalize the horse intravenously before medication with quinidine in an attempt to reduce tachyarrhythmias at the point of conversion and those associated with quinidine toxicity. Nephrotoxicity with uremia and diarrhea can occur at lower doses. It is transient and repairs rapidly following withdrawal of the drug, but the serum urea concentration and urine should be monitored during therapy in addition to cardiovascular function.

Oral and IV flecainide has been used with mixed success to convert horses in atrial fibrillation. Flecainide is an antiarrhythmic agent of class 1c of the Vaughan Williams classification. It slows intracardiac conduction by blocking the fast sodium channel and shortens the refractory period of the Purkinje fibers. Flecainide administration in humans is currently limited to patients without evidence of structural heart disease and normal left ventricular function. IV administration
of flecainide acetate (1–2 mg/kg BW) infused at 0.2 (mg/kg BW)/min was effective in converting experimentally induced atrial fibrillation in six horses and naturally occurring atrial fibrillation in two horses. These results are consistent with those of another study in horses with experimentally induced atrial fibrillation that indicated flecainide is effective in terminating atrial fibrillation of short duration. The plasma flecainide concentration at the time of conversion was 1.3 mg/L. Oral administration of flecainide acetate (4–6 mg/kg BW every 4 hours) also produced plasma flecainide concentrations that approximated 1.3 μg/mL for a number of hours. However, in a subsequent study in 10 horses with naturally occurring atrial fibrillation, IV flecainide failed to convert nine horses with long-standing atrial fibrillation to sinus rhythm, but it did convert one horse who had been in atrial fibrillation for 12 days. Oral administration of flecainide has also been used in horses to convert atrial fibrillation with moderate success. There do not appear to be persuasive reasons to use flecainide or amiodarone to convert horses in atrial fibrillation whenever quinidine is available.

Biphasic transvenous electrical cardioversion is an alternative treatment recommended in horses that fail to convert to oral or IV quinidine treatment, or manifest signs of quinidine toxicity during treatment, or in countries where quinidine is unavailable or prohibitively expensive. It is much safer than conventional monophasic electrical cardioversion. The goal is to deliver an electric shock to atrial myocardial tissue that electrically synchronizes the atrium and permits the return of a sinus rhythm. A custom-crafted biphasic shock synchronized with atrial electrical activity permits shock to atrial myocardial tissue that electrically produces more ventricular tachycardia than would be normally expected from such stimuli. Gang discharge and atrial fibrillation, except for the echocardiographic index left atrial fractional area change. This index reflects atrial contractile function, and if low (indicating poor atrial contractility) then the likelihood of recurrence is increased.

**Ruminants**

Ruminants with atrial fibrillation are not usually treated with specific antiarrhythmic drugs because the heart will usually revert to sinus rhythm following the correction of the underlying abdominal disorder and sufficient time (at least 1 week after return to normal physical health). However, the IV administration of quinidine (49 mg of quinidine sulfate per kg BW, at 0.20 (mg/kg/min) was successful in converting seven of nine cows to normal sinus rhythm at a mean plasma quinidine concentration of 3.6 μg/mL. Oral quinidine administration is not effective in ruminants because of the poor oral bioavailability. Side effects of IV quinidine administration in cattle include depression, ataxia, blepharospasm, diarrhea, and increased frequency of defecation. Response to treatment in sheep and goats is poor, although one ram was successfully converted to normal sinus rhythm using electrical cardioversion using 360 J and paddles placed over the right heart base (behind the triceps muscles) and the left cardiac apex close to the sternum.

**Paroxysmal Tachycardia**

Paroxysmal tachycardia may arise from an irritant focus within the atria (paroxysmal supraventricular tachycardia) or the ventricles (paroxysmal ventricular tachycardia), but in large animals paroxysmal ventricular tachycardia is more common, particularly immediately after a race in which the increase in vagal tone during recovery appears to facilitate paroxysms of ventricular ectopic activity, some of which may be followed by torsades-like polymorphic ventricular tachycardia. Atrial paroxysmal tachycardia (see **Fig. 10-5**) and atrial flutter are rare and are transient rhythm disturbances that can lead to atrial fibrillation.

In paroxysmal tachycardia, the increase in heart rate is abrupt and the fall to normal is equally sudden. This characteristic usually serves to distinguish this arrhythmia from the transient increases in heart rate that may normally follow such factors as excitement. Also, the heart rate is elevated to a rate far in excess of what would be normally expected from such stimuli.

Usually the excitable focus discharges repetitively over a long period of time to produce more continual ventricular tachycardia associated with ventricular extrasystoles. Sustained tachycardia is not normal and can lead to myonecrosis; three parturient dairy cows with sustained tachycardia (heart rate >120 beats/min) had multifocal areas of necrosis throughout the myocardium...
characterized by myofibrillar lysis and disarray.

**VENTRICULAR TACHYCARDIA**

Ventricular tachycardia may produce either a regular heart rate or an irregular heart rate and rhythm. When the discharge rate of the irritant focus far exceeds that of the SA pacemaker, the ectopic focus will take over completely as the pacemaker of the heart. On examination of the cardiovascular system, a rapid but regular heart rate and pulse is detected, and there is no irregularity of rhythm or of pulse amplitude or intensity of heart sounds. This is known as ventricular tachycardia with AV dissociation. This abnormality is easily overlooked clinically but should be suspected in any adult horse or cow in which the heart rate exceeds 90 beats/min and is frequently the cause of heart rates in excess of 120 beats/min. Ventricular tachycardia should also be suspected when the heart rate is higher than that expected from the animal’s clinical condition.

The diagnosis is seen on ECG when multiple regular QRS complexes with abnormal amplitude and duration of the QRS and T complexes are seen and the T wave is oriented in a direction opposite to the QRS complex (see Fig. 10-5). P waves may be detected on the ECG, but they have no relationship to the QRST complex and are frequently lost within them.

When the discharge rate of the irritant focus within the myocardium is similar to that of the SA node, the ventricular tachycardia can be manifested by a gross irregularity in rhythm. This is a common manifestation in large animals. In this situation, many of the discharges that originate in the sinus node are transmitted to the ventricle during a refractory period from a previous ectopic focus, but some reach the ventricle when it is not in a refractory state and are conducted normally. At some periods ventricular complexes may be initiated by the discharges from both sites.

The varying influence of each pacemaker on ventricular contraction produces a marked irregularity in cardiac rhythm, and it is frequently not possible to establish clinically a regular pattern to the heart rhythm. Variations between beats in the degree of atrial filling and in the diastolic filling period will result in a marked variation in the intensity of the heart sounds and in the amplitude of the pulse. Frequently at fast heart rates there is a pulse deficit. Cannon atrial waves can be observed in the jugular vein when atrial contraction occurs at the same time as a ventricular extrasystole. The ECG shows runs of extrasystoles interspersed with normally conducted complexes and usually there is the presence of fusion beats.

**Ventricular tachycardias** or the presence of multiformal or polymorphic ventricular complexes on an ECG are evidence of severe cardiac disease and are usually accompanied by signs of acute heart failure. They may result from primary myocarditis, nutritional cardiomyopathy, or myocardial neoplasia or be secondary to valvular disease and myocardial ischemia. Ventricular arrhythmias are common in certain plant poisonings and other toxicities and in severe electrolyte and acid-base disturbances as well as in the final stages of heart failure. If uncorrected, ventricular tachycardia may lead to ventricular fibrillation and death; frequently specific antiarrhythmic therapy is indicated during the period that the prime cause is being corrected.

**Treatment**

**Lidocaine** is the drug of first choice for treating hemodynamically important ventricular arrhythmias in large animals. It is an antiarrhythmic agent of class Ib of the Vaughan Williams classification, and slows intracardiac conduction by blocking the fast sodium channel while shortening the refractory period of myocardial tissue. Typically, 2% lidocaine is given as an IV bolus at 0.5 to 1.0 mg/kg BW every 5 minutes for a total of four treatments (total dose 2–4 mg/kg BW). An alternative treatment protocol is IV administration of 2% lidocaine at 0.6 mg/kg over 15 minutes.17 or an IV constant rate infusion at 0.05 mg/kg/min.17 Lidocaine has the advantages of widespread availability, low cost, and low cardiovascular toxicity, and the major disadvantage is its very short duration of action (half-life is 40 minutes in the horse). The most common initial sign of lidocaine toxicity is muscle fasciculations, which occur at a serum lidocaine concentration of 1.9 to 4.5 mg/L. If infusion is continued, then sedation and altered visual function are apparent; the latter is manifested as rapid eye blinking, anxiety, and attempts to inspect closely located objects. Temporary recumbency, excitement, sweating, and convulsions occur with higher doses.

**Quinidine sulfate** is the drug of second choice for use in horses.19 Quinidine is an antiarrhythmic agent of class 1a of the Vaughan Williams classification, and slows intracardiac conduction by blocking the fast sodium channel and prolongs the action potential duration. An initial dose of 20 mg/kg is given orally, followed by a dose of 10 mg/kg given every 8 hours. The drug is not effective until 1 to 2 hours following administration. IV quinidine gluconate (0.5–2.2 mg/kg BW bolus every 10 minutes to a total of 12 mg/kg BW) may be of greater value in those rare instances when oral quinidine is not indicated. Serum quinidine concentrations of 4 mg/L appear effective in treatment of cattle with ventricular tachycardia, but serum concentrations following an oral dose of 20 mg/kg vary widely between cows and slow IV infusion is the preferred method of therapy. There is a very narrow therapeutic index in cattle, and death can occur in some cows at doses that are therapeutically effective in others. Quinidine treatment in cattle should be approached with caution.

**Phenytoin sodium** is a good alternative to quinidine sulfate, and has been effective in treating ventricular arrhythmias in horses. Phenytoin is an antiarrhythmic agent of class 1b of the Vaughan Williams classification (same as lidocaine), and slows intracardiac conduction by blocking the fast sodium channel while shortening the refractory period of myocardial tissue. The recommended dosage protocol for the horse requires an initial oral dose of 20 mg/kg BW every 12 hours for four doses, followed by a maintenance oral dose of 10 to 15 mg/kg BW every 12 hours, with monitoring of phenytoin plasma concentrations. Plasma concentrations of 5 to 10 mg/L appear to be effective in treatment of horses with ventricular tachycardia. High plasma phenytoin concentrations are associated with sedation, recumbency, and excitement, and the dosage protocol should be altered in horses that appear sedated. The major advantage of phenytoin over lidocaine is its long duration; conversely, its major disadvantage is the initial time required (2–6 hours) to exert an antiarrhythmic effect. An IV form of phenytoin sodium has been administered to a pony with digitalis-induced ventricular arrhythmias, but the alkaline pH of the infused solution carries a high risk of thrombophlebitis.

**Magnesium sulfate** administration at 2 to 6 (mg/kg BW)/min of MgSO4 (equivalent to 1.8 to 5.4 mL of 50% MgSO4/450 kg horse/min) to effect under ECG monitoring has been recommended as part of the treatment of ventricular arrhythmias. A different dose protocol has been used in one adult horse that included 25 g of magnesium sulfate in 1 L of 0.9%NaCl administered IV over 15 minutes.17

The severity of ventricular tachycardia is augmented by factors that increase sympathetic tone, and affected animals should be kept in quiet surroundings.

**VENTRICULAR FIBRILLATION**

Ventricular fibrillation is not usually observed clinically. It occurs in the terminal stages of most suddenly fatal diseases, including lightning stroke, plant poisonings such as acute Phalaris toxicity, overdose with anesthetics, severe toxemia, and in the terminal phases of most acquired cardiac diseases. There is complete absence of the pulse and heart sounds, the blood pressure falls precipitously, and the animal rapidly becomes unconscious and dies within a minute or two of onset. Treatment is usually impractical, although deaths during anesthesia may be prevented by immediate and aggressive external cardiac massage. Electrical defibrillation is not feasible in large animals because of the bulk of the animal and the current required. Intracardiac injections of epinephrine are often
used in acute cardiac arrest but do not correct fibrillation and are of little value.

Diseases of the Heart

VALVULAR DISEASE AND MURMURS

SYNOPSIS
Etiology Valvular disease is acquired or congenital. Endocarditis is the most common cause. Some murmurs are functional and not indicative of disease.

Epidemiology Functional murmurs are common in the horse, vary with breed and training, and their presence and severity do not appear to be associated with racing performance. Little information is available on the epidemiology of acquired valvular disease.

Clinical findings Murmur defined by location, timing, character, intensity, and radiation, and are possibly precordial thrill, cardiac insufficiency, and, in severe cases, congestive heart failure.

Diagnosis confirmation Blood culture and echocardiography.

ETIOLOGY
Acquired
- Endocarditis, the most common cause (see the following section)
- Endocardiosis, common only in pigs
- Rupture of the chordae tendineae, either spontaneous or secondary to endocarditis
- Laceration, detachment of aortic valve leaflets, either spontaneous or secondary to endocarditis
- Dilatation of the right AV valve annulus, such as occurs in brisket disease and secondary to some myocardial disease; may result in functional insufficiency of the valves.

Congenital
- Pulmonic valve stenosis
- Fenestration of the aortic and pulmonic valves in horses. The cause of the lesions is unknown, although their presence in very young animals, including newborn foals, suggests that some may be congenital defects. The importance of these lesions as causes of valvular insufficiency is doubtful, although they may cause valvular murmurs if they are present close to the attachments of the cusps.
- Blood cysts are common on the AV valves of cattle. They are lined with endothelium, can occur congenitally, and their incidence and size may increase with age. They have no clinical significance. Serious cysts occur occasionally on the mitral valve of cattle.

EPIDEMIOLOGY
There is limited information on the epidemiology and the age-specific incidence of valvular disease or murmurs in large animals, although slaughter surveys show a high prevalence of endocardial lesions. Studies at clinical centers indicate that valvular disease is often undiagnosed in both cattle and horses and that its presence may not be detected in more than 50% of cases.

Horses
Auscultatory surveys show a high prevalence of murmurs with breed and horse-use differences. Functional (physiologic) murmurs are particularly common in trained, fit racehorses. In a survey of 545 clinically normal horses in England, murmurs were heard in 68%, with a higher prevalence in flat racing and National Hunt horses than in competition and pleasure horses. Murmurs with the characteristics of functional ejection murmurs were detected on auscultation over the left hemithorax in approximately 50% of horses and the right side in 8%. Murmurs with the characteristics of early diastolic functional murmurs were detected on the left side in 15% and on the right side in 13%. Murmurs with the characteristics of regurgitation at the mitral, tricuspid, and aortic valves were detected in 3.5, 9.2, and 2.2% of horses, respectively. Aortic regurgitation is more common in older horses and is usually not associated with clinical signs of heart disease. Mitral regurgitation is the most common valvular disease associated with atrial fibrillation, ventricular arrhythmias, and congestive heart failure. Tricuspid valve regurgitation is associated with atrial fibrillation, pulmonic valve regurgitation, and congestive heart failure. An extensive abattoir survey suggests that valvular lesions may be more common in the horse than is clinically appreciated. Approximately 25% of horses had lesions, and the majority was nodular or distorting lesions on the valves or chordae tendineae of the left side and, in a significant proportion, murmurs were detected before slaughter. Chronic trauma of the valve leaflets was considered an important initiating factor.

Cattle
A slaughter survey in cattle has reported endocarditis in 5.2 hearts per 10,000 animals.

Pigs
In an extensive slaughter survey, the prevalence of valvular lesions was observed in 63% and tricuspid endocardiosis in 18% of pigs. The prevalence and severity increases with age. These lesions can be associated with prolapse of the mitral valve and jet impact lesions. They have little significance in growing pigs, but the significance of endocardiosis to clinical cardiac disease in older sows needs examination. Bacterial endocarditis in slaughter pigs has been recorded with a prevalence of 3.1 per 10,000 animals.

PATHOGENESIS
The main clinical indications of valvular disease are audible murmurs and palpable precordial thrills. Murmurs may occur at any phase of the cardiac cycle and are caused by the vibrations of turbulent flow of blood transmitted to the surface of the chest. Vibrations of strong intensity may also result in palpable vibrations at the surface of the chest.

Generation of Murmurs
Blood flow is normally laminar and without turbulence. Turbulence in flow may be produced by a sudden change in the diameter of the vessel through which the blood is flowing. Its occurrence is directly related to the velocity of flow and inversely related to blood viscosity.

Valve Lesions
With murmurs associated with valvular lesions the valve lesion produces a sufficient change in stream bed diameter to result in turbulent flow. The turbulence may occur when the valves do not close properly (regurgitation or insufficiency) and blood is forced through AV orifices during ventricular systole, or through semilunar orifices during ventricular diastole. Turbulence may also occur when the valves do not open completely (stenosis) and blood is forced through a stenotic semilunar orifice during ventricular systole or enters the ventricle through
a narrow AV orifice during ventricular diastole.

The severity of the turbulence and hence the murmur can be increased with higher flow velocities such as occur with exercise and by factors that decrease blood viscosity such as anemia or hypoproteinemia.

Acquired valvular disease usually results in insufficiency of the affected valve and less commonly both insufficiency and stenosis. Congenital lesions more often result in stenosis of the valve.

Murmurs Without Valvular Disease
A change in vessel diameter such as occurs with dilatation of the aorta or pulmonary artery can produce turbulence and a murmur. A reduction in blood viscosity contributes to the frequency of murmurs occurring in anemic and hypoproteinemic states and hemic murmurs are common in anemic cattle, particularly over the pulmonic valve.

Functional Murmurs
Turbulent flow may occur in the absence of a change in stream bed diameter if a certain critical velocity of flow is exceeded. This is thought to be the case of functional or ejection murmurs that occur commonly in horses and lactating dairy cows during the rapid ejection phase even at rest and especially following exercise.

Effects of Valvular Disease
Stenosis of the outflow valves results in an increased pressure load on the heart and compensatory hypertrophy (concentric hypertrophy). Insufficiency of the semilunar valves or of the aortic or pulmonic valve produces a volume load on the heart and is followed by compensatory dilatation and hypertrophy (eccentric hypertrophy). If the valves on the left side of the heart are affected, especially the aortic valve, changes in ejection of the blood from the ventricle alters the character of the peripheral pulse. Involvement of the tricuspid valve will produce changes in the jugular pulse.

Cardiac Reserve
The presence of valvular lesions and murmurs may mean little except that some degree of cardiac reserve is lost. This may be small in degree, and moderate stenosis or incompetence can be compensated and supported for long periods. The importance of valvular lesions that do not result in cardiac insufficiency rests in their possible contribution to disease in other organs by the liberation of emboli, and the necessity for close examination of the heart when they are present.

The purpose for which the animal is maintained also has some bearing on the significance of a murmur. Valvular lesions are of much greater importance in racing animals than in those kept for breeding purposes. The challenge to the clinician is to determine the significance of a murmur to the health and performance of the horse and to the safety of the rider. The presence or severity of an auscultable murmur or echocardiographically identified valvular regurgitation is not associated with athletic performance in racehorses, although a deleterious effect on a small number of horses may exist. The likelihood of valvular regurgitation increases with training in the horse, indicating that valvular regurgitation is an expected response to training in endurance athletes. In other words, valvular regurgitation should not be assumed to indicate the presence of serious valvular pathology in a well-performing horse.

CLINICAL FINDINGS
Only the clinical findings referable to valvular disease are discussed here. The clinical findings in chronic (congestive) heart failure, which may coexist, are discussed elsewhere.

Technique of Examination
Auscultation is the fundamental basis of examination and knowledge of the optimum areas of auscultation and the significance of the murmurs encountered is essential. When a murmur is detected, it should be categorized according to its timing and duration, intensity, location, and character. There is room for improvement in the correct identification of heart murmurs, and specialist clinicians can more accurately identify the likely site of heart murmurs than other clinicians.

Timing
Timing allows a subdivision into systolic, diastolic, and continuous murmurs and immediately shortens the list of possible defects present. There is little problem in differentiating systolic from diastolic murmurs at slow heart rates because of the temporal difference between the length of the systolic and diastolic period. However, where there is a murmur present at fast heart rates this distinction is less obvious and it is possible to misclassify the period of the cycle in which the murmur is occurring.

- A continuous murmur or one that occurs during both systole and diastole may be associated with both stenosis and insufficiency of the same valve or with multiple valvular lesions but more commonly results from the turbulent flow of blood from a high-pressure to a low-pressure system with no intervening valve, such as occurs with a patent ductus arteriosus.

Duration
Duration during systole or diastole is determined by a careful examination of the murmur with a relationship to the period between the heart sounds. Systolic murmurs are further classified as early, late, holosystolic, or pansystolic according to their occurrence and duration in the period between the first and the second heart sounds and diastolic murmurs as early (occurring between S2 and S3), holodiastolic, or presystolic (occurring between the atrial fourth heart sound and S1). Pansystolic and pandiastolic murmurs, occurring throughout the systole or diastole, have greater significance than murmurs that occur, for example, only in early systole and early diastole.

Intensity
Intensity or loudness of a murmur provides a guide to its significance. A system of grading the intensity of murmurs that has been found to be of clinical value is as follows:

- Grade I. The faintest audible murmur; generally only detected after careful auscultation by an experienced clinician
- Grade II. A faint murmur that is clearly heard after only a few seconds auscultation
- Grade III. A murmur that is immediately audible as soon as auscultation begins and is heard over a reasonably large area
- Grade IV. An extremely loud murmur accompanied by a precordial thrill; the murmur becomes inaudible if the stethoscope is held with only light pressure on the chest
- Grade V. An extremely loud murmur accompanied by a precordial thrill; the murmur can still be heard when the stethoscope is held with only light pressure against the chest

Grade I murmurs are not clinically significant, whereas grades IV and V invariably are. The significance of grade II and III murmurs varies according to their cause. A system that grades on a six-grade basis is also used and differs only in a further subcategorization of moderately loud and loud murmurs.

The presence of a precordial thrill is determined by palpation over the point of maximal intensity of the murmur and palpation on the chest over other areas of the heart. A precordial thrill indicates that there is considerable energy generated by the turbulent flow and defines the intensity of the
murmur in the top two grades in both grading systems.

Location and Radiation
Location and radiation of a murmur is related to its areas of generation and transmission. The point of maximum intensity is noted with reference to the areas of maximum audibility of the heart valves described earlier. Low-intensity murmurs are generally restricted to the auscultatory area overlying their area of generation. The auscultatory areas of the heart and of the individual heart sounds have been described earlier in the section on arrhythmias. The vibrations associated with very loud murmurs may be transmitted to other auscultatory areas but generally they are most intense near the area of generation, as is any associated thrill. Murmurs and thrills can be restricted to local areas, and it is essential to examine several auscultatory areas over both sides of the heart.

Character
Character is determined by change in intensity during the duration of a murmur and is defined as crescendo, crescendo–decrescendo, decrescendo, or plateau. Murmurs may also be described according to their frequency characteristics by terms such as blowing, honking, musical, and buzzing, but these interpretations are very subjective and often not repeatable between examiners. Blowing murmurs do not have a major frequency peak of harmonics and therefore do not have an easily identifiable pitch. In contrast, musical, honking, and buzzing murmurs have a primary frequency and associated harmonics. Musical murmurs have a higher fundamental frequency (pitch) than honking or buzzing murmurs, whereas honking murmurs are shorter in duration than buzzing murmurs.

Interpretation
Following this examination the functional defect producing the murmur and the valve involved are determined from the characteristics of timing and duration, location, and radiation, and also any secondary effects that may be present in arterial or venous pulse characteristics. The severity of the lesion is judged in part on the intensity of the murmur but also on the degree of cardiac insufficiency that is present. As a rule all pansystolic mitral and tricuspid murmurs, all holodiastolic murmurs, all right-sided murmurs, and all murmurs with a palpable precordial thrill should be considered pathologic. The cause of the lesion cannot be determined from auscultation but may be determined from the results of general clinical and special pathologic examinations and by a knowledge and consideration of the common causes of valvular disease that involve the particular valve affected in the animal species being examined.

Functional (Innocent) Murmurs
Murmurs not associated with cardiac abnormality occur in all large-animal species, but particularly the horse and the lactating dairy cow. Those associated with turbulence produced during periods of high-velocity flow are often called functional murmurs or flow murmurs; those associated with turbulence resulting from decreased viscosity and increased flow are often called physiologic murmurs.

Functional systolic ejection murmurs are very common in young, fit horses and occur occasionally in cattle, sheep, and pigs. In horses, they are heard best over the base of the heart, usually on the left side over the aortic valve region, and in some horses on the right side, but not usually on both sides in the same horse. They are early to midysystolic murmurs of low intensity (grade 1–3), and arc crescendo–decrescendo or decrescendo in character. In horses they are usually more audible at heart rates slightly elevated above the resting rate. Occasionally in horses, an ejection murmur is audible over the pulmonary valve.

In cattle they are most common at the base of the heart on the left side. A systolic ejection murmur is very common over the left anterior heart base in lactating dairy cattle, and this murmur is thought to be caused by turbulence at the pulmonic valves. Auscultation of this murmur requires placement of the stethoscope directly over the pulmonic valve; this murmur is usually not auscultable when the heart is auscultated at the fourth to fifth intercostal space. Holosystolic murmurs (grade 1–3) are heard in some calves in the first 2 to 3 weeks of life. They are possibly associated with minor deformation of the AV valves by hematocysts at the edge of the valve leaflets, which are common in young calves.

An early diastolic murmur occurs in horses, most commonly in young thoroughbreds and standardbred horses, and is thought to be caused by vibrations associated with the rapid flow of blood into the heart in early diastole. It is a soft (grade 1–2), high-pitched, early diastolic murmur. When heard over the apex area, it is probably a variation of the S3 sound.

A presystolic murmur of grade 1 to 2 intensity and rumbling sound is occasionally heard in horses and is probably a component of the atrial fourth heart sound.

Recumbent cattle commonly have a low intensity (grade 1–3) crescendo–decrescendo systolic murmur that is auscultated over the right side. It will disappear when the animal stands. A similar murmur occurs where there is ruminal distension and bloat.

In newborn calves and foals a systolic murmur is frequently audible over the base of the heart, and it is thought to be caused by a partial temporary patency of the closing ductus arteriosus. In newborn pigs a continuous murmur may be heard, which is often replaced by an early systolic murmur audible for the first week of life.

Insufficiency of the Right AV Valve
Tricuspid valve insufficiency resulting from endocarditis is the most common acquired valvular lesion in cattle, pigs, and sheep. Insufficiency may also result from dilatation of the valve annulus in chronic anemia and with cor pulmonale in conditions such as high altitude disease in cattle. Tricuspid regurgitation can also occur with general heart failure that follows left-sided failure. Because of the association with bacterial endocarditis, tricuspid insufficiency in cattle, pigs, and sheep is usually indicative of significant cardiac disease or the presence of marked pulmonary hypertension. However, in horses, the murmur of tricuspid insufficiency may be present with little evidence of impaired performance.

There is a harsh holosystolic or pansystolic plateau-type murmur most audible over the tricuspid valve area. Loud murmurs project dorsally and to the cranial part of the thoracic cavity on both right and left sides. The murmur is usually accompanied by an exaggeration of the systolic component of the jugular pulse. Congestive heart failure, if it occurs, will be manifested in the greater circulation.

Insufficiency of the Left Atrioventricular Valve
This is the second most common acquired valvular disease in horses, cattle, and pigs. The insufficiency may result from endocarditis or rupture of the mitral valve chordae. There is a loud harsh holosystolic or pansystolic murmur that is most intense in the mitral area. The murmur transmits dorsally and in severe cases may also be heard on the right side. There is frequently marked accentuation of the occurrence of the third heart sound, which may be mistaken for the second sound. A late systolic crescendo murmur has also been associated with mitral insufficiency.

The pulse characteristics are unchanged until the stage of cardiac failure. Cases of mitral insufficiency may compensate at rest and may be only evidenced by decreased work tolerance. Failure, if it occurs, will be initially associated with left ventricular volume overload; however, in some cases the retrograde flow of blood through the mitral valve may lead to pulmonary hypertension and the additional occurrence of right-sided heart failure.

Acute-onset heart failure is usually associated with rupture of the valve chordae. In the horse, mitral insufficiency may predispose the animal to atrial fibrillation.

Insufficiency of the Aortic Valve
Insufficiency of the aortic valve is the most common acquired valvular defect in horses. There is a loud holodiastolic murmur,
frequently accompanied by a thrill caused by the reflux of blood from the aorta into the left ventricle during diastole. The murmur is generally audible over the left cardiac area and is most intense at the aortic valve area and radiates to the apex. It may modify the second heart sound or start immediately following. The murmur may be noisy or musical and the relative intensity varies from horse to horse. Frequently it is decrescendo in character but other variations in its intensity occur. Valvular insufficiency of a sufficient degree to have functional significance is accompanied by an arterial pulse of very large amplitude and high systolic and low diastolic blood pressures (water-hammer pulse). The pulse wave may be great enough to cause a visible pulse in small vessels and even in capillaries. Rarely this lesion is accompanied by a diastolic jugular pulse caused by transmission of the impact of the reflex wave across the ventricular septum to the right side of the heart.

**Stenosis of the Aortic Valve**
There is a harsh systolic murmur, most audible high up over the base of the heart on the left side and posteriorly. The murmur replaces or modifies the first heart sound and is often crescedo–decrescendo in character. A systolic thrill may be palpable over the base of the heart, and the cardiac impulse is increased as a result of ventricular hypertrophy. The stenosis has most functional significance when the pulse is abnormal, with a small amplitude rising slowly to a delayed peak reflecting the diminished left ventricular output. There may be signs of left-sided heart failure, and this lesion may also be associated with syncope.

**Stenosis and Insufficiency of the Pulmonary Valve**
Acquired lesions of this valve are rare in large animals. The auscultatory characteristics are similar to those produced by aortic valve lesions, but there are no abnormalities of the arterial pulse. Pulmonary stenosis produces a distinct murmur at the third intercostal space on the left side of the chest, but some cases of pulmonary stenosis in the horse have no murmur. Murmurs may also be audible anterior to the aortic valve area on the left side of the chest. Heart failure, if it occurs, is right sided.

**Stenosis of the Right or Left Atrioventricular Valves**
Stenosis of either AV valve is uncommon. There is a diastolic murmur caused by passage of blood through a stenosed valve during diastolic filling and audible over the base of the heart on the relevant side. The severity of the lesion will govern the duration of the murmur, but there is likely to be a presystolic accentuation caused by atrial contraction. Right AV valve stenosis may be accompanied by accentuation of the atrial component of the jugular pulse. Some degree of mitral stenosis may occur in acquired lesions that manifested primarily as an insufficiency.

**CLINICAL PATHOLOGY**
Clinicopathologic findings will reflect the changes caused by the primary disease and are significant only when there is endocarditis. Two-dimensional echocardiography, Doppler echocardiography, and color flow Doppler echocardiography are the most valuable noninvasive methods for the examination of valvular disease and allow a detection of the defect, its nature, and its severity. Echocardiography may detect regurgitant flow and flow through stenotic valves that is not detected by auscultation.

**NECROPSY FINDINGS**
Care is needed when the heart is opened to ensure that the valves can be viewed properly and the reflux of blood from the aorta into the left side and posteriorly. The cardiac impulse is most intense at the aortic valve area and is often crescendo–decrescendo in character but other variations in its intensity occur. Valvular insufficiency of a sufficient degree to have functional significance is accompanied by an arterial pulse of very large amplitude and high systolic and low diastolic blood pressures (water-hammer pulse). The pulse wave may be great enough to cause a visible pulse in small vessels and even in capillaries. Rarely this lesion is accompanied by a diastolic jugular pulse caused by transmission of the impact of the reflex wave across the ventricular septum to the right side of the heart.

**Differential Diagnosis**
Murmurs must be differentiated from pericardial and pleural friction sounds and from murmurs caused by congenital defects with shunts.

**TREATMENT**
There is no specific treatment for valvular disease. Methods for the treatment of congestive heart failure and endocarditis are discussed under their respective sections.

**Etiology**
Most cases of endocarditis in farm animals are caused by bacterial infection but whether the infection gains entrance by direct adhesion to undamaged endothelium, or through minor discontinuities of the valvular surfaces, or by hematogenous spread through the capillaries at the base of the valve, is uncertain. A number of different organisms have been associated with this disease. The common infectious causes of endocarditis in animals are listed below.

**Cattle**
- *Truiperella (Arcanobacterium or Actinomyces or Corynebacterium)* pyogénés
- *Helcococcus ovis*
- α-Hemolytic streptococci
- *Micrococcus and Staphylococcus spp.*
- *Pseudomonas spp.*
- *Clostridium chauvoeii* (blackleg)
- *Mycoplasma mycoides*
- *Bartonella bovis* (rare)
- *Erysipelothrix rhustopathiae* (insidiosa) (rare)

**Horses**
- *Actinobacillus equuli*
- *Streptococcus spp.*, including *S. equi* and *S. zooepticus*
- *Pasteurella/Actinobacillus spp.*
- *Pseudomonas spp.*
- *Migrating Strongylus spp. larvae*

**Pigs and Sheep**
- *E. rhustopathiae* (insidiosa)
- *Streptococcus spp.* including *S. equisimilis, S. dysgalactia, S. suis*
EPIDEMIOLOGY
There is limited information on the epidemiology of endocarditis. The majority of cases of endocarditis are usually not diagnosed clinically, and lesions are identified at necropsy or slaughter.

Chronic bacteremia predisposes to endocarditis. There may be a history of an ongoing septic process such as mastitis, metritis, foot abscess, or traumatic reticular peritonitis, or of a procedure, such as the use of an indwelling IV catheter, that might lead to bacteremia. Often there is a history suggestive of low-grade infection. In cattle, ill-thrift with periodic, dramatic but temporary fall in milk production is a common history. The animals often have a lower body condition than expected for their stage of production, and there is frequently a history of intermittent lameness. Horses may present with similar suggestive histories, including shifting leg lameness, intermittent joint distension, coughing, seizures, jugular vein thrombosis, colic, diarrhea, poor growth, and umbilical infection. In sows it is common for agalactia to develop in the first 2 to 3 weeks after farrowing, followed by a loss of weight, intolerance to exercise, and dyspnea at rest.

PATHOGENESIS
Endocarditis may arise from implantation of bacteria onto the endocardium from the bloodstream or by bacterial embolism of the valve capillaries. Endocarditis is predisposed by trauma to the endothelial surface exposing collagen and leading to binding of platelets, activation of the extrinsic coagulation cascade with deposition of fibrin, and the formation of sterile platelet–fibrin deposits.

Endothelial damage may occur along the lines of closure of valves in association with turbulent flow and also can occur for the same reason on areas of the mural endocardium. These areas are subsequently colonized by circulating bacteria, and the organisms grow in these areas enmeshed in a tight, avascular network of fibrin and platelets with further serial deposition of platelets and fibrin. This is the mechanism of endocarditis that occurs secondary to turbulent flow in congenital heart disease and of that produced by trauma such as cardiac catheterization. Myocardial disease may lead to edema of the valves, which may also predispose the animal to endothelial damage.

Endocarditis in large animals is most common as secondary to a chronic infection at some distant site and a persistent bacteremia without predisposing lesions in the heart. Certain organisms have the ability to directly adhere to endothelium, and it is probable that this is the major pathogenic factor.

The major clinical abnormalities associated with endocarditis result from the effect of endocarditis on heart function and from the effects of the embolic showering of microorganisms, which can lead to infarction or infection at other sites in the body. The valvular lesions may be vegetative in the early stages of the disease or, more often, there may be fibrosis and shrinking, distortion, and thickening of the valve cusps. Both interfere with valve function, leading to cardiac insufficiency and possibly cardiac failure. The functional defect produced by valvular endocarditis is usually, but not invariably, valvular insufficiency. Infected emboli most often produce pulmonary embolism with miliary pulmonary abscessation, or infection or abscesses in other organs, including myocardium, kidneys, and joints.

Valve Predilection
In cattle, endocarditis is most common on the right AV (tricuspid) valve. The left AV (mitral) valve is the second valve of predilection, and bilateral involvement of the AV valves is not uncommon. In the horse the most common site of infection is the aortic valve, with the left and the right AV valves being the second and the third valve sites of predilection. Endocarditis of the pulmonary valve is uncommon but is recorded. The AV valves are the predilection sites in sheep and swine.

CLINICAL FINDINGS
The diagnosis of endocarditis in the living animal remains a challenge. A random effects meta-analysis of 460 bovine endocarditis cases provided mean sensitivity estimates (in parentheses) for the following clinical findings: positive blood culture (87%), echocardiographic identification of a lesion (84%), presence of persistent tachycardia (80%), presence of a murmur (60%), presence of a fever (46%), presence of lameness/polyyarthritis (44%), and presence of clinical signs of heart failure (37%). Specificity estimates for the same variables varied widely.3

Cardiac Signs
The important finding is a murmur on auscultation or a thrill on palpation of the cardiac area. Details of the specific findings for individual valve abnormalities can be found in the preceding section on valvular disease. A major problem with diagnosis based on the presence of murmurs is that they are not always present or detected in cases of endocarditis, particularly with right-sided lesions. Persistent tachycardia should be regarded as the most consistent clinical sign in endocarditis.

Emboli
Chronic bacteremia and embolic showering of microorganisms results in signs referable to infection and infarction at other sites in the body. There is a constant moderate, fluctuating fever, and secondary involvement of other organs may cause the appearance of signs of peripheral lymphadenitis, embolic pneumonia, nephritis, arthritis, tenosynovitis, or myocarditis. There is usually much loss of condition, pallor of mucosae, and an increase in heart rate.

Clinical Course
The clinical course in endocarditis may be as long as several weeks or months, or animals may drop dead without premonitory signs. Endocarditis is also a cause of acute heart failure and sudden death in sows. Because sows are confined with minimal exercise during much of the production cycle, the presence of cardiac insufficiency from chronic endocarditis can be masked, and sows with chronic endocarditis may have acute heart failure and die at times of intense exercise, such as mating or during movement to other housing.

Rupture of the Chordae Tendineae
Rupture of the chordae tendineae of the mitral valve in horses may be predisposed by endocarditis or may occur spontaneously and occurs in both adults and foals. It is manifested by sudden onset of acute heart failure in horses apparently previously healthy or, when a complication of a preexisting endocarditis, as a sudden onset complication of the disease or a cause of death. There are signs of acute left failure, and there is usually a prominent third heart sound. The rupture may involve the chordae of any of the cusps of the valve. Rupture of the medial cusp of the aortic valve to produce acute left heart failure and rupture of the pulmonary valve producing right heart failure can also occur.

Electrocardiography
Electrocardiographic findings suggestive of endocarditis are sinus tachycardia and decreased QRS amplitudes in a base–apex lead; ectopic foci may also be present.

Echocardiographic findings suggestive of endocarditis are hypoechoic and echogenic masses, irregular thickening of valves, and rupture of the chordae tendineae.3 The sensitivity of valvular thickening or the presence of a vegetation on the valves for diagnosing endocarditis in cattle ranges from 75% to 100%, with the sensitivity depending on the site of the lesion.

CLINICAL PATHOLOGY
A nonregenerative anemia, leukocytosis, neutrophilia, hyperfibrinogenemia, and hypergammaglobulinemia are common but not specific for endocarditis. In chronic cases, where the lesions are due largely to scarring of the valves, hematologic findings may be normal. Hypergammaglobulinemia is the most common and consistent finding and an indication of chronic bacterial infection. Where there is passive hepatic congestion, there may be an increase in serum alkaline

• Escherichia coli
• Trueperella (Acinarobacterium or Actinomyces or Corynebacterium) pyogenes
phosphatase and γ-glutamyl transferase activity. Repeated examination of the urine may reveal transient episodes of proteinuria and the shedding of bacteria associated with renal embolization and infarction.

**Blood cultures** should be attempted. The avoidance of skin contamination is important and the site should be adequately prepared by initial skin cleansing with 70% alcohol followed by 1% providone iodine applied in a circular pattern around the intended venipuncture site. A contact time of at least 2 minutes should be allowed before obtaining blood for culturing. The ratio of blood to broth culture medium should be 1:10 to 1:20, and the broth should be incubated at 37°C for 24 hours before being examined for the presence of turbidity and plated onto traditional blood agar plates. Blood culture is frequently negative, and it is recommended that three samples be obtained from separate venipuncture sites during a 1-hour period. Sampling at the start of a fever is preferred but clearly impossible; however, in animals with a more constant bacteremia, repeat culturing without regard to fever is successful. Determination of the susceptibility of the organism to antimicrobial agents may aid in treatment.

**Necropsy findings**
The lesions are termed vegetative when they are large and cauliflower-like and verrucose when they are small and wartlike. The former are present on the valves in most fatal cases. In the latter stages the valves are shrunken, distorted, and often thickened along the edges. This stage of recovery is rare in farm animals but may be observed in the seminiferous vases in horses. Spontaneous healing is rare, and in most cases treatment is commenced at too late a stage.

Embolic lesions may be present in any other organ. Culture of the valvular lesions should be undertaken, but in many cases no growth is obtained. Recent studies have demonstrated that culture should be extended for longer than normal (at least 3 days) because some pathogens are slow growing. Moreover, *H. ovis* may have been extensively overlooked in the past as a common cause of bovine endocarditis because its isolation requires cross-streaking a blood agar plate with *Staphylococcus aureus*. The examination of direct smears should always be undertaken.

**Differential diagnosis**
- Pericarditis
- Bristle disease (cattle)
- Cardiac lymphosarcoma

**Treatment**
Treatment is not highly successful because of the difficulty in controlling the infection. The thickness of the lesions prevents adequate penetration of antimicrobial agents and unless the susceptibility of the causative organism is known a range of antibacterial drugs may have to be tried. For this reason there should be repeated attempts at blood culture until the causative organism is cultured to allow drug selection on the basis of susceptibility testing. The choice of antimicrobial agent should be one that allows high concentrations in serum relative to the minimal bactericidal concentration that has minimal side effects over a prolonged period of administration and has a prolonged half-life.

In the absence of a positive culture the types of organism usually isolated in cattle suggest the use of penicillin, possibly combined with gentamicin, or the use of a potentiated sulfonamide. The variety of causative organisms in horses recommends the use of broad-spectrum antibacterial treatment.

**Duration of treatment** needs to be prolonged. It is difficult to judge the duration of therapy required. A fall in temperature can be taken as an indication that infection is being brought under control, but treatment needs to be continued if therapy is to be successful. A period of continual treatment for 4 months with periodic treatment continuing for 14 months in a cow has been recorded.

Relapse is common. Treatment is expensive and in food animals must be extralabel; this is probably uneconomic except for particularly valuable animals. Consequently, the treatment of endocarditis should be approached with reservation. Case fatality is high if signs of congestive heart failure are present.

**The sequel** of embolic lesions in other organs and permanent distortion of valves resulting in valvular insufficiency also militate against a satisfactory outcome. The use of parenteral anticoagulants, as used in humans to prevent further deposition of material on vegetative lesions and to limit embolic disease, has questionable value and requires monitoring not usually available in veterinary practice.

**Myocardial Disease and Cardiomyopathy**

**Synopsis**

**Etiology**
Certain bacterial, viral, and parasitic infections, some nutritional deficiencies

**Epidemiology**
Specific to causative agent

**Clinical findings**
Reduction of cardiac reserve and decreased exercise tolerance, cardiac arrhythmias, congestive heart failure, or acute heart failure

**Clinical pathology**
Electrocardiography, echocardiography, and serum cardiac troponin I concentrations; other examinations directed at determining the specific cause

**Necropsy findings**
Myocarditis, myocardial degeneration

**Treatment**
For cardiac insufficiency, specific therapy, if available, for specific cause

**Etiology**
A number of diseases are accompanied by inflammation, necrosis, or degeneration of the myocardium. These include several bacterial, viral, or parasitic infections and some nutritional deficiencies and toxicities. In most cases, the involvement of the myocardium is only part of the total spectrum of these diseases, although the cardiac manifestations may be clinically preeminent. The term cardiomyopathy is generally restricted to those diseases in which myocardial damage is the prime manifestation. Causes of myocardial dysfunction are discussed in the following sections.

**Bacterial Myocarditis**
- Following bacteraemia, as in strangles or from navel-ill
- Tuberculosis, especially horses
- Tick pyemia in lambs
- *Clostridium chauvoei*
- *Histophilus somni* in feedlot cattle
- Extension from pericarditis, epiparitis, or endocarditis

**Viral Myocarditis**
- Foot-and-mouth disease, especially young animals
- African horse sickness
- Equine viral arteritis
- Equine infectious anemia
- Equine herpesvirus-1 in fetus
- Swine vesicular disease
- Parvovirus in piglets
- Encephalomyocarditis virus infection in pigs
- Porcine reproductive and respiratory syndrome virus in piglets
- Bluetongue in sheep

**Parasitic Myocarditis**
This is primarily associated with *Strongyulus* spp. (migrating larva) cysticercosis, *Sarcocystis* spp., and *Neospora caninum* (in the
Nutritional Deficiency
- Vitamin E/selenium deficiency in all large-animal species
- Some forms of chronic copper deficiency in cattle (falling disease), experimental copper deficiency in swine
- Iron deficiency in piglets and veal calves
- Copper/cobalt deficiency in lambs.

Toxicity
- Inorganic poisons: selenium, arsenic, mercury, phosphorus, thallium
- Gossypol from cotton seed cake
- The mycotoxin fumonisin when ingested by pigs and horses
- Fluoroacetate (1080) and poisoning by *Acacia georgiana*, *Gastrolobium*, and *Oxysolium* spp., *Dichapetalum cymosum*
- Trees, including gidgee, yew, oleander, and avocado
- Grasses, including *Phalaris tuberosa*, corynytoxins in *Lolium rigidum* infested with nematodes, and *Corynebacterium* spp. (also tunicamycin in rain-damaged infected wheat, pigs), cantharidin in hay infested with blister beetles (horses)
- Drugs including succinylcholine, catecholamines, and xylazine (ruminants) monensin, especially in horses, but also cattle, sheep, and pigs; lasalocid and salinomycin in horses, pigs, cattle, and sheep; maduramicin in cattle and sheep fed poultry litter; and adriamycin (used experimentally to produce cardiomyopathy); overdosing with doxycycline in sick calves, but cardiomyopathy could not be reproduced by overdosing in healthy calves
- Vitamin D and myocardial and endocardial calcification following ingestion of *Cestrum diurnum, Solanum malacoxylon, Trisetum flavescens* (see enzootic calcinosis); calcification also occurs with hypomagnesemia in milk-fed calves.

Venoms
- Rattlesnake (*Crotalus* spp.) venom in horses
- *Vipera palaestinae*

**Embolic Infarction**
- Emboli from vegetative endocarditis or other embolic disease such as bracken fern poisoning in cattle

**Tumor or Infiltration**
- Enzootic bovine leukosis of swine
- Other cardiac neoplasia
- Cardiomyopathy in horses caused by amyloid infiltration of the myocardium

**Inherited**
- Malignant hyperthermia of swine
- Hypertrophic cardiomyopathy in swine
- Arrhythmogenic right ventricular cardiomyopathy (arrhythmogenic right ventricular dysplasia) in horses
- Congenital cardiomyopathy of Polled Hereford and Horned Hereford calves with dense curly coats in Australia, and Japanese Black calves
- Bovine dilated cardiomyopathy in cattle of Holstein-Friesian origin, occurring in Red Holstein-Simmental crossbred cattle (Fleckvieh) in Switzerland and Austria; Red Danish dairy cattle in Denmark; Holstein-Friesian cattle in the UK, Austria, Denmark, Sweden, Japan, Canada, and Australia (inherited as an autosomal recessive gene)
- Glycogen storage disease, α-1,4-glucosidase deficiency in Shorthorn and Brahman cattle and Corriedale sheep

**Unknown or Uncertain Etiology**
- Myocardial necrosis and hemorrhage secondary to acute lesions in the central nervous system
- Exertional rhabdomyolysis of horses, capture myocardy of wild ruminants, and restraint stress in swine
- Sudden death in young calves associated with acute heart failure and myocardial necrosis and precipitated by periods of intense excitement such as that experienced at feeding time
- Myocardial lipofuscinosis (brown atrophy) in aged or cachectic cattle, especially Ayrshires, but often found in healthy animals at slaughter
- Myocardial disease following mild upper respiratory disease in horses, especially when training or exercise is continued through the respiratory disease episode
- Dilated cardiomyopathy in a neonatal alpaca
- Asymmetric hypertrophic cardiomyopathy in an adult alpaca
- Dilated cardiomyopathy in sheep in Switzerland

**PATHOGENESIS**

- The primary effect of any myocardial lesion is to reduce cardiac reserve and limit compensation in circulatory emergencies. Minor lesions may only reduce performance efficiency, whereas more severe lesions may produce greater clinical effect.

- Usually myocardial disease results in arrhythmias and conduction disturbances from primary involvement of the conduction system or establishment of excitatory foci within the myocardium. While the animal is at rest, there may be minimal evidence of cardiac disease, but catastrophic disturbances in cardiac conduction may occur under the adrenergic influences of exercise or excitement. The effects of pharmacologic cardioactive agents in poisonous plants are frequently also initially manifest when the animals are moved or otherwise excited.

- Endogenous or synthetic catecholamines, in their own right, can produce multifocal myocardial necrosis, especially in the left ventricle. Sympathetic overactivity and local catecholamine release in the myocardium has been postulated as the cause of myocardial disease accompanying acute brain lesions in domestic animals and myocardial disease associated with some forms of stress and overexertion.

- Myocardial disease may also result in congestive heart failure through its primary effect on the myocardium and the function of the heart as a pump.

**CLINICAL FINDINGS**

In early cases, or cases with mild or moderate myocardial damage, a decreased exercise tolerance is the usual initial presenting sign. This is usually accompanied by an increase in heart rate and heart size, although the latter may only be detectable by echocardiography. There may be clinically recognizable arrhythmia, particularly tachyarrhythmias, associated with multiple ventricular ectopic foci. The characteristics of the pulse and heart sounds are also changed (see arrhythmias).

Animals with suspect myocardial disease but with no or minimal arrhythmic disturbances at rest can be judiciously exercised, which will frequently result in the expression of conduction or arrhythmic abnormality. Exercise or excitement should be avoided in animals with overt arrhythmias at rest.

In the late stages, or in cases with more severe myocardial damage, there may be sudden death or attacks of cardiac syncope caused by acute heart failure, or severe dyspnea or general edema caused by congestive heart failure. Details of the clinical findings associated with conduction disturbances, arrhythmias, and heart failure have been given earlier.

**CLINICAL PATHOLOGY**

Electrocardiography and echocardiography are used in special examination. A mass within the right atrium of cattle is suggestive of multicentric lymphosarcoma caused by enzootic bovine leukosis, but the lesion should be differentiated from endocarditis. Hematologic examination, blood culture, and serology may be of value in determining the cause of myocardial disease, and a full
biochemical profile is advisable to determine whether multisystemic problems are present. Myocardial infarction and necrosis may be associated with the release of cell enzymes into the bloodstream during the acute phase and the determination of the serum activities of LDH, creatine kinase, and aspartate aminotransaminase are of value. The cardio-specific isoenzyme troponin I provides the most sensitive and specific indication of cardiac necrosis (see chronic congestive heart failure section), whereas the predictive value of serum creatinine kinase and LDH activities is much lower. Toxicologic examination and tests for nutritional trace element deficiencies may be indicated.

**DIFFERENTIAL DIAGNOSIS**

- Other cardiac causes of chronic (congestive) heart failure and acute heart failure
- Other causes of decreased exercise tolerance

The diagnosis and differential diagnosis of the specific etiology of myocardial disease rests with the epidemiologic and other considerations of the individual causes and may require specific bacteriologic and virologic examinations, toxicologic and nutritional analyses, or an examination of the environment.

**TREATMENT**

The primary cause must be treated and details are given under the individual headings of the specific diseases listed earlier. When possible, the primary cause of the myocardial damage must be corrected or treated, and details are given elsewhere for the various etiologies listed previously. The treatment of conduction disturbances, arrhythmias, and heart failure is discussed elsewhere in this chapter.

**REFERENCES**

**RUPTURE OF THE HEART AND ACUTE CARDIOVASCULAR ACCIDENTS**

Rupture of the heart occurs rarely in animals. It is recorded in cattle when a foreign body penetrating from the reticulum perforates the ventricular wall, and in the left atrium of horses as a consequence of chronic fibrotic myocarditis. Rupture of the base of the aorta is not uncommon in horses and has the same effect as cardiac rupture. The pericardial sac immediately fills with blood and the animal dies of acute heart failure caused by pericardial tamponade. A similar cardiac tamponade occurs when reticular foreign bodies lacerate a coronary artery or when foals suffer severe laceration of the epicardium during a difficult parturition.

**RUPTURE OF THE AORTA**

The aorta may rupture through its wall just above the aortic valves. The wall could have been weakened previously by verminous arteritis associated with migrating strongyles in horses or onchocerciasis in cattle or by the development of mediocneerosis. Another form of rupture occurs through the aortic root. Death occurs very suddenly; all cases reported by one author affected stallions and coincided with the time of breeding. Cardiac tamponade may occur, but the common finding is a dissecting aneurysm into the ventricular myocardium.

Aortic rupture and aortopulmonary fistulation occurs occasionally in Friesian horses near the ligamentum arteriosum. Formation of a fistula between the aorta and the pulmonary artery produces a sudden onset of cardiac failure and respiratory distress. Affected horses usually die shortly after the onset of clinical signs because of hemorrhage from aortic rupture but can survive up to 8 days or longer if a fistula forms. The rupture is predisposed by abnormalities in the vasa vasorum of the vessels and appears to have a familial occurrence. Antemortem diagnosis is challenging because of the anatomic location of the rupture.

Aortocardiac fistulas originating at the right aortic sinus are recorded in a series of older horses with sudden onset acute distress and exercise intolerance. Five of the seven horses had a characteristic continuous murmurs that was loudest at the right fourth intercostal space. Fistulas extended into the right ventricle or atrium in six horses and the left ventricle in one. Five had dissecting tracts in the septal myocardium.

Rupture of the aorta is the usual cause of death in calves with Marfan syndrome. Some have dissecting aneurysms of the aorta and pulmonary artery. Calves with Marfan syndrome are affected from birth. They have a loud systolic murmur over the base of the heart on the left side in association with enlargement of the aortic root. There are other phenotypic abnormalities, including long thin limbs, joint and tendon laxity, and ocular abnormalities including dorsal displacement of the lens and lens opacity. The nature of the inheritance in cattle is uncertain.

Rupture of an abdominal artery aneurysm in Holstein-Friesian cattle has been reported in more than 30 cattle, with the majority of reports from New York in the United States. Affected cattle are 2½ to 6
years of age and usually present as a sudden and unexpected death with a marked hemoabdomen. An aneurysm of the cranial mesenteric artery was diagnosed antemortem in a cow with severe abdominal pain and the presence of a large pulsatile mass at the root of the mesentery. This condition appears to be caused by an inherited defect in the wall of the abdominal aorta, left gastric artery, right ruminal artery, left ruminal artery, celiac artery, and cranial mesenteric arteries. An autosomal dominant mode of inheritance is suspected.

RUPTURE OF HEART VALVES

Sudden death, or sudden onset of acute heart failure, can also result from rupture of the components of the heart valves. Rupture of the chordae tendineae of the mitral valve occurs in horses both without apparent predisposing lesions and as a sequel to endocarditis and occurs in adult horses as well as foals. It is manifested by sudden onset of acute heart failure in apparently previously healthy horses or, when a complication of a preexisting endocarditis, as a sudden onset complication of the disease or a cause of death. The rupture may involve the chordae of any of the cusps of the valve. Rupture of the pulmonary valve producing right heart failure can also occur.

REFERENCES

COR PULMONALE

Cor pulmonale is the syndrome of right-sided heart failure resulting from an increase in right heart workload secondary to increased pulmonary vascular resistance and pulmonary hypertension. The most documented cause of pulmonary hypertension in livestock is alveolar hypoxia. Acute alveolar hypoxia (lowered alveolar PaO₂) is a potent cause of pulmonary hypertension in several species, but cattle are especially reactive. This is the cause of cor pulmonale in cattle at high altitudes, or bovine brisket disease, which is described in more detail later.

An outbreak of cor pulmonale with pulmonary vascular lesions similar to those seen with high mountain disease but occurring in calves not at altitude is recorded; it was postulated but not proved to be the result of the ingestion of feed contaminated with the pyrrolizidine alkaloid monocrotaline.

Pulmonary hypertension can also result from partial destruction of the pulmonary vascular bed and a reduction in its total cross-sectional area. Pulmonary thromboembolic disease can produce right heart failure by this mechanism. Chronic interstitial pneumonia and emphysema may also induce cor pulmonale by the same mechanism.

Chronic obstructive pneumonia, in which there is airway constriction and accumulation of fluid in distal airways, may induce pulmonary hypertension in cattle by a combination of chronic hypoxia and reduction of the pulmonary vascular bed. Mean pulmonary artery pressures in calves with respiratory disease was 42 mm Hg, compared with 22 mm Hg in healthy age-matched calves. Although pulmonary hypertension and right heart hypertrophy may occur in livestock with primary pulmonary disease, clinical cardiac insufficiency is usually minor, and right heart failure rare. Nevertheless, it can occur and is a cause of congestive heart failure in cattle. Despite the presence of one report of cor pulmonale in a horse, acute pulmonary obstruction in horses with recurrent airway obstruction does not usually induce cor pulmonale; this result is attributed to the relative short term of severe respiratory disease and focal rather than generalized alveolar hypoxia in horses compared with cattle.

In goats, cor pulmonale, with right ventricular and right atrial hypertrophy secondary to interstitial pneumonia, may lead to atrial fibrillation, and cor pulmonale leading to atrial fibrillation has also been recorded in horses.

In highly conditioned feedlot cattle, increased intraabdominal pressure resulting from excessive abdominal fat, forestomach engorgement, and recumbency can lead to pulmonary hypoventilation with decreased alveolar PaO₂ and subsequent right heart failure, which is a syndrome analogous to the Pickwickian syndrome in humans.

Chronic severe elevations in pulmonary venous pressure can lead to constriction and hypertrophy of the vascular smooth muscle of precapillary vessels with resultant pulmonary hypertension. An elevated left ventricular filling pressure is perhaps the more common cause and can set the stage for right heart failure in the left heart failure situations. The toxic principle in poisoning by Pimelea spp. appears to act in part by constricting the pulmonary venules producing pulmonary hypertension, which contributes to the clinical syndrome.

Persistent pulmonary hypertension of the neonate (PPHN) is a common problem in neonatal foals and calves, particularly in calves derived from somatic cell clone technology. Persistent pulmonary hypertension is characterized by persistent postnatal hypoxemia secondary to failure to adapt to extrauterine life. An imbalance between endogenous vasoconstrictors and vasodilators is thought to play a major role in the development and maintenance of PPHN. An increase in plasma concentration of endothelin-1 (a potent vasoconstrictor) has been observed in neonatal calves with PPHN, and the source of endothelin-1 is thought to be the placenta. Many cloned calves have abnormal placenta, characterized by a reduction in the number of established cotyledons that are enlarged and edematous. Treatment is symptomatic, focusing on intranasal oxygen administration and maintaining the calf in sternal recumbency.

HIGH ALTITUDE PULMONARY HYPERTENSION (BRISKET DISEASE, MOUNTAIN SICKNESS)

SYNOPSIS

Etiology Cor pulmonale secondary to pulmonary hypertension induced in susceptible cattle by exposure to high altitude (hypoxemia); heritable in autosomal dominant mode with incomplete penetrance related to gain of function mutations in the gene for hypoxia inducible factor (EPAS1).

Epidemiology Sporadic disease, at high altitudes, of cattle, particularly young or newly introduced; exacerbated by grazing locoweed

Clinical findings Right-sided congestive heart failure; pulmonary hypertension; the name derives from the edema that occurs in the brisket region

Clinical pathology No common hematologic or blood gas variables are useful in detecting or predicting the disease; measurement of pulmonary arterial pressures at higher altitudes; echocardiography

Necropsy findings Right-sided congestive heart failure

Diagnostic confirmation Clinical and epidemiologic; recovery with movement to lower altitudes

Treatment Move to lower altitudes

Control Identification of susceptible cattle by measuring pulmonary artery pressure at altitude; avoidance of grazing locoweed; possible genetic testing

ETIOLOGY

Alveolar hypoxia in cattle at high altitudes results in pulmonary hypertension, and the resultant increase in pressure load on the right ventricle can lead to cor pulmonale and heart failure. Bos taurus cattle have one of the greatest pulmonary artery pressure responses to acute or chronic hypoxia of any species, and this predisposes cattle to the disease. Any additional factor such as myocardial dystrophy, anemia, pulmonary disease, or hypoproteinemia exacerbates the primary condition. The additional effort required to obtain feed on sparse pasture at high altitudes could also be a predisposing cause.

The disease in Angus cattle appears to be associated with a gain of function mutation in the gene endothelial PAS domain
The congestial heart failure that develops at altitude is peculiar to cattle, although other animal species can show an effect from altitude. Horses that are moved up from 300 to 2400 m above sea level show standard increases in pulse and respiratory rates and hemoglobin and erythrocyte levels. Mules are much less susceptible and appear to be unaffected by altitudes as high as 3200 m. Goats, sheep, and donkeys are also reputed to be affected in that order of reducing susceptibility. Llamas and alpacas are adapted to hypoxia at high altitudes, in particular by an oxygen dissociation curve in their hemoglobin, which increases oxygen uptake.

**PATHOGENESIS**

Acute alveolar hypoxia (lowered alveolar \( P_{O_2} \)) is a potent cause of constriction of the capillary pulmonary vessels and pulmonary hypertension in several species, but cattle are especially reactive, and there is a genetic predisposition that determines the magnitude of the response. Prolonged hypoxia and persistent pulmonary vasoconstriction lead to muscular hypertrophy of the small pulmonary arteries and arterioles with a further increase in pulmonary vascular resistance and the development of cor pulmonale.

The disease can be produced experimentally in low-pressure chambers. The movement of cattle from an altitude of 1100 up to 3000 m has been shown to cause hypertrophy of the right ventricle, an increase in pulmonary arterial pressure from 27 mm Hg (3.6 kPa) to 45 mm Hg (6.0 kPa) to over 100 mm Hg (13.3 kPa) and the development of right heart failure.

**CLINICAL FINDINGS**

Affected cattle have a dejected appearance; lose condition rapidly; have a rough, lusterless coat; and stand with the elbows abducted.6 Jugular vein engorgement is followed by the appearance of edema of the brisket, spreading up the neck to the intermandibular space and back along the ventral aspect of the body. Abdominal enlargement caused by the development of ascites is accompanied by diarrhea.

There is hyperpnea at rest and dyspnea and weakness on slight exertion. The mucosae may be cyanotic, particularly after exercise, and the lungs sounds vary from an increased vesicular murmur to moist crackles and an absence of breath sounds when pneumonia is present and to crepitant crackles in the presence of emphysema.

Asusculation of the heart reveals tachycardia, increased absolute intensity of the sounds, or a decrease when there is hydropericardium and an increase in the size of the heart. A systolic murmur is usually present, and a "pistol shot" sound can often be heard with auscultation over the jugular vein. The appetite is normal until the late stages, and the temperature is normal unless secondary pneumonia develops.

**EPIDEMIOLOGY**

**Occurrence**

Brisket disease occurs sporadically in high mountainous areas in North America and South America. The disease also occurs in the highlands of Ethiopia and India. Cattle residing above 1500 m are predisposed and at altitudes above 2200 m an annual incidence of 0.5% to 2% is recorded.

**Risk Factors**

Brisket disease can occur in all ages and breeds of cattle that are maintained at high altitudes for a number of months. The incidence is highest in calves, yearlings, in late pregnant cattle, and in cattle newly introduced to these altitudes. Cattle can adapt to high altitudes, and the morbidity rate in indigenous cattle seldom exceeds 1%. In affected cattle, case fatality is high unless they are moved to lower altitudes. The disease can occur in susceptible cattle at altitudes as low as 1600 m. High rates of calf death (~4% of calves at branding) occur even in cattle herds that have selected for sires with low pulmonary arterial pressures at high altitude.

The ingestion of locoweed (Oxytropis sericea, active ingredient swainsonine) intensifies the effect of high altitude on the development of congestive heart failure.6 The mechanism is unknown, but when groups of cattle at high altitude graze locoweed the annual incidence can approach 100% with high case fatality. An unidentified plant is also thought to potentiate the disease in mountainous areas of Brazil.

**Horses**

Horses at high altitude can lose weight, fatigue easily, and become weak and rough-coated, and show pain but do not develop congestive heart failure.

**CLINICAL PATHOLOGY**

In sheep and cattle, a change to altitudes of 1800 to 3500 m causes a rise in hemoglobin (35% in sheep, 9% in cattle) and packed cell volumes (27% in sheep but no change in cattle) and hemoglobin concentration in red cells (~8% increase in cattle and sheep).

Pulmonary arterial pressures increase significantly immediately after cattle are moved to high altitudes, but the high pressures subside as adaptation develops. Pressures rise from a normal of 22 to 26 mm Hg (2.9–3.5 kPa) up to 37 to 55 mm Hg (4.9–7.3 kPa) depending on whether the calf is susceptible or resistant to the effects of altitude (Table 10-5). Cattle accustomed to live at high altitudes have much less pulmonary hypertension than introduced cattle.

There are no hematologic or blood gas variables that are significantly associated with pulmonary artery pressure in cattle and could act as substitutes for measurement of pulmonary artery pressure.

In clinical cases, there can be a significant reduction in the packed cell volume and in hemoglobin levels.

**Necropsy Findings**

There is enlargement of the heart, with dilatation of the right ventricle and hypertrophy of the right ventricular wall. Slight thickening of the heart valves may be present and there may be areas of calcification in the large arteries. Accumulations of edema fluid are within the pericardial sac, peritoneal and pleural cavities, and in subcutaneous tissues. This edema may also involve the wall of the alimentary tract. Typical congestive changes are evident in the liver: enlargement, rounding of the edges, an enhanced zonal pattern on capsular and cut surfaces, dilatation of the hepatic veins, and a marked deposition of fibrous tissue around the central veins. In the lungs, there is often severe alveolar emphysema and in some cases bronchitis and pneumonia are also present. Histologically, the changes include thickening of the tunica media of vessels in the pulmonary arterial tree and hypertrophy of cardiac myofibers. Microscopic findings in the liver are typical of chronic passive congestion.

**Samples for Diagnostic Confirmation**

- **Histology:** lung, liver, right ventricular myocardium (LM).

**Differential Diagnosis**

Other causes of congestive heart failure
Cor pulmonale associated with chronic pneumonia
**Table 10-5 Evaluation of pulmonary arterial pressure scores in cattle examined at high altitude**

<table>
<thead>
<tr>
<th>Pulmonary arterial pressure</th>
<th>Interpretation</th>
</tr>
</thead>
<tbody>
<tr>
<td>30–35 mm Hg</td>
<td>Low risk of disease. This score is considered excellent and highly reliable.</td>
</tr>
<tr>
<td>36–39 mm Hg</td>
<td>Low risk of disease for any animal over the age of 12 months. If the animal is less than 12 months of age, the score is still fairly reliable, but retesting before breeding is suggested.</td>
</tr>
<tr>
<td>&lt;41 mm Hg</td>
<td>Scores less than 41 mm Hg are reliable measurements in all animals more than 12 months of age. It is recommended that yearling cattle have a PAP measurement less than 41 mm Hg (depending on altitude of the test). The variation in scores 41 mm Hg and above is inconsistent and difficult to predict in some cattle as they age. Any animal measuring 41 mm Hg and greater should always be retested before use for breeding.</td>
</tr>
<tr>
<td>41–45 mm Hg</td>
<td>This range is acceptable only for older animals (i.e., more than 16 months of age). Animals less than 16 months scoring in this range should be retested to predict the future PAP of the animal accurately.</td>
</tr>
<tr>
<td>45–48 mm Hg</td>
<td>This range is acceptable only for older animals that have been in high elevations for an extended period of time. Animals with this score are more susceptible to environmental stresses leading to disease and should be considered at some risk. Elevations of the test site and where the animal lives must be evaluated closely for those in this PAP score range.</td>
</tr>
<tr>
<td>&gt;49 mm Hg</td>
<td>Animals that score in this range must always be considered high-risk candidates for developing brisket disease, not only for themselves but also their offspring. An option for these animals is to move them to a lower elevation. It is also recommended that offspring of these animals never return to high altitude.</td>
</tr>
</tbody>
</table>

PAP, pulmonary arterial pressure. These figures are based on cattle tested at or above 1800 m (6000 ft) and 12 months of age or greater.

**TREATMENT**

The only effective treatment is to move the affected cattle to a lower altitude. Pending this, avoidance of excessive exercise is advisable. Temporary improvement in severely affected animals might be achieved by treatment of the congestive heart failure, but this is not economical for commercial herds.

**CONTROL**

Control measures are difficult to implement because the prime predisposing factor is the grazing of cattle at high altitudes. Avoidance of grazing of locoweed is easy to state but almost impossible to implement. Restriction of grazing of cattle showing signs by hand-feeding a high-protein diet and prompt treatment of cases of pulmonary disease are recommended as worthwhile procedures, although they are really more treatment methods. Testing of cattle for pulmonary artery pressure at altitude allows the selection of sires and dams that do not have high pulmonary artery pressure and are therefore at lower risk of the disease. Development of genetic tests to detect cattle with the causative mutation might allow selection of cattle at lower risk of the disease, but this could be associated with lower rates of weight gain.

**ENCEPHALOMYOCARDITIS VIRUS DISEASE IN PIGS**

Encephalomyocarditis is a viral infection of rodents that is transmissible to domestic animals and humans. Although now isolated from many species (over 30), it is only a significant pathogen in pigs and elephants. It has caused a plague in primates after a rodent plague. Recently the virus was isolated from human cases in Peru. Mortality may reach 50% in young pigs.

**ETIOLOGY**

There are two phylogenetically distinct types: type A is usually responsible for reproductive disorders (e.g., a Belgian strain), and type B for myocarditis (a Greek strain), but some strains can cause both. They differ considerably in virulence.

The cause is a cardiovirus (family Picornaviridae), which is primarily a pathogen of rodents. There is no correlation demonstrated at the moment between genotype and clinical disease. Isolates from different countries have the ability to produce different clinical characteristics and show differences in pathogenicity and molecular and antigenic properties. A possible pneumotropic strain was identified in Quebec, Canada, and this caused interstitial pneumonia. The Belgian isolate is classified as a reproductive strain and the Greek isolate as a myocardial strain. Both strains are able to cause reproductive failure in sows in gestation and to cause myocardial lesions in piglets, but a difference in virulence between both isolates is evident.

**EPIDEMIOLOGY**

Encephalomyocarditis is found worldwide but may cluster in endemic areas, and its seriousness as a pathogen varies from probably inconsequential in the United States to important in Belgium. For example, in the UK antibodies were demonstrated in around 30% of the pigs sampled but no clinical case has ever been described. It is antigenically stable, but there is genetic variability.

It was first described as a cause of neonatal mortality in 1975. When the disease was first described, pigs from 3 to 6 weeks were affected with myocarditis and encephalitis. It is now known that the virus may cause reproductive failure in gilts and sows characterized by stillbirths and mummified fetuses. The prevalence of apparent infection in the swine population is high.

Outbreaks of the disease or serologic evidence of the virus have been reported from the United States, Canada, Australia, Italy, Greece, and many other countries including Central America and now Venezuela. In Europe the most serious outbreaks have occurred in Belgium and Italy. Most work appears to have been performed in Belgium, where there were major outbreaks from 1995 to 1996, which were caused by a new virus.

First reported in 1991 in Belgium, between 1995 and 1996 the disease was diagnosed 154 times in Belgium either as a cause of myocardial failure with sudden death in finishing pigs and suckling piglets or as a cause of reproductive failure in sows. This experience suggests that each isolate is specific for one age category and that the spread of the virus is limited. This recent finding suggests that rodents do play a part in the transmission of the virus but that pig-to-pig transmission is equally important as a source of infection but not yet proven.

In Iowa, infection is widespread in swine herds; the true prevalence of infection in
breeding stock is estimated at 13.8% and 8.5% in finishing animals. About 90% of the herds surveyed in Iowa had one or more seropositive animals, and seroprevalence increased with age. In Italy, most herds and 70% of pigs are seropositive for the virus. Clinical disease has been observed in very young suckling pigs to grower pigs up to 4 months of age but not in adults. It may occur as a sporadic disease or as an outbreak involving several litters of pigs, or pigs within a group. In outbreaks in Greece, in one herd of 100 breeding sows, 200 pigs 8 to 16 weeks of age died from the disease within 2 months. Population mortality in a group of young pigs is variable but it may approach 50% in younger pigs. Transmission is usually thought to be oral and spread among pigs is said to be limited, although because of the presence of virus clones there may be the occasional large outbreak as well. The role of rodents, especially the genus *Rattus*, always supposed to be the main reservoir of the virus for domestic pigs, has been suspected but not documented as the source of spread of the infection to pigs. No pig-to-pig transmission has been shown, and the pig is probably not a risk to man. Serologic surveys of free-living animal species in Iowa in the United States have failed to find evidence of infection in these species, and it is suggested that swine themselves are the main reservoir of infection. In an Australian outbreak, a plague of rats in the piggery may have been the source of the virus. The virus is relatively resistant to heat and chemical influences and a wide variety of pH but is sensitive to desiccation. Outbreaks are frequently associated with rodent plagues in the piggery or area, or with rodent infestation of feed stores. An epidemic in Australia was associated with a plague of mice that were present in all piggeries reporting the disease. It can occur sporadically within several litters at the time or as an outbreak involving a whole group of pigs. It may be related to a single farm or a group of buildings on the farm. It is thought that ingestion is the main means of infection either from infected feces or from rat carcasses. It can be transmitted experimentally from oral, nasal, or aerosol routes. Infection from rodents to man is not documented but has been suspected in Australia when a plague of rats occurred on a farm and mice on another. It has been isolated from a variety of arthropods including mosquitoes, ticks, houseflies, and fleas. No evidence has been found for the virus in free-living populations in the United States. Feed can be contaminated by rodent feces.

The virus is relatively resistant to heat and chemicals. The virus is now considered a major cause of reproductive failure in swine herds. The virus has been recovered from fetuses, antibodies to the virus have been demonstrated in fetal fluids, and histologic lesions supporting a diagnosis of the viral infection have been observed. The economic losses associated with reproductive and neonatal losses associated with the virus have been estimated at $100 per inventoried sow. Investigations of outbreaks on two Minnesota swine farms indicated that the monthly averages for the numbers of piglets born dead per litter reached 4.6 and 3.6, the preweaning mortalities 50% and 31%, and the farrowing rates 52% and 63%, respectively.

**PATHOGENESIS**

Critical factors appear to include virus strain, exposure dose, passage history, and individual sensitivity but also route of infection and age of the affected pigs. The portal of entry appears to be the tonsils and then macrophages may then disseminate the virus. Viral persistence may be most marked in the Peyer’s patches and the thymus. This is followed by the viremia and spread to the lymph nodes.

The effects of different experimental doses and ages in experimental infections of pigs are described in a paper from Greece. The pathogenesis of these Greek viruses has been described, and in most cases there is a viremia with the lymphoid tissues containing the virus, which are probably the main source of the virus replication. Inoculation of a suspension of heart, spleen, and lymph node tissues from affected pigs can result in sudden deaths of experimental pigs within 3 days. The highest titers of the virus are found in the areas of damaged heart muscle. Macrophages may play an important part in the virus replication and shedding. Cytokine production is also an important feature of infection (including IL-1β, TNF-α, and IL-6). The virus can cause fetal death if the pregnant sow is infected in late pregnancy. The experimental inoculation of the virus into pregnant sows at 46 to 50 days of gestation results in transplacental infection and fetal deaths. On the other hand, experimental infections of 4- to 6-week-old conventional pigs with an American isolate produced no overt clinical disease. There may also be a seasonal occurrence in the autumn where there are more rats.

**CLINICAL FINDINGS**

Usually encephalomyocarditis is an inapparent infection. Subclinical infection is the normal event, particularly in older or adult animals, but even here, occasionally, death may occur.

Rarely is there clinical disease because most cases are seen as sudden death without clinical signs as a result of circulatory failure.

The clinical course in young and growing pigs is short and manifested by inappetence, depression, trembling, incoordination, and dyspnea. In the United States, it has been described as associated with respiratory disease. There may be cyanosis of the extremities. Most frequently, pigs are found dead or die suddenly while feeding or when excited. Death appears to result from cardiac failure, and clinical signs referable to encephalitis are rare.

An outbreak in sows may last 2 to 3 months with continuing reproductive failure, characterized clinically by inappetence and fever, possibly to 41°C followed by farrowing at 109 to 111 days of gestation in affected sows. There are numbers of mid to term abortions. The numbers increase for stillborn piglets, mummified fetuses, and weak piglets, which are more susceptible to crushing and starvation and other common neonatal diseases. The course of the outbreak will usually last several weeks and possibly as long as 2 to 3 months with continuing reproductive failure with persistence of the virus. Animals with cardiac failure should be killed humanely because the heart damage does not resolve.

**CLINICAL PATHOLOGY**

Neutralizing antibodies to the virus are present in sows and healthy in-contact pigs on affected farms. They are found 5 to 7 days after infection. In outbreaks of reproductive failure, specific antibody to the virus can be found in both fetal and neonatal sera collected from abnormal litters. The hemagglutination inhibition and agar gel immunodiffusion (AGID) tests are comparable for the detection of antibodies to encephalomyocarditis virus in fetal thoracic fluids.

A microtiter serum-neutralization test is a relatively specific and sensitive test for the diagnosis. Antibodies of 1:8 are suspicious, and titers ≥16 are positive. Serum-neutralizing antibodies persist for several months, and it is necessary to examine paired samples. A nucleic acid probe can detect the presence of the virus in infected cell lysates. Enzymes such as serum creatine kinase-M5 and lactic dehydrogenase isoenzyme are also elevated.

**NECROPSY FINDINGS**

Young weak-born piglets are more prone to crushing, starvation, and other neonatal disorders so an underlying encephalomyocarditis may be missed.

At necropsy, there is reddening of the skin and excess peritoneal, pleural, and pericardial fluid frequently seen with fibrinous strands and edema of the omentum and mesentery. Sometimes there is pulmonary edema and liver enlargement. Characteristically, the heart appears pale and soft and there is diffuse or focal myocardial pallor involving the ventricles and associated with myocardial necrosis. These may appear as distinct white foci or streaks from 2 to 15 mm in diameter and these are most common on the right ventricular epicardium. A strain was isolated in Quebec that can cause pneumonia.

Histologically, there is diffuse or focal myocarditis, with infiltration by histiocytes, lymphocytes, plasma cells, and degeneration...
of cardiac muscle cells. The virus can be identified in the cytoplasm of cardiac muscle cells, and virus particles are also seen in the protrusions from the cell surface of the Purkinje fibers and endothelial cells of the capillaries and intracranially in the cardiac muscle fibers. In chronic cases these have healed in the only way possible—as fibrous plaques. In acute cases virus may be isolated from the heart muscle and also from the brain, spleen, and other tissues. Neutralizing antibody becomes detectable 5 to 7 days after infection.

The predominant histopathologic lesion in stillborn fetuses is myocarditis consisting of myocyte degeneration and necrosis with focal or diffuse mononuclear cell infiltration. In nursing piglets with the disease, histologically there are lesions of multifocal interstitial pneumonia, myocarditis, and mild multifocal nonsuppurative meningoencephalitis. In growing pigs and the peracute bacterial bowel edema and mulberry heart disease in stillborn fetuses is myocarditis consisting of nonsuppurative inflammation, cardiomyopathy, and necrosis with focal or diffuse mononuclear cell infiltration, which can be confirmed by immunohistochemistry. It is usually positive in the nuclei of the cardiac muscle cells, Purkinje cells, the endothelial cells of the capillaries and in the macrophages.

Samples for Confirmation

- Serologic samples for neutralizing antibodies, which is widely available and is specific or HI antibodies, may be helpful. Antibodies have been found in fetal fluids. Tests now include enzyme-linked immunosorbent assays (ELISAs), latex agglutination, and AGID.
- The virus can be isolated from stillborn pigs. It can also be demonstrated by polymerase chain reaction (PCR), reverse transcriptase (RT)-PCR, and one-step PCR. The RT-PCR can be followed by genetic typing using sequence analysis, and this is useful in molecular epidemiology. It has also been demonstrated by in situ hybridization.
- Histopathology on heart muscle is also useful with immunohistochemistry to follow to confirm. In the neonate, the brain histology may show a nonsuppurative meningoencephalitis, which can be confirmed by immunohistochemistry.

Diagnosis

Diagnosis of encephalomyocarditis is from the history, clinical signs, gross and microscopic pathology, and from isolation of the virus or demonstration of the antigen by immunohistochemistry. In some cases it may be necessary to consider vitamin E deficiency (mulberry heart disease). The reproductive form of the infection may need to be differentiated from porcine parvovirus infection.

TREATMENT AND CONTROL

There is no treatment for encephalomyocarditis and control of the disease currently rests with rodent control and eradicating in the piggery. There is now an inactivated vaccine available, which is an oil-adjutant vaccine developed to protect elephants. It has been shown to work in mice and pigs and is thought to produce high antibody titers in both domestic and wild animals.

ETIOLOGY

Cardiac glycoside is the parent or group name for the compounds cardenolid and bufadienolide. Chemically and structurally, they are an aglycone, which is related to the steroidal hormones, and contain one or more sugar molecules. Cardenolides are produced by plants, whereas bufadienolides are produced by both plants and animals. The most common cardenolide-containing plants toxic to large animals are Asclepias spp. (milkweed), Digitalis purpurea (foxglove), Kalanchoe spp. (lambkill and lambkill), Nerium spp. (oleander), Persea americana (avocado), and Rhododendron spp. (azalea and rhododendron). Bufadienolides present in some plants from southern Africa have a cumulative, neurotoxic effect (cotelodoneosis or krimpsiekte disease), whereas other bufadienolide-containing plants (genera Moraea and Drimia) produce more acute cardiac toxicity. Toxins in toads (genus Bufo) have affinities with the aglycones of bufadienolides and poison dogs, but poisoning of farm animals seems unlikely.

The plant genera or specific plant species and toxins known to contain cardiac glycosides that can be associated with an acute syndrome or a chronic cumulative disease (cotelodoneosis or krimpsiekte) are listed next.

Kalanchoe  
Ornithogalum  
Tylecodon5

**EPIDEMIOLOGY**

**Occurrence**

Poisoning occurs wherever the plants grow, and local extension agents or plant experts should be consulted for specific plant information. Many other related plants, and some in other species, are associated with clinical illness similar to cardiac glycoside poisoning. The acute poisoning syndrome is seen in several parts of the world, principally in southern Africa, northern America, and in Australia, but chronic poisoning (cotyledonosis or krimpsiekte) is confined to southern Africa.3-5

**Risk Factors**

**Animal Factors**

Cardiac glycoside-containing plants are highly toxic and only a very small amount needs to be ingested for toxicosis to occur. Morbidity rates vary with the intake,3,10 case-fatality rates are very high. Cattle,11,12 sheep,3 and goats13,15 are most often affected and llamas16 and horses17 less so. Wild animals appear to avoid the plants, and some are reputed not to be susceptible.

**Plant Factors**

Some of the plants are most readily eaten when they are in the flowering stage. Many are so unpalatable that they are unlikely to be eaten unless they are cut in with other plants and fed as hay or seed contaminates a crop of feed grain. Some of them, like N. oleander (oleander) and Rhododendron spp., are decorative plants, and animals gain access when they break into gardens, are fed prunings, or trees fall into their pastures.11 P. americana (avocado) may be intentionally fed to pet animals as a treat, when herds have access to the plant, or there is an avocado tree in their pasture or turnout.11 The plants do not lose their toxicity when dry. Insects and other plants that eat or parasitize plants containing cardiac glycosides may contain the substances in significant amounts.

**Human Risk Factors**

Humans ingesting grayanotoxin-containing honey produced by bees from the nectar of Rhododendron spp. have developed cardiac abnormalities, vomiting, sweating, dizziness, and impaired consciousness (mad honey disease). Secondary intoxication of dogs or humans who eat meat from affected livestock dying from krimpsiekte disease occurs even after the meat is cooked.3,5

**PATHOGENESIS**

Cardiac irregularity and insufficiency leads to acute or subacute heart failure. Cardiac glycosides are specific inhibitors of plasma membrane Na+-K+-ATPase, the cation pump responsible for maintaining cellular homeostasis. Inhibition results in decreased intracellular potassium and increased intracellular sodium concentrations and subsequent increases in intracellular calcium.2,10,18 Elevated intracellular sodium concentrations inhibit the Na+/Ca2+ channel exchange, increasing the force of cardiac contraction (positive inotrope) and raising the resting membrane potential.17,18 Electrical conduction is altered and in the heart, vagal tone to the SA, and AV nodes is increased resulting in cardiac arrhythmias and cardiac arrest.

Cotyledonosis or krimpsiekte disease is most common in sheep and goats after prolonged exposure to Cotyledon, Kalanchoe, or Tylecodon and in bufadienolide-containing plants found in Southern Africa.2 Chronic ingestion of these succulent plants (plakkies) generally results in the paraplegic syndrome known as krimpsiekte or “shrinking disease.” Mortality may reach 90%.1 Horses and domestic chickens with chronic ingestion have also become ill.1 Acute intoxication with signs of cardiac toxicosis may also occur, depending on the dose, specific plant, and other factors.3,7

**CLINICAL FINDINGS**

**Acute Poisoning**

Clinical signs, although common to the cardiovascular system, also involve the kidneys, gastrointestinal tract, and nervous system.2,12,13 Common signs are apathy, a tendency to stand with head bowed and abdomen tucked up, teeth grinding or grunting, cardiac arrhythmias (tachycardia or bradycardia and heart block), dyspnea, ruminal atony, bloat, diarrhea with mucoid or blood-stained feces, dehydration, and posterior paresis. Sudden death may occur, particularly during exertion. Poisoning by Homeria spp. in some parts of southern Africa only results in constipation rather than diarrhea. Additional signs include hypersalivation, tenesmus, dribbling urine, muscular tremors, dilated pupils, and seizures. Pigs are likely to vomit.

**Chronic Poisoning**

Cotyledonosis or krimpsiekte in small ruminants is characterized by animals lagging behind the flock, tiring easily, walking with the head loosely dangling and then lying down, and usually with the head and neck stretched flat along the ground.3,5 Many assume a characteristic posture with the feet gathered together beneath the body, the back arched, the head down, and the neck sometimes twisted toward one side. This torticollis can persist for months or years. Signs are aggravated by exertion; hyperesthesia, trembling, and tetanic spasms may also occur. Additional signs include drooping of the lower jaw, drooling of saliva, paralysis and protrusion of the tongue, and dysphagia with accumulation of half-masticated feed at the back of the mouth. Horses have pronounced torticollis and hyperesthesia and may show signs of colic or be paralyzed.

**CLINICAL PATHOLOGY**

Acute poisoning of sheep by H. pallida produces progressive hemocoagulation; hyperkalemia; hypochloremia; progressive hyperglycemia associated with rises in catecholamines, cortisol, and lactate; and progressive increases in plasma creatinine concentration, plasma α-hydroxybutyrate dehydrogenase, and LDH activities. Acute poisoning of cattle by Bryophyllum spp. also produces hemocoagulation, progressive hyperglycemia, glycosuria, and progressive increases in plasma urea and creatinine concentrations.

Electrocardiograms may show significant changes in the ECG of affected animals indicating the presence of ventricular fibrillation and ectopic foci in the myocardium.13 Reported ECG effects include bradycardia or tachycardia, prolonged PR interval, depressed or elevated ST segment, and increased amplitude and inverted T wave. The QRS complex may widen from delayed AV conduction. Other effects include AV dissociation, varying degrees of heart block, evidence of ectopic foci, and runs of ventricular tachycardia.16

Elevations of cTnI, a biomarker for cardiac disease, have been evaluated in a limited number of horses with oleander toxicosis. Of seven horses sampled, five had cTnI serum concentrations over the normal reference range, and two were within the reference range.7 Because of the sudden death in many cases, pieces of the toxic plant can often be identified in the stomach or rumen contents by botanical characteristics. In digitalis poisoning, digitoxin may be assayed in the ruminal contents.

**NECROPSY FINDINGS**

In acute poisoning, mild- to severe multifocal myocardial degeneration and necrosis is often present if the patient survives for more than 12 hours. Subendocardial and subepicardial hemorrhages and hemorrhages into
the mucosa and lumen of the large intestine are common in acute cases. Atelectasis of lung lobes is common, and pulmonary congestion and edema secondary to cardiac failure may be seen. Fragments of the plants responsible for poisoning may be recognized in stomach contents. Nephrosis has been seen occasionally. Hemorrhages of the rumen wall and necrosis and ulceration of the omasal leaves have been seen in animals affected for several days. Evidence of hepatic insufficiency, including jaundice, is present in some poisonings, but its pathogenesis is unclear.

Toxins may be detected in the rumen or stomach contents using chromatographic/mass spectrometry techniques.

DIFFERENTIAL DIAGNOSIS
The diagnosis depends on the detection of one of the toxic plants, either in the pasture or in conserved roughage, in the environment of animals showing characteristic clinical signs, or sudden death. Diagnosis confirmation is established by identification of the plant, cardiac glycoside, or both in ingesta in association with myocardial lesions.

**Differential diagnosis list:**
- Colic (torsion, etc.)
- Cyanide intoxicosis
- Fluoroacetate intoxicosis
- Gossypol intoxicosis
- Heavy metal intoxicosis (arsenic and lead)
- Ionophore (carboxylic) intoxicosis
- Lightnigletlectrocrution
- Myocarditis/endocarditis
- Plant poisonings: Albizia tanganjicensis, A. versicolor, Fadogia hombele (F. monticola), Galenia africana, Ornithoglossum viride, Pachystigma spp., Pavetta spp., Taxus spp., and Urechites lutea

TREATMENT
Primary Treatment
Removal of animals from the suspect pasture or changing the source of conserved roughage is usually obligatory. Activated charcoal is effective in adsorbing oleander toxins; clay smectite is less effective.20

**Supportive Treatment**
IV or oral fluid replacement therapy is recommended for rehydration and correcting azotemia. Parenteral antirhythmic drug therapy (lidocaine and procainamide), atropine for heart block, and propranolol for tachycardia have been used with varying degrees of success.14,15 Digoxin-specific antibody fragments have been used successfully in humans as an antidote for yellow oleander poisoning and anecdotally in animal species for several cardiac glycoside plant toxicoses.8 Their cost may preclude the use in large animals. The recovery rate declines sharply with the lapse of time between ingestion of the plant and treatment. The presence of cardiac arrhythmias is associated with non-survival in horses poisoned with oleander.17

CONTROL
Animals should be kept off contaminated pastures and access strictly enforced. Prunings from shrubs and trees should not be fed to animals or thrown into their pastures or drylots. Trees or branches falling in the pasture should be removed. Experimental vaccination for krimpsiekte disease has been successful in a limited number of sheep.1

The recovery rate declines sharply with the lapse of time between ingestion of the plant and treatment. The presence of cardiac arrhythmias is associated with non-survival in horses poisoned with oleander.17

**EPIEDEMOLOGY**
**Occurrence** All species of animals as well as humans are susceptible to toxicosis from taxaines present in yew plants. Most clinical cases of poisoning are accidental and occur from animals fed yew clippings or having access to them.

**Risk Factors**
**Animal Risk Factors**
Horses are the most sensitive to yew toxicosis with only 0.2 to 0.4 g yew leaves per kilogram BW required to reach a minimum toxicity (LDmin).1 They are closely followed by pigs (0.7 g yew leaves per kilogram BW), cows (2 g yew leaves per kilogram BW), sheep (2.5 g yew leaves per kilogram BW), and goats (12 g yew leaves per kilogram BW).12 White tail deer and roe deer in the United States appear to be insensitive to the taxaines present in T. baccata.13 Animals with hepatic disease may be at a higher risk of toxicosis as taxaines are metabolized in the liver.2

**Environmental Risk Factors**
The presence of yew plants in the animals’ environment, either alive or dead, is a high-risk factor. During the holiday season, yew cuttings may be incorporated into wreaths or swags; horses have been accidentally poisoned when these were used to decorate stalls, boxes, or fence lines. The incidence of poisoning may be higher in the winter when there is no other green plant material for animals to eat.1

**Transmission**
Taxines A and B are present in clippings and dried plants and poisonous when ingested by animals.12
PATHOGENESIS
Taxine alkaloids are absorbed orally, distributed to most body tissues except the central nervous system and testes, metabolized by hepatic P450 enzymes, and excreted at least to some extent in the bile. Elimination in the milk has not been reported, but discard ing milk is recommended. Taxine alkaloids are calcium channel antagonists acting on the cardiac myocytes. There are differences in the cardio toxicity of the alkaloids, and taxine B is much more cardiotoxic than taxine A. Taxine B intoxication results in chronotropic effects more cardiotoxic than taxine A. The general syndrome appears about 12 hours after the toxic plant is ingested and includes sudden death without other signs or a syndrome of hypersensitivity, frenzy, dyspnea, cyanosis, tachycardia with rates up to 300 beats/min, cardiac arrhythmias, ataxia, recumbency, and convulsions. Minor signs include moderate bloat, appearance of signs when animals are driven, and frequent micturition. Death may follow in a few minutes to several hours. Necropsy lesions include myocardial necrosis, pulmonary congestion and edema, and generalized venous congestion.

In northern inland Australia, poisoning by Acacia georgiae has been associated with heavy mortalities in cattle and sheep and has seriously reduced the productivity of large areas of grazing land. The fluoroacetate ion is concentrated in the young leaves and seed pods. At necropsy, there is congestion of the alimentary mucosa, flabbiness of the myocardium, and multiple subendocardial and subepicardial hemorrhages. There may be edema and congestion of the lungs. Gastrolobium spp. (42 species known or suspected to be toxic) are also sources of poisoning in Australia, mostly in the southwest, and Palicourea maracgravii (South America) and Chailletia toxicaria (Dichapetalum spp. Africa) are responsible for many outbreaks in South America. Twelve species of Dichapetalum, e.g., D. cymosum (Gibbilar), D. ruhlandii, and D. barteri, are poisonous shrubs in Africa but are also found generally in the tropics. Their fresh green leaves contain fluoroacetate. Acetamide (2 g/kg) given experimentally soon after the ingestion of Dichapetalum spp. appears to have helped animals against the poison.

- Myocarditis/endocarditis

TREATMENT
There is no antidote and no specific treatment is generally provided as sudden death is the normal outcome. Absorption and removal should be minimized with the use of activated charcoal and a cathartic such as magnesium sulfate in monotonic cases and ruminants in ruminants. Atropine and antitussive agents, including lidocaine, have been used in animals but were found to be ineffective in human cases.

MONOFLUOROACETATE PLANT TOXICOSIS
Plants containing toxic amounts of fluoroacetate include the following:
- Acciaea georgiae (Georgina gidgee; Australia)
- Amorimia spp. (old Mascagnia spp.; South America)
- Arreludia bilabia (South America)
- Chailletia toxicaria
- Dichapetalum spp. (Africa)
- Gastrolobium spp. (poison pea; Australia)
- Oxylabium parviflorum (Australia)
- Palicourea maracgravii (South America)
- Spondianthus preussi (Africa)

Monofluoroacetate or sodium fluoroacetate occurs naturally in more than 40 plants native to Australia, Brazil, and Africa. Fluoroacetate in the body is converted to fluorocitrate, which inhibits the enzymes aconitase and succinate dehydrogenase in the tricarboxylic acid cycle (Kreb cycle) leading to the accumulation of significant amounts of citrate in tissues and to irreversible cardiac damage. Native herbivorous mammals in southwestern Australia have evolved a high level of genetic tolerance to this toxin, and this has been used as a genetic marker to trace the evolutionary history of some of the continent’s indigenous marsupials.

The general syndrome appears about 12 hours after the toxic plant is ingested and includes sudden death without other signs or a syndrome of hypersensitivity, frenzy, dyspnea, cyanosis, tachycardia with rates up to 300 beats/min, cardiac arrhythmias, ataxia, recumbency, and convulsions. Minor signs include moderate bloat, appearance of signs when animals are driven, and frequent micturition. Death may follow in a few minutes to several hours. Necropsy lesions include myocardial necrosis, pulmonary congestion and edema, and generalized venous congestion.

In northern inland Australia, poisoning by Acacia georgiae has been associated with heavy mortalities in cattle and sheep and has seriously reduced the productivity of large areas of grazing land. The fluoroacetate ion is concentrated in the young leaves and seed pods. At necropsy, there is congestion of the alimentary mucosa, flabbiness of the myocardium, and multiple subendocardial and subepicardial hemorrhages. There may be edema and congestion of the lungs. Gastrolobium spp. (42 species known or suspected to be toxic) are also sources of poisoning in Australia, mostly in the southwest, and Palicourea and Amorimia are responsible for many outbreaks in South America. Twelve species of Dichapetalum, e.g., D. cymosum (Gibbilar), D. ruhlandii, and D. barteri, are poisonous shrubs in Africa but are also found generally in the tropics. Their fresh green leaves contain fluoroacetate. Acetamide (2 g/kg) given experimentally soon after the ingestion of Dichapetalum spp. appears to have helped animals against the poison.

4-METHOXYPYRIDONE
PLANT TOXICOSIS

4-Methoxypryridone, a pyridoxine analog found in Albizia spp. ([A. versicolor, fever tree] and Albizia tanganicaensis [paperbark albizia]), especially in the dried pods is a cardiotoxin. Clinical signs in cattle include hypersensitivity, hyperthermia, dyspnea, ataxia, and tetanic convulsions with rapid blinking and nystagmus. Most cases recover spontaneously.

Cardiomyopathy is the diagnostic necropsy finding. Lesions also include petechiation in many tissues, pulmonary edema, and degenerative changes in the myocardium and other organs and in some cases the brain.

Pyridoxine is a satisfactory antidote, even if signs have already appeared.

REFERENCE

PLANTS CAUSING HEART FAILURE (UNIDENTIFIED TOXINS)

Several plants with unidentified toxins are associated with heart failure in large animals, and either cause congestive heart failure and cardiomyopathy and/or sudden death. These plants are listed below.

- Heart failure with sudden death or congestive failure and cardiomyopathy atalaya hemiglaucua (whitewood)
  Galenia africana
  Phalaris coerulescens (blue canary grass)
  Phalaris paradoxa
  Tanacetum exitiosum
  Tetrapertis spp.
  Urochites lutea

The following contribute to the African syndrome of gousieke (“quick sickness”); the toxin may be a polyamine, purified and identified as pavetamine.

Fadogia hombeli
Pachystigma latifolium
P. pygmaecum
P. thamnus
Pavetta harbortii
P. schuamanniana

IONOPHORE (CARBOXYLIC) TOXICOSIS

EPISTOLOGY
Carboxylic ionophores are used as polyether antibiotics for the control of coccidiosis in poultry and to promote growth and/or increase feed efficiency in ruminants. Currently, there are seven carboxylic ionophores approved for veterinary use: monensin, lasalocid, salinomycin, narasin, maduramicin, ladiomycin, and semduramicin. Of these, monensin, lasalocid, and salinomycin are used in ruminant production; monensin is the most widely studied of the three. In addition to labeled use and effects, monensin has shown to be beneficial in the treatment of acetonemia, lactic acidosis, bloat, and atypical interstitial pneumonia. The pharmacologic effects of ionophores are similar, but they differ chemically and have differing toxicities. Used properly the compounds are effective, but the margin of safety is small and careless use has been associated with major losses.

The recommended dose of monensin varies depending on the age and size of the livestock and the purpose for which it is administered. The manufacturer’s recommendations should be adhered to strictly. Approximate recommended levels, orally and usually in the feed, are cattle, 50 to 200 mg per head per day, 16.5 to 33 parts per million (ppm) and sheep 5 to 10 ppm in feed.

For monensin, dosage levels at which clinical signs of poisoning can be expected to occur are cattle 10 mg/kg BW, sheep 4 mg/kg BW, swine 7.5 mg/kg BW, and horse 1 mg/kg BW. The comparative LD₅₀ are cattle 26.4 mg/kg BW, sheep 11.9 mg/kg BW, swine 16.7 mg/kg BW, goat 24 mg/kg BW, and horse 2 to 3 mg/kg BW. It is common for cattle to be poisoned with more than 10 times the recommended dose. Toxic feed concentrations for pigs are 200 to 220 mg/kg of feed. For lasalocid, the reported lethal dose in horses is 21.5 mg/kg BW; in cattle it is 50 to 100 mg/kg BW, and in swine it is 58 mg/kg BW. The LD₅₀ for salinomycin for the horse is 0.6 mg/kg BW. The effects of the compounds are cumulative and may not be observed for some weeks after administration is discontinued.

EPIDEMIOLOGY

Occurrence
All animal species are affected by ionophore toxicosis. Horses are the most sensitive to it, but deaths have been reported in cattle, sheep, goats, pigs, camels, water buffalo, and other species. Poisoning incidents are most often reported in countries where animal husbandry is intensive and high levels of stall feeding are practiced.

Risk Factors

Animal Risk Factors
These compounds are specifically prohibited for use in horses at any time because of their toxicity for that species. Horses are often poisoned by ingesting premixes meant specifically for cattle. If the level of ingestion is low enough, no harm is done, but most commonly horses eat more than the no effect level and become symptomatic.

Cattle carrying reticular retention boluses of monensin to control bloat by delivering accurate daily doses of the drug may die suddenly of acute heart failure caused by myocardopathy, a condition associated with monensin. The compounds main use as a coccidiostat is in poultry, and deaths from congestive heart failure have occurred in cattle and sheep fed dried poultry litter from farms feeding salinomycin or maduramicin.

Along with these major involvements of monensin and lasalocid there are a number of less well-known ones. There is a risk that cattle fed on a nitrogen-rich diet will be likely to suffer an outbreak of nitrite poisoning if they are also fed monensin. Another undesirable outcome may be a fall in butterfat because of shift from acetate to propionate production in the rumen.

The concurrent administration of monensin and selenium to lambs enhances the toxicity of the selenium. Continuous feeding of monensin to male pigs (50 ppm for 52 days) reduces blood levels of testosterone and is associated with dystrophy of seminiferous tubules and reduced sperm counts.

The concurrent administration of monensin or salinomycin and tiamulin, chloramphenicol, triacytyleydoamycin, or other macrolide antibiotics at recommended doses can be associated with ionophore poisoning in pigs. Outbreaks may occur when the product is introduced into the pigs’ drug regimen to control swine dysentery when the pigs’ ration already includes the ionophore as a growth promotant, or when the two drugs are combined as a coccidia prevention package.
Swine Risk Factor (Tiamulin)

The myotoxicity of monensin for pigs is enhanced by the simultaneous administration of the two antibiotics (monensin or salinomycin and tiamulin). All three of the substances are used as coccidiostats, and it is not unusual for farmers to combine them. However, all of the agents use the same detoxification pathways in the liver with tiamulin having the priority. Tiamulin inhibits mitochondrial CYP3A enzymes that stimulate monensin metabolism, allowing accumulation of monensin. Monensin (or salinomycin) accumulates to the point of being toxic. The clinical syndrome consists of anorexia and weight loss, and at necropsy there are lesions of myonecrosis in the tongue, diaphragm, and limbs. A similar toxicologic situation arises in pigs with simultaneous dosing with tiamulin and salinomycin in which the toxic interaction is dose related.

When tiamulin is used at therapeutic levels in feed, water, or by injection and salinomycin is used at 60 ppm, toxic reactions and deaths occur. The interaction does not occur when the two antibiotics are used concurrently and the tiamulin is used at the recommended prophylactic (30–40 ppm) or growth promotant (11 ppm) levels, and independently of whether the administration is oral or by injection, but only if a gap of 72 hours has elapsed between the last exposure to salinomycin and the first exposure to therapeutic levels of tiamulin and vice versa.

PATHOGENESIS

All of the compounds are cationic agents, causing an altered balance of cations (especially Ca\(^{++}\), Na\(^{+}\), and K\(^{+}\)) in cells and organelles. The net result is a disruption of ATP generation, cellular dysfunction, and cellular death. Monensin is rapidly absorbed, metabolized in the liver, and excreted in the bile and feces. Other ionophores appear to follow a similar pharmacokinetic pathway. Horses have less efficient cytochrome P450 demethylating enzymes and do not appear to remove monensin from systemic circulation as rapidly as other species; this may be the reason they are more susceptible to toxicosis.

The principal target organ for monensin toxicity is striated muscle (cardiac and skeletal). The exact mechanism of action is unknown, but it appears the origin of muscle damage is related to large cellular influxes of calcium and sodium resulting in degeneration and necrosis of muscle cells. In cattle the cardiac and skeletal muscles are affected about equally, in sheep and pigs the skeletal muscle is most seriously affected, and in horses the myocardium is the focus of the damage. In the latter case, acute or congestive heart failure may result, with signs often delayed for weeks until additional stress, such as late pregnancy or parturition, precipitates cardiac insufficiency. When the damage is principally skeletal muscle, the syndrome is one of weakness, ataxia, and recumbency; myoglobinuria is a common accompaniment.

In addition to myocardial degeneration, lasalocid toxicity in horses has been associated with neurotoxicity with focal axonal degeneration and myelin sheath swelling present at postmortem.

CLINICAL SIGNS

The most consistent and frequently reported clinical sign in all species is anorexia. The incidence of other signs varies among species but commonly include diarrhea, dyspnea, depression, weakness, ataxia, recumbency, and death.

Cattle

The onset of signs begins in 24 hours with heavy doses but may be delayed for up to 5 days when the ingestion is lower. Signs begin with anorexia followed by diarrhea, tremors, weakness, tachycardia, and ruminal atony, and animals may die at this stage from acute heart failure. Those that survive for a day or two develop congestive heart failure manifested by brisket edema, engorgement of the jugular veins, ascites, fluid feces, dyspnea, and tachycardia. Deaths may occur in days or months after the major outbreak and are usually caused by the exertion of calving. When smaller doses are taken over a long period, the syndrome is one of congestive heart failure in all of the cases.

Sheep

The syndrome may be acute followed by hyperesthesia; tremors, especially of the head; disappearance of the pupillary light reflex; recumbency; and convulsions with death occurring during a convulsion. More commonly the disease begins with anorexia, diarrhea, rumen stasis, and depression, followed by muscle weakness, stifled gait, and recumbency. Chronic cases show atrophy of the muscles of the hindquarters and a stiff gait.

Swine

Monensin poisoning is associated with dyspnea, anorexia, ataxia, paresis, myoglobinuria and cyanosis, diarrhea, tympany, and pruritus. Death follows in about 6 hours. Salinomycin is associated with the same general syndrome but also includes an unwillingness to stand and, when forced to stand, tremors, especially in the hindlimbs; swaying; fetlock knuckling; and abrupt lying down. Exercise exacerbates the signs. Respiratory distress in the form of irregular breathing occurs. Feed intake is down 50%, and sham drinking is characteristic. Red urine is evident for up to 5 days after discontinuation of the drug.

Horses

Anorexia is the most consistently reported sign. Restlessness, respiratory distress, diarrhea, mucosal congestion, profuse sweating, sometimes myoglobinuria, cardiac dysrhythmias, and tachycardia (50–60 beats/min) have been reported but may depend on the specific ionophore ingested. Some horses are just found dead. The course of the cardiac disease is short and affected horses may not show much clinical evidence of heart failure at the time of the poisoning, but survivors may develop a poor performance syndrome or congestive heart failure up to several months later.

Rarely, horses show skeletal muscle involvement with fever, red or dark urine (caused by the extensive muscle breakdown), difficulty in rising, stiff gait, knuckling of the fetlocks, and final recumbency after a period of days to as long as several months. Colic is also recorded during the acute phase but this may be the restlessness and frequent lying down and getting up of acute myositis. Euthanasia is the usual outcome of these cases because of irreparable muscle damage.

CLINICAL PATHOLOGY

In all species, laboratory tests show increases in serum levels of creatine phosphokinase, LDH, alkaline phosphatase, and aspartate aminotransferase; myoglobinuria is frequent and often prolonged. However, results of clinical pathology tests may vary substantially among individual affected animals. Samples of feed and stomach contents, obtained by stomach tube, are desirable specimens for analysis. Some feeds fed to horses have contained as much as 125 to 250 g/ton of feed, and their stomach contents have contained 50 to 100 ppm.

Evaluation of the cardiovascular system in animals poisoned by ionophores is important, often challenging, and necessary for long-term prognosis. ECGs and ultrasound evaluation of cardiac function in animals are useful for evaluating early myocardial disease but may not be helpful long term. Doppler imaging and two-dimensional speckle tracking may more accurately evaluate left ventricular function on a chronic basis. The cTnI, a biomarker for myocardial injury in humans, has been used to diagnose cardiac disease in horses, cattle, and sheep and may be a valuable, noninvasive tool to assess and monitor the extent of myocardial damage from ionophore intoxication.
Human point of care cTnI analyzers have been used to measure serum and plasma cTnI concentrations in normal horses and cattle, and monensin-intoxicated horses.

**NECROPSY FINDINGS**

In cattle there is cardiomyopathy, pulmonary edema, enlargement of the liver and heart, hydropericardium, hydrothorax, and ascites. Gross lesions at necropsy are not always evident, and multiple samples of susceptible tissues should be collected and preserved in formalin for microscopic evaluation.

In sheep postmortem changes include necrosis in both skeletal and cardiac muscles with hydrothorax, hemopericardium, pulmonary edema, and petechial hemorrhage.

In horses necropsy lesions in acute cases include myocardial necrosis, pulmonary congestion, hepatic swelling, and in some cases pulmonary petechiation. Skeletal muscle necrosis may be evident. Myoglobinuric nephrosis and myoglobinuria are secondary lesions. Chronic cases show marked cardiac myopathy and possibly skeletal myopathy with obvious fibrosis.

**DIFFERENTIAL DIAGNOSIS**

| In all species syndromes of acute or congestive heart failure caused by acute cardiac myopathy or limb paresis or recumbency caused by skeletal myopathy are sufficiently common to necessitate a positive assay for one of the ionophores in the feed or stomach contents for diagnostic confirmation. Liquid chromatography/mass spectrometry analysis is currently available for monensin, lasalocid, salinomycin, and narasin.

**Differential diagnosis list:**

- **Cattle**
  - Congestion of other ionophores
  - Infectious diseases, bovine rhinotracheitis, and shipping fever complex
  - Nutritional deficiency of vitamin E or selenium
  - Poisonous plants: cardiac glycocides (Nerium oleander, others), Taxus spp. (yew), Karwinskia humboldtiana (coyote plant), Cassia occidentalis (coffee senna), Vicia villosa (hairy vetch), and Eupatorium rugosum (white snake root)

- **Pigs**
  - Congestion of other ionophores
  - Goysopy poisoning
  - Nutritional deficiency of vitamin E or selenium
  - Poisonous plants: cardiac glycocides (Nerium oleander, others), Taxus spp. (yew), Karwinskia humboldtiana (coyote plant), Cassia occidentalis (coffee senna), Vicia villosa (hairy vetch), and Eupatorium rugosum (white snake root)

- **Porcine stress syndrome**
appearing in the veterinary literature; however, their general importance is low. The cause of congenital cardiac defects is unknown, but it is assumed they result from injury during development or from single recessive genes or polygenic sets that have lesion-specific effects on cardiac development. Ventricular septal defects have been observed in twin cattle. Heritable ventricular septal defect is recorded in miniature pigs and suspected in cattle and Arabian horses.1

**EPIDEMIOLOGY**
Congenital cardiac anomalies occur in all species but are not common in any one of them. The prevalence is probably highest in cattle and lowest in horses.

**Cattle**
The relative frequency of individual cardiac defects in calves at postmortem examination in one study was

- Ventricular septal defect: 14%
- Ectopic heart: 13%
- Right ventricular hypoplasia: 13%
- Left ventricular hypoplasia: 13%
- Dextroposed aorta: 10%
- Valvular hematomas: 9%
- Patent ductus arteriosus: 6%
- Patent foramen ovale: 6%
- Endocardial fibroelastosis: 4%
- Common aortic trunk: 4%
- Other cardiac defects: 10%

The animals were neonatal calves and the relative frequencies are biased toward defects that are incompatible with longer life. Generally, ventricular septal defect is the most common cardiac defect in cattle.

**Sheep**
In a large series of necropsy examinations on lambs, 1.3% had cardiac anomalies, of which approximately 90% were ventricular septal defects.

**Horses**
A review of 82 publications on congenital cardiac defects in horses showed the following prevalence in the total cases:

- Ventricular septal defect: 28%
- Tetralogy of Fallot: 16%
- Truncus arteriosus: 8.5%
- Aortic, pulmonary, or mitral valve abnormalities: 13.2%
- Tricuspid atresia: 14.6%
- Abnormality of the aorta: 4.8%
- Patent ductus arteriosus: 3.7%
- Atrial septal defects: 1.2%
- Other lesions account for the remainder.

**Pigs**
The relative frequency of congenital cardiac malformations in pigs has been reported as

- Dysplasia of the tricuspid valve: 34%
- Atrial septal defect: 25%
- Subaortic stenosis: 18%

Ventricular septal defect: 9%
Persistent common AV canal: 9%
Other defects: 10%.

**PATHOGENESIS**
Congenital cardiac defects may result in a pressure load or a volume (flow) load in one or more chambers of the heart. Generally, the left ventricle can tolerate a pressure load better than the right ventricle and the right ventricle can tolerate a volume load better than the left ventricle. The heart may compensate for the increase in load with minor loss in cardiac reserve, or the defects may lead to cardiac failure.

**Shunts**
The mixing of oxygenated and venous blood caused by the presence of an anatomic abnormality that allows a shunt of blood from the pulmonary circulation to the systemic circulation in the face of high pulmonary vascular resistance is an important factor in the pathogenesis of the clinical signs of some congenital cardiac defects. The resulting anoxic anoxia causes severe dyspnea, and cyanosis may be marked if the right-to-left shunt is large. There is a notable absence of fever and toxemia if intercurrent disease does not develop. Cardiac enlargement is usually detectable if the animal survives past the first week of life.

**Age at Manifestation**
Animals with some congenital cardiac defects can survive to maturity and be productive and perform adequately. Acute heart failure or chronic (congestive) heart failure may occur when the animals are subjected to a physical stress such as the first pregnancy or activity on the range. The primary appearance of signs of cardiac disease when an animal is 2 to 3 years of age should not eliminate congenital defects from consideration.

**CLINICAL FINDINGS**
A general description of the more common defects is given next. Some of the defects described in this section are actually defects of the vascular system but are described here for convenience. Diagnosis can be confirmed by the detection of a pressure differential across valves, the detection of shunts by dye dilution and serial blood gas analysis, and by angiography. Echocardiography has developed as an important aid to diagnosis.

**Ectopic Heart**
An abnormal position of the heart outside the thoracic cavity is most common in cattle, with the displacement usually in the lower cervical region. The heart is easily seen and palpated and there is an accompanying divergence of the first ribs and a ventrodorsal compression of the sternum, giving the appearance of absence of the brisket. Affected animals may survive for periods of years, as they also may with an abdominal displacement, but those with a displacement through a defective sternum or ribs rarely survive for more than a few days.2

**Patent Foramen Ovale**
This defect of the atrial septum is reasonably common in cattle, usually causes no clinical signs if present as an isolated defect, and is detected incidentally at necropsy. Ostium secundum defects are also common in cattle. Large defects may allow a shunt in both directions. Relative resistance to outflow from the atria is greater in the left than the right and the shunt, if it occurs, is from left to right. This induces a moderate flow load on the right side of the heart, which is well tolerated. Large flows will generally increase pulmonary vascular resistance and result in moderate right ventricular and right atrial hypertrophy. The increase in outflow resistance from the right atrium results in a decreased flow across the shunt and control of the effects of the defect. Atrial septal defects are of much greater significance when they are present with other cardiac defects, and it is extremely rare for an atrial septal defect alone to cause clinical signs of circulatory failure. If these result in a severe right ventricular hypertrophy, the shunt may reverse from right to left and cyanosis will occur.

**Ventricular Septal Defects**
These are one of the most common congenital cardiac defects in sheep, cattle, and horses. They are almost invariably subaortic defects occurring high in the septum at the pars membranaceae. In the absence of other defects their presence results in the shunting of blood from the left to the right ventricle, producing a volume load on the left ventricle and left atrium.

On auscultation there is a loud blowing pansystolic murmur audible over both sides of the chest. It is usually audible over a large area on both sides but most intense at the left fourth intercostal and the right third intercostal space and more intense on the right than the left side. The murmur in this defect is one of the loudest and most obvious murmurs encountered. It does not modify the heart sounds, which are usually increased in intensity. A precordial thrill is frequently palpable on both left and the right sides.

The outcome is determined by the magnitude of the shunt and the degree of resistance to flow from the right ventricle as determined by pulmonary vascular resistance. With large defects the shunt of blood can be considerable and the animal may die at birth or show clinical signs at a few weeks to a few months of age. The major presenting signs during this period are of left-sided heart failure with lassitude, failure to grow well, and dyspnea with moderate exercise. The shunt may be less severe and allow an apparently normal existence until maturity, when left-sided or right-sided failure can occur, or
cause no apparent problem during life and be detected incidentally on necropsy or abattoir examination. Horses with this defect have raced successfully, 1 and a small number of dairy cows have had many productive lactations. However, it is more common for calves with ventricular septal defect to die or be culled before reaching 2 years of age. 2 Most horses with a ventricular septal defect greater than 3.5 cm in diameter or left-to-right shunt velocity of less than 3 m/s will develop congestive heart failure and consequently a shortened life expectancy.

**Complications**

An increase in pulmonary vascular resistance occurs as the result of increased pulmonary blood flow. In cattle, this increase may be sufficient to cause reversal of the shunt, and cyanosis develops. This syndrome, sometimes referred to as an Eisenmenger complex, develops in young calves but also in mature animals between 1 and 3 years of age and should always be suspected when there is a sudden onset of cyanosis and exercise intolerance in an animal of this age.

The turbulence associated with flow across the defect may produce secondary changes in the valves located close to the defect, which may complicate the clinical picture. Cattle are prone to develop endocarditis in the region of the septal cusp of the right AV valve. In horses, endocarditis more commonly involves the medial cusp of the aortic valve, but there is one report of tricuspid valve endocarditis in a horse with a ventricular septal defect. 3

Other complications are prolapse of the cusps into the septal defect caused by lack of aortic root support with the development of aortic regurgitation. Rupture of the valve may occur to produce a severe additional flow load on the left ventricle, with rapid onset of acute left heart failure and death.

Ventricular septal defects may occur in association with other congenital cardiac or vascular defects, and the clinical findings are varied.

**Prognosis**

There is no practical correction for ventricular septal defects in large animals. Closure of a small ventricular septal defect has been reported in a horse, but spontaneous closure is thought to be uncommon. It should be emphasized that small defects can produce dramatic auscultatory findings and, unless signs of cardiac insufficiency are present, care should be taken in giving an unfavorable prognosis in pleasurable or breeding animals. Food animals can be sent for early slaughter.

There is insufficient information on the advisability of breeding animals that have this defect. An inheritable predisposition has been suspected in Hereford cattle, and chromosomal abnormalities have been demonstrated in association with this defect in cattle. Ventricular septal defects have high prevalence in calves and lambs with microphthalmia.

**Tetralogy of Fallot**

This is almost always a lethal defect in farm animals. The tetralogy consists of three primary abnormalities (ventricular septal defect, pulmonary stenosis, and dextroposition of the aorta so that it overrides both ventricles) and secondary right ventricular hypertrophy. The marked increase in resistance to outflow into the pulmonary artery causes a shunt of blood from the right to left with the major outflow of blood through the aorta. The condition presents with clinical signs very early in life, frequently results in death at or shortly following birth, and has been reported predominantly in foals and calves. Occasionally, affected animals may live for longer periods and cases are recorded in mature animals.

Affected animals show lassitude and dyspnea after minor exertion such as suckling, with the clinical signs resulting primarily from systemic hypoxemia. Cyanosis may or may not be present, depending on the degree of pulmonary stenosis, but is usually prominent, especially following exercise. On auscultation a murmur and sometimes a thrill is present and most intense in the left third or fourth intercostal space.

Other cardiac defects that result in cyanosis as a prominent sign occur when there is right-to-left shunting of blood through a patent foramen ovale, a patent ductus arteriosus, or ventricular or atrial septal defects as a result of tricuspid atresia or pulmonary atresia. Right-to-left shunting through these defects is rare and, if present, is usually a terminal event.

Tetralogy of Fallot should be differentiated from an even rarer condition, double-outlet right ventricle; the latter is characterized by having both the aorta and pulmonary artery arise from a distinct conus originating from the morphologic right ventricle and from which no fibrous continuity with the AV valves can be demonstrated. Double-outlet right ventricle has been diagnosed in three calves and a foal, with clinical signs similar to tetralogy of Fallot.

**Patent Ductus Arteriosus**

This defect results from a failure of closure of the ductus arteriosus following birth and is probably the third most common defect in horses after ventricular septal defect and tetralogy of Fallot. There is some controversy over the period of time involved in normal closure in large animals. Clinically, murmurs associated with a patent ductus arteriosus are frequently heard during the first day after birth in normal foals and may persist for periods of up to 5 days. Physiologic studies in foals suggest that functional closure occurs between 48 and 72 hours after birth, 4 whereas anatomic closure is slightly delayed to 4 days of age. Patent ductus arteriosus is not a common clinical cardiac defect in older animals, but can occur. The ductus arteriosus closes within minutes of birth in calves.

Patent ductus arteriosus produces a loud continuous murmur associated with the left-to-right shunting of blood from the aorta to the pulmonary artery. The intensity of the murmur waxes and wanes with each cycle because of the effects of normal pressure changes on blood flow, giving rise to the name of machinery murmur. The systolic component of the murmur is very loud and usually audible over most of the cardiac auscultatory area, but the diastolic component is much softer and confined to the base of the heart. The pulse is large in amplitude but has a low diastolic pressure. Surgical correction is possible.

**Complete Transposition of the Great Arteries**

Complete transposition of the great arteries is characterized by an aorta arising from the morphologic right ventricle and the pulmonary artery arising from the morphologic left ventricle, resulting in two circulations running in parallel with circulatory mixture via a ventricular septal defect. Calves usually present with severe arterial hypoxemia, poor growth rate, and exercise intolerance. 5

**Persistent Truncus Arteriosus**

This defect and other defects of the outflow vessels, including pulmonary and aortic hypoplasia and congenital absence of the aortic arch, have been recorded in animals but their prevalence is low.

**Coarctation of the Aorta**

Constriction of the aorta at the site of entrance of the ductus arteriosus causes a syndrome similar to that of stenosis of the aortic semilunar valves; there is a systolic murmur and a slow-rising pulse of small amplitude.

**Double-Outlet Right Ventricle**

Double-outlet right ventricle is characterized by dextropositioning of the aorta (partial transposition) that results in the aorta and pulmonary artery arising from the right ventricle. The concurrent presence of a ventricular septal defect permits blood from the left ventricle to circulate. Reports of double-outlet right ventricle are scarce in large animals but may be most common in horses. 6

**Fibroelastosis**

Congenital fibroelastosis has been observed in calves and pigs. The endocardium is converted into a thick fibroelastico coat and, although the wall of the left ventricle is hypertrophied, the capacity of the ventricle is reduced. The aortic valves may be thickened and irregular and obviously stenosed. The syndrome is one of congestive heart failure. The defect may cause no clinical abnormality until the animal is mature.
Subvalvular Aortic Stenosis
Stenosis of the aorta at or just below the point of attachment of the aortic semilunar valves has been recorded as a common, possibly heritable, defect in pigs, but its differentiation from other causes of heart failure is difficult. Clinically affected animals may die suddenly with asphyxia, dyspnea, and foaming at the mouth and nostrils, or after a long period of ill-health with recurrent attacks of dyspnea. In the acute form death may occur after exercise or be unassociated with exertion.

Parachute Left Atrioventricular Valve
This is an extremely rare congenital anomaly defined by the presence of a single papillary muscle that receives all chordae tendineae from the left AV valve. An 8-month-old colt with a loud left-sided holosystolic murmur was diagnosed with this condition using echocardiography.

Valvular Abnormalities
A 9-week-old Standardbred colt was diagnosed with dysplasia of the mitral valve and tricuspid valve. A quadricuspid aortic valve was identified in a stallion with a ventricular septal defect.

Anomalous Origin of Coronary Arteries
Either or both coronary arteries may originate from the pulmonary artery instead of the aorta. The resulting anoxia causes myocardial weakness in the ventricle of the affected side. Congestive heart failure usually follows. Congenital deformities of the coronary arteries have been recorded in cattle and pigs.

Persistence of the Right Aortic Arch
Persistence of the right fourth aortic arch causes constriction of the esophagus with dysphagia and regurgitation. The aorta is situated to the right of the esophagus and trachea and the ligamentum arteriosum in its connection to the pulmonary artery encloses the esophagus in a vascular ring and compresses it against the trachea. Clinical signs are usually evident soon after birth and consist primarily of regurgitation of milk from the mouth and nostrils after suckling, but survival until 5 years of age has been recorded in a bull that showed chronic bloating and visible esophageal dilatation. Resistance to the passage of a stomach tube is encountered just behind the first rib, and the diagnosis can be confirmed by radiologic examination following a barium swallow (Fig. 10–7). Medical treatment is concerned with the control of aspiration pneumonia, but the correction of the defect is surgical.

Aberrant Right Subclavian Artery
The most common vascular ring anomaly is persistence of the right fourth aortic arch. A much rarer vascular ring anomaly was reported in an adult Friesian horse with repeated esophageal obstruction. Necropsy revealed esophageal and tracheal stenosis secondary to an aberrant right subclavian artery. The artery constricted the esophagus, resulting in mucosal sloughing.

Inherited Cardiovascular Defects

BOVINE HEREDITARY DILATED CARDIOMYOPATHY

Bovine hereditary dilated cardiomyopathy is a group of progressive degenerative diseases of the myocardium causing congestive heart failure. At least three different types have been reported: dilated cardiomyopathy in cattle of Canadian Holstein origin, cardiomyopathy in Japanese Black cattle, and cardiomyopathy in Hereford cattle.

Pedigree analysis of 75 animals in three age classes and five diagnostic classes based on clinical and pathologic findings using the Pedigree Analysis Package provided strong evidence for autosomal recessive inheritance of a single major gene responsible for the disease. Pedigree analyses of affected animals in Canada, Japan, and Switzerland revealed the Holstein bull “ABC Reflection Sovereign,” the son of Canadian Holstein sire Montwick Red Apple Sovereign, as the common ancestor. This disease in cattle is being used as a research model of human dilated cardiomyopathy. Using proteomic analysis (the examination of tissue from younger cattle that are genetically diseased but have not yet developed clinical disease), a number of proteins have been identified whose abundance is altered significantly to suggest a possible pathogenetic mechanism for the onset of the disease.

REFERENCES
The disease has now been reported in Denmark in the Red Danish Dairy breed, Holsteins, and Red Holsteins. Pedigree analysis of 12 cases found both maternal and paternal relationship to the Canadian sire Montwick Red Apple Sovereign, and several sires were identified as carriers of the disease. These sires originated from breeding lines used to upgrade Danish cattle populations and pose a potential animal health problem. The introduction of the defect into the Danish cattle population is an example of how widespread a genetic disease can become in a short period of time. During their active life, two sires used for artificial insemination obtained a total of approximately 62,000 living progeny.

There can be a high incidence in certain herds, possibly associated with some unrecognized environmental precipitating factor but probably caused by autosomal recessive trait concentrated by a high coefficient of inbreeding. There are three types recorded in cattle, which will be discussed next.

**Type 1 Calf: Acute Heart Failure**

Sudden death of Poll Hereford and horned Hereford calves up to 3 months of age may be caused by inherited cardiomyopathy. The calves are often identifiable before death by their very rapid growth rate, short curly coat, and moderate bilateral exophthalmos. Death is usually precipitated by stress or exercise and is characterized by dyspnea, the passage of bloody froth from the nose, and a course of a few minutes to a few hours. Less acute cases have a syndrome of congestive heart failure for several days before death. Life expectancy is less than 6 months. At necropsy there is an obvious patchiness of the myocardium, reminiscent of a bad case of white muscle disease. The disease appears to be conditioned by a single autosomal recessive gene.

**Type 2 Calf: Pulmonary Edema**

A second form of inherited cardiomyopathy is recorded in Japanese Black cattle. Death is preceded by a brief period (a few minutes to a few hours) of agonizing dyspnea in calves aged 30 to 120 days. At necropsy there is edema, ascites, hydrothorax, and marked dilatation of the left ventricle. This is matched by acute myocardial necrosis. A new autosomal recessive gene is credited with initiating the disease.

**Type 3: Young Adult Congestive Heart Failure**

This occurs in young adult cattle and has been reported in Holstein-Friesian cattle in Japan, Canada, the UK, and Australia, and in Simmental-Red Holstein crossbred cattle and Black Spotted Friesian cattle in Switzerland.1 Similar family lines in Holstein breeds have been identified in affected cattle in all three countries, and it has been suggested that there is an inherited predisposition to cardiomyopathy in the Holstein breed. Pedigree analysis of hereditary dilated cardiomyopathy in Holstein-Friesian cattle in Japan suggests an association with hereditary myopathy of the diaphragmatic muscles. The disease is endemic in Switzerland, occurring mainly in the Simmental × Red Holstein crossbreed of cattle.

The disease occurs in cattle from 1.5 to 6 years of age, with the peak prevalence in 3- and 4-year-old cattle. The stress of pregnancy and lactation may precipitate clinical disease, and the majority of cases occur in late pregnancy or early lactation. The onset is sudden and the majority of cases have signs of congestive right heart failure. Edema of the submandibular area, brisket, ventral abdomen, and udder is prominent and there is venous engorgement, hepatomegaly, interstitial nephritis, pleural and pericardial effusion, and ascites. Muffling of the heart sounds, tachycardia, and a gallop rhythm are evident on auscultation of the heart. There is no characteristic biochemical or hematologic change.

Necropsy findings include congestive heart failure and histologic findings compatible with congestive cardiomyopathy. There is dilatation of the chambers of the heart; thickening or thinning of the ventricular wall; subcutaneous, mesenteric, and pulmonary edema; hydrothorax; hepatomegaly; and ascites. Histologically there is fibrosis, myocardial degeneration, and vacuolation of cardiomyocytes and infiltration of mononuclear cells into the myocardium. In some cases, interstitial nonsuppurative nephritis is present. Using electron microscopy, the sarcoplasm of the hypertrophic fibers is seen to be filled with fine structures of low electron-density, together with thin filamentous material, suggesting myofibrillar lysis.

The disease is inherited as an autosomal recessive gene located on bovine chromosome 18.1 Following introduction of an eradication program based on culling of carriers in the sire population, the incidence in Switzerland has decreased.

**INHERITED VENTRICULAR SEPTAL DEFECT**

Ventricular septal defects are common in food animals; reports of their occurrence in lambs and Hereford cattle suggest that the condition can be inherited.

**INHERITED AORTIC ANEURYSM**

An inherited defect of the abdominal aorta, resulting in a high mortality rate from intraabdominal hemorrhage, has been observed in an unidentified breed of cattle in Holland and is an important feature in Marfan syndrome of humans.

**BOVINE MARFAN SYNDROME**

A model of human Marfan syndrome, this disease of cattle is an autosomal dominant disorder caused by mutations in the fibrillin-1 gene.1 It is manifested primarily by cardiovascular lesions and signs but lacks the skeletal abnormalities of the human disease. Necropsy lesions include aortic and pulmonary artery aneurysm, with consequent cardiac tamponade in some fragments. Fragmentation of elastic laminae in the vessels is also characteristic.

**REFERENCE**

Traumatic pericarditis is also recorded in the horse and in a lamb. Localization of a blood-borne infection occurs sporadically in many diseases. Direct extension of infection from pleurisy or myocarditis may also occur in all animals, but the clinical signs of pericarditis in such cases are usually dominated by those of the primary disease. In most cases of pericarditis in horses no causative agent is isolated. There is usually a history of upper or lower respiratory tract disease. Most cases are fibrinous or septic and associated with systemic inflammatory response syndrome, but an effusive non-septic form is also described and has been called idiopathic effusive pericarditis. Pericarditis in horses occurs predominantly in adults. Idiopathic effusive pericarditis has been diagnosed in two dairy cows.

**Cattle**
- Mannheimia haemolytica
- Black disease (if patients survive more than 24 hours)
- Sporadic bovine encephalomyelitis
- Haemophilus spp., including Histophilus somni
- Tuberculosis
- Pseudomonas aeruginosa
- Mycoplasma spp.
- Klebsiella pneumoniae
- Actinobacillus suis
- Malignant peripheral nerve sheath tumor in the right atrium, epicardium, and pericardium
- Idiopathic effusive (nonseptic) pericarditis.

**Horses**
- Streptococcus spp., including S. equi subsp. equi, S. equi subsp. zooepidemicus and S. faecalis
- Tuberculosis
- Corynebacterium pseudotuberculosis
- Actinobacillus equuli
- In association with EHV-1 infection
- Effusive, fibrinous pericarditis in horses during outbreaks of mare reproductive loss syndrome associated with exposure to Eastern Tent Caterpillars or similar species.

**Sheep and Goats**
- Pasteurellosis
- Staphylococcus aureus
- Mycoplasma spp.

**Pigs**
- Pasteurellosis
- Mycoplasma spp. especially M. hyorhinis
- Haemophilus spp. (Glasser’s disease and pleuropneumonia)
- Streptococcus spp.
- Salmonellosis

**PATHOGENESIS**

In the early stages, inflammation of the pericardium is accompanied by hyperemia and the deposition of fibrinous exudate, which produces a friction sound when the pericardium and epicardium rub together during cardiac movement. As effusion develops, the inflamed surfaces are separated, the friction sound is replaced by muffling of the heart sounds, and the accumulated fluid compresses the atria and right ventricle, preventing their complete filling. Congestive heart failure follows. A severe toxemia is usually present in suppurative pericarditis because of the toxins produced by the bacteria in the pericardial sac. Gas will occur along with fluid in the sac if gas-producing bacteria are present. If sufficient gas is present, the classical washing machine sound of fluid splashing with each heart beat will be auscultated. This is not as common in clinical cases as muffling of the heart sounds.

In the recovery stage of nonsuppurative pericarditis the fluid is reabsorbed and adhesions form between the pericardium and epicardium to cause an adhesive pericarditis, but the adhesions are usually not sufficiently strong to impair cardiac movement.

**Horses**

**CLINICAL FINDINGS**

In the early stages there is pain, avoidance of movement, abduction of the elbows, arching of the back, and shallow abdominal respiration. Pain is evidenced on percussion or firm palpation over the cardiac area of the chest wall, and the animal lies down carelessly. A pericardial friction sound is detectable on auscultation of the cardiac area. The temperature is elevated to 39.5°C to 41°C (103°F to 106°F) and the pulse rate is increased. Associated signs of pleuritis, pneumonia, and peritonitis may be present.

In most cases of pericarditis caused by traumatic reticuloenteritis, hematogenous infection, or spread from pleuritis the second stage of effusion is manifested by muffling of the heart sounds, decreased palpability of the apex beat, and an increase in the area of cardiac dullness with decreased amplitude of the peripheral pulse. If gas is present in the pericardial sac, each cardiac cycle may be accompanied by splashing sounds. Signs of congestive heart failure become evident. Fever is present, the heart rate is markedly increased, and toxemia is severe, although this varies with the types of bacteria present. This is the most dangerous period, and affected animals usually die of congestive heart failure, or of toxemia, in 1 to 3 weeks. Those that survive pass through a long period of chronic ill health during which the toxemia subsides relatively quickly, but congestive heart failure diminishes slowly. In this stage of chronic pericarditis additional signs of myocarditis may appear. The heart sounds become less muffled and fluid sounds disappear altogether or persist in restricted areas. Complete recovery is not common. Idiopathic hemorrhagic effusive (nonseptic) pericarditis has been reported in a small number of cattle; three of these cattle lived for months after initial diagnosis and treatment with pericardial drainage and corticosteroid treatment but subsequently died from epicaldial lymphosarcoma.

In the horse, both the idiopathic effusive/fibrinous and the septic forms of pericarditis present with marked muffling of the heart sounds, tachycardia, distension of the jugular veins, and pericardial friction sound associated with exposure to Eastern Tent Caterpillars or similar species.

**CLINICAL PATHOLOGY**

A marked leukocytosis and neutrophilia, as well as hyperglobulinemia, are usually present in traumatic pericarditis because this has many of the characteristics of a large internal abscess. In the other forms of pericarditis changes in the blood depend on the other lesions present and on the causative agent. In the stage in which effusion occurs a sample of fluid may be aspirated from the pericardial sac and submitted for bacteriologic examination. This technique is not without danger, as infection may be spread to the pleural cavity.

**Pericardial fluid** can also be examined cytologically but usually the smell (reminiscent of retained placenta and toxic metritis in cattle) is sufficiently diagnostic in cattle with traumatic pericarditis. In septic pericarditis the fluid represents an inflammatory response, whereas in idiopathic effusive pleuritis in horses there are very few cells in the sediment. Mean right ventricular diastolic and intrapericardial fluid pressures are increased in a corresponding manner in cows with clinical signs of right-sided heart failure. Cattle with muffled heart sounds and a large pericardial fluid volume also have a decrease in cardiac output to approximately two-thirds of normal values.

**Electrocardiography** can aid in diagnosis. Electrocardiographic changes include sinus tachycardia and, in animals with right-sided heart failure and hydrothorax, diminished amplitude of the QRS complex. Contrary to popular belief, hydropericardium in the absence of hydrothorax leads to an increase, and not a decrease, in QRS amplitude. Moreover, removal of large volumes of pericardial fluid does not usually result in an immediate change in QRS amplitude. Also contrary to popular belief, electrical alternans is not commonly present in dogs and humans with pericardial effusion.
effusion and if present, occurs only within a narrow range of heart rates. The prevalence of electrical alternans is unknown in large animals with pericardial effusion but is suspected to be extremely low because the pericardium and heart are much more fixed in position within the thorax.

Radiography may be of diagnostic value, with six of seven cows having a gas–fluid interface present on standing lateral thoracic radiographs. Radiography has the additional benefit of potentially identifying the location of the penetrating wire; this information would assist surgical removal of the wire via a rumenotomy. Radiography may also aid in the clinical differentiation of pericardial effusion from pleural effusion.

Echocardiography is the most valuable diagnostic procedure and will show the presence of fluid in the pericardial sac and the presence or absence of fibrin deposition on the epicardium. In cattle with traumatic reticulospericarditis, hepatic ultrasonography reveals hepatic congestion, manifested as round liver margins; a round and dilated CVC; and a dilated portal vein.16,6

NECROPSY FINDINGS
In the early stages there is hyperemia of the pericardial lining and a deposit of fibrin. When effusion occurs, there is an accumulation of turbid fluid, and tags of fibrin are present on the greatly thickened epicardium and pericardium. Gas may also be present and the fluid may have a putrid odor. When the pericarditis has reached a chronic stage, the pericardium is adherent to the epicardium over a greater or lesser part of the cardiac surface. Loculi containing serous fluid often remain. Embolic abscesses may be present in other organs. Lesions typical of the specific causative diseases listed earlier are described under their specific headings.

DIFFERENTIAL DIAGNOSIS

• Pleuritis
• Cardiac valvular disease
• Mediastinal abscess
• Hydropericardium occurs in congestive heart failure, mulberry heart disease of pigs, herd toxicosis of pigs, gossypol poisoning, clostridial intoxications of sheep, and lymphomatosis

TREATMENT
Antibacterial treatment of the specific infection should be undertaken if possible on the basis of susceptibility of organisms cultured from the pericardial fluid. When the infecting agent cannot be grown, a broad-spectrum antibiotic or a combination to give a broad spectrum is used. A combination of penicillin and gentamicin is common and provides cover of the likely organisms associated with this infection. Pericardiocentesis, copious lavage with warmed 0.9% NaCl solution, and drainage should be conducted as required to relieve the fluid pressure in the pericardial sac and decrease the transmural pressure gradient across the atrial and ventricular walls and caudal and cranial vena cava, facilitating diastolic filling. Pericardiocentesis should be ideally performed under ultrasonographic guidance and with electrocardiographic monitoring.

The prognosis varies with the etiologic agent, but it is generally grave in cases of septic pericarditis in horses mainly because the stage of effusion is followed by one of fibrosis and constrictive pericarditis. Success in treatment of a series of six cases of septic pericarditis in the horse is recorded with the use of indwelling pericardial drains to allow twice-daily lavage and drainage and the instillation of antibiotics directly into the pericardial sac. This allows high concentrations of antimicrobial agents, and the twice-daily infusion of 1 to 2 L of fluid may help prevent the development of constrictive pericarditis. In cattle thoracotomy and pericardiectomy are used to establish drainage or to allow marsupialization of the pericardium to the body wall. Low treatment success rates are generally reported for the disease in cattle with or without surgical drainage, and it is likely that cases that responded to fifth rib resection and pericardial marsupialization would have responded to pericardial drainage and intrapericardial lavage and antimicrobial administration.

There is a more favorable prognosis for the treatment of idiopathic effusive pericarditis in horses and cattle with aggressive therapy and the use of pericardiocentesis, pericardial drainage and lavage, intrapericardial water-soluble antibiotics, and systemic corticosteroids or NSAIDs as an effective therapy.8 In cattle with pericardial effusion caused by cardiac lymphoma, repeated pericardiocentesis was effective in maintaining a good quality of life for 4 weeks associated with increased milk production; this treatment may be considered in late gestation cows with cardiac lymphoma and no evidence of metastasis to optimize delivery of a viable fetus.8

Diseases of the Blood Vessels

ARterial Thrombosis, Embolism, AND Rupture

SYNOPSIS

Etiology Arteritis leading to thrombus formation causes ischemia of the tissues supplied by the affected artery; rupture of abdominal arterial aneurysm in cattle; rupture of the aorta in the Friesian horse.

Clinical findings Reduced function or ischemic necrosis vary with the site of the obstruction. Aortoiliac thrombosis manifests with lameness, muscular weakness, and decreased pulse amplitude in affected leg. Arterial rupture associated with massive acute hemorrhage.

Necropsy findings Thrombosis and embolic lesions, muscle ischemia and necrosis, abdominal or thoracic hemorrhage in arterial rupture.

Diagnostic confirmation Ultrasonography for aortoiliac thrombosis.

Treatment Fibrinolytic enzymes; surgical removal of thrombus.

ETIOLOGY
Injury to vascular endothelium, alteration to normal blood flow (turbulence or stasis), and alterations to the coagulability of blood can predispose thrombosis and thromboembolism. Weakness to the arterial wall can lead to aneurysmal formation and, in some animals, rupture of the artery and massive acute intraabdominal or intrathoracic hemorrhage.

Coagulopathies Coagulopathies and disseminated intravascular coagulation are important in the pathogenesis of thromboembolism, which occurs in many infectious diseases.

Parasitic Arteritis

• Strongylus vulgaris in horses. Migrating larvae cause arteritis of the anterior mesenteric artery, iliac arteries, and base of aorta as well as occasionally cerebral, renal, or coronary arteries. This is a major cause of arteritis and associated clinical disease in horses.

• Aortoiliac thrombosis in horses. There is some controversy over the etiology of...
this disease. It may result from strongyle-related thromboembolism with organization of thrombi and their incorporation into the arterial wall with centripetal development of progressive thrombosis. Alternatively, spontaneous degenerative vascular disease of unknown etiology, but particularly at the aortic quadrifurcation, may result in thrombosis in the area and subsequently thromboembolism of more distal vessels.

- Onchocerciasis and elaeophorhiasis in cattle, sheep, goats, and horses.

**Viral Arteritis**

- Important in pathogenesis of several viral diseases, including malignant catarrhal fever, equine viral arteritis, African swine fever, hog cholera, bluetongue, and African horse sickness.

**Bacterial Arteritis**

- Including septicemia salmonellosis, erysipelas, *Histophilus somni*, *Haemophilus pleuropneumoniae*, and pasteurellosis

**Embolic Arteritis and Thromboembolism**

- From vegetative endocarditis or emboli from arterial thrombi in various sites
- Hyperlipemia and hyperlipidemia in horses
- Fat emboli following surgery
- Associated with subclinical *Salmonella* Dublin infection in calves
- Rupture of abscesses into blood vessels (pulmonary embolism resulting from caudal vena caval thrombosis or jugular thrombosis)
- From indwelling catheters

**Microangiopathy**

- Vitamin E/selenium deficiency
- Cerebrospinal angiopathy
- Terminal in most septicemic disease

**Calcification**

- Enzootic calcinosis
- Arterial calcification in horses
- Vitamin D toxicity
- Chronic hypomagnesemia in calves
- Lymphosarcoma in some horses

**Vasoconstrictive Agents**

- Ergot poisoning
- Fescue poisoning

**EPIDEMIOLOGY**

Clinical atherosclerosis occurs rarely in farm animals. It has been recorded in a horse in which sufficient vascular occlusion occurred to cause severe central nervous signs and a fatal outcome. Spontaneous atherosclerosis is a common necropsy finding in swine, cattle, goats, horses, and wild animals but is not associated with clinical disease. Arteriosclerosis and calcification are major findings in enzootic calcinosis and occur following overdosing with vitamin D or its analogs in the prevention of milk fever in cattle and in hypomagnesemia in calves. Arterial calcification appears to be common in racehorses but its pathogenesis and clinical significance remain unknown.

**PATHOGENESIS**

In parasitic arteritis, inflammation and thickening of the arterial wall result in the formation of thrombi, which may partially or completely occlude the artery. The common site is in the anterior mesenteric artery; obstruction of this vessel causes recurrent colic or fatal ischemic necrosis of a segment of the intestine. Lesion cases include the origin of the iliac artery at the abdominal aorta causing iliac thrombosis, the base of the aorta leading to rupture and hemopericardium, and the coronary arteries causing myocardial infarction.

With other causes of arteritis, the clinical syndrome is dependent on the site of arteritis or embolism. Arteritis associated with bacterial and viral infections is usually widespread and several organ systems are involved. Bacterial emboli have a predilection to lodge in the
- Vascular plexuses in the kidney to produce renal disease
- Synovial membranes to produce arthritis and tenosynovitis
- Endocardium to produce endocarditis

Less common is that they may lodge in other vascular plexuses such as the rete cerebri. Large emboli that lodge in the pulmonary arteries cause anoxic anoxia. Embolism in the renal artery causes acute cortical necrosis and gross hematuria.

Vasoconstrictive alkaloids produced by *Claviceps purpurea* infestation of grass seed heads and *Acremonium coenophialum*, which infects *Festuca arundinacea* and *Lolium perenne*, cause arteriolar constriction and result in ischemic necrosis and gangrene of distal extremities in cattle.

**CLINICAL FINDINGS**

The clinical findings in mesenteric verminous arteritis of horses and renal and myocardial infarction, gangrene associated with *C. purpurea*, or endophyte infestation of grasses and other diseases listed earlier are described elsewhere under those headings. The clinical signs of aortoiliac thrombosis and pulmonary embolism are described here.

**Aortoiliac Thrombosis in the Horse**

Aortoiliac thrombosis is most common in racehorses but occurs in other breeds. It is primarily a disease of horses of over 3 years of age. Either one or both hindlegs may be involved. Diagnosis rarely occurs during the early stages because clinical signs are thought to only occur when >75% of arterial flow is compromised. Early mild cases are usually detected in racehorses or horses subjected to maximal exertion in which the disease may be a cause of poor performance. In early cases there is lameness only on exercise, and the animal returns to normal after a short rest. If the horse is forced to work when lameness develops, the signs may increase to resemble those of the acute form. The lameness takes the form of weakness, usually of one hindlimb, which tends to give way, especially when the animal turns on it. Frequent lifting of the foot or cow-kicking may also be shown. In more severe cases, lameness or refusal to work may be evident after minimal exercise. The disease is chronic and progressive, but occasionally the onset may be acute. In the acute form there is great pain and anxiety and the pulse and respiration rates are markedly increased. Profuse sweating may be evident, but the affected limb is usually dry and may be cooler than the rest of the body. The pain is often sufficiently severe to cause the animal to go down and refuse to get up. Suspect animals should be examined following exercise.

- The affected limb is cool from the midgaskin distally, and there is usually diminished or variable sweating over this area.
- The amplitude of the pulse in the common digital artery is less in the affected limb than in the normal limb or the front limbs.
- Slow filling of the saphenous vein of the affected limb can usually be detected.
- Palpable abnormalities on rectal examination include enlargement and firmness of the aortic quadrifurcation, irregularity and asymmetry of the internal and external iliac arteries, and decreased amplitude or absence of an arterial pulse.

**Recovery**

by the development of collateral circulation or shrinkage of the thrombus is unlikely to occur, and the disease is usually chronically progressive with a poor prognosis.

Until recently the detection and diagnosis of the occurrence of this abnormality was limited to horses showing clinical signs and horses in which abnormality could be palpated on rectal examination. Ultrasonography is a more sensitive method of detection than rectal palpation. The use of ultrasonography as a diagnostic technique may lead to a better definition of the occurrence of this disease and ultimately its pathogenesis. Iliac thrombosis may also be associated with impotence in stallions caused by failure to mount or accompanied by testicular atrophy. It has also been associated with a syndrome of ejaculatory failure in which the stallion has excellent libido, good coupling, and vigorous thrusting but a failure to ejaculate. The
Aneurysm occurs sporadically and very rarely, with a case series of 33 cases being reported over a 25-year period in upstate New York. Affected cattle are 2 to 6 years of age and all were of the Holstein-Friesian breed. Cattle are found dead without any signs of illness. Histologic examination indicates a marked disruption of the tunica media and a decreased amount of elastin in the artery at the site of the rupture. The lesions were consistent with chronic damage to the arterial wall and acute rupture and massive acute hemorrhage.

**CLINICAL PATHOLOGY**

Extensive thrombus formation is usually associated with a leukocytosis and a shift to the left, and there is an increase in serum fibrinogen concentration. In the majority of cases of iliac thrombosis serum aspartate aminotransferase (AST) and CK activities are within the normal range both before and after exercise, but in severe cases there may be enzymic evidence of myonecrosis with secondary hyperkalemia and uremia. Elevated serum CK and aspartate transaminase activities are present in aortic and iliac thrombosis in calves. Angiography or ultrasonography is used for diagnostic confirmation.

**NECROPSY FINDINGS**

Obstruction of the affected artery is easily seen when it is opened. The thrombus or embolus is adherent to the intima and is usually laminated. Local or diffuse ischemia or infarction may be evident if the embolus has been present for some time and may have progressed to the point of abscess formation.

**DIFFERENTIAL DIAGNOSIS**

**Aortoiliac thrombosis in the horse**
- Paralytic myoglobinuria
- Hypokalemic periodic paralysis

**Aortoiliac thrombosis in calves**
- Vertebral osteomyelitis (spinal abscess)
- White muscle disease
- Vertebral fracture
- Clostridial myositis
- Pulmonary embolism
- Pneumonia

**TREATMENT**

Treatment with parenteral anticoagulants or enzymes is performed rarely, and reported treatment successes are based on small numbers of cases without an untreated control for comparison. Variable doses of aspirin (12–100 mg/kg orally every 8–48 hours) have been administered to affected horses to prevent thrombus growth by inhibiting platelet aggregation; however, oral bioavailability appears variable in the horse, no doubt resulting in the large range in dosage protocols. Aspirin does not inhibit platelet aggregation in the cow, therefore, aspirin is not indicated as part of the treatment of thrombosis in cattle. Low molecular weight heparin (such as dalteparin at 50 U/kg subcutaneously every 24 hours) has been administered to horses to prevent thrombus growth, but may be cost-prohibitive. Unfractionated heparin (15–80 U/kg subcutaneously every 12 hours) is much less expensive than low molecular weight heparin but has unpredictable efficacy in horses and can result in undesirable side effects such as thrombocytopenia and erythrocyte agglutination. Warfarin (0.018 mg/kg orally every 24 hours) is usually used because of its low cost, ease of administration, wide availability, and suitability for long-term administration.

There are several records of positive results in iliac thrombosis in horses after the IV injection of sodium glutonate or fibromyolytic enzymes such as recombinant tissue plasminogen activator, and retrograde catheterization of the ventral coccgeal artery can allow the deposition of these materials at high local concentrations. Ivermectin and fenbendazole are commonly administered to horses to address *S. vulgaris* as a potential initiating agent. Many other adjunctive treatments have been administered, including butyloxyclopamine bromide, metimazole, acepromazine, isoxsuprine, and pentoxifylline, but case numbers are too few to comment on their efficacy. A gradually increasing exercise program may improve collateral circulation. Surgical treatment is recorded by partial or complete removal of the thrombus with a thrombectomy catheter. Treatment response can be monitored clinically, by palpation of arterial pulses during per rectal palpation, or most accurately by periodic transrectal Doppler ultrasonography of the affected artery.

Stallions with ejaculatory failure have had some success at service following treatment with phenylbutazone to reduce pain and gonadotropin-releasing hormone to maximize sexual arousal and lower the ejaculatory threshold.

**PURPURA HEMORRHAGICA**

**SYNOPSIS**

Etiology: Deposition of immune complexes in the walls of capillaries with subsequent...
Of 53 horses with purpura hemorrhagic treated at a referral center, 17 had been exposed to or infected with S. equi, 5 had been vaccinated with S. equi M protein, 9 had been infected with C. pseudotuberculosis, and 5 had a history of apparently infectious respiratory disease of undiagnosed cause. Fifteen of 53 horses had no history of recent infectious disease.

Among clinicians there is a strong suspicion of an association between purpura hemorrhagica and vaccination. However, vaccination against S. equi infection has not been clearly demonstrated to be a risk factor for purpura hemorrhagica. Certainly, cases of purpura do occur in horses that have been vaccinated against strangles, but presumably there was a high probability that such horses were at increased risk of developing strangles. The consensus is that vaccination with vaccines containing M protein or avirulent S. equi is associated with increased risk of purpura. Edema of the lower limbs does occur after vaccination with streptococcal M protein and may represent a mild form of the disease. It is recommended by some authorities that horses with high serum antibodies titers to streptococcal M protein not be vaccinated against strangles, although definitive data to support this recommendation are not available.

There does not appear to be breed, age, or sex predisposition to the disease. Horses as young as 6 months of age, and possibly younger, can be affected.

The case–fatality rate with appropriate treatment is approximately 10%. Purpura accounted for 2% and 8% of 2028 and 1245 deaths among horses shipped from the UK and the United States, respectively, to South Africa during the Boer War. This mortality rate was before the advent of antimicrobials or corticosteroids, which have presumably decreased the case–fatality rates.

**PATHOGENESIS**

The basis of the disease process is an aseptic vasculitis of capillary walls accompanied by extravasation of plasma and blood into the tissues. Thrombocytopenia does not occur, and there is a defect in coagulation in most cases. Prolonged clotting times (activated clotting time, partial thrombin time, and thromboplastin time) occur in severely affected horses with infarctive purpura hemorrhagica. Skin lesions predominate but other organs, including the kidney, muscles, and gastrointestinal tract, are affected.

**CLINICAL FINDINGS**

Affected horses are usually depressed and have reduced or absent appetite. The temperature is elevated in approximately 60% of cases, as is the heart rate. Extensive subcutaneous edematous swellings are the characteristic sign of the disease. They are most common about the face and muzzle but are often present on other parts of the body and are not necessarily symmetric in distribution. The swellings may appear suddenly or develop gradually over several days. They are cold and painless, pit on pressure, and merge gradually into normal tissue without a definite line of demarcation. There is no discontinuity of the skin, although it may be tightly distended and even ooze reddish serum. Swellings about the head may cause pressure on the pharynx with subsequent dyspnea and dysphagia. Lesions in the lungs are usually not clinically apparent without radiographic or ultrasonographic examination of the chest. Extensive edema of the limbs occurs in almost all cases. Rare cases of the disease in horses do not have edema.

**Infarctive purpura hemorrhagica** is an uncommon manifestation of the disease characterized by infarction of multiple tissues including the gastrointestinal tract and muscle. Affected horses have signs of colic and muscle swelling. The course is usually 3 to 5 days and death, which is the most common outcome, and is associated with severe colic and rapidly deteriorating metabolic status. Colic is attributable to infarctions in the intestine but can be caused by intussusception of the small intestine secondary to infarctive lesions. The course of the disease is usually 1 to 2 weeks, and many animals die of blood loss, dyspnea caused by laryngeal or pharyngeal swelling, and secondary bacterial infections. Relapses are uncommon among appropriately treated horses.

**Hemopathologic changes** are typically a mild anemia (usually <32% but >20%, <0.32 L/L but >0.20 L/L) with a neutrophilic leukocytosis and hyperfibrinogenemia. The platelet count is normal. Hypergammaglobulinemia can be present. There is an elevation in serum activity of CK and AST in affected horses, likely as a result of muscle lesions, in approximately 25% to 30% of cases. Horses with infarctive purpura have marked elevations in serum activity of CK and AST, neutrophilia, and in severely affected horses, there is evidence of disseminated intravascular coagulation.

**Diagnostic confirmation** is achieved by skin biopsy, especially of early lesions, and reveals leukocytoclastic vasculitis. Immunofluorescence staining of sections of skin may
reveal the presence of antibodies, antigens, or complement in the walls of small blood vessels.

**NECROPSY FINDINGS**

Ecchymotic and petechial hemorrhages are present generally throughout the body. The subcutaneous swellings contain plasma, which may be bloodstained, or sometimes whole blood. The lungs are edematous and congested. Histologically, the changes are also dominated by bland hemorrhage, but a leukocyctlastic vasculitis is usually observed in scattered vessels. Samples of lung, muscle, and gastrointestinal tract, in addition to skin, should be examined via light microscopy to check for the presence of vasculitis.

Horses with infarctive purpura have dark red to black, multifocal coalescing hemorrhages in skeletal muscles. Hemorrhages also occur in the lungs and gastrointestinal tract. Histologic examination reveals coagulative necrosis of muscle and other tissues. There is inflammation of the blood vessels.

**DIFFERENTIAL DIAGNOSIS**

**Horses**

Causes of edematous swelling include the following:
- Equine viral arteritis and equine herpesvirus-1 or equine herpesvirus-4 infection, which do not have petechiation and are readily distinguished by their epidemiologic characteristics and by serologic testing
- Equine granulocytic anaplasmosis (ehrlichiosis), which can be differentiated by the presence of granular inclusions in the cytoplasm of neutrophils
- Congestive heart failure, which should be apparent on clinical examination
- Angioneurotic edema, which is not associated with petechiation
- Stachybotryotoxicosis

Causes of petechial hemorrhages include the following:
- Equine infectious anemia
- Thrombocytopenic purpura
- Stachybotryotoxicosis

**Cattle**

Hemorrhagic septicemia, poisoning by bracken fern and sweet clover, thomobocytopenia associated with bovine viral diarrhea, and stachybotryotoxicosis are more likely the causes of a hemorrhagic syndrome than is purpura hemorrhagica.

**TREATMENT**

The principles of treatment are to reduce inflammation of the blood vessels, remove the inciting cause, and provide supportive care. Because of the possibility that the disease is caused by an adverse drug reaction, administration of any drugs that the horse is receiving at the time the disease develops should be discontinued.

**Reduction of inflammation of the blood vessels** involves mitigation of the immune response and removal of the source of the antigenic stimulus. The immune response, and its associated inflammatory reaction in blood vessels, should be treated with corticosteroids such as dexamethasone (0.05–0.2 mg/kg, IV or intramuscularly every 24 hours) or prednisolone (0.5–1 mg/kg, intramuscularly or IV every 24 hours). Prednisolone might not be as effective as dexamethasone. The dose of corticosteroid can be gradually reduced as the clinical signs improve, and the drug can be given orally.

**NSAIDS** (phenylbutazone 2.2 mg/kg orally or IV every 12 hours, or flunixin meglumine 1.1 mg/kg orally or IV every 12 hours) may reduce inflammation and provide some analgesia.

**Removal of the source of the antigenic stimulus** of the disease is difficult, especially in cases when an antecedent infection or disease is not readily identified. On the assumption that purpura hemorrhagica is often a sequela to S. equi infection, and the suspicion that occult S. equi infection is present and the source of antigen associated with the disease, affected horses are usually treated with penicillin G (procaine penicillin, 20,000 IU/kg, intramuscularly every 12 hours, or potassium penicillin G, 20,000 IU/kg, IV every 6 hours) until the clinical signs resolve. Treatment with antibiotics might need to be continued for as long as 20 days.

**Supportive care** includes bandaging of swollen limbs, care of wounds, hydrotherapy, and IV fluid administration. Swelling of the head and pharynx may necessitate placement of a nasogastric feeding tube to permit enteral feeding of dysphagic horses. Respiratory distress can develop very rapidly, and emergency tracheotomy may be required to relieve respiratory distress and prevent asphyxiation.

**CONTROL**

There are no specific preventive measures. However, control and prevention of upper respiratory tract infections in horses should lead to a reduction in the incidence of purpura hemorrhagica. Careful consideration should be given to the use of vaccines containing streptococcal M protein or avirulent S. equi in horses at low risk of developing strangles. Although the relationship between M protein-containing vaccines and purpura hemorrhagica is not definitive, circumstantial evidence and the opinion of authorities in the field support such an association. Measurement of serum antibodies to M protein might be useful in determining the need for vaccination of horses in endemic areas or at high risk. Horses with antibody titers >1:3200 should not be vaccinated.

**VENOUS THROMBOSIS**

The development of thrombi in veins may result in local obstruction in venous drainage; in liberation of emboli that lodge in the lungs, liver, or other organs; and in the development of septicemia or of endocarditis.

**THROMBOPHLEBITIS**

Thrombophlebitis is inflammation of the vein wall accompanied by the presence of thrombosis. Thrombophlebitis typically involves the classic triad of (1) blood vessel trauma, (2) stasis of blood flow (common in severely ill horses), and (3) a hypercoagulable state. Thrombophlebitis may be caused by localization of a blood-borne infection, by extension of infection from surrounding diseased tissues, by infection of the umbilical veins in the newborn, and by irritant injections into the major veins. The jugular vein is most frequently affected in large animals because it is the vein usually used for IV injections and catheter placement.

Thrombophlebitis is a complication of injections or catheterization in some animals and occurs in all species. It can result from damage to the vascular endothelium by cannula or indwelling IV catheters, inflammation caused by chemical irritation, or bacterial invasion from contamination during insertion of the needle or catheter or migration along the catheter from the skin. Clipping of the skin over the jugular furrow markedly decreases bacterial counts on the skin surface of the horse, as does application of two common skin disinfectants, chlorhexidine and povidone iodine. Clipping allows easier visualization of the jugular vein, minimizing trauma during catheterization, and minimizes the potential for foreign material to be introduced under the skin during catheter placement. The incidence of catheter- or injection-related thrombophlebitis is therefore thought to be decreased by clipping and aseptic preparation of the venipuncture site, although direct evidence of this assumption appears to be lacking in large animals. Phlebitis develops and can be detected clinically 24 to 72 hours after catheter insertion. A retrospective study of 46 cases in horses indicated that ongoing infectious disease was a risk factor for the development of catheter-associated thrombophlebitis, and thrombophlebitis is especially common in horses with severe gastrointestinal diseases that are accompanied by endotoxemia. The catheter acts as a nidus for clot formation, particularly at the site of insertion into the vein. The catheter tip, depending on its mechanical properties and blood flow velocity, may resonate in the lumen and mechanically damage the.
adjacent venous endothelium. Horses are also at higher risk of thrombophlebitis following surgery. Severely ill cows are also more likely to develop jugular vein thrombophlebitis than healthy cows.

IV injections of irritating materials, such as tetracycline, phenylbutazone, 50% dextrose, hypertonic solutions of calcium gluconate, borogluconate and chloride, or hypertonic saline (7.2% NaCl), may cause endothelial damage followed by cicatricial contraction, with or without thrombus formation. Jugal phlebitis with thrombosis is not uncommon in feedlot cattle that have received repeated IV antibiotic medication and may lead to thromboembolic respiratory disease. Accidental injection of irritating material around the vein usually causes a marked local swelling, sometimes with necrosis and local sloughing of tissue, which may be followed by cicatricial contraction of local tissues.

Venous thrombi are relatively common in strangles in the horse, and may affect the jugular veins or the CVC. The odds of developing thrombophlebitis are markedly increased in horses with fever or concurrent endotoxemia, salmonellosis, hypoproteinemia, or undergoing intensive care. Although IV administration of phenylbutazone is frequently associated with the development of phlebitis and jugular thrombosis at the site of injection, one study identified injection of phenylbutazone or flunixin meglumine through the catheter as protective for the development of thrombophlebitis. Massive pulmonary thromboembolism probably occurs more often as a sequel of systemic illness in horses and cattle than is currently realized. In a recent case series involving six systemically ill horses, emboli that were thought to be generated somewhere in the venous circulation (particularly associated with localized thrombophlebitis) became lodged in the pulmonary circulation; small emboli cause local infarcts with minimal to no clinical signs. In contrast, lodging of large emboli in the pulmonary circulation can rapidly lead to bronchoconstriction, tachypnea, cardiac failure, and sudden and unexpected death.

Thrombosis of the CVC caused by hepatic abscessation results in embolic pneumonia and pulmonary arterial lesions in cows and is described together with cranial vena caval thrombosis in Chapter 12. Caudal vena caval thrombosis can also result from inflammatory foci elsewhere; there is one report of thrombosis associated with treatment of lameness in a Holstein-Friesian cow that had deep digital sepsis that necessitated multiple regional IV perfusions. Ultrasonography is very helpful in diagnosing caudal vena caval thrombosis in adult cattle, and excellent images of the thrombus have been obtained by placing a 7.5-MHz probe in a sterile rectal palpation sleeve during a right flank laparotomy with the cow in the standing position.

Less common examples of venous thrombosis are those occurring in the cerebral sinuses, either by drainage of an infection from the face or those caused by the migration of parasite larvae. Purpling and later sloughing of the ears, which occur in many septicemias in pigs, are also caused by phlebitis and venous thrombosis. Thrombosis of the tarsal vein is a complication of infections in the claw of cattle and IV administration of antimicrobial agents as part of the treatment of septic arthritis or the distal interphalangeal joints.

**CLINICAL SIGNS**

Clinical signs of venous thrombosis are engorgement of the vein, pain on palpation, and local edema. In unsupported tissues rupture may occur and lead to fatal internal or external hemorrhage. If the venous thrombosis is peripheral and on a limb, lameness and swelling distal to the venous thrombus may be evident. Thrombosis of the portal vein in a neonate may result in hyperammonemic encephalopathy. Massive pulmonary thromboembolism may be associated with acute tachypnea, fever, and collapse, or be clinically inapparent.

Ultrasonographic examination greatly assists the diagnosis, and the detection of a cavitating area within the thrombus supports a diagnosis of septic thrombophlebitis. Ultrasonographic findings include a dilated and incompressible vein, no change in luminal volume when gentle pressure is applied at the thoracic inlet over the jugular furrow to occlude venous flow, a thickening of the wall of the vein consistent with phlebitis, and the presence of echoic or hyperechoic material in the lumen of the vein consistent with a thrombus. Ultrasonographic changes are evident 24 hours before clinical signs of thrombophlebitis become apparent. Angiography can also assist in diagnosis but is no longer used with the widespread availability of high-resolution ultrasonographic units.

Bacteriologic culture should be attempted, preferably from the tip of the removed catheter. A variety of different organisms have been isolated from different cases. There are no typical findings on clinicopathologic examination, but there is often an abnormal leukogram and hyperfibrinogenemia. At necropsy the obstructed vessel and thrombus are usually easily located by the situation of the edema and local hemorrhage.

Diagnosis depends on the presence of signs of asymmetric local venous obstruction that is hot and painful to the touch in the absence of obvious external pressure by tumor, enlarged lymph nodes, hematomas, or fibrous tissue constriction. Veins with thrombophlebitis are usually firm and resist compression. Pressure of a fetus may cause symmetric edema of the perineum, udder, and ventral abdominal wall during late pregnancy, and can be easily differentiated from thrombophlebitis by its symmetry and lack of pain. Local edema caused by infective processes such as blackleg, malignant edema, and peracute staphylococcal mastitis are accompanied by fever, severe toxemia, acute local inflammation, and necrosis.

**TREATMENT**

The long-term outcome for thrombophlebitis is variable. The vein usually becomes recanalized and varying degrees of blood flow are reestablished; however, the thrombus may fibrose without recanalization, restricting venous return and causing the development of a collateral circulation. Parenteral treatment with antimicrobial agents and hot fomentations to external veins to assist drainage of purulent material (particularly in cattle), or treatment with a topical antiinflammatory agent such as 50% dimethyl sulfoxide, is usually instituted to remove the obstruction or alter the swelling. If a catheter is used, it should be immediately removed.

Treatments used for arterial thrombosis should theoretically have similar efficacy in the treatment of venous thrombosis, but usually aggressive treatment is not needed unless the venous thrombosis is extensive and enlarging. Serial ultrasonographic examinations are very helpful in monitoring recanalization of the thrombosed vein and measurements of the external jugular vein diameters are available for cattle.

**ELAEOPHORIASIS (FILARIAL DERMATITIS IN SHEEP)**

*Elaeophora* spp are filarial nematodes that inhabit blood vessels. Relatively nonpathogenic species include *E. bohmi*, which has been reported in horses in Austria, and *E. poeii*, which occurs in cattle in Africa and Asia. Of greater clinical significance is *E. schneideri*, which is primarily a parasite of mule deer and moose in North America. Elk, white-tailed deer, and moose may act as reservoir hosts. This species causes chronic disease in adult sheep grazing at high altitudes during the summer months. Horse
flies such as *Hybomitra* and *Tabanus* spp. are intermediate hosts. In sheep, larvae develop in the leptomeningeal arteries for 4 to 5 weeks after which they migrate into the common carotid and internal maxillary arteries, although they may also be found in other arteries. The adults grow to 120 mm in length and mature in about 5 months.

**Elaeophorosis** usually produces no detectable effects in the natural host (the mule deer). Clinical signs in abnormal hosts attributable to migrating worms are thought to be the result of the prolonged sojourn of the larvae in smaller blood vessels. This reduces blood flow and may result in blindness, deafness, and circling. It also means that the larvae are larger when they pass through the cerebral retina to get to the common carotid and rupture of a rete artery, hemorrhage, and death may follow. Further signs are caused by the microfilariae. Sheep usually show a severe dermatitis on the poll, forehead, face, feet, and ventral abdomen. Initially the lesions are small and circumscribed but the irritation produced by them is so intense that scratching causes extensive areas of bleeding, with a granular surface containing numerous small abscesses. On the feet, the lesions extend from the coronary band to above the fetlock and cause a great deal of local swelling. Recurrent periods of quiescence occur and scabs form over the lesions, but 2 to 3 days later scratching recommences. The number of microfilariae in the skin of sheep is always low, and negative results may be obtained in known positive sheep.

**Treatment** with piperazine (220 mg/kg) has been suggested. Unfortunately, the death of adult parasites in heavily infected sheep has been suggested. Unfortunately, the death of adult parasites in heavily infected sheep may cause the death of the host, presumably by blocking branches of the carotid arteries. Information is lacking on the activity of modern drugs on this infection.

---

**Vascular Neoplasia**

Neoplasia of the vascular system is rare in ruminants, horses, and pigs.

**HEMANGIOMA AND HEMANGIOSARCOMA**

Hemangioma and hemangiosarcoma are rare in large animals but are described and may be associated with hemorrhage related to the site of the tumor.

**HEMANGIOMA**

Hemangiomas in the skin are most common in horses aged less than 1 year and may be congenital. The most common site in horses is the skin of the distal limb. Clinically, the lesions are usually solitary, firm to fluctuant, and bluish to black in color. The tumors grow with age; those on the skin may ulcerate and bleed and may necessitate euthanasia because of their eventual size. Similar tumors may occur in the mouth as pedunculated pink granular masses that ulcerate and bleed. Local hemangiomas on the skin and in the mouth may respond to surgical excision, thermocoagulation, or radiation therapy. Widespread disseminated hemangiomatosis is also recorded in young cattle presenting with multiple skin lesions and organ involvement. Hemangiomatosis has also been reported with moderate prevalence affecting the ovaries of sows.

**HEMANGIOSARCOMA**

Hemangiosarcoma occurs in horses but is not a common tumor. It is more prevalent in middle-aged and older animals. Affected horses may present with a bleeding subcutaneous mass or with signs of disseminated hemangiosarcoma. Disseminated hemangiosarcomas in horses cause anemia due to hemorrhage into the tumor or into body cavities. In addition there is weight loss, but good appetite, and weakness. Metastasis is extensive to lung, myocardium, brain, retroperitoneum, and skeletal muscle, and myocardial lesions can lead to cardiac arrhythmias. Lesions in skeletal muscle cause difficulty in movement, and tumors in the nervous system present with signs of ataxia. The thoracic cavity is a common site for metastasis and can also be a primary site of the neoplasm.

A common clinical manifestation is pectoral effusion and hemorrhage and a clinical picture that requires differentiation from other causes of thoracic mass with effusion, which in the horse is more commonly mediastinal abscess, lymphosarcoma, squamous cell carcinoma, or pleurisy. Hemoperitoneum, detectable by paracentesis, is present with peritoneal tumors. All the tumors are cavitative and bleed profusely if incised. Early histopathologic diagnosis may permit a cure in animals with localized masses that can be surgically resected. If masses are not interfering with quality of life and the horse is medically stable, observation may be warranted because spontaneous resolution has been reported.

Abnormalities of Plasma Protein Concentration

Plasma contains hundreds of proteins, including albumin, immunoglobulins, clotting factors, acute-phase proteins, hormones, and cytokines. The proteins in plasma are produced by the liver (albumin, acute-phase proteins [fibrinogen, serum amyloid A], clotting factors) and lymphoid organs (the gamma-globulins and many cytokines). The plasma proteins serve as sources of amino acids for tissues, serve as carrier molecules, maintain plasma oncotic pressure, regulate immune function, and function in hemostasis and fibrinolysis. Defects or deficits of individual proteins can result in specific diseases, including immune deficiency, defective hemostasis, and endocrinopathy. The individual diseases resulting from loss of activity of specific proteins are discussed under the headings of those diseases. Provided here is an overview of hypoproteinememic and hyperproteinemic states.

HYPOPROTEINEMIA

ETIOLOGY

Hypoproteinemia is a plasma or serum total protein concentration that is below that expected in animals of the same age, sex, physiologic state, and species.
Hypoproteinemia can be a result of a reduction in concentration of albumin and globulins, or a reduction in either albumin or globulin concentrations. Abnormalities in plasma protein concentration include the following:

- Panhypoproteinemia with hypoalbuminemia and hypoglobulinemia
- Hypoproteinemia with hypoalbuminemia and normal globulin concentration
- Hypoproteinemia with hypoglobulinemia and normal albumin
- Normal total protein concentration with hypoalbuminemia and hyperglobulinemia; less commonly, hyperalbuminemia and hypoglobulinemia

The specific deficiency has important diagnostic significance.

**Panhypoproteinemia**

Hypoproteinemia with hypoalbuminemia and hypoglobulinemia can be either relative or absolute.

Relative hypoproteinemia occurs when plasma protein concentrations are lower than normal, but the absolute content of protein in the vascular space is normal. This is a dilutional hypoproteinemia and is attributable to either excessive fluid therapy or excessive water intake. These causes are readily determined from a review of the history and treatment of the animal, and cases resolve within hours of discontinuation of fluid therapy or restriction of fluid intake.

Absolute hypoproteinemia occurs when there is a reduction in the amount of plasma proteins in the vascular space in the presence of normal or almost normal plasma volume. The reduced protein concentration can be the result of impaired production or accelerated loss. Reduced production of all plasma proteins occurs only as part of malnutrition and starvation. Liver disease can cause a reduction in the concentration in plasma of those proteins produced by the liver (see following discussion) but in large animals is an unusual cause of hypoproteinemia. Loss of protein is a more common cause of hypoproteinemia.

The loss of proteins can be either from the vascular space into the extravascular compartment (e.g., endotoxemia, vasculitis) or from the body (compensated hemorrhage, glomerulonephritis, protein-losing enteropathy). This situation is evident as a reduction in concentrations of both albumin and globulins, and in hemorrhagic disease, by a reduction in hematocrit. Loss because of vascular leakage is usually evident as hypoproteinemia with normal or elevated hematocrit. Diseases causing panhypoproteinemia include the following:

- Hemorrhage—hypoproteinemia occurs when plasma volume is restored after severe hemorrhage, or in normovolemic anemia when there is persisting loss of blood. All causes of chronic blood loss can cause hypoproteinemia.
- Endotoxemia—protein loss is secondary to leakage of protein from the vascular space into interstitial spaces because of increased capillary permeability.
- Vasculitis—increased capillary permeability and leakage of protein result from vasculitis; it is evident in many systemic diseases, including African horse sickness, purpura hemorrhagica, swine fever, and malignant catarrhal fever.
- Protein-losing enteropathy—the initial change is in plasma albumin concentration, but panhypoproteinemia ensues as the disease progresses. Diseases causing protein-losing enteropathy include the following:
  - Intestinal parasitism
  - Abomasal ulceration in cattle
  - Lymphosarcoma in cattle and horses
  - Granulomatous/inflammatory intestinal disease in horses (granulomatous enteritis, eosinophilic enteritis) and cattle (Johnes’ disease)
  - Enteritis/colitis (salmonellosis, equine neorickettsiosis [Neorickettsia risticii])
  - Nonsteroidal antiinflammatory drug (NSAID) toxicosis
  - Lawsonia intracellularis proliferative enteropathy in young horses and pigs

- Urinary tract disease, including cystic calculi, pyelonephritis, glomerulonephritis
- Acute, severe inflammation of the peritoneal or pleural membranes (peritonitis, pleuritis). The hypoproteinemia occurs early in the disease; if the disease becomes chronic, hypergammaglobulinemia ensues.
- Chronic heart failure

**Hypogammaglobulinemia**

Hypogammaglobulinemia with normal plasma albumin concentration occurs in few diseases. Notably, it is a feature of failure of transfer of passive immunity in neonates (see Chapter 20). Hypoglobulinemia is an unusual isolated defect in other diseases. It can be detectable in immunodeficiencies causing decreased production of gamma-globulins, such as combined variable immunodeficiency in horses.

**Hypofibrinogenemia**

Hypofibrinogenemia usually only occurs as part of disseminated intravascular coagulation, although it could conceivably occur in chronic liver failure.

**PATHOPHYSIOLOGY**

Panhypoproteinemia and hypoalbuminemia cause a reduction in the plasma concentrations of proteins essential for a variety of functions. Overall, the reduction in plasma albumin concentration results in a low plasma oncotic pressure. Low plasma oncotic pressure allows movement of fluid from the vascular space, causing a reduction in plasma volume and increases in extravascular volume. The reduction in plasma volume lowers blood flow to tissues and can result in organ dysfunction. The increased extravascular volume is sometimes evident as ventral body wall or submandibular edema.

Low plasma albumin concentration, in addition to the reduction in plasma oncotic pressure, reduces opportunities for transport of substances in the plasma, including hormones and electrolytes (calcium).

Hypogammaglobulinemia increases the risk of infectious disease, especially when it occurs as a consequence of failure of transfer of passive immunity to neonates.
CALCULATIONS:

\[ \text{Volume of plasma required} = \frac{\text{Desired plasma albumin content} \times \text{Desired albumin content} \times \text{Current plasma albumin content}}{\text{Dose} \times \text{Current albumin content}} \]

For example, a 500-kg horse with a plasma albumin concentration of 2.5 g/dL and a target plasma albumin concentration of 3.0 g/dL:

\[ \text{Volume of plasma required} = \frac{(3.0 \times 0.05 \times 150)}{(8 \times 0.05 \times 150)} = 5.3 \text{L} \]

NECROPSY

The changes observed at necropsy are those of the inciting disease, or secondary infection in animals with hypogammaglobulinemia. Edema can be present in subcutaneous and internal connective tissues.

TREATMENT

The principles of therapy are similar to those of the inciting disease and correction of hypoproteinemia or low plasma oncotic pressure. Correction of hypoproteinemia (hypalbuminemia, hypogammaglobulinemia) is achieved by administration of plasma by transfusion. Unless anemia is also present, plasma transfusion is preferred over blood transfusion. The amount of plasma transfused to neonates is discussed in Chapter 20. Plasma transfusion to adult horses and cattle is often limited by the cost of the plasma. Ideally, plasma should be transfused to increase plasma albumin concentrations to more than 2.0 g/dL (20 g/L). This can be calculated as follows (where 0.05 is the proportion of body weight that is plasma):

Current plasma albumin content = body weight (kg) \times 0.05 \times (plasma albumin concentration in g/L)

Desired plasma albumin content = body weight (kg) \times 0.05 \times (desired albumin concentration in g/L)

Amount of albumin required (g) = Desired plasma albumin content - current albumin content

Volume of plasma required (L) = Amount of albumin required (g) / albumin concentration in transfused plasma (g/L).

A numerical example for a 500-kg horse with a plasma albumin concentration of 1.5 g/dL (15 g/L) and a target plasma albumin concentration of 2.5 g/dL (25 g/L) is as follows:

Current plasma albumin content = 500 (kg) \times 0.05 \times 15 (g/L) = 375 g

Desired plasma albumin content = 500 (kg) \times 0.05 \times 25 (g/L) = 525 g

Amount of albumin required (g) = 525 - 375 = 150 g

Volume of plasma required (L) = 150 (g) / 30 (g/L) = 5 L.

It is a frequent observation that transfusion of the calculated volume of plasma leads to improvement in clinical signs, but it does not result in the expected increase in the plasma albumin concentration. This is probably because transfusion of albumin results in an increase in plasma oncotic pressure and a net movement of fluid from the extravascular space into the vascular space, with subsequent expansion of the plasma volume. The expansion of plasma volume dilutes the administered albumin and attenuates the increase in plasma protein concentration.

Plasma oncotic pressure can be increased by IV administration of hydroxyethyl starch or high-molecular-weight dextrans. The dose is 8 to 10 mL/kg of 6% solution delivered intravenously over 6 to 12 hours.9

HYPERPROTEINEMIA

ETIOLOGY

Panhyperproteinemia, an increase in concentration of all plasma proteins, occurs only in situations in which there is a reduction in plasma water content. This occurs in animals that are severely dehydrated through lack of access to water, inability to drink, loss of protein-poor body fluids (diarrhea, vomitus), or excessive polyuria with inadequate water intake.

Hyperglobulinemia

Hyperglobulinemia occurs as a consequence of chronic inflammation or abnormal production of globulins. Chronic inflammation causes a polyclonal gammopathy, whereas plasma cell neoplasia (plasmacytoma, myeloid leukemia, see “Leukoproliferative disease”) causes a monoclonal gammopathy. Any chronic inflammatory disease, including those of infectious, toxic, or neoplastic origin, can cause hyperglobulinemia.

Hyperfibrinogenemia

Fibrinogen is an acute-phase protein (along with serum amyloid A, haptoglobin, C-reactive protein, and others), the concentration of which increases in plasma in response to inflammation. Any disease that causes inflammation can increase plasma fibrinogen concentration.

PATHOPHYSIOLOGY

Chronic inflammation results in chronic stimulation of the immune system, with subsequent increased production of immune globulins and acute-phase proteins. Monoclonal gammaglobulinemia occurs as a result of unrestrained production of gammaglobulins by neoplastic plasma cells.

CLINICAL SIGNS

The clinical signs are of the underlying inflammatory disease.

REFERENCES

Hemorrhagic Disease

Hemorrhagic disease is manifest as the presence of hemorrhage of unusual duration or severity, either externally from apparently minor wounds, or into body cavities, or as the presence of petechial and ecchymotic
hemorrhages in mucous and conjunctival membranes and the skin. Petechial and ecchymotic hemorrhage, spontaneous hemorrhage, or excessive bleeding after minor injury can result from increased capillary fragility, disorders in platelet function, or defects in the coagulation mechanism of the blood.

**DIAGNOSIS**

Diagnosis of the cause of hemorrhagic disease is based on the demonstration of abnormalities in the activity, concentration, or function of components of blood coagulation and fibrinolysis. The exception is diagnosis of vasculitis, which is achieved by biopsy, usually of skin, and histologic examination and demonstration of inflammatory lesions in the walls of blood vessels. Vasculitis is not normally evident as a hemorrhagic disease.

Demonstration of prolonged bleeding time is achieved using devices that inflict a controlled wound on either the skin or a mucous membrane (template bleeding time). A wound is inflicted in the skin, and blood is periodically collected onto absorbent filter paper until bleeding ceases. The time from discharge of the device until bleeding stops is the bleeding time. The mean template bleeding time is less than 5 minutes in most healthy animals, although the test has poor repeatability in healthy horses, and the reference range is too wide to make the test clinically useful.

Care must be taken when collecting specimens of blood for measurement of factors involved in coagulation or fibrinolysis. Blood samples collected into containers that do not contain an anticoagulant will rapidly clot, and the resulting serum sample will be minimally useful for any tests of factors involved in clotting or fibrinolysis. The ideal anticoagulant for most assays of clotting and fibrinolysis is trisodium citrate (1 part of 3.8% trisodium citrate to 9 parts of blood). Sodium citrate decreases the concentration of ionized calcium in blood and thereby inhibits platelet activity. Heparin, both unfractionated (conventional) and low-molecular-weight formulations, inhibits thrombin activity and activates platelets and is not a suitable anticoagulant for measurement of clotting times or platelet activity. Potassium ethylenediamine tetraacetic acid (EDTA) interferes with platelet function. An integrated measure of the capacity of blood to clot is the activated clotting time. In this test, blood is collected into plastic syringes that do not contain an anticoagulant and then immediately injected into glass tubes containing diatomaceous earth. The tubes are gently agitated and then incubated for 1 minute in a water bath at 37°C (98.6°F). The tubes are then removed from the water bath and examined for clotting of blood by gently rolling the tube. The tube is then returned to the water bath and reexamined every 30 to 60 minutes.

The rate of clot retraction of blood collected into a glass tube that does not contain anticoagulants is a measure of platelet activity. The time until maximum clot retraction is 1 to 2 hours in most species when the blood is held at 37°C (98.6°F).

Measurements of prothrombin time (an indicator of activity of the extrinsic clotting system), activated partial thromboplastin time (an indicator of functionality of the intrinsic clotting system), and thrombin time (common pathway) are routinely performed for animals. The tests are reliable when performed properly; however, values for normal animals can vary, and the recommendation is that when submitting a sample from an animal with suspected coagulopathy, a sample from a similar healthy animal should also be examined. If prothrombin or activated partial thromboplastin time are prolonged, other tests to determine the specific factor(s) involved might be warranted.

Measurement of the activity or concentration of blood clotting factors is routine in human medicine, and many of these tests have been adapted for use in animals. Chromogenic assays of factors VII, VIII: C, IX, and X developed for testing of human plasma are reliable when used for testing of horse plasma. An ELISA for von Willebrand factor is available that is suitable for use in a number of species, including horses, pigs, and cattle. Whereas most functional assays, including chromogenic assays, are suitable for use among species, most immunologically based assays developed for use in humans are not suitable for use in animals. It is important that assays should be validated in the species of interest before clinical use in animals.

**Fibrinogen** is an essential substrate for clot formation, and low plasma concentrations of fibrinogen, such as can be encountered in animals with disseminated intravascular coagulation, can impair blood clotting. Measurement of fibrin (fibrinogen) degradation products (FDPs) has been used to detect disseminated intravascular coagulation in horses, but the test has poor sensitivity and specificity. Measurement of D-dimer concentration has the potential to be more useful than FDP in assessment of fibrinolysis and detection of thromboembolic disease, although measurement of elevated D-dimer concentrations in foals is not associated with the presence of disseminated intravascular coagulation and coagulopathies.

Performance characteristics vary among assays and kit suppliers, and these should be ascertained before clinical use of kits or assays. The FDP assay was found to have low sensitivity (<40%) for diagnosis of disseminated intravascular coagulation in horses with colic, whereas the most accurate D-dimer kit had 50% sensitivity and 97% specificity. The activity of antithrombin (previously antithrombin III), a cofactor of heparin, is measured in horses as a means of assessing the anticoagulant activity of plasma. Activity of antithrombin is reduced in animals with coagulopathies secondary to gastrointestinal disease. This factor is best measured in concert with thrombin–antithrombin complex concentration and protein C and plasminogen activity to detect hypercoagulable states.

**Platelet count** in blood should be evaluated in any animal with a hemorrhagic diagnosis. Caution should be exercised in interpreting low platelet counts determined by automated analyzers because clumping of platelets can cause artificially low values. This pseudothrombocytopenia can be a result of anticoagulant-induced ex vivo aggregation of platelets, which can be readily detected by microscopic examination of the blood smear. Platelets counts of less than 100,000 cells/μL are considered abnormal, although excessive hemorrhage is usually not apparent until platelet counts are below 40,000 cells/μL. Determination of the proportion of platelets that stain with thiazole orange dye (reticulated platelets) can be useful in determining the bone marrow regenerative response in horses, and probably other species, with thrombocytopenia. Reticulated platelets are those platelets that have been recently released from bone marrow. Healthy ponies have 1.3% to 2.8% of platelets in circulation that stain with thiazole orange, and horses have 1% to 3.4%. Thrombocytopenic, equine-infectious-anemia-positive ponies have 11% to 48% thiazole-orange-staining platelets in the circulation, and thrombocytopenic, equine-infectious-anemia-negative horses have 2% to 9%.

**Platelet function** can be evaluated using platelet function analyzers designed for use with human blood, ultrastructure, and flow cytometry. Impaired platelet aggregation can be detected as a prolongation in closure time using cartridges with collagen–adenosine diphosphate (CT-ADP) and collagen–epinephrine (CT-Epi) as platelet agonists. In normal horses calculated reference ranges are 60.5 to 115.9 seconds and 158.5 to more than 300 seconds for CT-ADP and CT-Epi, respectively. Disorders of platelet function can be both acquired and congenital (genetic). Genetic disorders of platelet function in large animals include Glanzmann thrombasthenia in Oldenburg, Thoroughbred, Quarter horse, and Peruvian Paso breeds of horses; thrombopathia in Simmental cattle; and Chediak–Hegashi syndrome in Japanese Black Cattle. This is in addition to the occurrence of von Willebrand’s disease (type 2) in Quarter horses and Thoroughbreds.

**Thromboelastography** (TEG) is a viscoelastic, whole-blood-based assay that integrates information from both the cellular and soluble components of coagulation, providing a global evaluation of the hemostatic
system, unlike conventional coagulation assays. Measurements of platelet count, prothrombin time (PT), activated partial thromboplastin time (aPTT), and fibrinogen concentration (FIB) individually provide information about one component of the hemostatic process, and evaluation of these assays is needed for a complete evaluation of hemostasis.6

Thromboelastography measures indicators of the intrinsic and extrinsic clotting cascades (noting that this terminology is increasingly archaic and being replaced with a more integrated description of clotting cascades) incorporating both the cellular and noncellular components of the clotting cascade. Several variables are measured (Fig. 11-1), including the following:6 coagulation time, which is the time in seconds between activation of clotting and formation of the first measurable clot; clot formation time, which is the time needed to increase the elasticity of the clot from 2 mm to 20 mm and corresponds to the initial activation of platelets; angle (α), which indicates hypo- or hypercoagulability; and maximum clot firmness, which corresponds to the maximum strength of the clot and depends on both platelet and fibrinogen activation in the presence of factor XIII. Hemolysis interferes with the reliability of testing.9 There are marked effects of even short-term (<30 minutes) storage of equine blood, with significant increases in indicators of coagulation.9

Utility of viscoelastic evaluation of blood has been reported in healthy dairy cows at various stages of lactation, in healthy and sick neonatal foals, in horses with gastrointestinal disease, and in horses with disorders of platelet function.10-12 Assay validation, and careful attention to sample collection and processing, is essential for reliable results of viscoelastic testing.8,15,16 The recommended anticoagulant for viscoelastic testing of blood is sodium citrate in a precise ratio of 1:9 (citrate solution to blood) using blood collected by jugular venipuncture.15

In normal animals, values of the variables just discussed have been reported inconsistently and are available in textbooks dealing with hematology. Values in foals and calves can vary with age, and this should be considered when interpreting coagulation variables in neonates and young animals.2,17,18 Values for camels and young animals are reported.9

**TREATMENT OF COAGULOPATHIES**

**Plasma** is often administered to animals with hemorrhagic diatheses to replace clotting factors that are deficient because of failure of production (e.g., warfarin intoxication), increased consumption (e.g., disseminated intravascular coagulation), or dilution (e.g., in animals with severe hemorrhage treated by administration of large quantities of fluids). The actual concentration or activity of factors involved in clotting or fibrinolysis depends on the methods used to collect and store the plasma. Fresh frozen plasma kept at −80°C (−112°F) retains much of the activity of clotting factors (VII, VIII, etc.) and inhibitors of coagulation, including antithrombin, protein C, protein S, and antitrypsin, for up to 1 year, whereas plasma stored at higher temperatures might not retain as much activity.20 The dosage varies from 2 to 10 mL/kg body weight (BW) intravenously, but this has not been critically evaluated. Platelet-rich plasma, which requires more sophisticated collection techniques, is useful for treatment of severe thrombocytopenic purpura.21 Treatment can be delayed until there are clinically important signs of hemorrhage, such as petechiation in mucous membranes or epistaxis. Platelet-rich plasma can be prepared by centrifugation of blood at 150 × g for 20 to 30 minutes, with care taken to avoid exposure of the blood to glass, which activates plasma, or storage at less than 15°C (59°F), which irreversibly reduces platelet function.22 Platelet-rich plasma should be administered within hours of collection or stored for no more than 5 days with constant agitation.21 Plasma is preferred over whole blood for treatment of nonanemic hemorrhagic diatheses.

**Aminocaproic acid** (30 to 100 mg/kg IV) reduces plasma fibrinogen concentration and decreases partial thromboplastin time of horses for up to 5 hours after administration. At the higher dose, alpha-2-antiplasmin activity is increased and fibrinogen concentration is decreased, consistent with an action of the drug to inhibit fibrinolysis. In vitro studies indicate that concentrations of epsilon aminocaproic acid necessary to inhibit fibrinolysis in horses are as much as 20 times lower than those for humans, suggesting that the dose rate for horses is unnecessarily high.21 The utility of aminocaproic acid to inhibit bleeding in clinical situations and the appropriate dosage have not been determined. A similar situation exists for tranexamic acid.22

**Tranexamic acid** inhibits fibrin degradation and is used as adjunctive treatment in animals with hemorrhagic diathesis. Its efficacy in farm animals has not been reported. **Carbazochrome** is a compound that stabilizes capillary membranes and is used for treatment of exercise-induced pulmonary hemorrhage in horses, although with undetermined efficacy.23 Formalin has been suggested as an effective treatment of excessive hemorrhage in horses, although it does not appreciably alter bleeding time or indices of coagulation. A common dose for an adult horse is 1 L isotonic electrolyte solution (saline or lactated Ringer’s solution) with a final concentration of formalin of 0.5% to 0.74%. Adult goats administered a 5.5% solution of formalin in lactated Ringer’s solution IV had a marked decrease in clotting time. However, this dose in horses is expected to be toxic.

Administration of **aspirin** to horses inhibits platelet function in a dose-dependent fashion for 48 hours after a single dose of 12 mg/kg. This is not the case in cattle, in which aspirin does not inhibit platelet aggregation even at doses of 100 mg/kg orally, even though it has a potent antiinflammatory effect.23,24 Aspirin irreversibly inhibits activity of thromboxane synthetase in both cattle and horses for a prolonged period (days) despite having a short plasma elimination half-life (hours). The bleeding time in horses is not restored until the affected platelets have been replaced by unaffected platelets. Dosages of aspirin in horses range from 15 to 100 mg/kg orally every 8 to 12 hours to 10 mg/kg orally every 48 hours.

**Warfarin** reduces the concentration of vitamin-K-dependent clotting factors by inhibiting hepatic production of these compounds. Therapeutic use of warfarin was limited to treatment of navicular disease in horses, although its use for this purpose is now archaic.

**Heparin** and the newer heparin-related compounds (low-molecular-weight heparins) dalteparin and enoxaparin have been used in horses with, or at risk of developing, coagulopathies. The low-molecular-weight heparins appear to be effective in reducing the frequency of coagulopathy in horses with colic without the adverse effect of heparin on hematocrit and clotting time. Calcium heparin causes in vivo red cell aggregation in
horses, with a resultant reduction in hematocrit and hemoglobin concentration and a reduction in platelet count. The low-molecular-weight heparins are dosed on the basis of anti-factor-Xa activity. At doses of these compounds that prolong factor Xa activity and thrombin time, they have a minimal effect on bleeding time or activated partial thromboplastin time in horses. Various doses of heparin calcium have been employed, ranging from 40 IU/kg BW IV or subcutaneously (SC) every 12 to 24 hours to 150 IU/kg BW initially followed by 125 IU/kg BW every 12 hours for 3 days and then 100 IU/kg BW every 12 hours. Dalteparin (50 and 100 anti-Xa U/kg) should be administered every 12 hours to maintain antifactor Xa activity within or above the suggested thromboplastylact time in healthy horses.27 The clinical utility and pharmacodynamics in septic horses or horses at increased risk of thrombosis are unknown. The doses of dalteparin required for healthy or septic foals to achieve therapeutic activities of antifactor Xa are double that of adult horses.28 Enoxaparin (40 and 80 anti-Xa U/kg) can be administered once daily to horses, although its pharmacodynamics are not reported.

Sodium pentosan polysulfate, a compound with heparin-like activity used for treatment of arthritis in horses, at doses of 3, 6, or 10 mg/kg, causes dose-dependent increases in partial prothrombin time that persist for 24 to 48 hours. This drug is not used for treatment of coagulopathies.

Hirudin, an anticoagulant originally derived from leeches but now available as a recombinant compound, is a specific inhibitor of thrombin that is independent of anti-thrombin activity. The compound could be useful in treatment of hypercoagulable states in which there is diminished thrombin activity. Recombinant hirudin has been investigated in horses, in which the maximum plasma concentration occurred at approximately 130 minutes and declined with a terminal half-life of approximately 600 minutes. A doubling of activated partial thromboplastin time occurred 1.5 hours after SC administration of 0.4 mg/kg. The clinical efficacy of recombinant hirudin has not been determined.

Tissue plasminogen activator increases the activity of plasmin, thereby facilitating dissolution of clots. Its use in farm animals has not been reported, with the exception of its injection into the anterior segment of the eye to dissolve fibrin associated with uveitis in horses. Recombinant tissue-type plasminogen activator (alteplase) at a dose of 1 mg/kg IV to healthy adult horses has an elimination half-life of ~170 minutes and results in increased ex vivo thrombotic activity, although its clinical utility is unknown.27

Streptokinase and urokinase have been used to facilitate dissolution of fibrin clots in farm animals, but there has been no critical analysis of their effectiveness.

DISEASES CAUSING HEMORRHAGE

VASCULITIS

Septicemic and Viremic Diseases
Vasculitis is associated with endothelial damage occurring as a direct result of infection of the endothelium (e.g., equine herpesvirus-1 myeloencephalopathy, African horse sickness) or from immune-mediated events centered on the endothelium (e.g., purpura hemorrhagica). It can be complicated by defects in blood coagulation and platelet disorders, depending on the infection. In many instances coagulation defects are a manifestation of early disseminated intravascular coagulation. Clinically, petechial and ecchymotic hemorrhages associated with septicemia are most obvious in the mucous membrane of the mouth, vulva, and conjunctiva or in the sclera, but they are widely distributed throughout the body on postmortem examination. Diseases causing vasculitis include the following:

- Systemic viral diseases: equine viral arteritis, equine infectious anemia, African horse sickness, malignant catarrhal fever, bovine ephemeral fever, bovine virus diarrhea, bluetongue, hog cholera, swine fever, equine herpesvirus-1 myeloencephalopathy
- Chlamydial and rickettsial diseases: Anaplasma phagocytophilum
- Bacterial diseases: salmonellosis, Histophilus somni infection, Actinobacillus spp. pleuropneumonia infection, pasteurellosis, erysipelas in pigs
- Miscellaneous: aspergillosis, Strongylos vulgaris infection

Purpura Hemorrhagica
Purpura hemorrhagica is a hemorrhagic disease of horses associated with leukocytoclastic vasculitis. The majority of cases occur as sequelae to strangles (clinical disease caused by infection with Streptococcus equi subsp. equi).29 Cases also occur following immunization against S. equi and as sequelae to infection with other streptococci. The disease appears to be an immune-complex-mediated disease with deposition of IgA containing immune complexes on vessel walls. Hemorrhagic tendencies in the disease include petechial and ecchymotic hemorrhages but also can result in large extravasations of blood and serum into tissues. The hemorrhage and exudation of serum can cause anemia and a reduced circulating blood volume. Hemorrhage associated with purpura is usually treated with blood transfusions and corticosteroids. A fuller description of the syndrome is given elsewhere (Chapter 11).

Necrotizing Vasculitis
Of unknown etiology but possibly immune mediated, necrotizing vasculitis occurs in all species. It is similar to purpura and can be local or generalized, with petechial hemorrhage and serosanguineous exudation subcutaneously and into tissue spaces. Hemorrhagic tendencies associated with vasculitis can be confused with those associated with a defect in the clotting mechanisms, such as abnormal platelet number or function, as the primary cause. Differentiation depends on accurate laboratory examination.

TREATMENT

Treatment of vasculitis centers on removal of the inciting cause and minimizing or eliminating inflammation in the vessel. Disease-specific treatments are discussed under each of those topics. Inflammation can be reduced by administration of glucocorticoids, the selection and dose of which vary with species (see Formulary in the Appendix). General supportive treatment can include the administration of blood or plasma if severe anemia or hypoproteinemia occur.

COAGULATION DEFECTS

Coagulation defects can be either acquired or inherited. Acquired defects are usually related to exposure to compounds that interfere with production of clotting factors, or that cause depletion of these factors. Inherited defects are usually present in young animals, but defects that only marginally increase clotting time might not be detected until the animal undergoes surgery or suffers trauma. Demonstration of defects in blood clotting is based on observation of signs of excessive hemorrhage, with confirmation achieved by measurement of bleeding time, noting earlier comments about its variability and limited clinical utility, and laboratory examination of the activity or concentration of cellular and soluble blood-clotting factors.

Acquired Hemostatic Defects

Acquired clotting defects include those associated with intoxications that impair the production or function of clotting factors and those related to depletion of clotting factors. Disseminated intravascular coagulation is a common cause of hemorrhagic diathesis in animals and is discussed in detail under that heading. Protein-losing nephropathy is associated with loss of antithrombin in urine and increased risk of thrombosis in cattle. Similarly, horses with protein-losing enteropathy have low plasma concentrations of antithrombin, which could contribute to the thrombotic tendency noted in these animals.

Reduction of vitamin-K-dependent clotting factors II, VII, IX, and X results from coumarol poisoning following ingestion of coumarol-containing plants, such as Mellilotus alba, Anthoxanthum odoratum, Apium nodiflorum, Ferula communis (giant fennel), or warfarin, bromidocoum, and...
related compounds. This syndrome is discussed in detail under each of those headings. A cluster of cases in racehorses of massive, fatal hemorrhage during exercise was associated with detection of traces of brodifacoum, diphacinone, or bromadiolone in the liver of the affected, but not the unaffected, horses. It is speculated that large increases in arterial blood pressure during exercise lower the threshold for toxicity of these compounds. Vitamin K deficiency, other than that induced by intoxication with the compounds listed earlier and the disorder in postweaned pigs discussed in the following paragraph, has not been reported in farm animals, probably because forage contains high concentrations of this compound.

A hemorrhagic syndrome in postweaned pigs has been recorded in the United States, New Zealand, France, Japan, Germany, Brazil, and South Africa. The syndrome occurs as an outbreak with anemia, hemarthrosis, spontaneous hemorrhage under the skin of the legs and body, and hemorrhage following management procedures such as castration. There is a high case fatality, and the syndrome is particularly common in pigs a few weeks after weaning. There is prolongation of the prothrombin time and activated partial thromboplastin time. The outbreaks resolve promptly following the injection of vitamin K or its inclusion in the diet. An association has been made with housing on mesh floors. The disease is believed to result from a deficiency of vitamin K in the diet coupled with housing that precludes intake of vitamin K, from the feces or bedding and decreased synthesis in the gut as a result of antibiotics in the feed, especially sulfonamides.

Snake venom can have procoagulant or anticoagulant action. In both cases coagulation defects occur as procoagulant toxins result in the activation, consumption, and depletion of prothrombin and fibrinogen, leading to coagulopathy, prolonged clotting times, and epistaxis.

Carcass hemorrhage, or blood splash, in slaughter lambs has been associated with extended prothrombin times because of prior grazing of coumarin-producing plants. The method of electrical stunning at slaughter can also result in carcass hemorrhage. *Parafilaria bovicola* produces large extravasations of blood under the skin of cattle and to some extent in tissue spaces. Bleeding from the skin can be the presenting sign of infestation.

**A number of fungal toxins can cause hemorrhagic disease when ingested:**
- *Aspergillus* spp.
- *Penicillium rubrum*
- *Lolium rigidum*
- *Trichothecium spp.*
- Toxins associated with *Penicillium*
- Grass nematodes that infest *Lolium rigidum*

Hydroxyethyl starch solution (Hetaspar) is used to increase plasma oncotic pressure in animals with hypoproteinemia, prolongs cutaneous bleeding, prothrombin, and activated partial thromboplastin times and decreases fibrinogen concentration and von Willebrand antigen and factor VIII:C activities in ponies. In vitro studies suggest that the anticoagulant effect is attributable to inhibition of platelet function and not solely to dilution of soluble clotting factors.

Navel (umbilical) bleeding in newborn piglets is a syndrome of unknown etiology. Following birth and for periods up to 2 days afterward, blood drips or oozes from the umbilicus of affected pigs to produce severe anemia, with death frequently occurring from crushing. The navel cords are abnormally large and fleshy and fail to shrink after birth. The defect appears to be one of immaturity of collagen so that a proper platelet clot does not form. Ear-notch ing for identification is also followed by excessive bleeding. A variable number of piglets within the litter may be affected, and the syndrome may have a high incidence on certain problem farms. The addition of vitamin K and folic acid to the sows' ration may be followed by a drop in incidence, but controlled trials with menadione have shown no effect. Vitamin C given to pregnant sows for at least 6 days before farrowing appears to prevent the syndrome. Jejunal hemorrhage syndrome in cattle is discussed in Chapter 9.

Ingestion of sheep by *Fasciola hepatica* shortens activated partial thromboplastin time and prolongs prothrombin and thrombin times.

**Inherited or Congenital Defects in Hemostasis**

Hemophilia A

Factor VIII: coagulant (VIII:C) deficiency, hemophilia A, is recorded in Thoroughbreds, Standardbreds, Arabian and Quarter horse colts, Japanese Brown* calf* and sheep and is associated with a deficiency in factor VIII. The disease in the Quarter horse colt also involved deficiency of factors IX and XI. It is inherited as a sex-linked recessive trait, with the defective gene located on the X chromosome. Clinically affected foals show signs of a hemorrhagic tendency within a few weeks of birth, with the development of hematomas, persistent nasal bleeding, bleeding from injection sites, and sudden death from massive internal hemorrhage. Affected foals are anemic. The diagnosis is made by the finding of very low plasma factor VIII:C activity (usually < 10% of values in unaffected animals). Treatment requires fresh frozen plasma or plasma concentrates but is not recommended because of the unavailability of sufficient plasma concentrates, the recurrent nature of the problem, and the poor prognosis for long-term soundness. The disease in Japanese Brown* calf* is caused by a missense mutation of the factor VIII gene and is evident as hemorrhagic tendency with prolonged activated partial thromboplastin time and markedly reduced factor VIII activity with normal von Willebrand factor activity.

**Von Willebrand Disease**

*Von Willebrand factor is a large adhesive glycoprotein that mediates adhesion of platelets to exposed subendothelium and also is a carrier for coagulation factor VIII, protecting it from degradation in the circulation. There are three variations of von Willebrand’s disease: types I, II, and III. Two variations of von Willebrand’s disease are recorded in pigs, both inherited as simple autosomal-recessive traits. The disease in pigs is used as an experimental model for the disease in humans, and the pig gene for von Willebrand factor is similar in size and complexity to its human counterpart, with affected pigs having a point mutation within the vWF gene. Type I von Willebrand’s disease occurred in an 8-day-old Quarter horse colt that was examined because of extensive purpura. The colt had a concentration of von Willebrand factor that was 9% of that of normal horses. The dam of the colt also had prolonged bleeding time and a concentration of von Willebrand factor that was 30% of that of normal animals, suggesting a familial and possibly heritable trait. Type II von Willebrand disease is recorded in a Quarter horse with hemorrhage associated with trauma, prolonged bleeding at an injection site lasting several hours, and spontaneous conjunctival hemorrhage, and in a Thoroughbred mare and her colt.1 The hemorrhage in the Thoroughbred mare and foal was not life-threatening. Type III von Willebrand’s disease is usually associated with low concentrations of factor VIII. Suspect factor VIII deficiency has been reported in Hereford calves. The prime manifestation was death shortly following castration, with bleeding from the surgical site, intra-abdominal hemorrhage, and severe anemia. The disease also occurs in sheep and is linked to the X chromosome.

Diagnosis is based on the observation of prolonged bleeding after minor trauma or surgery, prolonged activated partial thromboplastin time (although this can be minimal), normal prothrombin time, and decreased factor VIII:C activity and von Willebrand antigen concentration. The ristocetin cofactor activity of von Willebrand factor is reduced in animals with type II von Willebrand’s disease. An ELISA is available that is suitable for use in a number of species, including horses, pigs, and cattle. Chromogenic assays of factors VII, VIII:C, IX, and
X developed for testing of human plasma are reliable when used for testing of horse plasma. Desmopressin increases the release of von Willebrand factor from vascular endothelium and is used for treatment of the disease in humans. There are no reports to date of its use in farm animals or horses. The disease can be managed by housing to minimize trauma and administration of plasma before elective surgery, although such measures were not shown to completely prevent excessive bleeding.

**Factor XI Deficiency**

Factor XI deficiency is recorded in Holstein–Friesian cattle in Canada and in Great Britain. It is transmitted as an autosomal-recessive gene, and occurrence in Britain has been traced to the importation of Canadian semen, with genetic links between carriers in the two countries. Heterozygous cattle have decreased levels of factor XI but are usually asymptomatic. The severity of clinical disease varies in homozygous cattle, but they usually show prolonged or repeated bleeding episodes after trauma such as dehorning and hemorrhage following venipuncture. There are occasional deaths associated with multiple hemorrhages. Heterozygote carriers have decreased factor XI coagulant activity, but measurement of factor XI activity is not a sensitive test for the carrier status, and a DNA-based test is available that accurately identifies heterozygotes.

Other Clotting-Factor Disorders

Prekallikrein deficiency is also recorded in a family of miniature horses. The condition was not associated with clinical disease in these horses, but blood samples failed to clot. It has also been recorded in three Belgian horses and was detected in this group because one hemorrhaged following castration. The mode of transmission is not known, but the familial nature of the disease suggests that it is heritable.

Heritable fibrinogen deficiency was found in a Border Leicester lamb, manifest with inflammation and bleeding at the umbilicus and ear tag wound at 7 weeks of age, and in Saanen goats.

**PLATELET DISORDERS**

Disorders of platelets include alterations in the number of platelets in blood (thrombocytopenia or thrombocytosis) and their function (with reduced function referred to as thrombasthenia). The physiology of platelets varies in important ways among the farm animal species. For instance, aggregation of platelets from horses, but not cattle, is inhibited by aspirin (acetylsalicylic acid), and horse platelets adhere to immobilized autologous fibrinogen, whereas those of sheep do not. Platelets of different species respond differently to some agonists of platelet aggregation, such as ristocetin.

**Thrombocytopenia**

Clinical signs associated with thrombocytopenia or thrombasthenia are petechial and ecchymotic hemorrhages, prolonged bleeding after venipuncture or from injection sites, epistaxis, hyphema, and melena. A combination of some or all of these clinical signs is referred to as purpura. Thrombocytopenia can result from decreased production of platelets in the bone marrow or by increased consumption, increased peripheral destruction, or a combination of these factors.

Decreased platelet production is commonly associated with disorders that impair bone-marrow function, and there is usually simultaneous suppression of granulocyte and erythrocyte production. Thrombocytopenia and neutropenia develop before anemia because of the short life span of these cells relative to erythrocytes. Increased destruction, that is, the abnormal consumption of platelets, is most commonly an immune-mediated response. Increased consumption also occurs with severe trauma and disseminated intravascular coagulation, both of which increase the rate at which platelets are incorporated into clots.

**Pseudothrombocytopenia** occurs as a result of aggregation of platelets after collection into a glass tube containing EDTA. Ex vivo aggregation can occur with other anticoagulants, including heparin. This situation can be recognized by the presence of abnormally low platelet counts in animals without evidence of excessive hemorrhage, or by the presence of clumps of platelets on microscopic examination of blood smears. Collection of blood into an anticoagulant other than EDTA or heparin, such as citrate, and measurement of a normal platelet count will confirm the diagnosis of pseudothrombocytopenia.

**Differentiation** of the causes of thrombocytopenia is by clinical examination to detect underlying disease, hematology, examination for antiplatelet antibody, and examination of bone-marrow aspirates.

**Decreased Production**

Thrombocytopenia resulting from decreased production, as opposed to increased destruction, within the marrow usually occurs with granulocytopenia because of the short intravascular half-life of both granulocytes and platelets. This occurs with poisonings by *Poisonous* species, such as *Strychnos nux vomica* and *Digitalis* spp., which produces a trichothecene in cattle, pigs, sheep, and horses; chronic furazolidone poisoning in calves; poisoning caused by trichloroethylene-extracted soybean meal; drugs that cause bone-marrow suppression; and radiation injury. Severe myelophthisis, such as is associated with myeloid dysplasia or myelofibrosis, causes thrombocytopenia in association with anemia and leukopenia.

A familial myelofibrosis is reported in pygmy goats with anemia, granulocytopenia, and thrombocytopenia.

The syndrome is predominantly one of spontaneous hemorrhage but is complicated by bacteremia and fulminant infections facilitated by severe leukopenia. A granulocytopenic syndrome of unknown origin, occurring in all ages of cattle and manifest with a severe hemorrhagic diathesis, high morbidity, and high case fatality, has been reported on various occasions in Australia.

Familial diseases resulting in thrombocytopenia secondary to decreased production are recorded in Standardbred horses, in which there is generalized bone-marrow hypoplasia. Pancytopenia secondary to bone-marrow aplasia is reported in a Holstein heifer. Bovine neonatal pancytopenia is discussed elsewhere in this chapter.

**Increased Destruction**

**Inflammation and Infection.** The most common causes of thrombocytopenia are severe gastrointestinal disease (strangulating intestinal obstruction, anterior enteritis, colitis) and infectious and inflammatory disease, where a combination of increased destruction and increased consumption is the cause.

**Infection** by a variety of viral, bacterial, or rickettsial agents causes mild to severe thrombocytopenia. African horse sickness, equine infectious anemia, *Anaplasma phagocytophilum* (equine granulocytic ehrlichiosis), and infection by *Neorickettsia risticii* (Potomac horse fever) cause mild to moderate thrombocytopenia. Infection of cattle by lumpy skin disease virus causes thrombocytopenia, along with other abnormalities of the leucogram.

Infection such as occurs in hog cholera and African swine fever can result in thrombocytopenia and contributes to the hemorrhagic tendency seen in these diseases. Outbreaks of hemorrhagic disease as a result of thrombocytopenia in veal calves have been attributed to infection with bovine virus diarrhea (BVD) virus type 2, and the disease has been reproduced experimentally with noncytopathic BVD virus. The appearance of hemorrhage was directly related to the number of circulating platelets, and bleeding was seen when platelet numbers fell below 500 mL. Calves that developed thrombocytopenia had low (+1:32) BVD neutralizing titers. The virus infects megakaryocytes. Thrombocytopenia with a bleeding tendency (bloody diarrhea, petechial and ecchymotic hemorrhage) is also recorded in approximately 10% of adult cattle with acute BVD infection.

**Bovine neonatal pancytopenia (BNP)** is a disease syndrome in newborn calves of up to 4 weeks of age, first observed in southern Germany in 2006 but subsequently reported more widely. The case-fatality rate is over 80%, and death is attributable to thrombocytopenia and hemorrhagic anemia, or
Thrombocytopenia in adult animals with normal prothrombin times and partial thromboplastin times and with no evidence of disseminated intravascular coagulation is considered most likely to develop by autoimmune-mediated mechanisms. Immune-mediated thrombocytopenia can be induced by drugs or can be secondary to infectious or neoplastic disease, but most cases are idiopathic. The disease is reported most commonly in horses but does occur in cattle.

Idiopathic thrombocytopenia of adult horses occurs at any age. The cause is usually not identified, but the disease can be associated with administration of drugs, especially penicillin, although this might reflect the frequency of use of this antimicrobial in horses. The disease is caused by binding of IgG to platelets or to megakaryocytes, with subsequent impaired maturation, enhanced clearance, or both, resulting in low platelet counts in blood. Petechiation and hemorrhage can be confined to single systems, such as the respiratory system, with epistaxis and hematomas in the nasal sinuses, or the genital tract, producing a bloody vulval discharge, with no detectable abnormality at other mucous membranes. More generalized involvement with widespread petechiation of mucous membranes, epistaxis, and melena can also occur. Diagnosis is by measurement of blood platelet concentration and elimination of disseminated intravascular coagulation or primary diseases. Demonstration of platelet-surface-bound IgG on a significant proportion of platelets is diagnostic. Fewer than 0.15% of platelets from normal horses have IgG bound to the surface, whereas more than 4% of platelets of thrombocytopenic horses have IgG on the surface. Treatment includes the immediate removal from any medication and the administration of dexethasone (0.040 mg/kg intramuscularly [IM], IV, or orally, once daily) or prednisolone (1 mg/kg orally), but not prednisone. This is usually effective in restoring platelet count and controlling hemorrhage. Resolution of hemorrhage can occur even before there are marked changes in platelet count. Treatment might need to be continued for days to weeks. Most horses do not require long-term treatment. For horses with life-threatening hemorrhage, administration of platelet-rich plasma or blood is needed. A transfusion volume of 10 mL blood per kg BW can be effective. Successful treatment with azathioprine in horses that do not respond to glucocorticoids is reported (0.5 to 1.5 mg/kg orally every 24 hours). Splenectomy has been used to treat horses with chronic idiopathic thrombocytopenia that is refractory to medical therapy. However, surgical treatment should be undertaken only in extreme cases, and with attention to the effect of thrombocytopenia on hemostasis during surgery.

Idiopathic thrombocytopenia purpura is also recorded in a 10-month-old bull, and immune-mediated thrombocytopenia and anemia occurred in a cow after vaccination with a polyvalent botulism vaccine. Corticosteroid-responsive thrombocytopenia occurred in two beef-breed cows with subcutaneous hematomas and epistaxis.

Increased Consumption
Increased consumption of platelets occurs in animals with severe trauma or disseminated intravascular coagulation.

Other Causes
Thrombocytopenia occurs in horses with lymphosarcoma or myeloproliferative disease. Thrombocytopenia is usually associated with myelophthisic disease and is therefore a result of reduced platelet production. Heparin causes thrombocytopenia in horses, but the mechanism has not been determined.

Thrombasthenia
Disorders of platelet function can result in purpura even in the presence of normal platelet counts. Disorders of platelet function can be congenital or acquired.

Acquired defects of platelet function are usually secondary to severe metabolic abnormalities such as uremia, liver failure, or septicemia, or to administration of drugs. Among the compounds commonly administered to animals, aspirin is most notable in that it inhibits platelet aggregation in horses but not in cattle, despite inhibition of platelet generation of thromboxane-2 in both species. Other NSAIDs have minimal, if any, effect on platelet function. Dextan inhibits platelet function when administered to horses.

A bleeding tendency is present in the Chédiak–Higashi syndrome in cattle. A prolonged bleeding time is demonstrable despite the presence of normal soluble coagulation factors and platelet numbers, and it is a result of a defect in platelet aggregation. Thrombasthenia, possibly also associated with variant von Willebrand factor, is also recorded in bleeding disorders in Simmental and Simmental crossbred cattle in Canada and the United States, and manifests with epistaxis in cold weather, subcutaneous hematomas, and prolonged bleeding following minor procedures such as vaccination and ear-tagging. Platelet dysfunction and purpura were diagnosed in a 3-day-old Simmental heifer. Umbilical bleeding in calves has also been reported as an inherited condition in Japanese black cattle with low adenosine diphosphate (ADP)-induced platelet aggregation. Affected cattle die by 1 year of age from repeated umbilical cord hemorrhage.

Thrombasthenias are also reported in horses. Glanzmann’s disease is reported in horses with a prolonged history of epistaxis not associated with exercise. The horses had prolonged bleeding time, markedly delayed clot retraction, and a decrease in

Immune-Mediated (Idiopathic) Thrombocytopenia. Most instances of thrombocytopenic purpura in the past have been described as idiopathic. However, the development of newer diagnostic tests, including flow cytometry, that can reveal the presence of antibodies on the surface of platelets has permitted the classification of many of these cases as immune-mediated. Among the immune-mediated thrombocytopenias there are autoimmune and isooimmune diseases.

Isoimmune thrombocytopenia can be a complication in neonatal isoerythrolysis in foals and mules as a result of absorption of colostrum containing antiplatelet antibodies. The disease also occurs as only thrombocytopenia in mule foals and is attributable to antiplatelet IgG antibodies in the mule foal’s serum. In addition to thrombocytopenia, there is also depression of platelet aggregation in these foals, probably because of binding of IgG to collagen-binding sites on the platelet surface. Thrombocytopenia and neutropenia, assumed to be isoimmune-mediated, were found in foals with ulcerative dermatitis and mucosal ulceration. The foals had purpura and responded to supportive treatment and administration of corticosteroids.

The disease is observed in newborn pigs as a result of maternal isoimmunization, and it has been reproduced experimentally. Piglets are normal at birth but become thrombocytopenic after suckling colostrum containing antiplatelet antibody. Clinical signs do not develop until after the fourth day of life. There is a heavy mortality rate, with death being preceded by a generalized development of submucosal and subcutaneous hemorrhages, drowsiness, weakness, and pallor. There is no practicable treatment. The sow should be culled. Thrombocytopenic purpura has occurred in a group of lambs given a single cow’s colostrum and was manifest with multiple hemorrhages and death by 2 days of age.
Thrombocytosis with Heinz-body anemia is infection, septic arthritis, and colitis. In horses include pneumonia, inflammation in the animal. Common causes clinical examination for a cause of chronic thrombocytosis should prompt a thorough be more susceptible, but the condition can days in duration, and usually of several production. Primary thrombocytosis is myeloproliferative disorder and vincristine can increase platelet counts, circulation. Although exercise, epinephrine, and vincristine can increase platelet counts, the most important cause of primary thrombocytosis is myeloproliferative disorder resulting in an abnormal rate of platelet production. Primary thrombocytosis is rare in farm animal species.

Secondary thrombocytosis occurs in animals with severe systemic inflammatory or infectious diseases of more than several days in duration, and usually of several weeks in duration. Young animals appear to be more susceptible, but the condition can occur in animals of any age. Detection of thrombocytosis should prompt a thorough clinical examination for a cause of chronic inflammation in the animal. Common causes in horses include pneumonia, Rhodococcus equi infection, septic arthritis, and colitis. Thrombocytosis with Heinz-body anemia is reported in cattle fed cabbage.

PATHOPHYSIOLOGY
DIC, or consumption coagulopathy, can develop in a number of diseases that, in themselves, are not diseases that primarily affect hemostatic mechanisms. The pathogenesis involves systemic activation of coagulation with intravascular deposition of fibrin leading to thrombosis of small and medium-sized blood vessels, with subsequent organ failure.23 Depletion of platelets as a result of platelet activation and binding to fibrin to form clots, and of coagulation factors, results in excessive bleeding. The systemic formation of fibrin results from increased generation of thrombin and the simultaneous suppression of anticoagulation mechanisms (which are detectable in animals as reduced concentration of antithrombin) and impaired fibrinolysis. Products of fibrinogen activation, including fibrinopeptides A and B, contribute to systemic vasoconstriction and the hyperperfusion of some organs. The disorder, in its most extreme form, involves both excessive coagulation and, seemingly paradoxically, bleeding.

Systemic activation of coagulation is part of the systemic inflammatory response syndrome, which is dominated by interleukins 1 and 6 and tumor necrosis factor-alpha. There might be a contribution of complement activation to the hypercoagulability. Activation of clotting occurs through either damage to endothelium or activation and release of tissue factor. Tissue factor expression is increased by one or more of the proinflammatory cytokines (interleukin-1, interleukin-6, interleukin-8, and tumor necrosis factor), which are almost universally increased in diseases that feature systemic inflammation. Generation of tissue factor results in activation of the extrinsic clotting cascade, with resultant increases in thrombin. The increased activity of the coagulation cascade is temporally associated with increased generation of thrombin and the simultaneous suppression of anticoagulation mechanisms (which are detectable in animals as reduced concentration of antithrombin) and impaired fibrinolysis. Generation of tissue factor results in activation of the extrinsic clotting cascade, with resultant increases in thrombin. The increased activity of the coagulation cascade is temporally associated with decreased removal of these compounds and induces a vicious cycle of disease. DIC can be initiated by a variety of different mechanisms, including the following:

- **Extensive tissue necrosis**, such as occurs in trauma, rapidly growing neoplasms, acute intravascular hemolysis, and infective diseases such as blackleg, can cause excessive release of tissue thromboplastin and initiate exuberant coagulation via the extrinsic coagulation pathway.
- **Exuberant activation of the intrinsic pathway** can occur when there is activation of the Hageman factor by extensive contact with vascular collagen, as occurs in diseases with vasculitis, or those associated with poor tissue perfusion and tissue hypoxia with resultant endothelial damage.
- **Factors that initiate platelet aggregation**, such as endotoxin; that cause reticuloendothelial blockage, such as excessive iron administration to pigs; or that cause hepatic damage to interfere with clearance of activated clotting factors can contribute to the occurrence of DIC.

**CLINICAL SIGNS**
As discussed previously, defects in hemostasis and fibrinolysis range from those that are detectable by clinicopathologic examination but are not associated with clinical signs of excessive bleeding or coagulation, through fulminant hemorrhagic diathesis.

The presence of a hypercoagulable state that is not associated with signs of excessive bleeding or thrombosis nonetheless worsens the prognosis of severe diseases. This is probably a result of DIC-induced injury to organs that is not detectable against the background of damage caused by the primary disease but that has an important or pivotal effect on the animal’s well-being. The next progression of the disease is enhanced thrombosis, most evident as thrombosis of large vessels after minor damage such as that associated with
intravascular catheterization or simple venipuncture. In some cases, vessels can thrombose without obvious inciting cause. An example of a common manifestation of this stage of the disease is jugular vein thrombosis in horses or cattle with severe disease and low plasma concentration of antithrombin.

An unusual, but severe, manifestation of DIC in horses is thrombosis of the distal limbs, resulting in ischemic necrosis of the limbs and death of the animal. This clinical manifestation of DIC occurs in foals and, to a lesser extent, in adults with evidence of septicemia or severe gastrointestinal disease.

The most severe acquired hemostatic defect in animals with systemic disease is DIC. This extreme of the clotting disorder is manifested by local or generalized bleeding tendencies that vary in severity from occurrence of petechial hemorrhages in mucous membranes to life-threatening hemorrhage or infarction of organs. Ischemic damage to a wide variety of organs is possible, with the gastrointestinal tract and kidneys being commonly affected.

**CLINICAL PATHOLOGY**

There are a large number of hemostatic and fibrinolytic factors that can be measured in research laboratories, only a few of which are routinely available in clinical laboratories. The following measures are commonly used to detect hypercoagulable states or DIC in clinical situations:

- **Platelet count**—The abnormality consistent with DIC is thrombocytopenia.
- **Prothrombin time**—This is usually prolonged in animals with DIC but can occasionally be shortened in animals with a hypercoagulable state.
- **Activated partial thromboplastin time**—This measure of hemostasis is usually prolonged in animals with coagulopathies.
- **Serum markers of fibrinogen activation/fibrin degradation (FDPs)** have poor sensitivity and specificity for detection of DIC.
- **Plasma D-dimer concentration** is more sensitive for detection of abnormalities in hemostasis/fibrinolysis, and a normal D-dimer concentration is useful in ruling out a diagnosis of sepsis in foals.
- **Fibrinogen concentration**—Classical descriptions of DIC include hypofibrinogenemia as a common finding. However, this is uncommonly the case in horses and cattle, probably because fibrinogen is an acute-phase protein that increases in inflammatory diseases in these species. Declines in plasma fibrinogen concentration, with values remaining above the lower bound of the reference range, are often noted in horses with coagulopathy and impending death.
- **Antithrombin activity** is often reduced in animals with a hypercoagulable state or DIC.
- A number of studies provide detailed descriptions of the occurrence, and time course, of abnormalities in hemostatic and fibrinolytic function in horses with gastrointestinal disease. The general pattern is that of prolonged clotting times (PT, aPTT) with diminished activity of antithrombin and protein C and increased plasma concentrations of fibrinogen and fibrin degradation products. D-dimer concentration increases in horses with gastrointestinal disease.

Platelet concentration is reduced in horses with colic and evidence of coagulopathy. Abnormalities in hemostatic factors are more common in the peritoneal fluid than in the blood of horses with colic. Tissue plasminogen activator, plasminogen, protein C, antithrombin, and alpha-2-antiplasmin activities and concentrations of fibrinogen and fibrin degradation products are greater in the peritoneal fluid from horses with colic than in the peritoneal fluid of healthy horses. Compared with healthy foals, the PT, aPTT, and whole-blood recalciﬁcation times are signiﬁcantly longer in septic foals. The concentrations of fibrinogen and fibrin degradation products, percentage plasminogen, alpha-2-antiplasmin and plasminogen activator inhibitor activities, and tumor necrosis factor and interleukin-6 activities are greater, and protein C antigen and antithrombin activity are lower, in septic foals.

**Cattle** with displaced abomasum often have abnormalities in one or more of PT, aPTT, thrombin time, platelet count, and plasma concentration of fibrin degradation products. **Pigs** with induced endotoxemia have increases in the activity of tissue factor, plasminogen activator, and plasminogen activator-inhibitor, increases in the concentrations of thrombin–antithrombin complexes and fibrin monomer; and a decline in fibrinogen and factor VII concentrations.

**NECROPSY EXAMINATION**

It is important to differentiate the abnormalities at necropsy caused by DIC from those of the underlying disease. This can be challenging. The presence of DIC is suspected by the presence of hemorrhage in the carcass. Hemorrhage can vary from occasional petechiation to frank hemorrhage into body cavities. Horses dying of DIC usually have widespread lesions, including petechiation of mucosal and serosal surfaces, including the mesentery and pleura. There is often hemorrhage into the parenchymatous organs (kidneys, adrenals), lungs, and myocardium, and infarcts in the adrenals and kidney. Microthrombi are detectable in the intestine and kidney of some horses with DIC.

DIC is diagnosed by the presence of clinical signs of a hemorrhagic diathesis and laboratory confirmation of abnormalities in hemostasis and fibrinolysis. A conventional definition of DIC requires the presence of clinical evidence of coagulopathy and the presence of at least three abnormal measures of coagulation or fibrinolysis. It is likely that this definition will change as our understanding of the spectrum of abnormalities and manifestations of the disorder matures.

Differential diagnoses include all of the acquired or inherited coagulopathies. However, the cardinal differentiating attribute of DIC or the lesser hypercoagulable states is the presence of severe inciting disease.

**TREATMENT**

Most recommended therapies for DIC have been extrapolated from the human literature and may not be applicable to farm animals. However, generally stated, the principles of therapy are as follows:

- **Treatment of the underlying disease and correction of acid–base, inflammatory, electrolyte, and perfusion abnormalities**
- **Restoration of normal activity or concentration of clotting factors in blood**
- **Halting or attenuating the increased coagulopathy**
- **Minimizing effect of microthrombi and thrombi on organ function**

DIC is invariably secondary to an initiating primary disease. Vigorous therapy should consequently be directed toward correction of the primary initiating disease. Aggressive IV fluid administration to maintain tissue perfusion and to correct any acid–base and electrolyte imbalance is also very important. There should be aggressive treatment of endotoxemia and of diseases likely to induce endotoxemia. Treatment of endotoxemia is discussed elsewhere in this text (Chapter 5), and current reviews are available.

The plasma concentration of clotting factors should be restored, or supplemented, in horses with clinical or clinicopathological evidence of a coagulopathy. The practice of blood component therapy is well accepted in human medicine but because of technological limitations is not generally available in farm animals. However, stored plasma, preferably fresh or fresh frozen, can be administered to increase the concentration of clotting factors that are depleted during hypercoagulable states or DIC. Antithrombin is often readily measured, and horses with low plasma antithrombin activity should be administered plasma. The dose of plasma necessary to increase blood antithrombin activity to appropriate levels has not been determined. However, many clinicians use a plasma antithrombin activity 60% of that of healthy horses as a minimal acceptable activity. This choice has not been verified empirically.
10 mL/kg IV. Platelet-rich plasma, or whole blood, can be used to treat thrombocytopenia.

Heparin and low-molecular-weight heparin are used to treat horses with hypercoagulable states, and their use is discussed earlier in the chapter. The aim is to prevent formation of thrombi and microthrombi. Heparin requires antithrombin as a cofactor, and it might not exert its full therapeutic activity in horses with abnormally low blood antithrombin concentrations.

Aspirin is used to inhibit platelet activity in horses with prothrombotic states. Its efficacy in reducing morbidity or case-fatality rate has not been determined.

DISEASES CHARACTERIZED BY ABNORMALITIES OF THE CELLULAR ELEMENTS OF THE BLOOD

Anemia

SYNOPSIS

Etiology
Deficiency of circulating erythrocytes associated with hemorrhage and increased destruction or the inefficient production of erythrocytes. There are a large number of specific etiologies.

Epidemiology
Specific to the underlying cause of the anemia.

Clinical findings
Palor of mucousae, tachycardia, lethargy, exercise intolerance, arrhythmia, ileus, decreased ruminations, and colic. Petechial and ecchymotic hemorrhages, icterus, hemoglobinuria, and bleeding tendencies can be seen if the underlying cause is excessive hemorrhage.

Clinical pathology
Examination of erythron, bone marrow, and serum total protein for nature and severity of anemia; clinical chemistry for associated organ damage. Specific tests for etiology.

Necropsy findings
Palor of tissues. Findings specific to specific etiology.

Diagnostic confirmation
Decreased erythrocyte count, hemoglobin concentration, or packed cell volume.

Treatment
Treatment of specific etiology. Transfusion of whole blood, packed red cells, or stromal-free hemoglobin if the anemia is severe. Corticosteroids for immune-mediated anemia and supportive treatment.

Etiology
Anemia can be classified as hemorrhagic anemia, hemolytic anemia, or anemia resulting from decreased production of erythrocytes. Another classification system is based on evidence of regeneration of anemia, with anemia classified as either regenerative or nonregenerative. Both classifications are useful in determining the cause, treatment, and prognosis. Diseases causing anemia in horses are listed in Table 11-1, and those causing hemolytic anemia in cattle are listed in Table 11-2.

Hemorrhagic Anemia
Acute hemorrhage and hemorrhagic shock are discussed in Chapter 5. The diseases discussed here are those that cause normovolemic anemia. Although anemia occurs after restitution of plasma volume in animals with severe hemorrhage, most diseases that cause normovolemic anemia do so because of the chronic loss of blood either from the body or into a body cavity. The most common route of loss is through the gastrointestinal tract. Diseases include the following:

- Parasitism—intestinal nematodiases: Teladorsagia circumcincta or Haemonchus contortus in lambs and sheep; Ostertagia ostertagi in cattle; Strongylus spp. and cyathostomes in horses; trematodiases, including Fasciola hepatica, in sheep and cattle; hematophagous lice and ticks, including Linognathus vituli in calves
- Gastrointestinal disease, including the following:
  - Abomasal ulceration in cattle (both spontaneous and associated with abomasal lymphoma)
  - Gastric ulceration in horses (anemia is an unusual manifestation of this disease)
  - Gastric squamous-cell carcinoma in horses in which anemia is a common finding
  - Esophageogastric ulceration in pigs
  - Proliferative enteropathy in pigs (usually a peracute disease)
  - Bleeding from lesions in the small intestine (neoplasia, fungal infection, mural hematoma)
- Respiratory tract disease, including the following:
  - Guttural pouch mycosis in horses
  - Ethmoid hematoma in horses
  - Caudal vena cava thrombosis and pulmonary embolism in cattle
- Genitourinary tract disease, including the following:
  - Enzootic hematuria in cattle (bladder cancer) and bladder transitional cell and squamous-cell neoplasia (horse)
  - Pyelonephritis
  - Vaginal varicose vein hemorrhage in mares
  - Ruptured corpus cavernosum and ureteral lesion causing hematuria in geldings and stallions
  - Middle uterine artery rupture of mares (usually a peracute disease)
  - Idiopathic renal hematoma in horses
- Hemorrhage into body cavities, including the following:

THROMBOSIS (HYPERCOAGULABILITY)

Abnormal formation of thrombi is often a consequence of diminished concentrations or activity of anticoagulant factors, such as antithrombin, protein C, and antiplasmin; increased concentrations of plasminogen activator–inhibitor; or abnormalities of vessel walls. Thrombotic disease is usually a consequence of a primary disease that depletes anticoagulant factors and involves mechanisms discussed earlier under disseminated intravascular coagulopathy (DIC). Thrombosis of the jugular vein is discussed elsewhere (Chapter 11). 1 Other diseases involving thrombosis are thromboembolic colic and aortoiliac thrombosis in horses, although each is likely associated with inciting damage to the arterial endothelium. 2 Pulmonary embolism in horses is associated with sepsis or severe inflammatory disease, and thrombosis of the portal vein can result from local metastasis of gastric adenocarcinoma. 3-5 Aortic thrombosis occurs in calves with existing severe inflammatory or septic disease. 6 Thrombosis of the caudal or cranial vena cava occurs in cattle and is fully described in Chapter 13. 7-9 Thrombosis of the caudal vena cava can occur in horses. 9

Idiopathic brachial artery thrombosis, which can be bilateral, occurs in adult horses without obvious preexisting clinical illness. 10,11

An apparently primary defect in protein C activity in a Thoroughbred colt with a hypercoagulable state has been described. The colt had repeated episodes of venous thrombosis and developed renal failure. Plasma concentrations of protein C were within the reference range for healthy horses, but the activity of protein C in plasma was 32% of that of healthy horses, suggesting a defect in the protein activity or concentration.

The common causes of hematuria in cattle are pyelonephritis and cystitis caused by Corynebacterium renale, nonspecific cystitis, and enzootic hematuria. Myoglobinuria occurs occasionally in young cattle affected with enzootic-nutritional muscular dystrophy and may be confused with hemoglobinuria.
Hemolytic Anemia

Cattle and Sheep
- Babesiosis, anaplasmosis, *Mycoplasma ovis* comb. nov. (formerly *Eperythrozoon ovis*) eperythrozoonosis, trypanosomiasis, nagana, theileriosis, *Mycoplasma wenyonii* alone or in various combinations
- Bacillary hemoglobinuria
- Leptospirosis (*L. interrogans* serovar *pomona*)
- Bovine virus diarrhea and mucosal disease
- Postparturient hemoglobinuria
- Associated with grazing *Brassica* spp., rape, kale, *chou moellier*, turnips, cabbage
- Associated with the excessive feeding of culled onions or cannery offal, especially tomatoes and onions
- Poisoning by *Mercurialis*, *Ditaxis*, *Pimelia*, and *Allium* spp.
- Poisoning by miscellaneous agents, including phenothiazine and guaifenesin
- Poisoning—chronic copper poisoning. In sheep, secondary to pyrrolizidine alkaloids, as in toxemic jaundice, or primary from the feeding of diets too high in copper. Cattle are much less susceptible than sheep, although preruminant calves are very susceptible.
- Treatment with long-acting oxytetracycline
- Water intoxication and drinking cold water in calves, and in goat kids fed water from a nipple bottle
- Inadvertent IV administration of hypotonic fluids
- Part of a transfusion reaction
- Rare cases of alloimmune hemolytic anemia (isoerythroylysis) in calves from vaccination of the dam with blood-derived vaccines, such as anaplasma vaccine, or as part of the bovine neonatal pancytopenia associated with vaccination of the dam with a specific BVD vaccine
- Autoimmune hemolytic anemia is recorded in calves but is rare. All reported cases have occurred in calves under 6 months of age.
- Immune-mediated anemia can occur in lambs that are fed cow colostrum as a source of immunoglobulin. This is not a common sequel to the feeding of cows’ colostrum and occurs only with the colostrum from certain cows. Anemia is evident at 7 to 20 days of age, but jaundice and hemoglobinuria are not usually present. The syndrome must be differentiated from immune-mediated thrombocytopenia, which occurs at a younger age in some lambs fed bovine colostrum.
- Rarely, in adults after vaccination
- Congenital anemia associated with dyserythropoiesis and accompanied by dyskeratosis and progressive alopecia is recorded in Polled Hereford calves. The anemia is present at birth, and the disease is probably inherited.
- A congenital anemia with jaundice is recorded in Murray Grey calves, and it is postulated that a defect in the red cell membrane leads to intravascular hemolysis.
- Immune-mediated anemia in cattle secondary to other systemic disease

Pigs
- Eperythrozoonosis is recorded, but hemolytic anemia is rare.
- Isoerythroylysis, thrombocytopenia, and coagulation defects are discussed in the previous section.
- Generalized cytomegalovirus infection

Horses
- Equine infectious anemia, although the pathogenesis of the anemia is probably multifactorial, including hemolysis and decreased red cell production
- Babesiosis
  - Hemotrophic mycoplasma infection in horses has been associated with a reduced red cell count. The syndrome and its importance are currently poorly characterized
- Phenothiazine poisoning—this anthelmintic is now used rarely in horses.
- Red maple leaf (*Acer rubrum*) toxicosis
- Ingestion of pistache (*Pistacia* spp.) leaves
- Ingestion of *Pimelia trichostachya* (St. George disease)
- Ingestion of dried garlic (>0.2 g/kg BW) results in development of Heinz bodies and hemolytic anemia.
- IV administration of hypotonic or hypertonic fluids (water, 20% dimethylsulfoxide)
- As a sequel to severe cutaneous burns—the severity of the hemolysis correlates with the amount of skin area burned. Hemolysis is a result of oxidative damage of red cell membranes that occurs within minutes of the burn. Prevention and treatment include immediate administration of polyionic fluids to prevent hemoconcentration and to prevent hemolytic uremia.
- As a sequel to clostridial abscission—the anemia occurs more than 10 days after development of the abscess and is associated with the presence of IgG or immunoglobulin M (IgM) on the surface of red cells
- Autoimmune hemolytic anemia (isoerythroylysis) of foals
  - Autoimmune anemia associated with *Rhodococcus equi* infection in foals (a rare complication)
  - Autoimmune hemolytic anemia—not common, but several series have been recorded.
- Immune-mediated hemolytic anemia and thrombocytopenia (Evan’s syndrome)
- Penicillin-induced hemolytic anemia—this is a rare event but can occur when horses develop IgG antipenicillin antibodies. These antibodies bind to penicillin on erythrocytes, with resultant red cell destruction. Penicillin-coated erythrocytes agglutinate with patient serum. It is probable that other immune-mediated hemolytic anemias in the horse are also associated with the development of antibody to therapeutic agents.
- Some snake envenomations cause intravascular hemolysis in dogs and cats, and hemolytic anemia can occur in snakebite in horses and calves.
- Lead intoxication in horses causes mild anemia, but signs of peripheral neuropathy are the more obvious manifestation.
- Abnormalities in red cell function can lead to increased removal of red cells from blood (extravascular hemolysis) and are discussed under “Abnormalities of Red Cell Function.”

Anemia Resulting From Decreased Production of Erythrocytes or Hemoglobin (Nonregenerative Anemia)
The diseases resulting from decreased production of erythrocytes or hemoglobin tend to affect all species, and thus they are presented here according to cause rather than according to animal species.

Nutritional Deficiency. Nutritional deficiencies impair production of hemoglobin or red cells. Specific deficiencies that result in anemia include the following:
- Starvation (chronic undernutrition) causes mild to moderate anemia.
- Cobalt and copper—these elements are necessary for all animals, but clinically occurring anemia is observed in only ruminants. Copper deficiency induced by zinc toxicity causes anemia in pigs.
- Iron—but as a clinical occurrence this is limited to rapidly growing animals, including baby pigs, young calves designated for the white veal market, housed lambs, and foals. This predilection of young animals for iron deficiency is attributable to their rapid
growth and hence requirement for relatively large intakes of iron (which, in addition to production of hemoglobin, is used in production of myoglobin and other iron-containing compounds), the low concentration of iron in milk, and management practices that deny access of the animals to pasture or soil from which they can obtain iron.

- Anemia in piglets can be caused by iron deficiency. The disease occurs in both housed piglets and those kept on dirt, although the disease is believed to be less common in those kept at pasture or on dirt, in part because of the availability of iron ingested in dirt.

- Iron deficiency should be considered as a possible cause of failure to perform well in housed calves. Male calves up to 8 weeks of age and on a generally suitable diet can show less-than-optimum performance in erythron levels, and the calves with subclinical anemia have deficits in growth rate and resistance to diarrhea and pneumonia. Calves fed 20 mg Fe/kg milk replacer develop hypoferremia and mild anemia, whereas those fed 50 mg Fe/kg do not.

- Iron-deficiency anemia occurs in housed lambs and is prevented by oral or parenteral supplementation with iron. Anemia and poor weight gain were not prevented in all lambs by a single administration of 330 mg of iron once orally at 1 to 5 days of age, although there was a marked increase in serum iron concentration. Treated lambs had higher hematocrit and greater weight gain than did untreated lambs.

- Microcytic anemia and hypoferremia occur in Standardbred foals kept at pasture for 12 hours per day. These changes are not prevented by oral administration of four oral doses of 248 mg of iron, suggesting that higher levels of supplementation are needed. Conversely, hypoferremia and anemia were reported in stable foals but not in a pastured cohort. The stable foals had clinical signs of anemia (lethargy) and low hematocrit, hemoglobin concentration, and serum iron concentration, which were restored to normal values by iron supplementation (0.5 g iron sulfate orally once daily, 3 g of iron sulfate top dressed on cut pasture fed to the foals and their dams, and unlimited access to a lick block containing iron). Whereas colostrum of mares is rich in iron, milk has much lower concentrations, probably explaining the low serum iron of some nursed foals and demonstrating the need for access to iron supplements or, preferably, soil or pasture. Supplementation of foals with iron should be undertaken cautiously because of the documented hepatotoxicity of large doses of iron given orally to newborn foals. Toxic hepatopathy develops in newborn foals administered iron fumarate at 16 mg/kg BW within 24 hours of birth, similar to the situation in piglets. Iron supplementation of foals should be done cautiously.

- A great deal of attention is paid to providing adequate iron to racehorses, often by periodic injection of iron compounds regularly during the racing season or provision of hematinc supplements. Given that strongylosis is all but unknown in racehorses in the current era of intensive parasite control programs and stabiling of horses, anemia is exceedingly rare in healthy racehorses. Supplementation with iron of horses on a balanced, complete ration is therefore unlikely to be necessary. Moreover, administration of excessive iron could be dangerous, although iron intoxication has not been documented in racehorses as it has in foals. Oral administration of 50 mg Fe/kg body weight to ponies for 8 weeks increased serum iron concentration, did not affect hematocrit, and did not induce signs of disease.

- Potassium deficiency is implicated in causing anemia in calves.

- Pyridoxine deficiency, produced experimentally, can contribute to the development of anemia in calves.

- Folic acid deficiency is rare in horses, has not been reported as a spontaneous disease in pigs, and is unlikely to occur in ruminants because of the constant production of folic acid by rumen bacteria. Plasma folic acid concentrations vary in pregnant mares kept at pasture and in their foals, but there is no evidence of folate deficiency in either mares or foals. Administration of antifolate drugs (trimethoprim, sulfonamides, pyrimethamine, methotrexate) could, theoretically, cause folate deficiency in horses. Folate deficiency causing anemia and leukopenia is reported in a horse treated for equine protozoal myelitis with antifolate drugs concurrent with oral supplementation with folic acid. IV administration of folic acid (0.055 to 0.11 mg/kg BW) resulted in rapid resolution of leukopenia and anemia. Paradoxically, oral administration of folic acid in monogastric animals receiving antifolate drugs impairs absorption of folic acid in the small intestine and causes folate deficiency. Administration of folic acid, sulfonamides, and pyrimethamine orally to pregnant mares results in congenital signs of folate deficiency in foals, including anemia and leukopenia.

**Chronic Disease.** Chronic inflammatory disease causes mild to moderate anemia in all species of large animals. The anemia can be difficult to differentiate from that of mild iron-deficiency anemia. The genesis of anemia of chronic inflammation is multifactorial and includes sequestration of iron stores such that iron availability for hematopoiesis is reduced despite adequate body stores of iron, reduced erythrocyte life span, and impaired bone-marrow response to anemia.14 The result is normocytic, normochronic anemia in animals with normal to increased serum ferritin concentrations. The clinicopathologic features of both iron-deficiency anemia and anemia of chronic disease are detailed in Table 11-3. Causes of anemia of chronic disease include the following:

- Chronic suppressive processes can cause severe anemia by depression of erythropoiesis.

- Radiation injury can cause anemia by reducing erythropoiesis.

- Poisoning by bracken, trichloroethylene-extracted soybean meal, arsenic, furazolidone, and phenylbutazone can cause depression of bone-marrow activity.

- Anemia can occur as a sequela to inclusion-body rhinitis infection in pigs.

- Porcine dermatitis and nephropathy syndrome can result in anemia.

- Intestinal parasitism (e.g., ostertagiasis, trichostrongylus) in calves and sheep can have this effect.

**Red Cell Aplasia.**

- Red cell hypoplasia is a fatal syndrome of anemia, immunodeiciency, and peripheral gangliopathy that develops at 4 to 8 weeks of age in some Fell pony and Dale pony foals.20-22

- Anemia in some horses follows the administration of recombinant human erythropoietin. The anemia is a result of pure red cell aplasia and is manifest as normocytic, normochronic anemia. The disease is attributable to injection of horses with recombinant human erythropoietin with subsequent development of substances in blood, presumably antibodies to rEPO, that cross-react with and neutralize endogenous erythropoietin in affected horses. Not all horses administered rEPO develop anemia, but the disease is reported as an outbreak in a stable of Thoroughbred racehorses that were given the compound. Severely affected

Table 11-3 Characteristic or expected changes in hematological and serum biochemical variables in anemic animals—cont’d

- Myelophthisic anemia as a result of myelofibrosis is reported in a pony and as a familial disease in pygmy goats.

**Pathogenesis**

**Anemic Hypoxia**
The most important abnormality in anemia is the hypoxemia and subsequent tissue hypoxia that result from the reduced hemoglobin concentration and oxygen-carrying capacity of blood. The anemia becomes critical when insufficient oxygen is delivered to tissue to maintain normal function.

**Oxygen delivery** is described mathematically by the Fick equation:

\[ \text{Oxygen delivery} = \text{Cardiac output} \times \text{Arteriovenous oxygen content difference} \]

Oxygen delivery is therefore the rate at which oxygen is delivered to the tissue—it is a combination of the rate at which oxygen arrives at the tissue in arterial blood and the proportion of that oxygen extracted from the capillary blood.

Cardiac output is determined by heart rate and stroke volume, whereas the arteriovenous difference in blood oxygen content is determined by the hemoglobin concentration, the hemoglobin saturation with oxygen in both arterial and venous blood, and the extraction ratio. The extraction ratio is the proportion of oxygen that is removed from the blood during its passage through tissues. In animals with a normal hematocrit and cardiac output, oxygen delivery to tissues exceeds the oxygen requirements of the tissue by a large margin, with the result that the oxygen extraction ratio is small (<40%). However, as the oxygen-carrying capacity per unit of blood declines (usually expressed as milliliters of oxygen per 100 mL of blood), then either blood flow to the tissue or the extraction ratio must increase to maintain oxygen delivery. In reality, both of these compensatory mechanisms occur during the acute and chronic responses to anemia. Heart rate increases to increase cardiac output and therefore the delivery of oxygen to tissues, and blood flow is preferentially directed to those tissue beds that are most essential for life or are most sensitive to deprivation of oxygen (heart, brain, gut, kidney). The extraction ratio increases and is evident as a decrease in venous blood hemoglobin saturation. Hemoglobin in arterial blood is usually thoroughly saturated with oxygen, and the limitation to oxygen delivery to tissues is the low hemoglobin concentration and consequent low arterial oxygen content. Assessment of arterial blood oxygen tension and content is discussed in Chapter 13.

Reductions in hemoglobin concentration are compensated for by increases in cardiac output and the extraction ratio so that oxygen delivery to tissues is maintained in mild to moderate anemia. As the severity of anemia increases, these compensatory mechanisms are inadequate, and oxygen delivery to tissues declines. At some point the delivery of oxygen fails to meet the oxygen needs of the tissue, and organ function is impaired. It is important to realize that this is not an all-or-none phenomenon and that there is not a particular point at which decompensation occurs. In fact, with progressive anemia there are progressive increases in cardiac output and the oxygen...
**Autoimmune Hemolytic Anemia**

Autoimmune hemolytic anemia is believed to result from an aberrant production of antibodies targeted against surface antigens of the erythrocyte as a result of an alteration in the erythrocyte membrane from systemic bacterial, viral, or neoplastic disease. An alternate hypothesis is the development of immunocompetent clones that direct antibody to the red cell membrane. Red cells are lost by intravascular hemolysis or removal by macrophages of the reticuloendothelial system, and anemia occurs when the capacity of the bone marrow to compensate for increased red cell destruction is exceeded. Autoimmune hemolytic anemia is considered to be idiothetic if it cannot be associated with an underlying disease and is considered to be secondary if associated with another condition. Often this is neoplastic disease. The antibodies are of the IgG or IgM class, may be agglutinating or nonagglutinating, and can also be temperature dependent. The antiglobulin test has been used to confirm the diagnosis in cases of nonagglutinating autoimmune hemolytic anemia, but demonstration of immunoglobulin on the surface of red cells by immunofluorescent cell staining and flow cytometry is much more sensitive and specific.

**Hemolysis**

Hemolysis results from rupture of red cell membranes as a consequence of injury to the membrane or osmotic lysis when serum tonicity is lower than normal. Hemolytic disease of any cause has the potential to overwhelm the normal clearance mechanisms for hemoglobin, with the result that hemoglobin concentrations in plasma are abnormally high. This can result in hemoglobinuric nephropathy (see Chapter 14).

**Methemoglobinemia and Oxidative Damage**

Methemoglobinemia results from oxidative damage of hemoglobin and occurs in disease such as red maple leaf toxicity in horses and nitrate poisoning in ruminants. Methemoglobin is reversible but important as an indicator of oxidative damage and because methemoglobin cannot transport oxygen. Oxidative damage to red cells results in denaturation of hemoglobin, with subsequent formation of Heinz bodies. Red cells damaged in this way are sensitive to osmotic lysis and fragmentation. Intravascular hemolysis and removal of damaged red cells by the reticuloendothelial system contributes to anemia.

**Clinical Findings**

The clinical signs and their severity depend on the degree of anemia (Table 11-4). Mild anemia in animals that are not required to be physically active, such as veal calves or housed lambs, might be apparent only as failure to achieve optimal weight gain. More severe degrees of anemia, or mild anemia in animals required to be physically active, such as foals at pasture or racehorses, can be evident as exercise intolerance, failure to perform athletically, or lethargy. Behavioral signs of anemia include prolonged recumbency; depressed mentation; reduced nursing, foraging, or grazing; and, in extreme anemia, belligerence.

Responses to anemia vary with the severity of the anemia and its duration. Adaptive responses to anemia, which include induction of expression of hypoxia-inducible factor and subsequent pleiotropic effects that modulate and attenuate the effects of anemia, and hypoxia, mean that animals with long-standing and slowly evolving anemia accommodate a low hematocrit with fewer clinical signs than do animals with acute anemia of the same extent that can have much more severe clinical signs.

Physical findings include pallor of the mucosae and conjunctiva, but appreciable degrees of anemia can occur without clinically visible change in mucosal, conjunctival, or skin color. The mucous membranes, conjunctiva, and skin in pale-skinned, sparsely haired animals, such as pigs, can be almost white in animals with severe anemia (Fig. 11-2). Hemolytic anemia causes jaundice in most cases.

A chart for examination of conjunctival color in sheep and goats has been validated as a means of assessing severity of anemia in

**Table 11-4 Acute hemorrhage: estimated blood loss**
these species. The chart (FAMACHA) was developed to aid in parasite control programs. Training programs are important in ensuring the accuracy and reproducibility of use of the chart. Conjunctival color is assessed on a scale of 1 to 5, in which 1 = red and 5 = white. The correlation between FAMACHA score and hematocrit is very good (R = -0.52 in sheep and -0.30 in goats). The sensitivity and specificity for detection of a hematocrit below 15% for FAMACHA scores of 4 and 5 were 83% and 89%, respectively, for sheep and 83% and 71%, respectively, for goats. This methodology appears to be very useful for detection of anemia in small ruminants and in increasing the adoption of appropriate anthelmintic programs by farmers trained in the technique.

The heart rate is increased, the pulse has a large amplitude, and the absolute intensity of the heart sounds is markedly increased in anemic animals. Terminally, the moderate tachycardia of the compensatory phase is replaced by a severe tachycardia, a decrease in the intensity of the heart sounds, and a weak pulse. A hemic murmur might be heard and is likely a result of the low viscosity of blood in anemic animals combined with increased ejection velocity of blood from the heart as a consequence of increased heart rate and cardiac output. Severe anemia can cause clinically important arrhythmia, including ventricular tachycardia and ventricular premature beats.

Dyspnea is not pronounced in anemia, with the most severe degree of respiratory distress appearing as an increase in depth of respiration without much increase in rate. Labored breathing occurs only in the terminal stages, and at those times the animals can be severely distressed.

Other signs of decompensated anemia include anxious expression, absent rumination, ileus, colic, anuria, and cardiac arrhythmia. Animals can appear quiet and comfortable unless they are forced to move or an event occurs that increases oxygen consumption and causes decompensation. An example is an animal that has compensated for its severe anemia but then develops a fever. Fever can increase whole-body oxygen requirements by 12% for each 1°C (1.8°F) increase in temperature, and this can cause a finely balanced animal to decompensate.

There can be signs of the inciting disease, and these can include edema, jaundice, petchial and ecchymotic hemorrhages in the mucosa, and hemoglobinuria. Adjunctive examination can include gastrointestinal, urinary, or upper respiratory endoscopy; radiography of the chest or abdomen; and ultrasonographic examination of affected regions.

**Clinical Pathology**

The clinicopathological characteristics of the common forms of anemia are provided in Table 11-3.

**Hematology**

Anemia is definitively diagnosed by measurement of red cell indices and demonstration of low hematocrit, red cell count, and hemoglobin concentration. Examination of various red cell indices can yield important information about the cause of anemia and evidence of regeneration. In addition to providing the diagnosis, serial monitoring of the hemogram is useful in detecting evidence of a regenerative response. At a minimum, repeated measurement of hematocrit will reveal a gradual increase when there is a regenerative response. Hematocrit of horses with induced anemia increases by approximately 1% (0.01 L/L) every 3 days.

The relationship between hematocrit (packed cell volume [PCV]) and hemoglobin concentration in cattle is: Hb (g/dL) = (0.3 PCV) + 3, where PCV is reported as a percentage (e.g., 42%).

Red cell morphologic abnormalities include variations in size, shape, and content:

- **Red cell size**
  - Anisocytosis is the presence of red cells of abnormal size. Abnormal cells can be either macrocytes or microcytes. (See bullet on red cell distribution width later in list.)
  - Macrocytosis (high mean corpuscular volume [MCV]) usually indicates a regenerative response. Ruminants have a prominent macrocytic response to anemia. The increase in MCV in horses can be so slight as to be undetectable, especially in mild to moderate regenerative anemia.
  - Microcytosis (low MCV) is found in classic deficiency anemias, such as iron-deficiency anemia.

- **Red cell distribution width** is a measure of the variation in red cell size in the population of red cells in blood. It is calculated by dividing the standard deviation of red cell volumes by the mean red cell volume and multiplying the product by 100. An increase in red cell distribution width indicates the presence of anisocytosis as a result of macrocytosis in regenerative anemia.

- **Red cell shape**
  - Spherocytosis is found in diseases that affect the red cell membrane, such as immune-mediated anemia and red maple toxicosis.
  - Schistocytes (small, irregularly shaped cells or red cell fragments) are found in diseases that cause intravascular physical injury to red blood cells, such as DIC or vasculitis with endothelial damage.
  - Echinocytes are normal-sized red cells that have uniform membrane projections. They are of uncertain importance.
  - Eccentrocytes are cells in which hemoglobin has been damaged and accumulated eccentrically in the cell, causing variation in the color density of the cell. It is usually associated with diseases causing oxidative damage.

- **Red cell content**
  - Polychromasia, the presence of erythrocytes of varying staining intensity, is usually a result of the presence of reticulocytes.
  - Hypochromia can be evident as reduced staining intensity and is a result of a reduction in red cell hemoglobin concentration.

The amount of hemoglobin in red cells can vary. Mean corpuscular hemoglobin (MCH) content increases in the presence of reticulocytes. False increases in MCH occur when there is free hemoglobin in plasma, either from in vivo or ex vivo hemolysis. Mean corpuscular hemoglobin concentration (MCHC) is reduced in the presence of reticulocytosis, and hemolysis falsely increases MCHC.

- **Nucleated red cells** appear in the peripheral blood only in ruminants among farm animals and only in response to severe anemia.
- **Howell–Jolley bodies** are nuclear remnants that are common in the regenerative response in ruminants, but less so in horses.
- **Heinz bodies** are round protrusions from the cell membrane or intracellular inclusions. The bodies are denatured hemoglobin and are found in diseases in which there is oxidative damage to red cells. Affected cells are fragile and susceptible to intravascular lysis or increased rate of removal by cells of the reticuloendothelial system.
- **Parasites** such as Babesia spp., Theileria spp., and Mycoplasma spp.
(formerly *Eperythrozoon* spp.) can be detected in parasitemic animals.

- Reticulocytosis—reticulocytes are immature red cells released from the bone marrow. Reticulocytes contain remnants of nucleic acid, and this can be detected by use of appropriate stains. Until recently, reticulocytosis in response to anemia was documented in ruminants and pigs, but not in horses. This was because equine reticulocytes do not stain with Romanowsky and other stains used for routine examination of smears of peripheral blood. However, use of oxazin, a stain that combines with nucleic acid, and fluorescent detection of labeled cells have revealed the presence of reticulocytes in the peripheral blood of horses. Horses develop reticulocytosis in response to anemia, as do other species.

- Reticulocyte volume and reticulocyte hemoglobin content increase in regenerative anemia in horses, but this increase has not been evaluated in other large animals.

**Agglutination** of red cells is apparent as irregularly shaped agglomerations of red cells. The clumps of red cells do not dissociate when blood is diluted 1:4 with 0.9% saline, as happens with rouleaux. Rouleaux are normal findings in the blood of horses and are apparent as rows of erythrocytes.

**Coombs testing** or use of direct immu

**nouffluorescent flow cytometry** can provide evidence of immune-mediated hemolytic anemia.

Other hematologic changes in severe anemia include leukocytosis and thrombocytosis.

**Bone Marrow**

Examination of bone marrow is useful for demonstrating a regenerative response, especially in horses in which a regenerative response can be difficult to detect in peripheral blood, and for determining the cause of nonregenerative anemia.

**Collection of Bone Marrow.** Samples of bone marrow can be obtained by aspiration, with samples submitted for cytologic examination, or biopsy, with core samples submitted for histologic examination. Bone-marrow aspirates are useful in that they provide samples in which the relative proportions of myeloid and erythroid cell lines can be determined. However, samples obtained by aspiration do not allow examination of the overall cellularity of the marrow or its architecture.

Samples of bone marrow can be obtained from the sternebrae, proximal aspects of the ribs, or tuber coxae. The preferred site in adult animals, and in calves, is the cranial sternum. The procedure is performed on standing adult animals or laterally recumbent calves. Animals should be adequately restrained, which could include administration of sedatives and analgesics. A site on the ventral midline over the second or third sternebra is clipped and aseptically prepared. Local anesthesia is induced by injection of lidocaine or similar local anesthetic (5 to 10 mL). The local anesthetic is injected subcutaneously and to the surface of the sternebra. A small skin incision is made, and the aspiration needle or biopsy instrument is introduced. Bone-marrow aspirates can be collected using a 13- to 15-gauge, 5- to 7-cm needle and stylet. Bone marrow core biopsies are performed using an 8-, 11- or 13-gauge 100- to 150-mm bone-marrow biopsy needle (TrapSystem).

Bone-marrow aspirates are collected from adult horses by advancing the needle approximately 2 to 3 cm into the sternebra. The stylet is then removed, a 5- to 10-mL syringe is attached, and bone marrow is aspirated. The samples should be placed on a clean glass slide and air-dried, or put in a Petri dish containing 0.5 to 1.0 mL of 2% EDTA.

Core samples of bone marrow are obtained by inserting the biopsy needle 2 cm into the cortex of the sternebra. The stylet is then removed and the needle is advanced with a rotating motion. This can require considerable effort in adult animals. The needle is advanced approximately 2 to 3 cm and then rapidly withdrawn. A sample of bone marrow will be evident as pink to red bone. The sample should be rolled on a clean, dry glass slide (for cytologic examination) and then placed in 10% neutral buffered formalin for histologic examination.

**Interpretation of Bone Marrow.** Bone marrow is examined for overall architecture, cellularity, the ratio of myeloid to erythroid cells (M:E ratio), and the presence of inflammation, necrosis, or abnormal cells. A subjective assessment of iron stores can be made by staining sections of marrow with Prussian blue stain.

A regenerative response is evident as a low M:E ratio as a result of erythrocyte hyperplasia and the presence of erythroid series cells in all stages of maturity. There are increased counts of reticulocytes in bone marrow, and the number of nucleated cells relative to the hematocrit increases. The MCV and reticulocyte hemoglobin content are high in regenerative bone marrow. These responses are evident as soon as 3 days after acute anemia and peak at approximately 9 days.

Abnormal white cells, such as seen in myelophthisic disease caused by myeloma or lymphosarcoma, cause displacement of erythroid series cells and a high M:E ratio. Similarly, a high M:E ratio is obtained when there is primary red cell aplasia. A normal M:E ratio is obtained when there is aplasia of both myeloid and erythroid series of cells, highlighting the need to evaluate the overall cellularity of the marrow. Normal marrow is approximately 50% fat and 50% combined myeloid and erythroid series cells.

**Blood-Gas Analysis, Oximetry and Lactate**

**Arterial Blood-Gas Analysis.** Arterial blood oxygen tension (mm Hg, kPa) in animals with anemia is almost always within the reference range for healthy animals unless there is coexisting lung disease. Anemia does not interfere with diffusion of oxygen from the alveolus into capillary blood. However, the arterial oxygen content (mL O₂ per 100 mL blood) is reduced because of the reduced arterial blood hemoglobin concentration (see Chapter 10). Arterial carbon dioxide tension is often reduced in severe anemia as a result of alveolar hyperventilation that is a response to arterial hypoxemia. Arterial pH and base excess decline as the severity of anemia increases and compensatory mechanisms are no longer able to ensure delivery of sufficient oxygen to tissue, indicative of metabolic acidosis resulting from tissue anaerobiosis.

**Venous Blood-Gas Analysis.** The ideal sample is mixed venous blood collected from the pulmonary artery or right atrium. However, these sites are only infrequently available for collection, so samples should be collected from a major vein (jugular vein, cranial vena cava). Samples collected from small leg veins are less than ideal. Measurement of venous blood-gas tensions, pH, base excess, hemoglobin saturation, and oxygen content are useful in evaluating the physiologic effect of anemia. As discussed under pathophysiology, reductions in oxygen content of arterial blood cause an increase in the oxygen extraction ratio in an attempt to maintain oxygen delivery to tissues. The increased extraction ratio is evident as a reduction in venous oxygen tension, hemoglobin saturation, and oxygen content. When oxygen delivery to tissues is less than that needed to maintain aerobic metabolism, venous pH, bicarbonate concentration, and base excess decline.

**Methemoglobinemia.** Measurement of methemoglobin concentration is useful in documenting the severity of diseases such as red maple leaf toxicosis and nitrate poisoning. Methemoglobinemia is reversible but is a sign of oxidative damage to red cells. Oxidative damage to red cells causes Heinz-body formation and eventual lysis of the cell. Methemoglobin is measured using a cooximeter and is combined with measurement of oxygen saturation. Methemoglobin concentration in the blood of healthy animals is usually less than 3%.

**Lactate.** Concentrations of lactate can be measured in blood (whole-blood lactate) or
plasma and are almost always increased above the normal range in animals that urgently require a transfusion. Whole-blood lactate concentrations are lower than lactate concentrations in plasma because red blood cells have lower lactate concentration than does plasma. Lactate concentrations can be measured using point-of-care analyzers, some of which have been validated for use in animals. Lactate concentration in blood or plasma increases when compensatory mechanisms are no longer effective and aerobic metabolism is impaired.

**Serum Biochemistry**

Serum biochemical abnormalities are those of the inciting disease or reflect damage to organs as a result of the anemia. Severe anemia can damage many organs, resulting in increases in serum concentration or activity of urea nitrogen, creatinine, sorbitol dehydrogenase, gamma-glutamyl transpeptidase, bile acids, bilirubin, aspartate aminotransferase, creatine kinase, and troponin, among others. Hemolytic anemia causes increases in plasma hemoglobin concentration (evident grossly as pink-tinged plasma or serum) and hyperbilirubinemia (unconjugated).

**Iron metabolism** in anemic animals is defined by measurement of serum iron concentration, serum transferrin concentration (total iron-binding capacity), transferrin saturation, and serum ferritin concentration. Serum ferritin concentration correlates closely with whole-body iron stores. Values of these variables in anemia of differing cause are provided in Table 11-3.

**Other Evaluations**

**Feces** should be examined for the presence of parasites (ova, larvae, or adult parasites), frank blood (hematochezia or melena), and occult blood. Detection of occult blood can be difficult, and samples should be collected on multiple occasions. Samples should not be collected soon after rectal examination because false-positive results can be found as a result of trauma to the rectal mucosa.

**Urine** should be evaluated for the presence of pigmentation, red cells, and casts. Pigmenturia should be differentiated into hemoglobinuria or myoglobinuria. Microscopic examination will reveal red cells, or ghost red cells, in animals with hematuria. Casts and isostenuria can be present in the urine of animals with hemoglobinuric nephrosis.

**Serum erythropoietin concentration** should be evaluated in animals with nonregenerative anemia. It is not a readily available assay. Concentrations of erythropoietin in adult horses are usually less than 37 mU/mL, but values are probably dependent on the assay used.

Tests for **specific diseases** should be performed as appropriate:

- Measurement of bleeding time, PT, aPPT, and platelet count in animals with evidence of excessive unexplained hemorrhage
- Examination for blood parasites
- Serologic testing for infectious causes of anemia
- Toxicologic testing

**Necropsy Findings**

Findings indicative of anemia include pallor of tissues; thin, watery blood; and contraction of the spleen. Icterus may be evident where there has been severe hemolytic anemia and petechial and ecchymotic hemmorhages with thrombocytopenia. Necropsy findings specific to individual diseases are given under those disease headings.

**Treatment**

The principles of treatment of anemia are ensuring adequate oxygen transport to tissues, prevention of the deleterious effects of anemia or hemolysis, and treatment of the inciting disease.

**Correction of Anemia**

The discussion here deals with normovolemic anemia. Acute anemia with hypovolemia (hemorrhagic shock) is discussed in Chapter 5.

**Transfusion.** The oxygen-carrying capacity of blood should be restored in the short term to at least the level at which oxygen use by tissues is not flow dependent, and to normal levels in the longer term. Short-term restoration of the oxygen-carrying capacity of blood is achieved by transfusion of whole blood or packed red cells or administration of a commercial stromal-free hemoglobin solution. Whole blood is recommended when there is anemia with hypovolemia (reduced blood volume) and is not ideal but acceptable when the facilities or time to prepare packed red blood cells is not available. Whole blood is often transfused to animals with acute hemorrhagic anemia. Packed blood cells are preferred for administration to animals with normovolemic anemia, such as occurs with chronic anemia or hemolytic anemia, and when the donor plasma contains alloantibodies to the recipient’s red blood cells. Commercial stromal-free hemoglobin has the same indications for administration as packed red blood cells, but its use in farm animals is limited because of the high cost and availability of the product.

The decision to transfuse an anemic animal should not be undertaken lightly for a number of reasons. Transfusion of blood or packed red cells is not without risk to the recipient, there is usually considerable cost in identifying a suitable donor and collecting blood, and it can be a time-consuming process. An important concern in performing a blood transfusion is the risk to the recipient. Acute reactions include anaphylaxis, acute host-versus-graft reaction (hemolysis of transfused red cells), and graft-versus-host disease (hemolysis of recipient red cells). Development of alloantibodies in the recipient with consequent problems with repeat transfusion or development of neonatal alloimmune hemolytic anemia in progeny of female recipients is a concern. The incidence of adverse events in 31 horses provided 44 transfusions of whole blood or packed red blood cells was 16% (7 of 44), and the type of adverse event varied from urticarial to anaphylactic shock.

For transfusion of whole blood, it is important to consider the relative benefits and risks of **cross-matching** donor and recipient before completing the transfusion. Unlike humans, in which blood typing is critical before transfusion of blood because of the universal existence of alloantibodies against red blood cell antigens, transfusion of whole blood cells between farm animals of the same species is unlikely to incite an acute adverse reaction for the first transfusion into a naïve animal. Furthermore, there are few, if any, laboratories that offer blood typing for ruminants, and only a limited number that offer the service for horses. The risk is increased with a second transfusion to a recipient, and such high-risk transfusions might warrant more careful consideration and attempts to determine suitability of the donor. When performed by a laboratory experienced in the procedure, cross-matching is highly reliable as assessed by high repeatability on multiple testing of the same freshly collected samples. Donor blood for cross-matching should be freshly collected because storage of donor samples for as little as 7 days results in an increased proportion of incompatible results compared with testing of fresh samples.

Cross-matching is complicated by the large number of blood groups in many species: 11 blood groups with more than 70 blood group factors in cattle; 8 blood groups and more than 22 factors in sheep; more than 6 blood groups in goats; at least 6 in camels; and 7 blood groups with 32 factors in horses. The importance of some, or all, of these blood-group factors in inciting transfusion reactions is unknown. Donkeys should not be transfused with horse blood unless the horse donor is confirmed not to have antibodies against donkey red blood cells. Depending on the urgency of the blood transfusion and the risk of adverse reactions, it is not imprudent to attempt an initial transfusion to a naïve recipient without prior cross-matching, although clearly cross-matching is preferred if it is available in a timely fashion.

Cross-matching should be both major (donor red cells and recipient plasma) and minor (donor plasma and recipient red cells) and should test for both hemagglutination and hemolysis. Ideally, blood typing and examination of plasma for alloantibodies of both donor and recipient would
be performed before transfusion. Adverse events include destruction of donor red cells by alloantibodies in the recipient or destruction of recipient red blood cells by alloantigens in the donor’s plasma. Risk of the latter is lowered by administration of packed, washed red blood cells.

The donor should be healthy and free from infectious diseases that could be transmitted to the recipient via the transfusion. Ideally, equine donors should be confirmed to be free of equine infectious anemia, and all donors should be free of blood-borne parasites (such as, but not limited to, Babesia spp., Theileria spp., and hematrophic mycoplasma species). Donors should not have been vaccinated with products that might cause production of alloantibodies, such as some BVD vaccines and vaccines for anaemia in cattle. Donors should have a normal hematocrit, leucogram, and plasma protein concentration.

Transfusion Triggers

**Indications** for transfusion ("transfusion triggers") are not straightforward. Because of the risk to the recipient and cost, blood transfusion should be performed only when indicated. Conversely, the severe adverse effects of anemia mean that animals should not be denied a transfusion if it is needed. There is no one variable for which a single outcome, or red cell count alone. Rather, the decision to provide a transfusion should not be based on hematocrit, hemoglobin concentration, or red cell count alone. Rather, the decision to provide a transfusion should be based on a holistic evaluation of the animal, including the history, physical abnormalities, and clinicopathological data. This information should be considered in total before a decision is made to provide a transfusion. Considerations regarding transfusion include the following:

- **History**—animals with acutely developing anemia are more likely to require transfusion at a given hematocrit than are animals with slowly developing anemia. Similarly, young animals with higher intrinsic metabolic rates might require transfusion at hematocrit values that would be tolerated by adults.
- **Physical findings**—these are some of the most important indicators of the need for transfusion and include the following:
  - Changes in demeanor and activity, including lethargy, belligerence, anxiousness, depressed mentation, anorexia, intolerance of minimal exercise (nursing, walking), prolonged or excessive recumbency
  - Tachycardia—there is no one value that is critical, but a heart rate that is 30% to 50% above the upper limit of normal is probably important.
  - Progressive increases in heart rate are indicative of the need for transfusion
  - Sweating, cold extremities, and other signs of sympathetic activation
  - Absent ruminination, ileus, gastrointestinal distension, colic
  - Arrhythmias, including ventricular premature beats
  - Anuria
- **Clinical pathology**
  - Decline in hematocrit with exacerbation of abnormalities on physical examination—transfusion should be considered in any animal with a hematocrit below 20% (0.20 L/L). Most animals do not need a transfusion at this level, but the proportion requiring a transfusion increases at lower hematocrits. Some horses with chronic anemia and a hematocrit of 10% (0.10 L/L) do not need a transfusion, whereas others with acute anemia of 15% (0.15 L/L) need a transfusion urgently.
  - Venous blood hypoxemia and declines in hemoglobin saturation—there is no one value that is critical because there are progressive and gradual declines in these variables as the oxygen content of arterial blood declines. Venous blood oxygen tension of less than 25 mm Hg is clinically significant, and values below 20 mm Hg probably represent the need for transfusion.
  - Venous pH and base excess. Development of acidosis (low base excess) and acidemia (low pH) are indications of tissue anaerobiosis and the need for transfusion. Unlike venous blood oxygen tension and saturation, these values are normal until decomposition occurs.
  - Lactate concentrations (arterial or venous)—blood lactate concentrations rise rapidly when decomposition occurs. Blood lactate concentrations above 2 and below 4 mmol/L should be cause for concern and prompt closer monitoring, whereas values above 4 mmol/L probably indicate a need for prompt transfusion.
  - Evidence of organ damage, including increases in serum creatinine or bile acid concentration as indicators of kidney or hepatocellular damage, and troponin as an indicator of myocardial injury

**Collection of Blood for Transfusion**

The amount of blood to be transfused depends on the clinical status of the recipient, but rules of thumb are available. For acute hemorrhagic anemia, the volume of blood lost should be estimated (this might not be accurate), and a combination of isotonc, polyionic fluids or isotonic saline and whole blood or packed red cells should be administered. The intent is to fully restore blood volume and ensure that the hematocrit is sufficient to meet the needs of the animal—it does not need to be restored immediately to prehemorrhage levels. For normovolemic anemia, and for hypovolemic anemia after restoration of circulating blood volume, the volume of transfusion can be calculated as shown in the accompanying box.

**Transfusion volume (mL) = Body weight of recipient (kg) × 80 mL/kg × \[(desired recipient PCV – actual recipient PCV)/donor PCV\] where 80 mL/kg is the normal circulating blood volume (i.e., the dilution space of the transfused red cells).

**Example:**

- 500-kg horse with PCV = 15%. Desired PCV = 25%; donor PCV = 38%. Transfusion volume required = 500 × 80 × \[(25 – 15)/38\] = 10,526 mL = 10.5 L
- The recipient requires ~10 L of donor blood as a transfusion.

For transfusion of packed red blood cells, assume that the donor PCV is 100%.

The median volume of whole blood transfused to horses with hemorrhagic or hemolytic anemia in one study was 15 mL/kg BW with a range of 5 to 26 mL/kg. The median volume of packed red cells transfused was 8 mL/kg. Transfusion to correct anemia in normovolemic animals should be done cautiously to minimize the risk of excessive expansion of the intravascular volume. Ideally, packed red cells can be administered to reduce the extent of blood-volume expansion. However, preparation of packed red cells can be a difficult and time-consuming process. An alternative with horses is simply to allow the collected blood to sit undisturbed for 1 to 2 hours, during which time the cells will settle to the bottom. The red cells can then be siphoned off and administered to the recipient.

Healthy, adult donors can provide up to 20% of their blood volume at one time. For example, up to 8 L of blood can be collected from a healthy 500-kg cow. Donors should be administered isotonic, polyionic fluids or isotonic saline IV in a volume equivalent to that of the blood collected after collection is complete. Blood should be collected over a 30- to 60-minute period.

Blood for immediate (<2 to 3 hours) transfusion can be collected into containers with sodium citrate (3.2% solution, 100 mL per 1 L of blood). Blood that will be stored for longer must be collected into acid citrate dextrose (ACD), citrate-phosphate-dextrose with adenine (CPDA), or similar solutions at a rate of 100 mL of solution per 1 L of blood, or according to the manufacturer's recommendation. Care must be taken to ensure that collection is aseptic and prevents microbial contamination of the collected blood.
This is especially important for blood that is to be stored.

The response to transfusion is almost immediate, with normalization of heart and respiratory rates, reduction of plasma or blood lactate concentration, reduction in serum creatinine concentration, increase in venous oxygen saturation, and improvement in demeanor.12 PCV of donors receiving whole blood increased from 12% to 17% after transfusion of ~15 mL/kg, and from 9% to 15% for horses receiving packed red cells.12 Increases in PCV are most marked in horses with normovolemic anemia (hemolytic or aplastic) treated with packed red cells and not administered concurrent isotonic fluids. Increases in PCV in horses with hemorrhagic anemia are lower, likely because of the expansion of blood volume caused by administration of whole blood and concurrent isotonic fluids,12,15 and for this reason assessment of efficacy of transfusion to horses with hemorrhagic anemia should be based on clinical variables and not on measurement of PCV.12 Fifty-four percent of the horses treated for hemorrhagic, hemolytic, or aplastic anemia were discharged from the hospital.

The survival of allogeneic red blood cells in horses is 95% at 24 hours (although this may be much lower in some horses), and the half-life of transfused red cells is approximately 20 days.16 Survival is reportedly longer for autologous transfusions, but this type of transfusion, with collection of the recipient's own blood days or weeks before the transfusion, is limited to elective or non-emergency situations.16 An exception is where autologous blood collected during surgery or as a result of hemorrhage into the pleural or peritoneal cavities is administered to the recipient.16,19

Adverse reactions to transfusion can be immune mediated (graft-versus-host disease, in which components of the donor's plasma cause hemagglutination or lysis of recipient's red cells; host-versus-graft disease, in which components of the host's plasma react with donor red cells; and anaphylactic or urticarial reactions), related to volume overload, or, with horses with hemolytic anemia and repeat transfusion, could be attributable to iron overload, as is documented in foals with alloimmune hemolytic anemia. The presumed immune-mediated reactions can occur when cross-matching is performed before transfusion and the transfusion is considered compatible, but are probably more common when cross-matching and demonstration of compatibility have not been performed.12 Adverse reactions range from mild urticaria, which does not require specific treatment, to acute anaphylaxis and death.12,13 See the earlier discussion for a description of cross-matching.

An alternative to transfusion of whole blood or packed red cells is the administration of a commercial preparation of stromal-free hemoglobin. This product is effective in increasing the oxygen-carrying capacity of blood in anemic horses and has been used for support of a foal with alloimmune hemolytic anemia until a blood transfusion was available. The compound is stable at room temperature and can therefore be stored for long periods of time and be readily available for use. However, it is expensive, and its effect is short-lived (<48 hours, and probably less). The recommended dose is 15 mL/kg BW IV, but lower doses have been used. The compound increases the oncotic pressure of plasma and causes expansion of the plasma volume.

Hematinics. Hematinic preparations are used in less severe cases and in animals with anemia resulting from iron deficiency or severe external blood loss (see Table of Drug Doses in the Appendix). Iron is administered to prevent iron deficiency in young animals denied access to pasture or soil. The use of recombinant human erythropoietin in horses has a risk of inducing anemia. Given that there are no known causes of low erythropoietin concentrations causing anemia in horses, with the exception of those horses with anemia subsequent to rEPO administration, the use of this compound in horses is specifically contraindicated. Cobalt salts are administered to horses to increase erythropoiesis.26 This approach has limited, if any, therapeutic value and is generally considered addition to glucocorticoids.

Supportive Care
The oxygen requirements of anemic animals should be minimized. This can be achieved by housing them individually in quiet stalls, the temperature of which is maintained in the animal’s thermoneutral zone, minimizing the need for exercise (such as grazing or following the mare to nurse), and maintaining a normal body temperature. Provision of supplemental oxygen is prudent, recognizing that oxygen delivery by red blood cells is already maximal and that additional oxygen delivery will be achieved by increasing the oxygen content in plasma.

Animals with hemolytic anemia and hemoglobinuria should be administered polyionic isotonic fluids intravenously to reduce the risk of hemoglobinuric nephrosis.

Treatment of Autoimmune Hemolytic Anemia
Some animals with autoimmune hemolytic anemia respond well to administration of corticosteroids. Compounds used include prednisolone and dexamethasone. Horses with refractory aplastic anemia or hemolytic anemia have been administered cyclophosphamide (2 mg/kg IV every 14 to 21 days) in addition to glucocorticoids.

References

All isoimmune hemolytic anemia of the newborn (neonatal isoerythrolysis, isoimmune hemolytic anemia of the newborn)
violet vaccine or cows with babesia or anaplasmosis vaccines can be associated with disease in their newborns. Overall survival rate in foals treated at a referral hospital was 75%.

Clinical findings Lethargy, recumbency, tachycardia, tachypnea, icterus, and hemoglobinuria.

Clinical pathology Anemia, hyperbilirubinemia.

Diagnostic confirmation Positive antiglobulin (Coombs test) or hemolysis test using mare's serum or colostrum and foal's red blood cells.

Treatment Transfusion of blood or packed red blood cells from suitable donor, or of mare's washed red blood cells. Supportive care.

Control Identify at-risk mares by blood typing. Examine mare's serum or colostrum for presence of incompatible antibodies before allowing foal to suckle.

Etiology Hemolytic anemia of newborn horse and mule foals, calves, and piglets occurs because of immune-mediated (antibody-dependent cellular cytotoxicity or type II hypersensitivity) destruction of the neonate's red blood cells by antibodies acquired from the dam. The specific antibodies are present in the colostrum, are absorbed by the neonate, and cause lysis and/or agglutination of red blood cells.

The disease is associated with the natural occurrence of inherited blood groups and only occurs if the dam is exposed to red blood cell antigens that she does not possess. In response to such exposure, the dam produces antibodies directed against the foreign red blood cell epitopes. If the neonate possesses a blood type against which the dam has developed antibodies and depending on the red blood cell factor involved, red blood cell destruction can occur. The newborn acquires the red blood cell types that are foreign to the dam through inheritance from the sire. Disease occurs after birth because the fetus is not exposed to the antibodies in utero because of the epitheliochorial placentation in mares and sows and the syndesmochorial placentation of cattle. Antibodies in serum are secreted into the colostrum in the peripartum period and are subsequently ingested and absorbed by the newborn. Mares that have anti–red blood cell factor antibodies in their serum almost invariably have the same antibody in their colostrum. The serum concentration of anti-Aa and Qa antibodies is highest in the last 3 months of gestation and peaks about 1 week after parturition. For neonatal isoerythrolysis to occur, the following characteristics are necessary:

- The dam must be exposed to the foreign-blood-group antigens that the fetus possesses.
- The dam must produce antibodies against the blood-group antigens of the fetus. Not all blood-group antigens are highly immunogenic or are associated with disease in the neonate.
- The newborn must ingest and absorb colostrum that contains antibodies directed against antigens on the newborn's red blood cells.

The disease occurs naturally in foals and piglets but is usually iatrogenic in calves. Exposure of the dam to foreign red cell epitopes may occur at parturition or during gestation as a result of placental lesions, although most incompatible pregnancies do not result in sensitization of the mare.

Mares might also be exposed by transfusion of incompatible blood. Although whole-blood transfusions to mares or fillies are unusual, plasma transfusions are increasingly being used to treat failure or partial failure of transfer of passive immunity to foals. Because plasma usually contains some red blood cells, transfusion of plasma from donors possessing blood-group antigens that the foal does not could immunize the filly against these factors, with the potential for disease when the foal matures and gives birth. However, most commercial plasma products are harvested from donors that do not have the blood-group antigens identified as being problematic.

Thirty-two blood-group antigens are recognized in horses:
- A, a, b, c, d, e, f, g
- C, a
- K, a
- U, a
- D, a, b, c, d, e, f, g, h, i, k, l, m, n, o, p
- P, a, b, c, d
- Q, a, b, c

Neonatal isoerythrolysis in foals is attributable in over 90% of cases to antibodies directed against either Aa or Qa antigens, although disease resulting from antibodies against Ab, Dc, Da, Db, Ka, Qb, Qc, Qrs, Pa, and Ua is reported. The presence in the mare of antibodies against Ca decreases the probability that she will develop anti-Aa antibodies.

Fifteen blood groups have been identified in pigs, and the disease is recorded as occurring spontaneously in association with antibodies to the E-group antigens. Historically, the main occurrence of neonatal isoerythrolysis in pigs was mannemade and related to repeated vaccination against hog cholera using the pooled blood, inactivated by addition of crystal violet, of affected pigs.

The disease has also occurred in calves whose dams had been vaccinated against babesiosis or anaplasmosis using a vaccine containing bovine blood. As a result of vaccination, the dam develops lytic antibodies against sire antigens, usually of the A and F blood groups, and antibodies in colostrum cause acute hemolytic anemia in the calves. A variant of this disease is that causing neonatal pancytopenia in calves of dams vaccinated against BVD using a vaccine prepared in a particular cell culture line.  

Epidemiology Horses and Mules

From 1% to 2% of Thoroughbred and Standardbred mares have antibodies capable of causing neonatal isoerythrolysis. The incidence is partially related to the proportion of the mare population at risk. An at-risk mare is one that lacks either the Aa or Qa blood group factor. The proportion of mares that lack one or both of these factors is breed dependent, with 19% of Thoroughbreds lacking either Aa or Qa antigens and 17% of Standardbred mares lacking Aa antigens. All Standardbred horses lack the Qa factor; neonatal isoerythrolysis in this breed is usually a result of antibodies against the Aa factor, with 10% of Standardbred mares having anti-Aa antibodies. Only 2% of Thoroughbred mares lack the Aa antigen, but this low proportion is important because approximately 50% of these mares will develop anti-Aa antibodies. Conversely, 16% of Thoroughbred mares lack the Qa antigen, but only 3% of these mares have the anti-Qa antibody. The risk of mares developing antibodies against certain red blood cell types is also related to the prevalence of the antigen in the horse population. For instance, Standardbred mares lack the Qa antigen, but because this antigen is not found in the breed, any Standardbred stallion the mare is mated to will not be Qa positive, neither will the foal, and there is no risk of the mare being exposed to the antigen.

The incidence of neonatal isoerythrolysis in mule foals (donkey sire × horse dam) can be 10% and is attributable to the universal presence of a unique blood-group antigen, “donkey factor,” in jacks and mule foals. Mares do not possess this factor, and therefore all donkey sire × horse dam pregnancies are incompatible. Progeny of horse sire × donkey dam matings are not affected.

A feature of naturally occurring neonatal erythrolysis in foals and piglets is that it rarely, if ever, occurs in offspring of primiparous dams because the induced anti–red blood cell (RBC) antibody titer is not sufficiently high to induce the disease. Subsequent exposure during later pregnancies elicits an amnestic response that results in higher anti-RBC antibodies and disease in the newborn. However, first-pregnancy offspring are often affected after vaccination of the dam with blood products.

Pathogenesis

The interaction between the antibody and the red cells of the newborn is followed by hemolysis with resultant anemia,
hemoglobinuria, and jaundice. Following ingestion and absorption into the systemic circulation, antibodies bind to RBC membranes. Parts of the cell membrane of the antibody-coated cells are removed from the circulation, probably by the spleen and associated reticuloendothelial tissues, and affected cells are eventually lysed and release hemoglobin into the circulation. The affected animal develops normovolemic anemia, and if the destruction of RBCs is sufficient, the animal develops anemic hypoxia and dies. The reaction between RBCs and antibodies occurs sufficiently quickly that the bone marrow is unable to compensate immediately for the loss of RBCs. DIC occurs and can contribute to the death.

Permeability of the intestine of the newborn foal to antibody disappears by 36 hours and in most cases much less. Hourly milking of the mare rapidly reduces the antibody content of the colostrum. The duration of the alimentary permeability in piglets has not been determined.

Clinical Findings

Horses and Mules

Pregnancy and parturition are uneventful, and the foal is normal for some hours after birth. Signs appear only if the foal ingests and absorbs colostrum containing anti-RBC factor antibody. The severity of disease ranges from clinically inapparent to fulminating, with death ensuing soon after birth.

- **Peracute cases** develop within 8 to 36 hours of birth, and the first indication of the disease may be collapse. Severe hemoglobinuria and pallor are evident, but icterus is not apparent initially. The mortality rate is high.

- **In acute cases** signs do not develop until 2 to 4 days after birth, and jaundice is marked, with only moderate pallor and hemoglobinuria.

- **Subacute cases** may not show signs until 4 to 5 days after birth. Jaundice is marked, but there is no hemoglobinuria and only mild pallor of mucosae. Many subacute cases recover without treatment.

The severity of the disease is related to the type and quantity of antibody ingested. Antibodies against Aa usually produce severe disease apparent within 24 hours of birth, whereas ingestion of anti-Qa antibodies causes a milder disease apparent at 3 to 4 days after birth.

General signs include lassitude, weakness, and disinclination to suck. The foal lies down in sternal recumbency for long periods and yawns frequently. There is no febrile response, but the heart rate is increased up to 120/min. Respiration is normal until severe anemia develops, when tachypnea (respiratory rate up to 80/min) and yawning are observed. Terminally, dyspnea and convulsions may develop.

**Bilirubin encephalopathy, or kernicterus,** is a complication of neonatal isoerythrolysis and accounts for death in approximately 10% of cases. It is apparent as altered mentation and seizures in foals with high serum bilirubin concentration.

The risk of a foal developing kernicterus is 17 times greater (95% CI, 1.8 to 165) if the serum total bilirubin is higher than 27.0 mg/dL. Survival of foals displaying signs of kernicterus is very poor.

Liver failure results in death of approximately 10% of foals. The risk of liver failure increases as the volume of blood products administered to the foal increases, indicating that liver failure could be related to iron overload secondary to hemolysis and transfusion. Foals administered 4 L or more of blood products have an ~20 times greater risk of developing liver failure than do foals administered a lower volume.

**Isolvmune thrombocytopenia** of foals and mules is evident as ecchymotic hemorrhages and a tendency to bleed from relatively minor wounds. A syndrome in foals characterized by ulcerative dermatitis, neutropenia, and thrombocytopenia appears to be related to ingestion of collostral antibodies. Affected foals have oral and lingual ulcers and crusting and erythema around the eyes, muzzle, perineum, trunk, and neck. There are ecchymotic and petechial hemorrhages in mucus membranes. Treatment with corticosteroids and antibiotics is associated with a good prognosis.

**Pigs**

Piglets show essentially the same syndrome, being normal at birth but developing jaundice at 24 hours and weakness at 48 hours, with most affected pigs dying by day 5. Peracute cases occur, and piglets may die within 12 hours of birth, showing acute anemia but no jaundice or hemoglobinuria. An proportion of subclinical cases also occurs in which hemolysis can be detected only by hematological examination. **Isolvmune thrombocytopenic purpura** of piglets can manifest as increased bleeding following routine management procedures such as tail docking.

**Cattle**

In calves, clinical signs develop within 24 to 48 hours after birth, and the calves die during the first week of life. Surviving calves are returned to normal health in 2 to 3 weeks. Peracute cases die within 24 hours, and at necropsy examination are characterized by pulmonary edema and splenomegaly.

**Clinical Pathology**

Hematological examination reveals acute anemia; erythrocyte counts, packed cell volumes, and hemoglobin concentrations are low, and there is greatly increased erythrocyte fragility and sedimentation rate. Depending on the severity of the disease and its duration, there can be leukocytosis, attributable to neutrophilia and monocytosis, and the presence of nucleated RBCs (in piglets and calves but rarely in foals). Affected mule foals, but not horse foals, are often thrombocytopenic. Isolelmune thrombocytopenia occurs rarely in foals and is not associated with neonatal isoerythrolysis, as it is in mule foals. In piglets, the erythrocyte count may be as low as 1 million/µL and the hemoglobin level below 2 g/dL, and thrombocytopenia is present. Serum biochemical analysis reveals an increased serum concentration of unconjugated bilirubin.

**Diagnostic confirmation** is achieved by demonstration of the presence of antibodies in the mare's serum or colostrum that cause hemagglutination or lysis of foal RBCs. Tests to demonstrate hemagglutination or lysis of foal RBCs exposed to mare serum or colostrum have been developed. Of these, the standard hemolysis test appears to have the greatest utility. However, for practical purposes a positive direct antiglobulin test (direct Coombs' test), confirming the presence of antibodies on the surface of RBCs in a foal with anemia, provides a diagnosis of neonatal isoerythrolysis. False-negative (foal has the disease but the Coombs' test is negative) results occur occasionally because of the hemolytic nature of the antibodies. The same principle is applicable to all species. Detection of antibodies on the surface of the neonate's RBCs is possible using direct immunofluorescence flow cytometry. The test identifies the presence of antibodies on red cells in some instances when the Coombs' test is negative.

The use of blood typing and other prepartum predictive tests in the prevention of the disease are discussed under control.

**Necropsy Findings**

In peracute affected foals, there is marked pallor but only slight jaundice. The liver may be mildly swollen and friable, but the spleen is greatly enlarged and is almost black as a result of the accumulation of lysed and lysing erythrocytes. In less severe cases jaundice is marked, but pallor is only moderate in degree. The kidneys are usually pale, and the urine is dark brown. The histopathological changes may include ischemic tubular necrosis and periacinic hepatic necrosis and degeneration. Erythropagocytosis is prominent, and depending on the clinical course and therapeutic regime, there may be widespread hemosiderin deposition.

Hemoglobinuria is an important sign in piglets, and jaundice or port wine coloration of tissues occur constantly. The presence of blood-stained peritoneal fluid and an enlarged spleen is also typical of the disease in piglets. Necropsy includes the following:

- Samples for postmortem confirmation of diagnosis
- Formalin-fixed liver, spleen, bone marrow, kidney, and lymph node for light microscopic examination
Treatment

The aims of treatment are as follows:

- Prevent the deleterious effects of anemia.
- Prevent or treat hemoglobinuric nephrosis, kernicterus, or liver failure.
- Prevent ingestion of further colostrum.
- Prevent secondary infection in severely ill animals.
- Restore normal fluid, electrolyte, and acid–base status.
- Provide adequate nutrition.
- Minimize stress and systemic oxygen requirements.

The treatment of choice for neonatal isoerythrolysis depends on the severity of the disease. The choice of treatment should be based first and foremost on the severity of the clinical signs and secondarily on the hematocrit and RBC count. Foals or piglets with mild clinical signs (minimal lethargy, mild tachycardia, slight exercise intolerance) need only protection from environmental and nutritional stresses to prompt recovery. However, such animals should be carefully monitored to ensure that their clinical condition does not worsen.

Severely affected animals need a transfusion of compatible blood to alleviate the anemia and intravenous administration of polyionic, isotonic fluids to ensure adequate urine flow and minimize the risk of hemoglobin nephrosis. In general, the younger the animal at the time the disease is evident, the more severe the disease and the more likely the need for intensive treatment. See Chapter 5 for a discussion of transfusion triggers.

Foals

Transfusion. Transfusion of an adequate quantity of whole blood or packed RBCs results in dramatic resolution of clinical signs and anemia. The decision to transfuse blood should be based on the foal's clinical condition, and not solely on the presence of a low hematocrit or RBC count (see “Blood Transfusion” in Chapter 11). In general, foals that are tachycardic, tachypneic, unable or reluctant to suck; have severe exercise intolerance; or are unable to stand should receive blood. These foals will usually have a hematocrit less than 15% (0.15 L/L). Recumbent foals usually have a hematocrit less than 10% (0.10 L/L). Foals that are mildly tachycardic and tachypneic but are able to suckle vigorously and keep up with the mare generally have hematocrits above 15% (0.15 L/L) and do not require transfusion of RBCs. The hematocrit should be monitored, and foals in which the hematocrit is declining rapidly will likely require transfusion of blood or packed red cells.

The volume of blood transfused depends on the clinical condition of the foal and the progression of the anemia. Foals often require transfusion of 1 to 4 L (20 to 100 mL/kg BW) of whole blood or 500 mL (approximately 10 mL/kg BW) of packed RBCs, and might require more than one transfusion. Blood should be administered slowly, 1 L/hour, and the foal’s condition should be monitored closely during the infusion. Packed red cells are preferred for transfusion because of the small volume administered. Transfusion of large quantities of blood should be performed slowly because of the risk of fluid overload of the circulatory system. The half-life for mare erythrocytes transfused into foals is about 5 days.

The optimal donor is a horse that does not have Aa and Qa blood-group factors or anti-Aa and Qa alloantibodies. The former should not be present because the maternal antibodies against Aa or Qa in the recipient foal’s plasma will destroy the transfused cells. Similarly, donor antibodies against Aa or Qa will cause further lysis of foal RBCs. Such donors must be identified in advance because of the time required for the blood type testing, and they are only likely to be available on large breeding farms or in specialized veterinary hospitals.

An ideal source of RBCs is the dam because the maternal alloantibodies in the foal’s plasma will not react with the mare’s RBCs. However, whole-blood transfusions from the dam are contraindicated because of the presence of alloantibodies in the dam’s plasma. This problem can be avoided by transfusing only the mare’s washed RBCs. Blood is collected from the mare (up to 25 mL/kg) into acid citrate dextrose or sodium citrate (10 mL of a 3.8% solution per 90 mL of blood). The mare’s red cells are then washed by removing the plasma, resuspending the cells in isotonic (0.9%) saline, thoroughly mixing, and subsequently removing the saline. Plasma and red cells can be separated by large-volume centrifugation or sedimentation. Adequate separation of red cells and plasma occurs by sedimentation within 1 to 2 hours if the blood is undisturbed.

If an ideal blood-typed donor is not available and the mare’s red cells cannot be washed in time, or are unavailable, then a donor should be chosen based on routine cross-matching. The sire will not be a suitable donor because the antigens against which the mare’s antibodies are directed were inherited from him. A cross-match should match the foal’s (or dam’s) serum against the donor’s RBCs and the donor’s plasma against the foal’s RBCs. The chance of finding a suitable donor is enhanced by selecting ponies or breeds other than Thoroughbreds, Standardbreds, and Arabians because of the higher prevalence of Aa- and Qa-negative animals in these breeds.

Emergency support of severely affected foals can be achieved by administration of a solution containing polymerized bovine hemoglobin. The survival rate in seven foals administered polymerized hemoglobin to treat hemolytic anemia was low (1/7 survived), although this might reflect the severity of their illness prompting administration of this product. This compound increases the hemoglobin concentration of blood, thereby increasing oxygen-carrying capacity. It is not a replacement for transfusion of blood or packed red cells, but it is a useful bridging procedure while a donor is identified and blood is collected. The recommended dose rate is 10 to 30 mL/kg administered slowly (10 mL/kg per hour IV). However, the cost of the compound might necessitate the use of lower doses (3 to 5 mL/kg).

Nutritional Support. The foal should not be permitted to nurse the mare until it is more than 36 hours old. Therefore nutritional support should provide approximately 100 kcal/kg per day in the form of mare’s milk (10 L per day per 50-kg foal), goat’s milk, or commercial mare’s milk substitutes. If the foal is more than 36 hours old, then it is highly unlikely that either the mare’s milk will still contain a significant quantity of antibodies or that the foal will be able to absorb them, and the foal should be allowed to continue to suckle the mare. In younger foals, an alternative feed should be supplied until the foal is at least 36 hours old. The mare should be milked out every 3 to 4 hours during this time to remove the colostrum.

The fluid, electrolyte, and acid–base status of moderately to severely ill foals should be assessed and corrected with intravenous administration of balanced polyionic fluids and sodium bicarbonate. Fluid administration should be used to ensure an adequate flow of urine to prevent hemoglobinuric nephrosis.

Liver Failure and Kernicterus. The liver failure affecting foals after administration of large volumes (>4 L) of blood products is suspected to be attributable to iron overload.

Differential Diagnosis

There are no diseases of the newborn that present the same clinical picture as that of alloimmune hemolytic anemia.

Differential diagnosis list for unexpected death and/or lethargy of neonates:

- Foals and calves
- Septicemia
- Neonatal maladjustment syndrome
- Uroperitoneum
- Prematurity
- Birth trauma
- Hypoglycemia
- Equine herpesvirus-1 infection
- Piglets
- Septicemia
- Birth trauma
- Hypoglycemia
Administration of deferoxamine (1 g, SC Q12 h) to healthy foals administered 3 L of packed red cells increased urinary excretion of iron and reduced iron concentrations in liver. Whether this approach would reduce the risk of liver failure in foals with hemolytic anemia administered large quantities of blood products containing RBCs is unknown.

Kernicterus in foals with alloimmune hemolytic anemia is associated with a poor prognosis. Treatment of two foals with severe hyperbilirubinemia (>365 μmol/L, reference range for healthy foals 0 to 80 μmol/L), but no signs of kernicterus, by plasma exchange transfusion reduced serum bilirubin concentrations by ~50%. Both foals survived.

Antibiotics. Broad-spectrum antibiotics should be administered to severely ill foals to prevent secondary infection (see “Principles of Providing Care to the Critically Ill Neonate”).

Nursing care should be provided to minimize stress and prevent the development of complications such as pressure sores in recumbent foals.

Piglets
In pigs the prevention of sucking for periods of up to 24 hours does not prevent the disease. The safest procedure is to remove piglets from the sow, feed them artificially for 48 hours, and then return them to the sow. Frozen bovine colostrum collected as soon as possible after calving is a satisfactory substitute for sow colostrum but is improved by the addition of pig serum. When transfusion is necessary the intrapartum route is practical and safe.

Control
The principles of control are as follows:

- Identification of incompatible matings by blood-group typing
- Identification of at-risk foals by testing of mare serum or colostrum for the presence of alloantibodies directed against blood factors possessed by the foal

Blood-group typing permits the identification of mares that are at risk of developing antibodies against Aa or Qa antigens. If an Aa- or Qa-negative mare is mated to a stallion that has Aa or Qa factors, then there is the potential for neonatal isoerythrolysis. If the stallion is Aa- and Qa-negative, then there is no risk of the disease caused by antibodies to these blood groups.

Measurement of alloantibodies in the serum or colostrum of at-risk mares is useful in identifying mares at increased risk of having affected foals. Serum from at-risk mares is collected during the last month (preferably 3 to 5 weeks before expected parturition) of pregnancy and examined for the presence of antibodies against the blood of the sire or, if a sample of the sire’s blood is not available, a range of blood-group factors including Aa and Qa. Mares that have such alloantibodies causing hemolysis at a titer greater than 1:16 are not permitted to suckle at-risk newborn foals. If the titer is between 1:2 and 1:16, it is measured again 1 to 2 weeks before anticipated parturition to determine whether the titer is rising, in which case the mare is likely carrying a foal with an incompatible blood group. Equine blood typing and detection of isoantibodies is performed by specialized laboratories in a number of countries, which can be identified by web searches.

The jaundiced foal agglutination test (JFA) is useful in determining the compatibility of mare’s colostrum and foal’s red blood cells (Table 11-5). In this test foal RBCs are added to serial dilutions (1:2 through 1:32) of colostrum, and the presence of agglutination is examined. Agglutination at dilutions of 1:16 in horses and 1:64 in mules are considered significant, and the foal should not be permitted to receive the mare’s colostrum. The foal should be fed colostrum from another, compatible mare or from a colostum bank. The mare should be milked out every 2 to 4 hours until the JFA titer is less than 1:16 or for 36 hours, after which the concentration of antibodies in the milk is negligible, and the foal can be permitted to suckle its dam. It is critical to the successful use of this test that it is performed before the foal is permitted to suckle the mare. If an incompatibility is detected the foal should be fed colostrum from a mare that does not have a positive jaundiced foal agglutination test to the current foal’s red cells.

Avoidance of vaccines based on whole blood or cellular parts of blood is recommended, and if they have to be used, it should be as far away as possible from parturition and should be restricted to one injection and one booster.

Erythrocytosis
Erythrocytosis is an increase in erythrocyte count, hemoglobin concentration, and hematocrit in blood. Polycythemia vera, a disease of humans and rarely small animals, and scarcely reported in cattle, is the result of an increase in the concentration of all blood cellular elements (erythrocytes, granulocytes, and platelets). Erythrocytosis, which is solely the result of an increase in red cell count, is either relative or absolute.

Relative erythrocytosis occurs when the total body red cell mass (i.e., the total amount of red cells in the body) is not elevated above normal, but the red cell count in peripheral blood is higher than expected. This is the most common form of erythrocytosis. Relative erythrocytosis occurs both as an abnormality and as a physiologic response to physical or psychological stress in animals with a capacious and capacious spleen. Abnormal relative erythrocytosis results from homoconcentration and is evident as an increase in concentration of red cells and serum total protein. The cause is a reduction in plasma volume, which is usually associated with dehydration resulting from either lack of water intake or excessive water losses (diarrhea, vomiting). The diagnosis is usually obvious, based on the presence of homoconcentration and other signs of the underlying disease. Physiologic relative erythrocytosis occurs most noticeably in horse as a result of either excitement or exercise. The blood in the spleen of horses has a hematocrit much higher than normal.

Interpretation
If no agglutination in the saline control tube, then the foal might have already ingested colostrum containing antibodies to the foal’s red blood cells. Some authorities recommend running a parallel test using mare’s red blood cells in place of foal’s red cells. This provides a negative control (there should be no agglutination of mare red cells by her colostrum) and aids interpretation of results especially for inexperienced operators.

REFERENCES
higher than that of blood (70% to 80%), and when relaxed the spleen contains many liters of blood. Excitement or exercise cause splenic contraction through an alpha-1-mediated event and ejection of the red-cell-rich blood into the peripheral circulation, with subsequent marked increases in hematocrit. The spleen of an adult horse can eject 5 to 10 L of blood into the circulation, which, together with a decline in plasma volume during exercise, increases hematocrit to 55% to 60% (0.55 to 0.60 L/L).

**Absolute erythrocytosis** occurs because of an increase in the number of red blood cells in the body. It is classified as primary or secondary, and within secondary erythrocytosis there is a further classification of appropriate or inappropriate. **Primary erythrocytosis** is attributable to proliferation of erythroid progenitors with maturation of the red cell series in the absence of arterial hypoxemia or increases in plasma erythropoietin concentration. It is a myeloproliferative disorder. Disorders resembling primary erythrocytosis are described in horses. These horses had marked increases in red cell count without evidence of diseases causing arterial hypoxemia or tissue hypoxia and without increases in serum erythropoietin concentration. A familial erythrocytosis is documented in cattle, but the disease resolved as the animals matured, which is not consistent with primary erythrocytosis attributable to a myeloproliferative disorder.

Secondary erythrocytosis is classified as either appropriate or inappropriate. **Appropriate secondary erythrocytosis** occurs as a consequence of diseases that cause tissue hypoxia with subsequent increases in plasma erythropoietin concentration. Tissue hypoxia is often inferred from the low arterial blood oxygen tension or content in these diseases. Tissue hypoxia can occur in the face of normal arterial blood oxygen tension when there is an abnormality in hemoglobin (such as chronic methemoglobinemia or carboxyhemoglobinemia), although this has not been reported as a cause of erythrocytosis in large animals. Diseases causing appropriate secondary erythrocytosis include chronic lung or respiratory disease and congenital cardiac anomalies in which there is right-to-left shunting (e.g., Eisenmenger's complex in cattle). 1,2 Physiologic appropriate secondary erythrocytosis occurs in animals living at high altitude.

**Inappropriate secondary erythrocytosis** occurs in animals that do not have arterial hypoxia or diseases causing tissue hypoxia. Plasma erythropoietin concentrations are elevated despite there being normal arterial oxygen tension and content, hence the term “inappropriate.” The disease is usually associated with hepatic or renal neoplasia.4,5 The disease in horses is described in foals or young animals with hepatoblastoma and adults with hepatic carcinoma. Erythrocytosis is recorded in a mare with a lymphoma that expressed the gene for equine erythropoietin, suggesting that anomalous production was the cause of the secondary inappropriate erythrocytosis. Erythrocytosis also occurs in horses with liver disease. The cause is not known, but could involve increased production of erythropoietin or decreased clearance because of reduced hepatic function. Inappropriate secondary erythrocytosis in ruminants or pigs is not reported, but probably occurs.

The **clinical signs** of secondary erythrocytosis are those of the underlying disease (dyspnea, congestive heart failure, cyanosis). In addition, the erythrocytosis can be evident as dark red or slightly purplish mucous membranes, lethargy, and an increased propensity for thrombosis. These signs occur because of the increase in blood viscosity that results from marked increases in red cell concentration. Treatment is directed toward the inciting disease. For animals with primary erythrocytosis, repeated phlebotomy and restriction of iron intake has been used to reduce the red cell count.

A syndrome is described in Standardbred trotters in Sweden that have normal red cell count at rest but counts during maximal exercise that are higher than expected. The syndrome is referred to as **red cell hypervol- emia** and is associated with poor race performance. The disorder, if it exists, is not related to a reduction in performance as part of the overtraining syndrome documented in athletic horses. Diagnosis is based on a history of poor performance and hematocrit or red cell counts during maximal exercise or after administration of epinephrine that are higher than expected. Treatment is prolonged rest, although some horses have had phlebotomy and therapeutic bleeding.

**REFERENCES**

**Abnormal Red Cell Function**

The primary function of red blood cells is to transport oxygen. Abnormal red cell function that results in anemia is described under that heading. Abnormalities of red cell function can include abnormalities in red cell metabolism or the structure or function of hemoglobin. Hemoglobinopathies are not well documented in large animals, with the exception of changes caused by ingestion of oxidants (nitrate, onions, kale, red maple leaves) that cause methemoglobinemia, or the recognition that inhalation of carbon monoxide causes carboxyhemoglobinemia. Both carboxyhemoglobinemia and methemoglobinemia decrease oxygen carriage by hemoglobin.

Reported abnormalities in red cell metabolism include the following: 7

- Diminished glucose-6-phosphate activity of red cells caused hemolytic anemia in an American Saddlebred colt.
- Flavine adenine dinucleotide deficiency was noted in a Spanish mustang with mild and variable anemia.
- Glutathione reductase deficiency causing hemolytic anemia was reported in a horse. Other abnormalities of glutathione metabolism, with minimal clinical expression, occur in sheep and horses.

**DISORDERS OF WHITE CELLS**

**Leukopenia**

Leukopenia does not occur as a specific disease entity but is a common manifestation of a number of diseases. Neutropenia, often accompanied by lymphopenia, occurs with a number of acute viral diseases, such as hog cholera and equine viral arteritis. It has also been observed in leptospirosis in cattle, although bacterial infections are usually accompanied by leukocytosis. Acute local inflammation can cause a transient fall in the leukocyte count because of withdrawal of the circulating cells to the septic focus. Neutropenia occurs as part of the response to toxemia, and in particular endotoxemia, because of enhanced migration of neutrophils from blood into tissues. The emigration of neutrophils occurs at a rate faster than their entry into the peripheral blood from bone marrow. Lymphopenia occurs as part of a stress response and as a result of administration of glucocorticoids.

Lymphopenia also occurs as part of a pancytopenia, in which all cellular elements of the blood are depressed. Agents that depress the activity of the bone marrow, spleen, and lymph nodes and result in pancytopenia occur in poisonings caused by trichloroethylene-extracted soybean meal, toluene, fungal toxins (e.g., fusariotoxicosis, notably that of Stachybotrys alternans), and bracken fern. Pancytopenia occurs also in radiation disease, in congenital anomalies in Fell, in foals as part of recognized hereditary diseases, possibly in Japanese Black calves, in calves as a result of furazolidone poisoning, and in calves and lambs as part of an alloimmune-mediated disease. Leukopenia in pigs can occur as a result of iron deficiency.

Administration of glucocorticoids causes lymphopenia and eosinopenia in most species. Lymphopenia is present in animals with immune deficiency, such as severe combined immunodeficiency in African foals and Fell and Dale pony foals with immunodeficiency. 2,3

The importance of leukopenia is that it can reduce the resistance of the animal to bacterial infection. Treatment of the
condition should focus on the underlying disease, but broad-spectrum antibiotics are often administered because of the presumed greater risk of bacterial infection in leukopenic animals.

REFERENCES

Leukocytosis
Leukocytosis is a white blood cell count in peripheral blood greater than expected in healthy animals, can be an appropriate physiologic response to an infectious or inflammatory process, a result of white cell dysfunction, or a result of leukoproliferative disease. In the latter, a particular situation is that in which there is neoplasia of the immune cells with subsequent production of growth factors or interleukins that stimulate inappropriate proliferation of other cell types that are detectable in the peripheral blood. An example is horses with intestinal lymphosarcoma that have peripheral eosinophilia. The leukoproliferative diseases are discussed under that heading.

Leukocytosis can be a result of an increase in the concentration of all white blood cells or a result of increases in count of a particular subset. The changes include lymphocytosis, neutrophilia, eosinophilia, monocytosis, and basophilia. Thrombocytosis is discussed under that heading.

Lymphocytosis not related to infection by bovine leukemia virus is unusual. Chronic viral or bacterial infections can result in mild increases in lymphocyte count in blood, but these changes have little diagnostic significance. The ratio of T lymphocytes to B lymphocytes changes in some disease processes, but these subsets are seldom differentiated in routine clinical practice.

Neutrophilia is almost always a response to an inflammatory process, with the exception of the neutrophilia associated with stress (“stress” leukogram). Subacute to chronic bacterial disease or inflammation causes marked increases in neutrophil count in peripheral blood. The neutrophilia is variable and can reduce even in the presence of continuing disease, such as *R. equi* pneumonia. A *mature neutrophilia* is evident as a high neutrophil count in the absence of immature forms (band cells). A regenerative neutrophilia is characterized by normal to elevated neutrophil counts and the presence of an excessive number of immature neutrophils (so-called “left shift”). The presence of a left shift suggests either rebound neutrophilia subsequent to neutropenia or ongoing severe inflammation. Mature neutrophilia suggests inflammation of longer standing but is not definitive for this time frame. Mature neutrophilia can occur during the recovery stage from anemia, especially hemolytic anemia. Profound neutrophilia occurs in calves with bovine leukocyte adhesion deficiency and in some septicemic foals.

Eosinophilia is usually associated with allergy or parasitism. Examples include milk allergy in cows and intestinal parasitism in horses. Eosinophilia can occur in horses with intestinal lymphosarcoma or multisystemic eosinophilic epitheliotropic disease.

Monocytosis and basophilia are unusual in large animals with the exception of that occurring as part of a rebound bone-marrow response to profound neutropenia.

REFERENCE

Abnormal White Cell Function
Abnormalities of white cell function can be either congenital or acquired. Congenital defects include Chédiak–Higashi syndrome and bovine leukocyte adhesion deficiency. Acquired defects include those associated with neoplasia of cells of the innate and adaptive immune systems, and dysfunction induced by disease, intoxication, or deficiency (such as iron deficiency impairing neutrophil function). A wide variety of infectious diseases can impair function of white blood cells, including phagocytosis of microorganisms by neutrophils or macrophages. Intoxicants such as some of the mycotoxins impair leukocyte function. Malnutrition, starvation, and specific deficiencies (e.g., iron) impair leukocyte function.

REFERENCE

Leukoproliferative Disease (Leukemia, Lymphoma)
The leukoproliferative diseases are neoplastic diseases of the myeloid (hemopoietic) or lymphoid tissues. The discussion here is divided into those diseases associated with abnormal lymphoid cells (lymphoproliferative) and those associated with abnormal myeloid cells (myeloproliferative). The most common leukoproliferative diseases of large animals are lymphoma and lymphosarcoma.

Myeloproliferative Diseases
Myeloproliferative disease is rare in large animals, but granulocytic, eosinophilic, monocytic, and myelomonocytic leukemias are reported:
- Acute (myelogenous) and chronic granulocytic leukemia are reported in horses, as is acute erythroid neoplasia.
- Acute granulocytic leukemia in a goat
- Systemic mastocytosis in a goat
- Acute basophilic leukemia in a calf and in pigs
- Acute mastocytic and megakaryocytic leukemia in a calf
- Histiocytosis in a piglet
- Acute myeloblastic leukemia in cattle and horses
- Myelomonocytic leukemia in a calf, a horse and in an inbred line of Miniature swine
- Malignant histiocytosis in cattle and horses
- Eosinophilic myeloproliferative disease in a horse
Cases manifest with nonspecific clinical signs, including weight loss, poor performance, episodic ventral and lower limb edema, petechial hemorrhage, splenomegaly, and lymph node enlargement or palpable masses in the abdomen in some. Thrombocytopenia and anemia are common because of myelophthisis. Abnormal cells are often apparent on examination of a smear of peripheral blood. Immunohistochemistry and immunostaining of cells for fluorescent cell sorting can identify the abnormal cells.

The diagnosis is often obtained at necropsy examination. Antemortem diagnosis can be facilitated by examination of peripheral blood smears and bone marrow obtained by aspiration or biopsy. There is no effective treatment, nor are there measures to prevent the disease.

Lymphoproliferative Disease
Lymphoproliferative disease occurs in all large animal species but is common only in cattle, where it manifests as lymphoma or lymphosarcoma (bovine viral leukosis). In addition to lymphoma or lymphosarcoma, the other lymphoproliferative disease is plasma cell myeloma, which occurs in ruminants and horses. Lymphangiosarcoma is a rare tumor of lymphoid endothelium in horses and cattle.

Plasmacytoma (Multiple Myeloma)
Plasmacytoma is a tumor of plasma cells that sometimes results in production of monoclonal globulins. The disease occurs in cattle, sheep, and horses and is characterized by proliferation of lymphoid cells that
produce an immunoglobulin or immunoglobulin fragment (often referred to as M-protein). The disease characteristically, but not always, involves the bone marrow, in which case it is referred to as multiple myeloma. The tumor cells might or might not secrete abnormal protein.

**Clinical signs** are often nonspecific and include weight loss, anorexia, limb edema, and recurrent infections. There can be signs of excessive bleeding as a result of minor trauma such as needle-sticks. The tumor can infiltrate any of a number of tissues, accounting for the protein nature of the clinical signs. Involvement of cranial nerves can result in dysphagia, and infiltration of cervical vertebrae can result in pathologic fracture and acute spinal cord compression. Involvement of the mediastinal lymph nodes can cause signs of an anterior thoracic mass. The clinical signs can be sufficiently vague that the disease is easily overlooked in its early stages. Radiography reveals the presence of osteolytic bone lesions in some animals.

**Anemia** is common, and thrombocytopenia occurs in about 20% of affected horses. Plasma cells can occasionally be seen in smears of peripheral blood. Hypoalbuminemia and hypergammaglobulinemia are common findings. Serum protein electrophoresis is useful in demonstrating the presence of a monoclonal proteinopathy in the alpha-2, beta, or gamma regions. Bence–Jones proteinuria occurs in approximately 20% of horses with myeloma. Serum concentrations of specific immunoglobulins are often increased; there are two reports of horses with myeloma and elevated concentrations of IgA. Hypercalcemia occurs in some affected horses and can be a result of increased concentrations of parathyroid-hormone-related protein. Examination of bone marrow obtained by aspiration or biopsy can reveal the presence of an excess number of plasma cells (>10%).

There is no effective treatment. Most animals present with advanced disease and die within days to weeks, but animals detected earlier in the disease process can live for more than 6 months.

**Lymphoma and Lymphosarcoma**

Bovine leukemia virus causes lymphoma in cattle and sheep, and infection with equine herpesvirus-5 is associated with lymphoma in horses, but with these exceptions the etiology of lymphoma in large animal species is unknown.

**Ruminants and Pigs.** Lymphosarcoma occurs as four distinct clinical entities in cattle:
- Juvenile multicentric lymphosarcoma occurs at birth or in early life. It is multicentric and commonly involves the bone marrow and most lymph nodes.
- Thymic lymphosarcoma develops in cattle from 3 months to 2 years of age and involves the thymus, occasionally spreads to other lymph nodes, and rarely infiltrates other organs.
- Cutaneous lymphosarcoma occurs primarily in cattle at 1 to 3 years of age.
- Adult multicentric lymphosarcoma occurs as a result of infection by bovine viral leukosis.

Lymphosarcoma in cattle is discussed in detail under the headings “Bovine Viral Leukosis” and “Sporadic Bovine Leukosis.”
- Lymphoma associated with infection by bovine leukemia virus occurs in sheep and in camels. The sporadic form of the disease can have a variety of presentations, including involvement of the brain, skin, and joints in addition to the expected localization in lymphoid tissue.
- Goats develop sporadic lymphoma, including a multicentric form, and exophthalmos can be a presenting sign.
- Pigs develop lymphosarcoma sporadically, with most forms being of B cells, although disease attributable to T cells is described. There is an inherited form of the disease.

The clinical signs of lymphosarcoma are similar to those described for the disease associated with bovine leukemia virus in cattle. Lymphadenopathy and clinical abnormalities arising as a result of lymphadenopathy (dysphagia, bloat, respiratory distress) are common presentations. Thymic lymphoma can be differentiated from hemotoma of the ventral neck on physical and hematological examination (tachycardia, anemia in cattle with hemotoma). T-cell lymphoma can manifest as skin or nasal cavity lesions in cattle. Radiography, echocardiography, and ultrasonography are useful diagnostic aids. Biopsy of lymph nodes can yield a diagnosis.

Clinicopathologic abnormalities are nonspecific and can include anemia and hyperfibrinogenemia. Hypoglycemia and hyperlactatemia are reported in a cow with enzootic bovine lymphoma.

Necropsy examination reveals lymphadenopathy and infiltration by neoplastic lymphocytes. There is no documented effective treatment. Administration of glucocorticoids might cause transient improvement because of lympholysis. Radiotherapy is feasible in small ruminants or pigs of sufficient monetary or emotional value, but has not been reported.

**Horses**

**Etiology and Epidemiology.** Some equine lymphomas are associated with infection by equine herpesvirus-5 (EHV-5). Of 13 horses with lymphoma, 67% were positive on polymerase chain reaction (PCR) testing of tissue for EHV-5, whereas 14% of 21 clinically normal horses were positive. Neoplastic samples positive for EHV-5 were classified as T-cell-rich B-cell lymphoma (three samples), T-cell lymphoma (one), and nondifferentiated (one), and two were not examined.

Although Koch’s postulates have not been met and therefore a strict causal association demonstrated, there is circumstantial evidence, including response to antiviral therapy, that EHV-5 infection causes lymphoma in horses. Otherwise, lymphoma and lymphosarcoma in equids is idiopathic.

Lymphoma is a neoplasm arising from lymphoid tissue, which may be in the lymph nodes, spleen, or intestine. The disease is more accurately described as neoplasia of one of many lymphoid cell lines, and with increasing sophistication of immunohistochemical staining it is possible to differentiate lymphoma by the particular cell line that is affected. At least 14 subtypes of lymphoma are recognized in horses. Furthermore, molecular genetic techniques may soon permit use of PCR or chromosomal (genomic) analysis to better characterize the origins of tumors. Both immunohistochemistry of fixed tissue sections and fluorescent cell sorting of cells in body fluids have been used to determine the abnormal cell type. An additional advantage of advanced testing is that tumors of uncertain origin (lymphoid, myeloid) can sometimes be characterized.

The tumors in horses are most commonly of T-cell or B-cell lines. Of 203 horses with lymphoma, multicentric lymphoma was most common (83 horses, 41%), followed by disease in the skin (38 horses, 19%), gastrointestinal tract (24 horses, 12%), mediastinum (5%), lymph nodes (5%), eye or periportal tissues (4%), spleen (3%), nasal cavity (2%), central nervous system (2%), oral cavity (2%), bone marrow (0.5%) and heart (0.5%). Equine T-cell-rich, large B-cell lymphoma is the most common of the equine lymphomas (87 of 203 horses, 43%) followed by peripheral T-cell lymphoma (45 horses, 22%) and diffuse large B-cell lymphoma (11%). B-cell lymphomas that contain large numbers of T cells (which are not neoplastic) or peripheral T-cell lymphomas are characteristically tumors of the spleen and thoracic and mediastinal lymph nodes. B-cell tumors that contain large numbers of T cells (T-cell-rich B-cell lymphoma) account for approximately one-third of equine lymphoma. These latter are typically tumors of the skin and subcutis. T-cell lymphomas account for approximately 20% of equine lymphomas and typically cause disease involving the mediastinal lymph nodes. Approximately 50% of equine lymphomas have cells that express progesterone receptors, but none express the estrogen receptor, which might explain the regression of tumors in mares during pregnancy.

The disease occurs in all ages of horse, being reported from animals as young as 2 months to as old as 31 years. Median age of diagnosis is 10 years. There is no
information on age-specific incidence. One study has reported cases in horses ranging from 4 months to 22 years of age, and the mean age of cases in this, and other case reviews, suggests that there is some increase in risk with increasing age. Limited slaughter surveys show a prevalence that varies from 0.7 to 3.2 cases per 100,000 animals. Thoroughbred horses are more likely to have cutaneous lymphosarcoma than are other breeds.19

**Clinical Signs.** The clinical manifestation of lymphosarcoma in horses is probably best described by the statement that the disease can manifest in a protean manner. Lymphosarcoma can exert an influence on the function of any organ system, and this is determined by where it occurs in the body. Most cases are multicentric, although they often present with organ-specific signs, and the multicentricity might not be recognized until further, more complete, clinical or post-mortem examination.20–23 External lymphadenopathy is usually a reflection of multicentric disease. Ocular lymphoma can be a solitary disease or part of a multicentric disease.22,24

Common presenting histories include chronic wasting and chronic diarrhea, upper respiratory distress with stertorous breathing or inspiratory dyspnea, lower respiratory distress with stertorous breathing, cough, and fever of unknown origin. **Clinical signs** include weight loss, anorexia, and depression in 30% of cases; ventral edema in 18%; pyrexia and anemia in 17%; diarrhea in 7%; and colic in 6%.17

Lymphosarcoma is the single most common cause of neoplasia in the thorax of the horse. A common syndrome is that of weight loss and ventral edema of the neck and thorax, sometimes accompanied by pleural or peritoneal effusion, anemia, dyspnea, cough, and abdominal masses palpable per rectum. In cases where the lesions are predominantly in the thorax, the syndrome is that produced by a space-occupying lesion, manifest by pectoral edema and jugular vein engorgement, but an absence of the jugular pulse and dyspnea. The heart may be displaced, and there may be cardiac murmurs. If there is compression of the esophagus, dysphagia is present. Thorascopic biopsy might be necessary to confirm an antemortem diagnosis.35

Another relatively common syndrome is chronic weight loss, with or without diarrhea, associated with infiltration of the intestine. The disease can affect multiple segments, as is the often the case in younger horses, or occur as a solitary lesion in older horses.26,27 The disease can present as acute colic or as a result of intussusception around a solitary lesion, multiple diverticula, or diarrhea.36–39 A case review of chronic diarrhea in horses found alimentary lymphosarcoma to be the cause in 5 of 51 cases. Oral glucose tolerance tests are adversely affected by the intestinal infiltration of lymphosarcoma, but an abnormal test is not pathognomonic for this disease, nor is it likely to detect the presence of solitary lesions. Lymphosarcoma is also a cause of recurrent colic in horses.

**Cutaneous lymphosarcoma** is a common disease in horses and might be the most common form of lymphoma in horses. Lymphoma comprises approximately 1.7% of skin lesions in equids, and affected animals have a mean age of 15 years.19 Thoroughbreds are 2.5 times more likely to be diagnosed with the disease compared with all other breeds,29 and Thoroughbreds have a predilection for T-cell lymphoma compared with other breeds, with approximately 33% of cutaneous lymphomas in this breed being of this type.27 Cutaneous lymphomas in Quarter horses are almost always T-cell-rich, large B-cell lymphoma.20 There is no sex predilection.

The cutaneous tumors can be solitary or multiple and are usually discrete, firm, non-painful swellings. The swellings are often haired, but in the more severe disease there is loss of hair. The lesions tend to be on the head, neck, and dorsal trunk, but they can be anywhere on the body. The tumors sometimes metastasize, but horses affected with a mild or waxing and waning disease can live for years.

Cutaneous lymphoma of equids is commonly the T-cell-rich, large B-cell lymphoma (84%) variant, with cutaneous T-cell lymphoma being the next most common (11%).30 Tumors that present as multiple nodules are more commonly T-cell-rich, large B-cell lymphoma.30 Solitary lesions are more likely to be cutaneous T-cell lymphoma.30 Diagnosis is by excisional biopsy. Another variation is mycosis fungoides, a T-cell lymphoma of the skin that appears to have a more aggressive course.30,31

Lymphosarcoma is the final diagnosis in a significant proportion of horses with fever of unknown origin. Lymphoma should be considered in the differential diagnosis of horses with signs of ataxia or other signs of neurologic disease.32,33 Signs of neurologic disease are usually the result of space-occupying lesions in the spinal canal or infiltration of peripheral nerves impairing normal neurologic function.30–33

The organ systems affected by lymphosarcoma in the horse are not restricted to those mentioned previously, and individual horses can have involvement of virtually any body system or organ, such as the spleen,26 mandible,26 heart,30 mammary gland,26 pharynx,21 and uterus and ovary (causing abortion).20 Ultrasound can aid in the location of tumor masses or accumulation of pleural or peritoneal fluid, and in aspiration of material from these sites. Radiography is useful for detecting mediastinal disease. Rhinolaryngoscopy permits detection and assessment of disease of the pharynx. Magnetic resonance imaging allows more precise localization of lesions of the head and rostral neck.21

Lymphoma is sometimes accompanied by signs of paraneoplastic syndrome, especially if the disease is multicentric. Signs of paraneoplastic syndrome can include pseudohyperparathyroidism, alopecia, and pruritus.34,35

**Clinical Pathology.** A specific diagnosis can be obtained by cytology, and needle aspirates or biopsy with cytologic examination of affected lymph nodes are diagnostic. Samples can be obtained from enlarged lymph nodes or from bone marrow. Cyto logic examination of fluid obtained by thoracocentesis or abdominocentesis where there is thoracic or abdominal involvement is also frequently diagnostic.

**Anemia** is a consistent finding in horses with advanced lymphosarcoma. The anemia can be a result of tumor cells occupying bone marrow or causing bone-marrow necrosis, but this is not a usual manifestation of the disease.41 More commonly, anemia is probably a result of increased destruction of red cells or anemia of chronic disease.41 Only a small proportion of horses with lymphadenopathy attributable to lymphosarcoma have concurrent leukemic blood changes. Sézary-like cells have been detected in the blood of a horse with B-cell lymphoma. Thrombocytopenia occurs in approximately 30% of cases.

Immunophenotyping cells obtained at necropsy examination, by biopsy of affected organs or lymph nodes, or from peripheral blood can aid in determining the cell type involved.

Hypergammaglobulinemia and hypobuminemia occur in some horses. Hypergammaglobulinemia in horses with lymphosarcoma is almost always caused by a polyclonal globulinopathy—in contrast to horses with plasma cell myeloma—and is probably attributable to the inflammatory response to the tumor. Plasma fibrinogen concentrations can be elevated in horses with lymphosarcoma for the same reason.

Low serum immunoglobulin concentrations have been reported in horses with lymphosarcoma, but this finding is not specific for lymphosarcoma. Detection of low serum IgM concentration has poor sensitivity and specificity for diagnosis of lymphosarcoma. The sensitivity and specificity of serum IgM below 60 mg/dL for diagnosis of lymphosarcoma in horses are 50% and 35%, respectively. This is not a good screening or diagnostic test for lymphosarcoma in horses.

Abnormalities in serum calcium concentration are uncommon and variable, with both hypocalcemia and hypercalcemia being reported. Hypercalcemia can be associated with elevated serum concentrations of parathyroid-hormone-related peptide.

**Treatment.** Reports of treatment of lymphoma in horses are few. Because most horses have advanced disease at the time of...

diagnosis and because therapeutic options are limited by cost or adverse effects, treatment is rarely undertaken. Surgical removal of isolated masses in the skin is appropriate in some cases of cutaneous lymphosarcoma and can result in cure, especially of solitary T-cell-rich, large B-cell lymphoma.30

Successful treatment of a mare with EHV-5 associated T-cell-rich, large B-cell lymphoma was achieved by surgical debulking of the lesion and administration of cyclophosphamide, vincristine, and dexamethasone for 1 month, followed by 4 months of administration of acyclovir (an antiviral drug) at 20 mg/kg orally every 8 hours.

Administration of oncolytic agents has resulted in remission of disease in some horses.32,36,40,43 Drugs used include prednisolone, vincristine, cyclophosphamide, cisplatin, and cytarabine (see Table 11-6 for examples). The glucocorticoids cause lysis of abnormal lymphocytes and can result in some improvement in clinical signs. A protocol that has met with some success involves administration of cyclophosphamide (2 mg/kg IV) once weekly for 4 to 6 weeks, and then once every 2 to 3 weeks, combined with oral administration of prednisolone (0.5 to 1.5 mg/kg every 24 to 48 hours). Another protocol involves administration of vincristine (0.008 mg/kg IV) and cyclophosphamide (2 mg/kg IV) once every 2 weeks for four to six treatments, combined with daily administration of prednisolone. The aim of all of these treatments is to induce remission or to reduce clinical signs of the disease when these signs are attributable to lymphadenopathy (e.g., dysphagia, dysnea). An example could be the treatment of a pregnant mare with retropharyngeal tumor that causes dysphagia, with a view to prolonging the mare’s life until parturition.

Radiotherapy of localized disease of the head and pharynx might be effective in treatment of lymphoma in horses; lymphoma in other species is radiosensitive.

BOVINE NEONATAL PANCYTOPENIA (BNP)

SYNOPSIS
Etiology Currently assumed to be caused by a commercial inactivated bovine virus diarrhea (BVD) vaccine, Premature BVD, that triggers an alloimmune reaction against specific bovine major histocompatibility complex (MHC) class I antigens contained as impurities in the vaccine. Vaccinated dams having produced antibodies against this specific MHC-1 epitope transmit these via colostrum to their calves. Calves that share the MHC-1 epitope contained in the vaccine will suffer damage of erythropoietic and bone-marrow cells through an alloimmune reaction triggered by maternal antibodies.

Epidemiology Observed with increasing incidence in several European and other countries where Premature BVD was marketed from 2007 to 2012. Incidence, Continued
ETIOLOGY

The etiology of bovine neonatal pancytopenia (BNP), a condition characterized by spontaneous internal and external bleeding and almost complete destruction of the red bone marrow in neonatal calves, is not yet entirely understood. The currently best established hypothesis is that BNP is caused by immunoglobulins contained in colostrum from dams of affected calves that damage calf’s bone marrow via an alloimmune reaction.1 The increasing incidence of BNP observed since 2007 in several European countries has been linked to the use of an inactivated bovine viral diarrhea vaccine (Pregsure BVD, Pfizer Animal Health). This vaccine contains cytopathogenic BVDV- serotype I grown on a bovine kidney cell line in combination with a novel adjuvant named Pregsure.2

With growing epidemiologic evidence corroborating the link between Pregsure BVD and BNP, the manufacturer announced a voluntary marketing cessation for Pregsure BVD in 2010, and later that year the European Medicines Agency (EMA) recommended to suspend the marketing authorization for this vaccine.3 In August 2011 Pregsure BVD was withdrawn from the market in New Zealand immediately after the first case was reported.4

The lag time of nearly 3 years between the introduction of Pregsure BVD and BNP, the occurrence of the first clinical cases that were observed in European countries but also in New Zealand is not entirely understood but has been explained with the requirement of repeated vaccination with Pregsure BVD to induce a significant alloreactive immune response able to induce BNP.5

Another puzzling observation is the wide regional variation of the disease incidence that cannot solely be explained by differences in frequency of Pregsure BVD use. Within Germany the highest disease incidence was observed in Bavaria, with an estimated 99 clinical cases per 100,000 sold vaccine doses, compared with an average disease incidence of 6 cases per 100,000 sold vaccines in Lower Saxony.6 A possible explanation for these regional differences was found in differences in vaccination protocols. Whereas in Bavaria repeated vaccination with Pregsure BVD following label instructions was common practice, in Lower Saxony a modified vaccination protocol consisting of an initial vaccination with Pregsure BVD followed by a booster with a modified life BVD vaccine was implemented.4 Accordingly, in Lower Saxony vaccinated animals were exposed to fewer doses of the incriminated vaccine compared with Bavaria, which may have contributed to the observed regional disease incidences.

PATHOGENESIS

Although the basic pathophysiologic mechanism behind BNP appears to have been unraveled, the detailed pathophysiology of the disease is not yet understood. According to the currently established hypothesis, vaccination with Pregsure BVD induces the production not only of BVD antibodies but potentially also of alloantibodies against the MHC class I epitopes with which the vaccine was contaminated. The MHC class I antigen contained in the vaccine originates from the bovine kidney cell line that was used in the vaccine production process and thus presents the specific MHC allotype of that cell line. Whether the vaccinated dam will mount an immune response against this allotype depends on the MHC-I allotype constellation of the individual animal. If the dam differs in its allotype repertoire it will recognize the MHC-I antigen as an antigen, against which it will mount an immune response and therefore be able to induce BNP in certain calves.3

If antibodies are produced, these will be transferred via colostrum to the neonatal calf. Calves carrying MHC-I allotypes similar to the MHC-I allotype contained in the vaccine but different from the maternal allotype are thus predisposed to develop BNP. In affected calves alloantibodies ingested with colostrum will lead to complement-dependent lysis and/or cytophagocytosis of cells expressing the MHC-I antigen.6,7

Alternatively, it has been proposed that the potent adjuvant contained in Pregsure BVD may not only amplify the production of alloantibodies against antigenic material contained in the vaccine but also against maternally derived fetal MHC-I antigens normally present during pregnancy.3

The severity of the clinical signs in susceptible calves is modulated by the amount of colostrum ingested, the quality of the colostrum, and the time of colostrum ingestion.6,7

It is currently not well understood why in calves with BNP only hematopoietic and bone-marrow cells appear to be affected even though the MHC-I gene is expressed and present on the cell surface of practically every nucleated cell. Although differences in the degree of MHC-I expression that would make cells expressing high levels of MHC-I, such as bone-marrow cells, more susceptible than other cells have been proposed as a possible explanation, it is probable that other yet unidentified pathophysiological mechanisms are at work.7

CLINICAL FINDINGS

Calves with BNP in general become clinically apparent between 10 and 20 days of age.
Calves older than 1 month of age are not affected, and there is no gender predisposition. The most prominent symptoms are cutaneous and mucosal bleeding (e.g., following trauma, injection, or ear-tagging), petechiae on mucous membranes, and melena. Persistently increased rectal temperature, often above 41.0°C (105.8°F), is frequently reported. Affected calves initially appear bright but rapidly become anemic, with pale mucous membranes, and they succumb to blood loss and secondary infection. In many cases animals die within 24 to 48 hours. The mortality rate reaches up to 90%. Subclinical cases may occur but have rarely been reported.

**CLINICAL PATHOLOGY**

The most prominent hematological findings are pronounced thrombocytopenia, leukopenia (neutropenia and lymphopenia), and nonregenerative anemia. In experimental studies a decline in the number of circulating lymphocytes, neutrophils, and monocytes by over 75% has been observed as early as 4 hours following ingestion of colostrum. Thrombocyte counts in BNP calves 8 hours after ingestion of colostrum were found to be at 40% of thrombocyte counts in control calves. Red blood cell counts were not altered in the first hours after colostrum ingestion. Reduced hematopoietic cell density in bone marrow, including erythroid cells, myeloid cells, and megakaryocytes, was observed in BNP calves 6 days but not 24 hours after ingestion of colostrum. This rapid initial depletion of leukocytes and thrombocytes combined with the protracted damage observed in the marrow suggests that pancytopenia is the result of a combination of extensive destruction of peripheral blood cells, probably resulting from complement-mediated lysis and/or enhanced phagocytosis of cells and decreased regenerative activity caused by bone-marrow depletion.

**NECROPSY FINDINGS**

At necropsy, affected calves have generalized petechiae or ecchymoses on mucosal and serosal surfaces and often hematomas in the subcutaneous tissue, especially over bony prominences. The peritoneal, pleural, and synovial fluids may be serosanguinous, and the content of the colon and rectum may be bloody. Overall, the carcass is often pale from excessive bleeding.

Microscopic lesions are multiple hemorrhages without obvious vascular or tissue reaction and bone-marrow hypoplasia/aplasia involving all three main hematopoietic cell series (total or trilineage hypoplasia), with an almost complete lack of megakaryocytes. In addition to hemorrhages, there will be diffuse depletion of lymphoid tissue in the spleen, lymph nodes, and thymus, in which T- and B-cell components are equally affected.

**Lymphadenopathy (Lymphadenitis)**

Lymph nodes can be enlarged because of inflammation (lymphadenitis) or infiltration with neoplastic cells. Enlargement of peripheral nodes causes visible and palpable swellings and in some cases obstruction to lymphatic drainage and subsequent local edema, as in sporadic lymphangitis of horses. Enlargement of internal nodes can cause obstruction of the esophagus or pharynx, trachea, or bronchi. Enlargement of the lymph nodes can occur as a result of infection or of neoplastic invasion. Lymphadenopathy as part of lymphoma and lymphosarcoma is discussed under “Leukoproliferative Diseases.”

**Lymphadenitis** occurs most commonly in response to infection or inflammation in the region of the body distal to, and drained by, the lymph node. Lymphadenitis also accompanies other signs in many other diseases, including strangles, bovine malignant catarrh, sporadic bovine encephalomyelitis, porcine reproductive and respiratory syndrome, East Coast fever, Ondiri disease, and ephemeral fever.

Infection and enlargement of lymph nodes is the major presenting sign in a small number of diseases, which include the following:

- Cases of lymphadenitis of sheep and ulcerative lymphangitis in horses and cattle resulting from infection with *Corynebacterium pseudotuberculosis*
- Internal abscessation associated with *C. pseudotuberculosis* in horses
- Anthrax, especially in the pig but also in the horse, which can initially manifest as cervical lymphadenopathy with considerable inflammation and swelling in the pharyngeal region and neck
- Strangles in horses associated with *S. equi* and lymphadenitis produced by *S. zooepidemicus*. Lymphadenopathy that causes enlargement of abdominal lymph nodes is a characteristic of infection with *S. equi* in the burro.
- Anorectal lymphadenopathy in young horses, causing extraluminal rectal obstruction with colic and sometimes urinary dysfunction
- Cervical adenitis (jowl abscess) of pigs, caused principally by group E type IV *Streptococcus* spp. but also by *Actinomyces* (Truperella) *pyogenes* and *Pasteurella multocida*
- Granulomatous cervical adenitis, which also occurs in pigs and is a common finding at slaughter. The lesions rarely cause clinical illness but are a public health concern because they may be tuberculosis. Most commonly they are associated with *R. equi* or atypical mycobacteria, but *Mycobacterium tuberculosis*, *Mycobacterium avium*, and *Mycobacterium bovis* are also causes.
- Tularemia, infection with *Francisella tularensis*, in tick-infested sheep
- Meloidosis associated with infection with *Burkholderia pseudomallei*
- Tick pyemia associated with *S. aureus* in sheep infected with the tick *Ixodes ricinus*
- Retropharyngeal lymph node enlargement up to three or four times normal, and colored bright green, has been identified in cattle as resulting from infection with the algae *Prototheca* spp.
- Tuberculosis

**Samples for Postmortem Confirmation of Diagnosis**

Samples for light microscopy include bone marrow smears, preferably from the sternum, femur, or humerus, and sections of bone marrow, spleen, and lymph nodes for histopathology.

**DIFFERENTIAL DIAGNOSIS**

| Bovine viral diarrhea/mucosal disease (BVD/MD) |
| Bluetongue |
| Idiopathic thrombocytopenia in calves (e.g., following bacterial septicemia or immune-mediated processes) |
| Simmental inherited thrombopathy (SHT) |

**TREATMENT**

There is currently no specific treatment for BNP available.

**CONTROL**

Pregsure BVD has been withdrawn from the market until further notice. Assuming this vaccine is indeed associated with the occurrence of BNP, this measure should prevent the emergence of extensive destruction of peripheral blood cells, probably resulting from complement-mediated lysis and/or enhanced phagocytosis of cells and decreased regenerative activity caused by bone-marrow depletion.

**REFERENCES**

• Lymphadenitis in lambs associated with *P. multocida*, and in some cases of actinobacillosis
• Morel’s disease of sheep associated with infection by *S. aureus* subsp. *anterioribus*
• Bovine farcy and atypical skin tuberculosis, the latter involving the lymphatics but not associated with lymph node enlargement.
• *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) causes lymphadenitis in cattle, sheep, goats, pigs, and horses.1

In acute lymphadenitis there is pain and heat on palpation, but the nodes are for the most part painless. Obstructions produced by enlarged lymph nodes can result in secondary signs such as respiratory difficulty with enlargement of the retropharyngeal lymph nodes and esophageal obstruction by enlarged mediastinal lymph nodes. Needle biopsy for cytology and culture can aid in the determination of the cause of lymphadenitis and can allow the differentiation between lymphadenitis and neoplastic enlargement. Ultrasound may also aid in diagnosis. The diseases listed here are discussed in more detail under their specific headings.

**Absence of lymphoid tissue** occurs as a congenital defect in Arabian foals with severe combined immunodeficiency and is recorded in an Angus calf.

**Diseases of the Spleen and Thymus**

The spleen serves a number of functions—it is a storage organ for blood, a source of extramedullary erythropoiesis in some species, a major component of the reticuloendothelial system, and an important component of the immune system.1 Its function is most evident in the horse, in which an intact and functioning spleen is necessary for normal work capacity. Blood in the spleen of horses has a hematocrit much higher than that of circulating blood (70% to 80% vs 35–45%), and when relaxed the spleen contains many liters of blood. Excitement or exercise causes splenic contraction through an alpha-1-mediated event and ejection of the red-cell-rich blood into the peripheral circulation, with subsequent marked increases in hematocrit. The spleen of an adult horse can eject 5 to 10 L of blood into the circulation, and together with declines in plasma volume during exercise, increase hematocrit to 55% to 60% (0.55 to 0.60 L/L).

Splenectomy is performed as part of treatment of idiopathic refractory thrombocytopenia, as a consequence of splenic infarction, and to control hemorrhage.2-5 Removal of the spleen (splenectomy) impairs the oxygen-carrying capacity of blood during exercise by preventing the normal increase in hematocrit, and it prevents the normal cardiovascular responses to exercise, including increases in right atrial pressure.6

**SPLENOMEGALY**

Diffuse diseases of the spleen that result in enlargement are usually secondary to diseases in other organs. **Splenomegaly** with complete destruction of splenic function is virtually symptomless, especially if the involvement occurs gradually, and in most cases clinical signs are restricted to those caused by involvement of other organs. An enlarged spleen can be palpable on rectal examination in the horse, and careful percussion might detect enlargement of the spleen in cattle, but in most instances involvement of the organ is not diagnosed at antemortem examination unless ultrasonographic examination or laparotomy is performed.5,7 Ultrasonography is useful in determining the size of the spleen and its anatomic placement (e.g., in horses with left dorsal displacement of the colon) and to detect masses or abnormalities in the composition of the spleen (infarcts, hematoma, neoplasia).5,8 Left dorsal displacement of the colon in the horse is a colic in which the spleen is displaced medially, and this may give the impression that the organ is enlarged. **Rupture** of a grossly enlarged spleen can cause hemoperitoneum and possibly sudden death resulting from internal hemorrhage.1 This is sometimes the cause of death in bovine viral leukaemia or equine amyloidosis. **Moderate degrees of splenomegaly** occur in many infectious diseases, especially salmonellosis, anthrax, babesiosis, equine infectious anemia, and diplococcus septicaemias in calves, and in some noninfectious diseases, such as copper toxicity in sheep. Amyloid is deposited in the spleen of affected cows.10 Animals that die suddenly because of lightning stroke, electrocution, and euthanasia can also show a moderate degree of splenomegaly, but the enlargement is minor compared with that observed in congestive heart failure, portal hypertension, and neoplastic change. **Neoplasms** of the spleen are not common in large animals but can be lymphosarcoma, hemangiosarcoma, myelocytic leukemia, malignant melanoma, or systemic granulomatosis in horses.11-13 Metastasis of hepatic carcinoma to the spleen of a dairy cow is reported. The abnormality is usually readily detected by ultrasonographic examination of the spleen or discovered incidentally during rectal examination.

**SPLENIC ABSCESS**

Splenic abscess can result when a septic embolus lodges in the spleen, but is more commonly caused by extension of infection from a neighboring organ. Perforation by a foreign body in the reticulum of cattle is the commonest cause of the disease in large animals, and gastric penetration by sharp metal or wires can cause splenitis in horses.15,16 Perforation of a gastric ulcer or an erosion of the gastric wall caused by *Gasterophilus intestinalis* or extension of a granuloma caused by larvae of *Habronema* spp. in horses can lead, by extension, to development of a supplicative lesion in the spleen. In those occasional cases of strangles in horses in which systemic spread occurs, splenic abscess occasionally occurs.

Splenic abscesses associated with *C. pseudotuberculosis* infection are diagnosed in horses in those parts of the world where the infection is endemic. The most common clinical signs are concurrent external abscesses, anorexia, fever, lethargy, weight loss, and signs of respiratory tract disease or abdominal pain. Diagnosis is based on the presence of appropriate clinical signs and ultrasonographic examination of the spleen.

If the abscess is extensive and acute, there are systemic signs of fever, anorexia, and increased heart rate. Pain is evidenced on palpation over the area of the spleen, and hematological examination reveals a marked increase in the total white cell count and a distinct shift to the left in the differential count.

**Abdominocentesis** usually provides evidence of chronic peritonitis by the presence of a large amount of inflammatory exudate. Peritonitis is often coexistent and produces signs of mild abdominal pain with arching of the back and disinclination to move. Mild recurrent colic may also occur. Anemia, with marked pallor of mucosae, and terminal ventral edema are also recorded. The spleen may be sufficiently enlarged to be palpable per rectum.

**Treatment** of splenic abscess is often unrewarding because of the extensive nature of the lesion before clinical signs appear. The systemic signs can usually be brought under control by treatment with antimicrobials, but relapses are common and death is the almost certain outcome. Splenectomy is recommended if adhesions and associated peritonitis are absent.

**SPLENIC HEMATOMA, RUPTURE OR INFARCTION**

Formation of a hematoma in the spleen or, in the more severe instance, splenic rupture, usually occurs as a result of trauma. The syndrome is best described in horses, occurring as a result of falling or blunt trauma to the left side of the ribcage. The clinical signs include colic, tachycardia, cold extremities, and pallor of the mucous membranes—all of which are suggestive of hemorrhagic shock.3,9 If a hematoma is present, ultrasonographic examination of the abdomen will reveal an abnormally shaped spleen containing a
hypoechoic mass. Rupture of the spleen will be apparent as accumulation of a large quantity of fluid within the abdomen. The fluid will have the ultrasonographic characteristics of blood (a swirling echodensity). Laporoscopy can be used to confirm the diagnosis. Hematocytometry can reveal leukocytosis and low hematocrit. Peritoneal fluid can be serosanguinous if the hematoma has not ruptured, or bloody if the spleen is ruptured.

Infarction of the spleen is reported rarely in horses, and thus predisposing factors are not identified. In other species splenomegaly predisposes to infarction. The clinical signs are mild to moderate colic, tachycardia, and signs of hemorrhagic shock. Ultrasonography and exploratory laparotomy are diagnostic. The spleen is enlarged and has numerous zones of varying echogenicity, which is in marked contrast to the usual homogenous echogenicity of the normal spleen. There can be excessive echogenic fluid in the abdomen consistent with blood. Treatment is surgical, although technically challenging because of the splenomegaly and risk of rupture of the spleen.

Treatment of a splenic hematoma is conservative, with enforced rest for a period of up to 3 months. Resolution of the hematoma can be monitored by periodic ultrasonographic examination. Horses with a ruptured spleen usually die within a short period of time. Emergency splenectomy might be attempted, with enforced rest for a period of up to 3 months. Resolution of the hematoma will have the ultrasonographic characteristics of a splenic hematoma is considered.

CONGENITAL ANOMALIES OF THE SPLEEN

Abdominal situs inversus likely occurs in most species and is reported in calves and foals. There can be polysplenia and clinical signs of chronic bloating in calves. Situs inversus totalis with primary ciliary dyskinesia and chronic respiratory disease occurs in horses.

References

THYMUS

The thymus is the source of T cells in animals and is essential for development of normal immune responses. These functions occur during late gestation and in the neonate. Primary diseases of the thymus are rare in farm animals. The thymus is largest, relative to body size, in neonates and atrophies in adults to the extent that it can be difficult to identify. Aplasia or thymic hypoplasia occurs as part of severe combined immunodeficiency in Arabian foals. Aplasia of the thymus occurs Holstein calves and Japanese Black cattle and results in increased susceptibility to infection. Extrathoracic thymus tissue occurs in lambs and can be mistaken for enlargement of the thyroid glands.

Neoplasia of the thymus occurs in most species. Thymic lymphomas are reported in horses, pigs, and calves. Thymoma and thymic carcinoma are reported in horses and cattle. The clinical syndrome is that of a cranial thoracic mass. There can be compression of the cranial vena cava with obstructed blood flow and signs of congestive heart failure. The jugular veins are distended, and there can be submandibular edema. There can be accumulation of excessive pleural fluid. Esophageal obstruction evident as bloat in cattle or dysphagia in cattle and horses occurs. Radiography or ultrasonography of the chest demonstrate the mass, and histologic diagnosis can be achieved at necropsy or in samples obtained by fine-needle biopsy.

Immune-Deficiency Disorders (Lowered Resistance to Infection)

Normal immune function, both of acquired and innate immunity, is essential for functional resistance to infection. Immune function that is less than optimal can be the result of decreased or nonresponsiveness to one particular antigen. Immunosuppression is a state of temporary or permanent dysfunction of the immune response resulting from damage to the immune system and leading to increased susceptibility to disease agents. In immunosuppression there is decreased immune responsiveness to all foreign antigens, whereas in immune tolerance there is a state of decreased or nonresponsiveness to one particular antigen. Immunosuppression can be associated with infectious and noninfectious agents. A review of the general aspects of immunosuppression and the various agents responsible is available. Infectious agents include bacteria, viruses, protozoa, and helminths; noninfectious causes include chemicals, hormones, some antimicrobials (e.g., chlortetracyclines), and toxins. Environmental factors such as extremes of temperature, humidity, high population density and mixing animals from different origins, and prolonged transportation have also been implicated as causes of immunosuppression, but the pathogenesis of these has not been well explained.

Various laboratory methods can be used to evaluate immunosuppression. The criteria that can be used to evaluate immune functions include the following:

• Gross and microscopic changes in the morphology of central or peripheral lymphoid tissues
• Changes in the concentration or ratios of different classes of immunoglobulins
• Changes in serum complement concentration
• Changes in the functional activity of immunoglobulins
• Changes in the functional activity of the immune response
• Interference with the results of vaccination
• Exacerbation in the course of disease associated with other agents
• Changes in the number and viability of cells from lymphoid organs

Perhaps within an associated low platelet count
• Low concentrations of immunoglobulins
The development of monoclonal antibody reagents and analysis of all or part of the genome of animals has allowed new approaches to veterinary immunopathology, particularly the identification and analysis of leukocyte subpopulations in health and disease.

Most of the diseases associated with immunologic deficiency states are discussed in systems or other categories of disease throughout this book, and only a checklist is provided here. Table 11-7 provides a summary of primary and acquired immunodeficiencies in horses.

### PRIMARY IMMUNE DEFICIENCIES

The primary immunodeficiencies can be in either innate immunity or adaptive immunity. Deficiencies of innate immunity include the following:
- Chédiak–Higashi syndrome, an inherited defect of many animal species, including cattle; a defect of phagocytic capacity via the neutrophils and monocytes
- Bovine leukocyte adhesion deficiency (BLAD) of Holstein calves, which results from a deficiency in CD18 and accumulation of profound numbers of neutrophils in circulation but not in tissue

Deficiencies of adaptive immunity include the following:
- Combined immunodeficiency (CID) of Arabian horses as a result of an inherited failure to produce and differentiate lymphoid precursor cells into B and T lymphocytes. See Table 11-7 for a listing of immunodeficiencies of horses. A similar disease is reported in an Angus calf.

### Table 11-7 Defects of acquired immunity causing disease in foals and horses

<tr>
<td>Failure of transfer of passive immunity</td>
<td>Failure of mare to produce adequate quantities of colostrum with specific gravity &gt; 1.060; prepartum loss of colostrum; failure of foal to ingest or absorb colostrum.</td>
<td>Epidemiology: Most common immunodeficiency of foals. Affects 5%–35% of foals. Rate is reduced by good management. Clinical signs: Bacterial infections, including bactereemia, septicemia, pneumonia, diarrhea, or septic arthritis/osteomyelitis, develop between 2 days and 4 weeks of age.</td>
<td>Measurement of foal blood or serum concentrations of immunoglobulin &gt; 18 hours after birth. Concentration should be &gt; 800 mg/dL (8 g/L).</td>
<td>Treatment: Administration of plasma (20–40 mL/kg) IV. Prevention: Check colostrum specific gravity at foaling. Ensure foal nurses mare within 3 hours of birth. Supplement with banked colostrum. Routinely measure foal serum IgG at 18–24 hours of age.</td>
</tr>
<tr>
<td>Severe combined immunodeficiency of Arabians</td>
<td>Failure of V(D)J recombination secondary to a defect of the catalytic subunit of DNA-protein kinase coded for by the DNA-PKcs gene.</td>
<td>Epidemiology: Restricted to Arabians. Autosomal inheritance Clinical signs: Adenoviral pneumonia or diarrhea develop after ~4 weeks of age.</td>
<td>Severe lymphopenia (&lt;1 × 10^9 cells/L); no IgM in presuckle serum sample or sample collected at 4-5 weeks of age; histologic demonstration of lack of lymphoid tissue. Confirmation by demonstration of homozygosity for the normal DNA-PKcs gene.</td>
<td>Treatment: None. Prevention: Identification and removal of carrier animals from the breeding population.</td>
</tr>
<tr>
<td>IgM deficiency</td>
<td>Unknown.</td>
<td>Epidemiology: Arabian or Quarter horse foals 2–8 months of age. Clinical signs: Pneumonia, septic arthritis, or enteritis.</td>
<td>Low to undetectable serum IgM concentrations with normal to elevated concentrations of other immunoglobulins.</td>
<td>Treatment: None specific. Symptomatic treatment. Rare foal reported to recover. Preventive: None.</td>
</tr>
<tr>
<td>Common variable immunodeficiency</td>
<td>Unknown in horses.</td>
<td>Epidemiology: Adult horses. Sporadic. Either sex. Clinical signs: Chronic or recurrent infections unresponsive to medical treatment. Meningitis. Liver disease can occur in combination with common variable immunodeficiency.</td>
<td>Low to undetectable concentrations of IgG, IgG(T), IgM, and IgA in serum. No or few B lymphocytes in blood or lymph nodes. Elevations in serum markers of liver disease.</td>
<td>Treatment: None specific. Affected animals die because of the opportunistic infections. Prevention: Prolonged antimicrobial administration of affected horses.</td>
</tr>
</tbody>
</table>
• Agammaglobulinemia of Standardbred and Thoroughbred horses, probably the result of an inherited failure to produce B lymphocytes; these horses live much longer than those affected with CID.
• Selective deficiencies of one or more globulins—a deficiency of IgM in Arabian horses and Quarter horses is listed. IgM and IgA combined deficiencies with diminished but discernible levels of IgG are observed occasionally in horses. A transient hypogammaglobulinemia (absence of IgG) has been reported in one Arabian foal, which was immunodeficient until it was 3 months old and then became normal.
• Selective IgG2 deficiency in Red Danish cattle.
• A syndrome of immunodeficiency in Fell ponies and Dale ponies.5,6
• Common variable immunodeficiency is described in adult horses.4,5
• Lethal trait A46 (inherited parakeratosis) of cattle is a primary immunodeficiency influencing T lymphocytes, with impairment of cellular immunity.
• Selective IgG2 deficiency of cattle causes increased susceptibility to gangrenous mastitis and other infections. It is a primary deficiency of IgG2 synthesis and is recorded in the Red Danish milk breed.
• Sheep and pigs—there are as yet no recognized primary immunodeficiencies in these species.

SECONDARY IMMUNE DEFICIENCIES

Secondary immune deficiencies include the following:
• Failure of transfer of passive immunity (i.e., of antibodies from colostrum to the offspring) is well known as the commonest cause of deficient immunity in the newborn and is discussed in Chapter 20.
• Atrophy of lymphoid tissue and resulting lymphopenia are associated with the following:
  • Viral infections such as equine herpesvirus in newborn foals, rinderpest, bovine virus diarrhea, swine fever, porcine circovirus, and hog cholera. All of these cause lymphatic tissue suppression and a diminished immunoresponsiveness.
  • Bacterial infections such as Mycoplasma spp. and Mycobacterium paratuberculosis have approximately the same effect as the viral infections.
  • Physiologic stress, such as birth, may cause immunosuppression in the fetus, making it very susceptible to infection in the period immediately after birth. There is a similar depression of immunologic efficiency in the dam immediately after parturition, which, for example, leads to periparturient rise of worm infestation in ewes.
  • Toxins such as bracken, tetrachloroethylene-extracted soybean meal, T2 mycotoxin, and atomic irradiation suppress leukopoiesis. Immunosuppression is also attributed to many environmental pollutants, including polychlorinated biphenyls, 2,4,5-T contaminants, DDT, aflatoxin, and the heavy metals.
  • General suppression of immune system responsiveness; examples include the following:
    • Glucocorticoids administered in large doses or over long periods reduce the activity of neutrophils and the number of circulating lymphocytes, although the reduction varies widely between species. The production of antibodies is also reduced.
    • Nutritional deficiency, especially of zinc, pantothenic acid, calcium, and vitamin E, causes general suppression. A total caloric deficiency has a similar effect. Addition of certain trace elements, such as copper, iron, zinc, and selenium, in animal feeds is necessary for an adequate immunity. Selenium, alone or in combination with vitamin E, can enhance antibody responses, whereas its deficiency results in immunosuppression. Selenium supplementation in animal feeds is important to enhance both antibody production and phagocytic activity of neutrophils. In cattle, copper deficiency induced by molybdenum or iron can cause an impairment in the ability of neutrophils to kill ingested Candida albicans. Nutrients that stimulate disease resistance when administered to animals deficient in these nutrients include carotenoids; vitamins A, E, and C; zinc; manganese; copper; and selenium. Neonatal calves may have low reserves of carotene and vitamins A and E and are dependent on obtaining them from colostrum, which contains highly variable quantities. Administration of drugs that impair folate metabolism can induce anemia and depletion of white blood cells, with subsequent bacterial infection.
    • Experimentally, a protein–energy malnutrition in neonatal calves results in loss of body weight and decreased lymphocyte interleukin-2 activity and lymphocyte proliferation compared with calves of similar age.

• Exposure to cold and heat stress for periods of several weeks in duration
• Events associated with parturition, in particular glucocorticoid release, that impair innate immunity
• Alloimmune disease that suppresses bone-marrow activity

REFERENCES

Amyloidoses

The amyloidoses are a group of diseases characterized by the deposition of an extracellular proteinaceous substance, amyloid, in the tissues, with subsequent disruption of normal tissue architecture that eventually leads to organ dysfunction. Amyloidosis in farm animals usually occurs in association with a chronic supplicative process elsewhere in the body and is the result of accumulation of AA amyloid. Another form of the disease involves accumulation of AL amyloid, especially as localized disease in horses.

ETIOLOGY AND EPIDEMIOLOGY

Amyloidosis occurs rarely, and when it does occur it is most common in animals exposed systemically and repeatedly to antigenic substances. Examples include repeated injections of antigenic material for commercial production of hyperimmune serum and long-standing supplicative diseases or recurrent infection, as in Chédiak–Higashi syndrome. Severe strongylid parasitism in the horse has been reported as a cause. Holstein calves with bovine leukocyte adhesion deficiency have accumulation of amyloid in tissue, although this is not the primary disease. Many cases of amyloidosis in large animals are without apparent cause.

The incidence of visceral AA amyloidosis in slaughtered cattle in a group of 302 cattle older than 4 years of age in Japan was 5.0%; rates previously reported from Japan and other countries ranged from 0.4% to 2.7%. Systemic AA amyloidosis associated with tuberculosis has been described in a European wild boar. Systemic amyloidosis occurs in goat kids with chronic arthritis associated with seroconversion to Erysipelothrix rhusiopathiae. AA renal amyloidosis in cattle is often associated with traumatic reticuloperitonitis, metritis, mastitis, or pododermatitis, although 5 of 25 cows with AA amyloidosis did not have coexisting chronic inflammatory disease.

Out of 16,000 horses referred for clinical examination to a veterinary teaching hospital over a period of 13 years, 9 horses were identified as having amyloidosis. Cutaneous
Amyloidosis has been associated with malignant histiocytic lymphoma in horses. A case of cardiac amyloidosis causing heart failure in a 16-year-old Thoroughbred gelding has been described. The disease resulted from accumulation of AL amyloid. The AL form of amyloidosis is characteristically associated with unstable monoclonal immunoglobulin light chains produced by plasma-cell dyscrasia and resulting in deposition of AL fibrils.

**PATHOGENESIS**

How amyloid is formed is uncertain, but hyperglobulinemia is commonly present. This fact, together with the circumstances under which it occurs, suggests an abnormality of the antigen–antibody reaction. Amyloidoses are classified by the types of amyloid protein deposited. AA amyloid is derived from serum amyloid-A protein (SAA), which is an acute-phase reactant produced by hepatocytes. However, increased concentrations of SAA alone are not sufficient to cause amyloidosis. AA (secondary) amyloidosis is associated with recurrent acute or chronic infections, inflammatory disease, or neoplasia.

Extensive amyloid deposits may occur in the spleen, liver, or kidneys and cause major enlargement of these organs and serious depression of their functions. The commonest form that is clinically recognizable in animals is renal amyloidosis. This presents as a nephrotic syndrome with massive proteinuria and a consequent hypoproteinemia and edema. Terminally, the animal is uremic, becoming comatose and recumbent. The edema of the gut wall and its infiltration with amyloid create the conditions necessary for the development of diarrhea. In horses, cases of multiple cutaneous lesions are recorded. The amyloid is present in 5- to 25-mm diameter nodes in the skin of the head, neck, and pectoral regions.

Rare cases of involvement of the upper respiratory tract (nasal cavities, pharynx, larynx, gullet pouch and lymph nodes of the head and neck, and conjunctiva) occur in horses. The amyloid material deposited in these tissues is usually of the AL form, whereas systemic disease is almost always the AA form.

AL amyloidosis is also reported in an adult cow with bovine leukocyte adhesion deficiency.

**CLINICAL FINDINGS**

Many cases of amyloidosis are detected incidentally at necropsy. The cutaneous form in horses is characterized by the presence of hard, nonpainful, chronic plaques in the skin. Most of the lesions, which can be widespread and severe, are on the sides of the neck, shoulders, and head. Respiratory tract involvement in the horse is usually limited to the nasal cavities, and this may cause dyspnea. There is deposition of AA amyloid in the ciliary body of horses with recurrent uveitis, although the clinical importance of this finding is uncertain.

Chronic heart failure as a result of cardiac amyloidosis secondary to systemic amyloidosis in a 16-year-old gelding was characterized clinically by weight loss, dysphagia, recurrent episodes of esophageal obstruction, and anorexia of a few weeks in duration. Ventral edema, tachycardia, and irregular heart rate associated with atrial fibrillation were present. The clinical findings were consistent with biventricular heart failure from ventricular dysfunction, atrial fibrillation, and pulmonary hypertension. The amyloid was of the AL form.

A case of systemic AL amyloidosis associated with multiple myeloma in a horse was characterized clinically by rapid weight loss, muscle atrophy, soft unformed feces, and ventral edema. Amyloidosis in this situation is considered a paraneoplastic disease.

Hemoperitoneum and acute death secondary to splenic or hepatic rupture occurs in horses with systemic amyloidosis. Clinical cases in cattle are usually secondary to traumatic reticuloperitonitis, mastitis, metritis, or pododermatitis and are characterized by emaciation and enlargement of the spleen, liver, or kidneys; involvement of the kidney causes proteinuria and is often accompanied by profuse and chronic diarrhea, polydipsia, and anasarca. In cattle the grossly enlarged left kidney is usually palpable per rectum. Cases can manifest within 2 weeks of calving. They are characterized by anorexia, watery diarrhea, anasarca, rapid emaciation, and death in 2 to 5 weeks.

Corpora amylocacea are small, round concretions of amyloid material found in the mammary tissue of cows. They are usually inert but may cause blockage of the teat canal.

**CLINICAL PATHOLOGY**

An extreme and persistent proteinuria should suggest the presence of renal amyloidosis. Electrophoretic studies of serum may be of value in determining the presence of hyperglobulinemia. Serum alpha-globulin concentration is usually elevated and albumin concentration markedly depressed. Hypoproteinemia can be marked, with ventral edema frequently being present when the serum albumin concentration is less than 1.0 g/dL. Horses with hepatic amyloidosis have elevated activities of gamma-glutamyltransferase and, to a lesser extent, bile acids. In cattle there is hypoproteinemia, hypoalbuminemia, hypocalcemia, hyperfibrinogenemia, hypomagnesemia, high serum urea and creatinine concentration, and low-specific-gravity urine. Serum amyloid A and haptoglobin concentrations in the serum of cows with amyloidoses are higher than those in healthy cows, but not compared with cows with chronic inflammatory disease in the absence of amyloidosis.

Biopsy of cutaneous plaques is an accurate diagnostic technique.

**NECROPSY FINDINGS**

Amyloid can be detected in most organs of cows with systemic AA amyloidosis by histologic examination, including the liver, kidney, thyroid gland, adrenal gland, gastrointestinal mucosa, heart, lung, lymph nodes, ovary, hypophysis, uterus, mammary gland, and skeletal muscle. Grossly affected organs are enlarged and have a pale, waxy
The pathology of AA amyloidosis in domestic sheep and goats has been described. Most sheep with amyloidosis had pneumonia and other signs of chronic inflammation. Amyloid was detected in all grossly affected kidneys using Congo Red staining. Experimental induction of amyloidosis secondary to pneumonia in sheep results in deposition of amyloid in the gastrointestinal tract from the tongue to the rectum, with the most abundant deposition in the duodenum. Other body systems have only mild deposition of amyloid.

Deposits of amyloid in tissues may be made visible by staining with aqueous iodine. Amyloid is detected as green birefringence of Congo Red-stained tissues viewed under polarized light. AA and AL amyloidosis can be differentiated by treatment of tissue sections with potassium permanganate. Tissue containing AA will lose its green birefringence after treatment with potassium permanganate, whereas tissue containing AL will continue to appear green after Congo Red staining and viewing under polarized light.

The Shtrasburg method is now available for the identification of AA amyloid and to distinguish it from amyloid types in a large number of domestic and wild animals.

**DIFFERENTIAL DIAGNOSIS**

| Enlargement of parenchymatous organs associated with chronic suppurative processes should arouse suspicion of amyloidosis, especially if there is emaciation and marked proteinuria. |
|--------------------|--------------------------------------------------|
| Pylonephritis, nonspecific nephritis, and nephrosis bear a clinical similarity to amyloidosis. |

**TREATMENT**

There is no effective treatment of the systemic disease. The localized disease as occurs in the upper respiratory tract of horses can be treated by surgical excision, but the results are not encouraging.

**ZOONOTIC POTENTIAL**

There is discussion of the potential for AA amyloidosis to be a transmissible disease, although there is no evidence of a risk to human health from ingestion of meat and organs from cows with clinically inapparent amyloidosis.

**ALLERGY AND ANAPHYLAXIS**

Immune-mediated diseases in animals included here are those in which the fundamental abnormality is an exaggerated or misdirected immune response. Many diseases, and in particular infectious diseases, have an important component of their pathophysiology that is attributable to immune responses to the inciting agent. Although these responses can sometimes be deleterious to the animal, they are part of an expected immunologic reaction to the infectious agent. Examples of where a component of the immune response to an infection has an important role in the pathophysiology of the clinical disease include pneumonia in calves infected by *Mycoplasma bovis*, pneumonia in foals secondary to equine influenza virus infection, and enteritis and colitis secondary to salmonella infection.

Diseases manifest by allergy or anaphylaxis are characterized by exaggerated immune responses or reactions to otherwise innocuous stimuli. Examples in large animal medicine include immediate hypersensitivity reactions (anaphylaxis), milk allergy in Jersey cattle, dermatologic diseases (such as Queensland itch), neonatal isoimmune erythrolysis of foals, and purpura hemorrhagica.

There are four major mechanisms for the induction of a hypersensitivity response. They are classified as types I through IV based on the immune mechanism that elicits the disease state. Types I through III are antibody-mediated responses to antigen and include such conditions as systemic anaphylactic shock (type I), autoimmune hemolytic anemia (type II), and the local Arthus reaction (type III). Type IV hypersensitivity is caused by the induction of sensitized T lymphocytes and thus has a cell-mediated mechanism. The following description is minimalistic, including minimal mention of Th1 and Th2 responses, and readers are referred to texts dealing with veterinary immunology for more detail.

**TYPE I**

Type I disease is caused by binding of specific antigens by antibodies with local and/or systemic responses that occur within minutes. The antibody involved is almost always IgE, or its functional equivalent in species in which this role is fulfilled by a different class of antibody, that is bound to specific receptors on the surface of mast cells. Binding of the antigen to the surface-bound IgE precipitates release of inflammatory and vasoactive mediators, including histamine, various prostaglandins and leukotrienes, and cytokines (IL-4, IL-5, IL-6, IL-13, tumor necrosis factor alpha, and others), from the cells (“degranulation”), with subsequent local reactions of hyperemia and heat and systemic reactions such as constriction of smooth muscles (importantly, bronchial smooth muscle). Degranulation of mast cells also attracts eosinophils to the site with their subsequent degranulation and release of a wide variety of compounds, including cytokines, chemokines, enzymes, oxidants, prostanooids, and cationic granule proteins. The difference in manifestation of acute, immediate-type hypersensitivity reactions between species appears to depend largely on differences in the tissue site of antibody binding and the route of entry into the body of the inciting allergen. For example, insect bite hypersensitivity (Queensland itch) is the result of an IgE-mediated response to antigens in the saliva of biting insects—the inciting allergen is deposited in the skin when the insect bites the host. The disease is only manifest in horses that do not have an appropriate tempering immunologic reaction.

The high incidence of atopic hypersensitivity with familial predisposition seen in humans and dogs does not occur as frequently in large animals, although it is notable that there are breed differences in cell-mediated and antibody-mediated hypersensitivity reactions in cattle. Type I hypersensitivity is considered to be the mechanism for self-cure of gastrointestinal parasitism in sheep.

Anaphylaxis is the systemic manifestation of widespread and massive release of inflammatory mediators from mast cells. Signs are acute, occurring within minutes of exposure to the allergen, and severe, resulting in bronchoconstriction and leading to death in many cases.

Treatment involves prevention of exposure or removal of inciting allergens, administration of corticosteroids, and, in anaphylaxis, administration of drugs that counteract the severe bronchoconstriction (epinephrine). Antihistamines are minimally effective, likely because histamine is only one of numerous inflammatory activators released by mast cells and eosinophils.

**TYPE II**

Type II hypersensitivity reaction is caused by the binding of antibodies to antigenic sites on specific cell types (antibody-mediated cell cytotoxicity). The disease can occur because of the presence of antibodies against specific natural proteins on cell surfaces, such as occurs with neonatal isoerythrolysis or reactions to blood transfusions, or when foreign antigens, such as viruses or virus particles, bind to cell surfaces. Diseases include neonatal isoimmune hemolysis and thrombocytopenia.

**TYPE III**

Type III hypersensitivity reaction occurs as a result of formation of antibody–antigen
complexes, which then induce an inflammatory response in the host tissue. Examples include Arthus-type reaction or the Arthus phenomenon, which is evident as induration, erythema, edema, hemorrhage, and necrosis of the skin a few hours after intradermal injection of antigen into a previously sensitized animal; deposition of antibody–antigen complexes in the glomeruli, with resultant inflammation and tissue damage evident as glomerulonephritis; purpura hemorrhagica in equids; and in many viral diseases in which viruses are not neutralized by circulating antibodies (equine infectious anemia). The lesion results from the precipitation of antigen–antibody complexes, which causes complement activation and the release of complement fragments that are chemotactic for neutrophils; large numbers of neutrophils infiltrate the site and cause tissue destruction by release of lysosomal enzymes.

**TYPE IV**

Cell-mediated or delayed hypersensitivity is the basis for tuberculin and bovine paratuberculosis skin tests in cattle. The response is mediated by T cells and natural-killer (NK) cells. Allergic contact dermatitis, a cutaneous form of type IV hypersensitivity, is commonly identified in dogs and cats, but less so in large animals. Cattle can develop an allergic reaction to calcium cyanamide, a nitrogenous fertilizer, evident as allergic contact dermatitis.7 The disease occurred in 9 of 250 dairy cattle housed on flooring to reduce the risk of environmental mastitis. The cows developed alopecia, erythema, and crusting and pruritus of the udder, teats, ventral abdomen, and dewlap—all areas that contacted the ground surface. The disease can be severe and markedly affect the health and well-being of affected cows. Diagnosis is confirmed by skin-patch testing using cyanamide.4 Cattle can also develop delayed hypersensitivity to rubber in milking machines.5

A more severe form of type IV–mediated skin disease is toxic epidermal necrolysis (also known as Stevens–Johnson syndrome). This disease in humans is often associated with administration of medications. It occurs in calves infected with Mycoplasma bovis and is evident as pneumonia, arthritis, and severe skin lesions manifest as marked thickening of the epidermis, detachment of the epidermis from the dermis, and blisters in the detachment sites.5 Affected calves recovered, apparently in response to treatment with antimicrobials, a single administration of corticosteroid and pentoxifylline.

**Erythema multiforme** is a milder form of cutaneous expression of delayed hypersensitivity. It occurs in horses and cattle and is manifest as sudden onset of roughly symmetric erythematous wheals on the neck and dorsum with peripheral expansion and central clearing forming donut-like lesions. Lesions can persist for days to weeks and be moderately painful. Scaling, crusting, and alopecia are unusual. Lesions heal spontaneously. A similar disease is associated with cutaneous equine herpesvirus-5 infection, although the skin lesions were most severe on the muzzle and face.8

Delayed hypersensitivity reactions can contribute to the pathology of many diseases, such as mycoplasmal pneumonia in swine, but those are considered clinically under their initiating etiology.

**TREATMENT**

The treatment of allergic states is based on immediate treatment of signs of inflammation or allergy, usually by the administration of corticosteroids, antihistamines, or, in anaphylaxis, epinephrine, and prevention of continued exposure to the inciting allergen. Antihistamines have very limited usefulness, whereas corticosteroids have wide applicability and potent efficacy. The NSAIDs, including such drugs as flunixin meglumine, phenylbutazone, and meclofenamic acid, all inhibit prostaglandin synthesis and thus reduce inflammation but have only slight effect in treating allergic diseases.

**ANAPHYLAXIS AND ANAPHYLACTIC SHOCK**

Anaphylaxis is an acute disease of often life-threatening severity caused by an antigen–antibody (IgE) reaction. If severe it can result in anaphylactic shock.

**ETIOLOGY**

Most commonly, severe anaphylactic reactions are seen in farm animals following the parenteral administration of a drug or biological product. Other routes of entry of the allergen, such as via the respiratory or gastrointestinal tract, can also result in anaphylactic reactions. The reaction can occur at the site of exposure or in other areas.

The disease occurs because the animal is sensitized to the inciting allergen by previous exposure. The initial exposure usually does not result in any immediate clinical abnormalities, but subsequent exposure of the animal to the antigen results in rapid degranulation of mast cells and, subsequently, eosinophils, with widespread release of vasoactive and inflammatory mediators resulting in anaphylactic shock.

Although severe anaphylactic reactions occur usually after a second exposure to a sensitizing agent, reactions of similar severity can occur with no known prior exposure. In large animal practice this is most likely to occur after the injection of sera and bacteria, particularly heterologous sera and bacteria in which heterologous serum has been used in the culture medium.

Hypersensitivity reactions are sometimes observed at a higher incidence than normal in certain families and herds of cattle. Anaphylactic reactions can occur in the following circumstances:

- Repeated injection of biological preparations
- Repeated blood transfusions from the same incompatible donor or donors9
- Repeated injections of vaccines (e.g., those against foot-and-mouth disease and rabies)
- Injection of penicillin—although many presumed penicillin-induced anaphylactic reactions are in fact reactions to inadvertent intravenous administration of procaine or benzathine
- Similar rare occurrences after the injection of lyophilized *Brucella abortus* strain 19 vaccine and *Salmonella* vaccine
- Assumed anaphylactic reaction to ingested protein occurs in animals at pasture or in the feedlot.
- Cows, especially Channel Island cattle, can develop anaphylaxis when milking is stopped because the cows are being dried off; severe urticaria and respiratory distress occur 18 to 24 hours later.
- A systemic reaction after *Hypoderma* spp. larvae are killed in their subcutaneous sites might be anaphylactic, but is more likely to be a toxic effect from breakdown products of the larvae.
- After inadvertent intravenous administration of mare’s milk to a foal10

**PATHOGENESIS**

Anaphylactic reactions occur as the result of antigen reacting with cell-bound antibody. In humans, horses, and dogs a specific class of reaginic antibody, IgE, has been identified and has particular affinity for fixed tissue mast cells. The tissue distribution of mast cells in part accounts for the involvement of certain target organs in anaphylactic reactions in these species. Homocytotropic antibody has been detected in farm animals, but the classes of antibodies involved in anaphylactic reactions have not been fully identified and might be diverse. Anaphylactic antibodies can be transferred via colostrum.

Antigen–antibody reactions occurring in contact with, or in close proximity to, fixed tissue mast cells, basophils, and neutrophil leukocytes result in the activation of these cells to release pharmacologically active substances that mediate the subsequent anaphylactic reaction. These substances include biogenic amines, such as histamine, serotonin, and catecholamines; vasoactive polypeptides, such as kinins, cationic proteins, and anaphylatoxins; vasoactive lipids, such as prostaglandins; and slow-reacting substance of anaphylaxis (SRS-A), among others. Knowledge of the type and relative
importance of pharmacologic mediators of anaphylaxis in farm animals rests with studies of severe anaphylactic reactions that have been induced experimentally, but it is likely that these mediators are also of significance in less severe reactions. From these studies it appears that histamine is of less importance as a mediator in farm animals than in other species and that prostaglandins and SRS-A are of greater importance. Bradykinin and 5-hydroxytryptamine (5-HT) are also known to act as mediators in cattle, but the reactions in all species are complex and involve a sequence of mediator effects.

In horses, there are four phases in the development of the anaphylactic response. The first is acute hypotension combined with pulmonary arterial hypertension 2 to 3 minutes after the injection of the triggering agent; it coincides with histamine release. In the second phase, blood plasma 5-HT levels rise, and central venous blood pressure rises sharply at about 3 minutes and onward. The third phase commences at about 8 to 12 minutes and is largely reflex and manifested by a sharp rise in blood pressure and alternating apnea and dyspnea. Finally, there is a second and more protracted systemic hypotension as a result of prostaglandin and SRS-A influence, which persists until the return to normality.

In cattle, there is a similar diphasic systemic hypotension with marked pulmonary venous constriction and pulmonary artery hypertension. An increase in mesenteric venous pressure and mesenteric vascular resistance causes considerable pooling of blood on the venous side of the mesenteric vessels. In both cattle and horses these reactions are accompanied by severe hemoconcentration, leukopenia, thrombocytopenia, and hyperkalemia.

Sheep, goats, and pigs also show a largely pulmonary reaction.11 In horses and cattle, the marked changes in vascular tone coupled with increased capillary permeability, increased secretion of mucous glands, and bronchospasm are the primary reactions leading to the development of severe pulmonary congestion, edema, and emphysema and edema of the gut wall.

Less severe reactions are also dependent on the effect of mediators on capillary permeability, vascular tone, and mucous gland secretion. The major manifestation depends on the distribution of antibody-sensitized cells and of susceptible smooth muscle in the various organs. In cattle, reactions are generally referable to the respiratory tract, but the alimentary tract and skin are also target organs. Sheep and pigs show largely a pulmonary reaction, and horses manifest changes in the lungs, skin, and feet.

Sensitization of an animal requires about 10 days after first exposure to the antigen and persists for a very long time, usually months or years.

**CLINICAL FINDINGS**

**Cattle**
In cattle, initially there is a sudden onset of severe dyspnea, muscle shivering, and anxiety. In some cases, there is profuse salivation, in others moderate bloat, and yet others diarrhea. After an incompatible blood transfusion, the first sign is often hiccup. Additional signs are urticaria, angioneurotic edema, and rhinitis (Fig. 11-4). Muscle tremor can be severe, and a rise in temperature to 40.5°C (105°F) is often observed. On auscultation of the chest there can be increased breath sounds, crackles if edema is present, and emphysema in the later stages if dyspnea has been severe. In most surviving cases the signs have usually subsided within 24 hours, although dyspnea may persist if emphysema has occurred.

In natural cases the time delay after injection of the reagin intravenously is about 15 to 20 minutes, but in experimentally induced cases a severe reaction may be evident within 2 minutes of the injection and death within 7 to 10 minutes. Clinical signs include collapse, dyspnea, wild paddling, nystagmus, cyanosis, cough, and the discharge of a creamy, frothy fluid from the nostrils. Recovery, if it occurs, is complete in about 2 hours.

**Sheep, Goats, and Pigs**
In sheep, goats, and pigs, acute dyspnea is common.11 Goats with disease induced by sensitization to horse serum had respiratory distress, evident as increased respiratory rate, irregular respiration, coughing, abnormal lung sounds, reluctance to move, shivering or muscle tremors, paddling, and kicking.11

**Horses**
In the horse, naturally occurring anaphylactic shock is manifested by severe dyspnea,
distress, recumbency, and convulsions. Death can occur within less than 5 minutes, but it usually requires about an hour. Laminitis and angioneurotic edema are also common signs in the horse. Experimentally induced anaphylaxis can be fatal but not in such a short time. Within 30 minutes of injecting the reagin the horse has anxiety, tachycardia, cyanosis, and dyspnea. These signs are followed by congestion of conjunctival vessels, increased peristalsis, fluid diarrhea, generalized sweating, and erection of the hair. If recovery occurs, it is about 2 hours after the incident began. Death, if it occurs, takes place about 24 hours after the injection.

Pigs
In pigs, experimentally produced anaphylactic shock can be fatal within a few minutes, with systemic shock being severe within 2 minutes and death occurring in 5 to 10 minutes. The disease appears to occur in only one phase, in contrast to the four fairly distinct states in horses. Labored respiration, severe cyanosis, vomiting, and edema of the larynx, stomach, and gallbladder are the usual outcome.

CLINICAL PATHOLOGY
There are no pathognomonic changes in serum biochemistry or hematological variables. There is a marked increase in packed cell volume, a high plasma potassium concentration, and neutropenia. Tests for sensitivity to determine the specific sensitizing substance are rarely carried out for diagnostic purposes, but their use as an investigation tool is warranted. Serologic tests to determine the presence of antibodies to plant proteins in the diet have been used in this way.

NECROPSY FINDINGS
In acute anaphylaxis in young cattle and sheep the necropsy findings are confined to the lungs and are in the form of severe pulmonary edema and vascular engorgement. In adult cattle there is edema and emphysema without engorgement. In protracted anaphylaxis produced experimentally in young calves, the most prominent lesions are hyperemia and edema of the abomasum and small intestines. In pigs and sheep pulmonary emphysema is evident, and vascular engorgement of the lungs is pronounced in the latter. Pulmonary emphysema and widespread petechiation in the horse may be accompanied by massive edema and extravasations of blood in the wall of the large bowel. There may also be subcutaneous edema and lesions of lamineitis.

TREATMENT
Treatment should be administered immediately; a few minutes’ delay can result in death of the animal. Epinephrine is the most effective treatment for anaphylaxis and anaphylactic shock. Epinephrine administered intramuscularly (or one-fifth of the dose given intravenously) is often immediately effective, with the signs abating while the injection is being made. Corticosteroids potentiate the effect of epinephrine and can be given immediately following epinephrine. Antihistamines have been considered and were used commonly in the past, but they are likely ineffective, based on studies in humans, because they antagonize only one of many inflammatory mediators involved in the disease.

The identification of mediators other than histamine in anaphylactic reactions in farm animals has led to studies of the effectiveness of drugs more active against these mediators than antihistamines. Acetylsalicylic acid, sodium meclofenamate, and diethylcarbamazine have all shown ability to protect against experimentally induced anaphylaxis in cattle and horses. One of the important clinical decisions, especially in horse practice, is to decide whether an animal is sufficiently hypersensitive to be at risk when being treated. An acute anaphylactic reaction, and even death, can occur soon after intravenous injection of penicillin into a horse. In suspect cases it is customary to conduct an intradermal or a conjunctival test for hypersensitivity with a response time of about 20 minutes, but these tests have their limitations. The types of sensitivity are not necessarily related, there is no sure relationship between anaphylactic sensitivity and either skin (or conjunctival) sensitivity or circulating antibody, and the test often gives false negatives. The reason why some animals develop systemic hypersensitivity and some develop cutaneous hypersensitivity is unknown.

OTHER HYPERSENSITIVITY REACTIONS
Other hypersensitivity reactions include anaphylaxis of a less severe degree than anaphylactic shock and cases of cell-mediated delayed hypersensitivity. The resulting clinical signs vary depending on the tissues involved, but are usually localized and mild.

ETIOLOGY
Exposure to any of the etiologic agents described under anaphylaxis may result in this milder form of hypersensitivity. Exposure may occur by injection, by ingestion, by inhalation, or by contact with the skin.

PATHOGENESIS
In anaphylactic reactions the clinical signs may depend on the portal of entry. Thus ingestion may lead to gastrointestinal signs of diarrhea, and inhalation may lead to conjunctivitis, rhinitis, and laryngeal and bronchial edema. Cutaneous lesions can result from introduction of the reagin via any portal. They are usually manifested by angioedema, urticaria, or a maculopapular reaction. All the lesions result from the liberation of histamine, serotonin (5-HT), and plasma kinins, as in anaphylactic shock.

CLINICAL FINDINGS
In ruminants, inhalation of a sensitizing antigen can cause the development of allergic rhinitis. On ingestion of the sensitizing agent there may be a sharp attack of diarrhea and the appearance of urticaria or angioneurotic edema; in ruminants mild bloat can occur. Contact allergy is usually manifested by eczema. In farm animals the eczematous lesion is commonly restricted to the skin of the lower limbs, particularly behind the pastern, and at the bulbs of the heels, or to the midline of the back if the allergy is a result of insect bites. In many cases of allergic disease the signs are very transient and often disappear spontaneously within a few hours. Cases vary in severity from mild signs in a single system to a systemic illness resembling anaphylactic shock. On the other hand, cases of anaphylaxis may be accompanied by local allergic lesions.

DIFFERENTIAL DIAGNOSIS
The transitory nature of allergic manifestations is often a good guide, as are the types of lesions and signs encountered. The response to antihistamine drugs is also a useful indicator. Skin test programs as applied to humans should be utilized when recurrent herd problems exist. The differential diagnosis of allergy is discussed under the specific diseases listed earlier.

TREATMENT
Administration of corticosteroids is usually highly effective. Continued exposure to the allergen may result in recurrence or persistence of the signs. Hypersensitization therapy
CASEOUS LYMPHADENITIS OF SHEEP AND GOATS

SYNOPSIS

Etiology Corynebacterium pseudotuberculosis

Epidemiology Disease of sheep and goats. Source of infection is discharge from pulmonary or skin abscesses. Infection is through intact skin or skin wounds. Transmission in sheep occurs at shearing and dipping in sheep and goats by direct contact.

Clinical findings Abscesses in superficial lymph nodes. Respiratory or wasting disease associated with internal abscesses.

Clinical pathology Enzyme-linked immunosorbent assay (ELISA) tests can be used to determine flock status, but sensitivity and specificity are inadequate to provide reliable identification of infected individuals.

Necropsy findings Abscesses in lymph nodes and internal organs.

Diagnostic confirmation The clinical and necropsy features are typical. Confirmation is by bacterial culture.

Treatment Surgical for superficial abscesses.

Control Culling of affected sheep or based on serologic testing, hygiene at shearing, avoidance of management risk factors, vaccination.

ETIOLOGY

Corynebacterium pseudotuberculosis is the specific cause of the disease. Ovine/caprine isolates are largely a clonal population, distinct from the equine/bovine biotype. Both biotypes produce an exotoxin, phospholipase D, which functions as a sphingomyelinase and is an immunodominant antigen. Variation in toxin production between strains may be related to differences in pathogenicity. The toxic lipid cell wall mediates resistance to killing by phagocytes and is also a virulence factor.

C. pseudotuberculosis is also the cause of ulcerative lymphangitis of cattle and horses and contagious acne of horses, but these have been discussed as separate diseases because they appear to have a separate pathogenesis and do not occur in association with caseous lymphadenitis.

EPIDEMIOLOGY

Geographic Occurrence

Caseous lymphadenitis occurs in the major sheep-producing countries in the world, including Australia, New Zealand, South Africa, the Middle East, North and South America, the United Kingdom, and most of northern and southern Europe. The disease did not occur in the United Kingdom and the Netherlands until the importation of infected goats in the late 1980s but subsequently spread to be an important disease in both countries.

Host Occurrence

Caseous lymphadenitis occurs in sheep and goats.

Sheep

Caseous lymphadenitis increases in prevalence with age and reaches a peak incidence in adults. In one Australian population of unvaccinated sheep the frequency of infection at slaughter was 3.4% for lambs and 54% for adult ewes, and a similar prevalence has been recorded in North and South America. In another large study of mature sheep in Australia the overall prevalence of lesions at slaughter was 3.4% for lambs and 54% for adult ewes, and a similar prevalence has been recorded in North and South America. In another large study of mature sheep in Australia the overall prevalence of lesions at slaughter was 3.4% for lambs and 54% for adult ewes, and a similar prevalence has been recorded in North and South America. In another large study of mature sheep in Australia the overall prevalence of lesions at slaughter was 3.4% for lambs and 54% for adult ewes, and a similar prevalence has been recorded in North and South America. Age and Sex

There is a higher prevalence in older sheep, which probably reflects greater exposure to risk factors such as shearing and dipping. In the United Kingdom a disproportionate number of rams are infected, and there is a significant prevalence of infection in terminal sire breeds, which are an important vector to otherwise closed flocks. The prevalence in rams may be related to the high stocking rate at which rams are kept for most of the year and fighting behavior with transmission through head wounds.

Breed

All breeds are susceptible, but in New Zealand, which has a mix of fine wool and meat sheep breeds, the prevalence of disease is higher in Merino and Merino-cross breeds. This may relate to greater susceptibility to skin damage at shearing because of their finer skin and the presence of neck wrinkles. In the United Kingdom, infection was initially more prevalent in terminal sire breeds but subsequently spread to hill and upland flocks.

Shearing

Shearing is a major risk factor in sheep; in general, infection rates increase with the...
number of times sheep have been shorn. When spread occurs, it occurs mostly within groups of sheep shorn together. Sheep may be infected by transfer of pus from abscesses discharging or cut at shearing, via shearing combs, but spread from sheep with discharging pulmonary abscesses to sheep with skin cuts is considered more important.

Close contact of recently shorn sheep in any circumstance may facilitate transmission through contact between infected respiratory secretions and susceptible skin. Sheep are commonly in close contact in collecting pens immediately following shearing, or before dipping, and infected nasal and oral secretions can be deposited directly onto shearing cuts. Keeping sheep under cover for more than an hour after shearing increases the odds for spread.

Poor hygiene in the shearing shed, allowing contamination of shearing boards and holding pens, may facilitate infection of sheep. Movement of infection between flocks can occur through contamination of shearing equipment, mobile shearing sheds, or dips and infection on the clothing of shearers. Contract shearing has been shown to be a risk factor in the United Kingdom.

**Dust**
Dust from contaminated yards may transmit infection to recently shorn sheep, although epidemiologic studies suggest that environmental contamination is not a major risk factor for disease in Australia.

**Housing**
Close contact associated with high stocking rates at pasture or indoor housing for much of the year may lead to high rates of infection. The difference in lesion distribution between sheep in the United Kingdom and Australia is believed to be the result of close contact at shared feed troughs under conditions of intensive husbandry in the United Kingdom.

**Dips**
The organism can persist in reused (plunge dip) or recycled (shower dip) fluids used for ectoparasite control. As few as 25 organisms/mL in the dip can produce infection. Sheep dipped in infected dipping fluid within a few days of having been shorn are especially susceptible to infection because of the ease of contact between the bacteria and the skin, but spread can also occur through dipping sheep shorn 6 months previously. In an experimental study in which infection-free sheep were shorn and exposed to artificially contaminated dips at 0, 2, 4, 8, and 24 weeks after shearing, a larger percentage of the sheep dipped immediately after shearing seroconverted and had lymph node lesions at slaughter. However, lesions also were present at slaughter in sheared dip 2 or more weeks after shearing, and there was no significant difference in their prevalence in the groups dipped at 2 to 24 weeks after shearing. This supports the observation that infection can occur through intact skin, possibly in the case of dip-associated infections, influenced by loss of wool grease because of wetting agents in the dip. Shower dipping of sheep immediately after shearing also significantly increases the odds of a high incidence of caseous lymphadenitis.

Although shearing and dipping are important risk factors, disease can also be transmitted from sheep with pulmonary abscesses to nonshorn sheep by aerosols.

**Goats**
Shearing is not a risk factor, other than with Angoras. The difference in abscess distribution in goats compared with sheep, with a predomiance in the head, neck, and sternum in goats, suggests that contact, fomites, and trauma are important vector mechanisms. Social contact, head butting, trauma from browse, and the use of common neck collars and feed troughs are probable risk factors. Pulmonary abscesses are not as prevalent in goats as in sheep and may be of lesser importance as a source of infection.

With both sheep and goats, contamination of soil on bedding grounds, in yards, or in shelters may result in persistence of the organism in the environment for periods significant to the transmission of the disease and can result in infection of wounds created by docking and castration and infection in the region of the sternum.

**Economic Importance**
In the majority of young infected animals there is no overt clinical disease or impairment of health other than visible abscessation, but the disease is of considerable economic importance to the sheep and goat industries. In sheep, infection has been associated with a 6.6% reduction in clean fleece weight in the first year of infection and a reduction in growth rate. Infection is a significant cause of condemnation of carcass for human consumption, with condemnation rates as high as 3% to 5% for mutton carcasses and 0.02% to 0.03% for lamb carcasses. Condemnation rates and economic loss vary depending on the country, with differences in the number of abscessed lymph nodes dictating condemnation rather than carcass trimming.

In goats the hide can represent a significant proportion of the value of the carcass, and blemishes produced by infection markedly reduce hide value. Clinical disease occurs in animals with disseminated visceral form, which is a cause of reproductive inefficiency, a major cause of the thin ewe syndrome, and a cause of death and culling in older sheep in infected flocks.

**Zoonotic Implications**
Human infection is rare, produces a lymphadenitis with a long and recurrent course, and is an occupational disease of shearsers and abattoir workers with infection occurring through cuts. *C. pseudotuberculosis* may be present in the milk of goats from udders where the mammary lymph node is affected.

**PATHOGENESIS**
Multiple microscopic abscesses develop in the draining lymph node by 1 day after experimental infection in the skin, and between 3 and 10 days of infection these coalesce to form typical pyogranulomas. The sphingomyelin-specific phospholipase D exotoxin produced by the organism is believed to facilitate spread of infection by promoting leakage of plasma from small blood vessels at the site of infection, with flooding of lymphatic spaces. Abscesses develop in 60% to 80% of infected sheep. The high lipid content of the bacterial cell wall gives resistance to the digestive enzymes of the phagocyte, and the organism persists as a facultative intracellular parasite.

The reduction of wool growth in the first year of infection probably results from the catabolic effects of cytokine and toxic metabolites released during the acute inflammatory and immune response to initial infection.

Hematogenous spread of the organism results in abscess formation in many organs, and these may occur in the absence of peripheral lesions. Up to 25% of affected sheep at abattoirs are recorded as having lesions only in thoracic viscera. This tendency for a high incidence of lesions in the lung appears to be general, but prevalence varies considerably between geographic areas. The abdominal visceral and somatic tissues are also commonly affected. Less commonly, hematogenous infection occurs in young lambs to produce septicaemic disease.

**CLINICAL FINDINGS**
There is palpable enlargement of one or more of the superficial lymph nodes. Those most commonly affected are the submaxillary, prescapular, prefemoral, supramammary, and popliteal nodes (Fig. 11-5). The abscesses commonly rupture, and creamy to caseated pus, with no odor, is discharged. Goats have a much greater proportion of lesions in the lymph nodes draining the head, related possibly to superficial injury during browsing. Abscesses may subsequently develop in other lymph nodes. In the United Kingdom, clinical signs of infection in sheep are most commonly associated with the superficial lymph nodes of the head and neck, although in one study over 30% of sheep were found to have visceral lesions. Both sheep and goats may also show abscess in the skin, particularly of the face, with loss of overlying hair.

In cases in which systemic involvement occurs, chronic pneumonia, pyelonephritis, ataxia, and paraplegia may be present, depending on the site of infection. The debilitating disease of adult ewes commonly
referred to as thin ewe syndrome is often associated with the occurrence of internal abscesses (81% of ewes), many of which contain *C. pseudotuberculosis* (86%). Other bacteria, especially *Moraxella* spp., are also commonly present. In ewes, local spread from the supramammary lymph node to the mammary tissue is common. The resulting fall in milk yield leads to poor growth and even death of lambs, and this may be a serious economic feature in badly affected flocks. Intrascrotal lesions are common in rams but do not involve the testicles or semen.

**CLINICAL PATHOLOGY**

There is an increase in blood lymphocytes and neutrophils. *C. pseudotuberculosis* can be cultured from pus obtained by needle biopsy or by transtracheal wash. Serologic tests that have been used in serodiagnosis include indirect hemagglutination, hemolysis inhibition, synergic hemolysis inhibition, immunodiffusion, and ELISA tests to detect antibody to cell-wall antigens or to the phospholipase exoenzyme. Many of these tests have good specificity but few have high specificity and sensitivity. Some have been used to determine flock infection and have been used in eradication schemes. As yet, none is sufficiently reliable to confidently detect infection in individual sheep. The sensitivity of equivalent tests in goats is generally higher, and they are used for official control schemes in goats in some countries, such as the Netherlands.

Radiography and ultrasonography may be useful diagnostic tests in sheep and goats with chronic weight loss and no enlarged external lymph nodes. Radiographs of the thorax may reveal the presence of abscesses in the mediastinal lymph nodes. Ultrasonography of the abdomen may reveal the presence of one or more liver or kidney abscesses. Classic ultrasonographic signs of caseous lymphadenitis abscess is an “onion peel” abscess, which is particularly easy to image in liver parenchyma (Fig. 11-6).

**NECROPSY FINDINGS**

Caseous abscesses filled with greenish-yellow pus occur chiefly in lymph nodes and to a lesser extent in internal organs. In the early stages the pus is soft and pasty, but in the later stages it is firm and dry and has a characteristic lamellated appearance. Locally extensive bronchopneumonia, with more fluid pus of a similar color, may also be present. Microscopically, nodal architecture is effaced by the abscess. As the lesion expands, the limiting fibrous wall keeps re-forming, creating the “onion-skin” layering noted grossly.

**Samples for Confirmation of Diagnosis**

- Bacteriology—lymph node, lung, culture swab from outer portion of abscess (CULT)
Differential Diagnosis

Melioidosis
Tularemia
Other causes of pneumonia in small ruminants
Lymphosarcoma (rare)

Suppurative lymphadenitis in lambs has also been found to be associated with infection with Pasteurella multocida, and a disease characterized by the presence of yellow–green pus in abscesses situated in close proximity to the lymph nodes of sheep is associated with a gram-positive micrococcus. The latter disease occurs in France and Kenya and is referred to as Morel’s disease.

Treatment

The organism is susceptible to antibiotics other than the aminoglycoside group, but treatment is not usually attempted because the abscess is encapsulated, the organism is intracellular, and response is poor. Subcutaneous abscesses can be treated with surgical drainage or extirpation.

Control Culling

A measure of control can be achieved by culling all animals with enlarged lymph nodes. Although this is a logical procedure, it is worth noting that it is not capable of detecting early lesions or of detecting those animals with internal abscess but no external abscesses. Ideally, control would be by the identification and culling of infected animals using serologic testing. Culling on the basis of serologic tests has been used in goat herds in the Netherlands, small pedigree flocks in the United Kingdom, and a larger flock of 1000 sheep in Scotland. The increased sensitivity and specificity of current ELISA tests (87% to 93.5% and 98%, respectively) makes this a feasible strategy, although large numbers of seropositive sheep may be detected and require culling (e.g., 159 following 9 tests in a flock that originally had 108 sheep). Thus, the cost-effectiveness of test and cull, as opposed to control using vaccination, will be marginal unless the test-and-cull strategy is supported by other funding.

Control of Spread

The Mules operation is being gradually phased out in Australian flocks, but all docking implements, ear-taggers, and shears used for this procedure should be dipped in strong disinfectant before each use. Similar attention should be given to the combs and cutters at shearing time. There should be good hygiene and disinfection in the shearing shed, especially of the shearing board and holding pens. Mobile shearing trailers should be cleaned and disinfected between farms. The importance of personal hygiene should be impressed on shearers, and farm-specific overclothing should be provided if possible. Younger age groups should be shorn first, rams second to last, and any sheep with palpable lesions last. Puś spilled on the shearing floor should be cleaned up and the area disinfected. All shearing cuts should be disinfected. There can still be a high abscess rate in flocks that practice these control procedures.

Close contact of sheep following shearing should be avoided. All efforts must also be directed to avoid contaminating dipping fluid; one discharging abscess is capable of contaminating an entire tank of fluid. Dipping after shearing may be undesirable in badly affected flocks. The addition of an efficient bactericidal agent to the dipping fluid is worthy of consideration.

Goat housing should be free of wire or other causes of skin trauma, and communal use of equipment such as neck collars should be avoided. External parasites must be controlled. Goat herds that are free of the disease should avoid the purchase of animals from herds with a history of abscession.

Vaccination

Vaccines formulated from concentrated, formalin-inactivated C. pseudotuberculosis culture supernatants containing phospholipase D have considerable efficacy and are available in many countries. Attenuated mutant vaccines also show promise. Vaccination does not provide complete protection against the development of abscesses. Controlled field trials show a significant reduction in the number of sheep that develop abscesses and a reduction in the number of abscesses in infected sheep. Vaccinated sheep have fewer lung abscesses than unvaccinated sheep, in one study 96% fewer, and are less likely to spread infection from this source. Compliance with the recommended full course of the vaccine has an important influence on the efficacy of vaccination. An Australian study showed that flocks that followed the recommended protocol of two priming doses to lambs with yearly boosters to adult sheep throughout their life had an average slaughter prevalence of infection in sheep of 3%, whereas the average prevalence of lesioned sheep at slaughter from flocks that only partially followed this protocol, by administering a single dose to lambs or not giving yearly boosters to adult sheep, varied from 22% to 33%.

Immunity to caseous lymphadenitis is believed to be associated with antitoxin activity and primarily cell mediated, but colostral immunity will protect against experimental challenge at 6 weeks of life. Colostral immunity will also affect the development of immunity from vaccination, and lambs in flocks with a high prevalence of caseous lymphadenitis should not be vaccinated at less than 10 weeks of age.

Vaccination appears less successful in goats, and although it protects against experimental challenge and spread of the organism from the site of infection, there has been little protection from natural infection in field trials.

Prevention

All potential introductions to a flock should be examined clinically for evidence of disease. Although this is not a particularly sensitive method of detection of infection, obvious clinical cases will be detected. Determining the infection status of the source flock is a safer procedure, and if high-level control or eradication is an aim, purchases should be direct and not through markets. The ultimate method of prevention would include serologic testing of individual animal introductions when tests with very high sensitivity become available.

Eradication

Eradication is reported in endemically infected flocks by initial culling of all sheep with clinical signs and subsequent serologic testing and culling of reactors. In one case, seropositive ewes were allowed to lamb before culling but lambs were removed at birth, isolated from the infected dams, and fed cow’s colostrum and milk replacer. These procedures were coupled with rigorous disinfection of facilities, removal of bedding and topsoil from barns and pens, isolation of seronegative sheep for 6 months from previously used pastures and tracks, and hygiene at skin-damaging management procedures. Serologically positive sheep were not detected after the second screening. Attempted eradication in an extensively managed hill flock in Scotland eliminated clinical disease for 2 years following eight tests during a test-and-cull program using an improved ELISA that lasted 2 years, although two seropositive sheep were detected at the last test.

Total herd or flock eradication and replacement with infection-free animals is also possible, but there is a risk of reintroduction of the disease given that the sensitivity of the current ELISA tests used for screening is only around 90%. The sensitivity and specificity of a bulk milk ELISA were 41.4% and 81.7%, respectively, and thus the screening of bulk milk may be a cost-effective way of initially detecting caseous lymphadenitis infection in dairy goats.

Further Reading

BOVINE FARCY

Bovine farcy, a chronic infectious disease affecting the lymph nodes of Zubu cattle; it is endemic in sub-Saharan Africa but has been reported in 19 countries in Africa, Asia, Latin America, and the Caribbean. In Africa, the disease is caused by *Mycobacterium farcinogenes* in the eastern and central regions and *M. senegalense* in the western region. Both species are rapidly growing, gram-positive, branching, and acid-fast mycobacteria. It is not yet certain whether *Nocardia farcinica* in other parts of the world causes cutaneous nocardiosis (farcy) in animals that mimics bovine farcy. 

Epidemiologic data indicate that bovine farcy occurs in adult cattle of the transhumance pastoralist tribes of the Sahel and Sudanian savannah zones. In some areas, 25% to 30% of cattle used to be affected, but the disease has disappeared from many countries where it was once a problem. Other domestic and nondomestic animals are not affected. It is not known whether the bacteria are zoonotic, even though an earlier study indicated that the human pathogen *Mycobacterium peregrinum* type II belongs to the species *M. senegalense*. Ixodid ticks, including *A. variegatum*, may play a role in disease transmission; breeds of cattle resistant to ticks (e.g., the N'Dama) are resistant to farcy.

Bovine farcy causes some economic losses as a result of damaged hides and also as a public health burden because the lesions resemble those of bovine tuberculosiss in carcasses, and thus the meat from affected animals is considered inappropriate for human consumption. For example, in a study involving 6680 bovine carcasses in Sudan, 400 caseous lesions were identified, only 12 of which were a result of bovine tuberculosis, whereas 59 were caused by bovine farcy. 

The clinical diagnosis of bovine farcy in the late stage of the disease is not difficult because the cordlike nodular lesions in the skin and lymphatics are almost pathognomonic. Laboratory diagnosis is by conventional smears stained with acid-fast stain and by culture. Molecular and serologic tests developed still need to be evaluated for sensitivity and specificity, but the ELISA can be used to support early clinical diagnosis, in epidemiologic surveys, and for screening before animals are exported to farcy-free regions.

The disease is slowly progressive, and lesions occur in superficial lymph nodes, mostly in the prescapular and precrural lymph nodes. Affected lymph nodes suppurate, and there is induration of the lymphatic vessels. There can be infection in the mesenteric lymph nodes, with some cases having lesions in the udder or the lung. Lesions are common in areas of the body where *A. variegatum* ticks attach. Histologic examination shows a severe granulomatous reaction characterized by lymphocyte, macrophage, epithelioid, and giant-cell infiltration, along with marked fibrin proliferation. The agent can be detected in tissue sections by acid-fast staining and by PCR techniques.

Treatment is not recommended and there is no vaccine. Most cases are detected at slaughter.

SPORADIC LYMPHANGITIS (BIGLEG, WEED)

Sporadic lymphangitis is also called Monday morning disease. It is an uncommon occurrence. It can affect any breed of horse but particularly heavy draught horses. It usually affects single horses, but occasionally outbreaks do occur. There are a few predisposing factors. The most frequent one is rest from work and exercise for 1 to 3 days. Another suspected factor is a change from a low-quality diet to a diet high in protein, such as peas or beans. Both of these may lead to a slowing down of lymphatic flow in the limbs, facilitating ingestion of any bacteria trapped on the legs in small wounds or cracks. Dirty stables may also predispose, although the condition is seen in very hygienic stables at times. Continual wet weather may also be a predisposing factor.

This is a noncontagious disease of horses characterized by acute fever, lymphangitis, and severe swelling of one or both hindlegs—forelimbs are rarely, if ever, affected. The disease commences abruptly with fever (40.5°C to 41°C; 105°F to 106°F), shivering, and a rapid pulse rate and respiration. Horses are usually very thirsty. The mouth may be hot and the mucous membranes injected. Lameness rapidly results. Pain in the acute disease can be severe. There is severe pain on palpation of the affected leg, and lameness may be so severe that the horse may refuse to put its foot to the ground. The limb is swollen and hot; the swelling extends from the top of the leg and down to the coronet. There is cording of the lymphatics on the medical aspect of the leg and palpable enlargement of the lymph nodes in some horses. There may be exudate on the skin. Affected legs may pit under pressure. The horses may show perspiration. The acute disease may last only 1 to 3 days, and recovery or conversion into a chronic phase with persistent and variable swelling of the leg, intermittent fever, and variable lameness follows. Occasionally abscesses develop in the lymph nodes and vessels, but usually there is no localization of the infection. There is a tendency for the disease to recur and cause chronic fibrotic thickening of the lower part of the limb extending to the level of the stifle in many horses. Swelling of the leg is often exacerbated by late pregnancy.

Horses that have had one attack appear to be prone to further attacks. Recurrences produce a “thick leg,” which is not a result of fluid but of connective tissue.

Sporadic lymphangitis can be associated with superficial wounds and ulcers on the lower parts of the limbs, but often there are no wounds detected. The disease is thought to develop as a lymphangitis and, potentially, lymphadenitis of the deep inguinal nodes as a result of these wounds. The affected lymph nodes and swelling of the limb obstruct lymphatic and venous drainage, causing lymphatic obstruction, edema, and, in some cases, cellulitis. Ultrasonographic examination reveals distended lymph vessels that contain fluid that is not echogenic. Ultrasound-guided aspiration of this fluid yields fluid with a low total protein concentration and mild neutrophilia (high proportion of the cells present in the fluid are neutrophils, although the absolute count is usually less than 1.0 × 10^9 cells/L).

Culture of the fluid is recommended. *Actinobacillus spp.*, *Staphylococcus*, *Streptococcus*, *Pasteurella*, *Pseudomonas*, *Fusobacterium*, and *Nocardia* have been isolated at times. In many cases there are negative culture results, possibly because the causative agent is difficult to culture, but in some cases *Corynebacterium pseudotuberculosis* has been isolated, and this appears to be a seasonal occurrence in the late summer and autumn in the United States. The clinical significance of results of culture of the fluid is unknown, but results could be used to guide the choice of antibiotics. Radiographic examination is usually unremarkable, apart from demonstrating soft tissue swelling. Affected horses, in both the acute and chronic stages, have mild neutrophilia and hyperfibrinogenemia.

It is a difficult disorder to treat effectively. Acutely affected horses should be treated aggressively. The principles of treatment are control of the presumed infection, reduction

REFERENCES

of inflammation, and reduction of swelling. Penicillin or other antimicrobials should be administered parenterally to control the infection. Infection with *Corynebacterium* requires Rifampin. NSAIDs (flunixin is the first choice, but also phenylbutazone, meglu- mine, carprofen, or similar) should be administered to control the inflammation and provide pain relief. The limb should be hosed with cold water once to twice daily to reduce heat and provided with gentle massage therapy. Manual massage of the limb might be beneficial. Supportive, compressive bandaging of the limb can reduce the swelling. The horse should be exercised as much as is practical and humane.

Horses with chronic disease should be treated with prolonged courses of antimicrobials (penicillin, sulfonamide—trimethoprim combinations, enrofloxacin, or rifampin in combination with sulfonamide—trimethoprim), nonsteroidal drugs, and local therapy. Acute exacerbations can be managed by administration of dexamethasone (40 μg/ kg orally or parenterally, once daily for 5 days, and then gradually tapering). This dose is not abortifacient in pregnant mares. Exercise and supportive bandaging are important in minimizing the swelling. The chronic disease requires prolonged and intermittent therapy, often for the rest of the horse’s life.

Differential diagnoses include cellulitis (inflammation of the connective tissues) and ulcerative lymphangitis. Ulcerative lymphangitis is often accompanied by cording of the lymphatics, the formation of hard nodules, and the occurrence of abscesses with a discharge of greenish fetid fluid. Epi- zootic lymphangitis caused by *Histoplasma farciminosum* in Asia and the Mediterranean is a differential diagnosis. In the Middle East, Eastern Asia, Eastern Europe, and North Africa, Glanders is also a possibility. Sporotrichosis *(Sporothrix schenckii)* can also be a differential diagnosis.

Prevention of the disease necessitates prompt and careful treatment of all wounds of the lower limbs. Provision of daily exercise, restriction of the diet during prolonged rest periods, and dry standing in the stable also help to prevent the disease. Animals compelled to stabling should have a reduced diet, with corn being replaced by bran mash. The legs should be kept clean and disinfected if animals are stabled. Animals affected with the chronic condition should be kept constantly at reasonable work.

**TICK-BORNE FEVER (ANAPLASMA PHAGOCYTOPHILA)**

**SYNOPSIS**

**Etiology** Anaplasma phagocytophilum

**Epidemiology** Occurs in the northern latitudes and is transmitted by Ixodes

---

**ETIOLOGY**

Tick-borne fever (also called pasture fever in cattle) is a tick-transmitted disease of sheep and cattle in the northern hemisphere and is caused by *Anaplasma phagocytophilum* (formerly *Ehrlichia phagocytophila*, *Cytocetes phagocytophila*, and *Ehrlichia equi*). The genus *Anaplasma* *(Rickettsiales: Anaplasma- phagocytophiaceae)* contains obligate intracellular gram-negative bacteria found exclusively within membrane-bound inclusions or vacuoles in the cytoplasm of both vertebrate and invertebrate (tick) host cells. The genus includes *A. marginale*, *A. centrale*, *A. bovis*, and *A. ovis* which are pathogens of ruminants; *A. phagocytophilum*, which affects a wide range of hosts, including humans, wildlife, and domestic animals; and *A. platys*, which infects dogs. *A. phagocytophilum* replicates primarily in the cytoplasm of neutrophils and is 0.4 to 1.3 um in size. The life cycle is biphasic, transitioning between the noninfectious reticulate cell that replicates and the smaller dense core form that is infective to mammalian and tick cells.1–2

There are strains (variants) of *A. phagocyto- philum* that have biological and ecological differences, including variations in host pathogenicity, vectors, and geographic distribution. Although the mechanisms for these differences remain largely elusive,3–5 the type IV secretion system (T4SS) may play a role in strain virulence of *A. phagocytophilum*.6 In sheep, different variants of *A. phagocytophi- lum* may exist simultaneously in the same sheep flock.

Tick-borne fever is also used as a name for similar, but less well-defined, diseases of ruminants that are associated with infection with related organisms such as *Anaplasma (Ehrlichia) bovis*. These are reported from other areas of the world, such as India and Africa, and are transmitted by the ticks *Rhipicephalus appendiculatus*, *Amblyomma variegatum*, and *Hyalomma truncatum*.

Currently, *A. phagocytophilum* is viewed as a single bacterial species capable of infecting a broad range of hosts and is based on 16S rRNA gene analysis.7 The description that follows is of tick-borne fever of sheep and goats and pasture fever of cattle associated with *A. phagocytophilum*.

**EPIDEMIOLOGY**

**Occurrence**

Infection with *A. phagocytophilum* occurs in a wide range of mammalian hosts, including humans, dogs, sheep, cows, horses, wild deer, and rodents. The association of *A. phagocyto- philum* with human granulocytic ehrlichiosis in the mid-1990s has led to much activity in defining its geographic occurrence by serologic surveys or detection in ticks by molecular methods. These studies have determined that the organism is present where the host ticks are present in Europe, North America, the Middle East, and Asia.8 *A. phagocytophilum* is arguably the most widespread tick-borne infection in animals in Europe.9

However, the disease tick-borne fever, as opposed to infection, occurs primarily in certain areas of the United Kingdom, Ireland, Norway, Finland, France, Germany, Spain, and Switzerland. Because ticks favor particular optimal environmental conditions, the geographic distribution of the ticks is usually restricted to a specific area (small or large), and tick-borne fever only occurs in these areas. Within these areas infection can be intense; in the endemic coastal area of Norway, close to 100% of sheep grazing *Ixo- des*-infested pastures are infected. Tick-borne fever has a seasonal occurrence in association with the feeding activity of the vector tick. Infection can be endemic in affected areas.

Sheep, cattle, goats, deer, and reindeer may be infected. The disease has long been known as a disease of sheep but in recent years is being recognized as a common infection in cattle at-risk areas. The incidence rate of infection is high, but clinical disease may be mild and not easily observed in many areas where this disease occurs because these areas are commonly wild with little human habitation and little frequent observation of at-risk livestock. Infection, as determined by seropositivity, can occur in sheep that have had no clinical evidence of disease because of the existence of variants with low pathogenicity. The disease in horses, previously known as Equine Granulocytic Ehrlichiosis, is described separately in this chapter as “Equine anaplasmosis”.

**Source of Infection and Transmission**

In Europe, *A. phagocytophilum* is transmitted by the three host tick *Ixodes ricinus*,...
which requires a single blood meal at each stage of development. The tick feeds for approximately 3 weeks every year and completes its life cycle in 3 years. The larval and nymphal stages will feed on any vertebrate, but the adult female will engorge and mate only on larger mammals.

*A. phagocytophilum* infects and multiplies in the epithelium of the midgut and salivary glands of ticks, from which it is transmitted to vertebrate hosts during feeding. A tick becomes infected by feeding on an infected host, and there is transstadial but not transovarial passage of the organism. It is estimated that the majority of ticks are infected with the organism in enzootic areas, and one former study of ticks from a field site found 44% of nymphs and 32% of adults infected but no infected larval stages. There is a close relation between tick density and the proportion of sheep and ticks infected with *A. phagocytophilum*, but it is nonlinear and complex.

In the United States, *Ixodes scapularis* has been implicated in transmission of the organism in eastern United States and *Ixodes pacificus* on the West Coast, as have *Ixodes persulcatus* and *Haemaphysalis longicornis* in Asia, but clinical disease in ruminants is not a feature in these locations.

Few cases of congenital infection of calves have been reported, and the organism is also present in leukocytes in milk during the acute phase of the disease, but the significance of this in the epidemiology of the disease is not known.

As few as one *A. phagocytophila*–infected cell may be enough to transmit infection, and use of a single needle between sheep in a group could possibly transmit infection.

It has been suggested that the presence of ticks in migratory birds could spread infection of this agent to other geographic regions.

**Experimental Reproduction**

The disease can be readily reproduced experimentally. The severity of the clinical response of sheep following experimental infection is not dose dependent, and there is no dose effect on the degree of bacteremia or neutropenia.

**Host Risk Factors**

Calves and lambs are much more susceptible than adults, although clinical disease may be less severe in very young lambs, possibly because of the mitigating effects of colostral antibody. Hyperimmunization of the pregnant ewe will produce high levels of colostral antibody that will protect the lamb against experimental challenge. However, in the field, colostral immunity does not protect against infection, and lambs born of ewes raised in endemic areas become infected. Natural infection is followed by a state of low-grade premunition as a result of the presence of the organism in the blood, which provides partial resistance to subsequent infections, with the disease manifesting itself in a less severe form. Once infected, animals probably remain carriers for life and act as reservoirs of infection for new generations of ticks.

The case-fatality rate is very low, and most reported mortality is in association with intercurrent disease. A significant indirect effect of tick-borne fever is that it increases the susceptibility of lambs to *staphylococcal pyemia, staphylococcal pneumonia*, septicemic and pneumonic *pasteurellosis*, loping-ill, and possibly other diseases. The mortality rate is negligible in cattle but may be higher in sheep.

**Pathogen Risk Factors**

The activity of the tick is seasonal, and consequently tick-borne fever has a seasonal occurrence. The tick is active at temperatures between 7° (44°F) and 18°C (64°F), and most ticks feed in the spring, with peak activity dependent on the latitude and elevation of the pasture but generally occurring in April and May. In some areas there is a second period of activity of a separate population of *I. ricinus*, in the autumn during August and September. Clinical signs in cattle occur predominantly in spring, 1 to 2 weeks after they start to graze.

**Zoonotic Implications**

Human granulocytic anaplasmosis (HGA) is associated with *A. phagocytophilum* and was first described in the United States in 1994 and is now regarded as an emerging disease. There are few reports from Europe, Russia, and Japan. Clinical and laboratory findings are fever, myalgia, headache, malaise, thrombocytopenia, leukopenia, anemia, mild hepatic injury, and splenomegaly, with symptoms varying from none to mortality. The disease presents most commonly as an undifferentiated, febrile, potentially severe illness occurring in summer or spring associated with occupational or recreational activities that allow exposure to infected ticks. There is no recognized direct zoonotic risk from exposure to infected animals, but the mammalian reservoir for *A. phagocytophilum* infection within the United States includes several rodents, foxes, and possibly other wild animals. These are infected with the human pathogenic variant (Ap-ha). Other animals, including the white-tail deer, are infected with different strains of the bacterium not infective to humans (Ap-V1). The organism is also present in leukocytes in milk during the acute phase of the disease, but the risk to humans consuming infected milk is probably minimal because strains of *A. phagocytophilum* differ in host infectivity.

**PATHOGENESIS**

*A. phagocytophilum* infects and replicates within the neutrophil, but can also infect endothelial cells. The organism has evolved the remarkable ability to subvert or hijack the powerful innate antimicrobial defenses of host cells. For example, *A. phagocytophilum* creates an intracellular membrane-bound compartment that allows replication and nutrition in seclusion from lysozymes and thereby suppresses respiratory burst. Furthermore, it subverts the innate immune system of neutrophils by inhibiting apoptosis (through activation of an antiapoptosis cascade) and by inducing autophagy, both to keep the host cell alive and to create a safe haven for replication. In addition, individual animals that survive acute infection develop persistent infection lasting for several months or even for life. The persistence of infection and recurrent bacteremia is a result of antigenic variation thought to be mediated by the bacterial major surface protein 2 (MSP2/p44). Furthermore, endothelial cells of the microvasculature may play a crucial role in the development of persistence because they may be an excellent site for dissemination of the organism to circulating neutrophils.

Tissue pathology is not associated with direct *A. phagocytophilum*–mediated injury but results from immunopathologic mechanisms associated with activated macrophages and elevation of levels of the proinflammatory cytokine, interferon gamma (IFN-γ), and chemokines. Fever develops in association with bacteremia and is the prominent clinical abnormality in the experimental disease. It persists for approximately 8 days, may exceed 41°C (105.8°F), and is accompanied by depression. Although this syndrome is of limited importance in the experimental setting, the occurrence of fever, dullness, and depression of the sucking drive can be a significant influence on the viability of lambs in the cold, wet, rough-grazing areas where this disease commonly occurs and may contribute to lamb mortality.

Tick-borne fever produces profound effects on immunologic defense systems. By impairing the function of neutrophils, the bacterium causes infected animals to become more susceptible to opportunistic infections. There is also a prolonged neutropenia lasting for 2 to 3 weeks combined with a thrombocytopenia. Up to 70% of the neutrophils are infected from the onset of the bacteremia. There is significant lymphocytopenia that develops 6 days after infection and that affects all T- and B-lymphocyte subsets. The antibody response of infected sheep to immunogens such as tetanus toxoid is also impaired.

Field observations and experimental challenge have shown that infected lambs are more susceptible to disease and mortality from intercurrent infections. The ability of an infection with *A. phagocytophilum* to predispose to secondary disease varies with the strain of the organism, which may explain...
why secondary complications are not observed in all flock infections with tick-borne fever. There is a clear relationship between infection with *A. phagocytophilum* and susceptibility to infection with *S. aureus* and the resultant disease tick pyemia. This is established both by epidemiologic and experimental studies.

Concurrent infection of sheep with the agent of tick-borne fever potentiates the pathogenicity of *louping-ill* virus in experimental infections, resulting in more severe disease and a higher mortality rate. Both diseases are transmitted by *I. ricinus*. However, in areas where both diseases are endemic, colostral immunity will delay infection of lambs with the *louping-ill* virus until the second year of exposure to the vector tick while allowing infection with tick-borne fever. Simultaneous primary infection with both agents may be uncommon in nature.

Infection also facilitates invasion and systemic myotic infection with *Rhizomucor pusillus*, resulting in diarrhea and dysentery and a high mortality rate. Concurrent experimental infection of sheep with *A. phagocytophilum* and *Chlamydia psittaci* results in chlamydial pneumonia, and simultaneous infection with parainfluenza-3 (PI-3) virus potentiates the pathogenic effect of PI-3 virus.

The immunosuppressive effect of tick-borne fever is believed to have resulted in the infection of sheep with *Parainfluenza-3* (PI-3) virus and resulting in diarrhea and dysentery. In experimen-
tal infection of sheep with *A. phagocytophilum* and *Chlamydia psittaci* results in chlamydial pneumonia, and simultaneous infection with parainfluenza-3 (PI-3) virus potentiates the pathogenic effect of PI-3 virus.

The reaction in young lambs is quite mild and manifested only by a fever, which fluctuates between 40° (104.0°F) and 42°C (107.6°F) for up to 10 days. Ewes exposed to the disease for the first time commonly experience outbreaks of abortion, and affected rams are temporarily infertile. Abortion is a major manifestation in northern Spain, whereas in the Scandinavian countries the main consequence of infection is immunosuppression leading to secondary infections with *S. aureus* (tick pyemia) and *P. hemolytica*.

**Goats**

Tick-borne fever in goats is characterized by high fever, dullness, and tachycardia.

**Horses**

See the section on equine granulocytic anaplasmosis later in this chapter for a description of the disease in horses.

**CLINICAL PATHOLOGY**

At the commencement of the fever there is severe but transient thrombocytopenia, and this is followed by more prolonged neutropenia and lymphocytopenia. The anaplasmas are demonstrable in the neutrophils and monocytes during each febrile period and for a few days afterward in cattle and for several weeks in sheep; they can be detected as intracytoplasmic inclusion bodies or morulas in Giemsa-stained blood smears and confirmed by electron microscopy or PCR.

Several PCR techniques (conventional, nested, or real-time) for the identification of *A. phagocytophilum* infection in blood and tissue samples have been established, primarily on the basis of the 16S rRNA, groEL, and p44 genes. In China, the rapid and simple loop-mediated isothermal amplification (LAMP) assay targeting the map2 gene of *A. phagocytophilum* was found to have a high level of sensitivity comparable to that of nested PCR and qPCR for the detection of the organism in rural human patients.

**TREATMENT**

Transmission of the disease for diagnosis may be affected by the IV injection of blood taken at the height of the fever.

**NECROPSY FINDINGS**

An enlarged spleen, up to 4 to 5 times the normal size, with subcapsular hemorrhages is indicative of tick-borne fever in sheep in endemic areas. Histologically, the only characteristic lesion is a depletion of lymphocytes from lymphoid tissues.

Multifocal leukomalacia (spongy change of white matter) and swelling of oligodendrocytes have been reported in the brain of aborted lambs, probably the result of fetal anoxia.

**DIFFERENTIAL DIAGNOSIS**

The geographic restriction of the disease and its relation to tick infestation are diagnostic features, but the clinical signs are quite nonspecific. Lesions attributable to concurrent bacterial, myotic, and viral infections may overshadow the primary disease in sheep and are more likely to be the cause of death. The disease in cattle has some similarity to bovine petechial fever (Ondiri disease), associated with *E. ondri*, which occurs only in Kenya.

**TREATMENT AND CONTROL**

**Treatment**

Long-acting tetracycline (20 mg/kg IM at early stages) (R1)

Oxytetracycline (10 mg/kg IV daily for 5 days at early stages) (R1)

**Control**

Long-acting tetracycline (20 mg/kg IM to lambs and calves at risk) (R2)
The best results are with tetracyclines, although cattle may recover without therapy. In sheep, a single dose of long-acting tetracyclines (20 mg/kg IM) or a 5-day course with oxytetracycline (10 mg/kg IV daily) given during the acute phase of the disease is effective in treatment, but infection is not eliminated in a significant proportion of sheep. In goats, good results are provided by a single dose of oxytetracycline (10 mg/kg BW IV). A potentiated sulfonamide containing trimethoprim and sulfadimidine, and sulfamethylphenazole (20, 50, and 50 mg/kg, BW respectively) were used in the past; ampicillin is ineffective. The Anaplasmataceae are obligate intracellular parasites of veterinary importance. Ann NY Acad Sci. 2006;1078:446.

**CONTROL**

Control of tick-borne fever depends on control of the tick population. The annual dipping of ewes with organophosphates or synthetic pyrethroid acaricides will help reduce tick numbers, and the double dipping of lambs during the tick season will help reduce disease in the lambs but can be difficult to achieve in the terrain and with the management practices of affected areas. Disease is reduced if the flock can be kept off the tick-infested pastures until the lambs are 6 weeks old and if the flock is dipped before introduction to the pasture. In some areas it may be possible to reduce tick numbers by pasture management systems that disturb the pasture microclimate required by the tick. In Norway, frequent pour-on applications of pyrethroids in lambs reduced tick infestation rate but did not reduce the seroprevalence of *A. phagocytophilum* on tick-infested pasture. Furthermore, frequent use of chemical acaricides has led to growing concerns about environmental safety, human health, increasing costs, and increasing resistance of ticks to pesticides. Studies on the biological control of ticks are ongoing. Vaccines against ticks and/or against *A. phagocytophilum* are also being studied.

The disease can be more severe when adult animals are exposed to infection for the first time, and naive late-pregnant cattle should not be introduced to tick-infested pastures during the tick-rise periods. A single administration of 20 mg/kg of long-acting tetracycline is reported to provide protection against experimental challenge for periods up to 3 weeks. The prophylactic administration of long-acting tetracycline to lambs and to calves during the season of tick activity is reported to reduce mortality and improve growth rates over untreated controls.

Stuen S. *Anaplasma phagocytophilum*—the most widespread tick-borne infection in animals in Europe. Vet Res Commun. 2007;(suppl 1):79.

Stuen S, et al. *Anaplasma phagocytophilum*: a wide range of hosts, including humans, wild animals, and domesticated animals; *A. platys*, which infects dogs. *A. marginale* is the type species of the genus; it is transmitted by ticks and other vectors and was first described by Sir Arnold Theiler in South Africa at the beginning of the twentieth century. *A. marginale* is the causative agent of anaplasmosis in cattle, buffalo, and wild ruminants, and *A. ovis* in sheep and goats. *A. centrale* is closely related to, or a subspecies of, *A. marginale* and causes mild anaplasmosis in cattle. It was originally isolated in Africa but has been introduced as an

**REFERENCES**

immunizing agent in Australia, South America, and Asia. Molecular studies have identified and characterized several major surface proteins (MSPs) in *A. marginale* involved in interactions of the organism with both vertebrate and invertebrate hosts.  

For example, MSP1a is involved with adhesion to bovine erythrocytes and to tick cells, and it can be used as a genetic marker for identifying strains of *A. marginale*. Many geographic strains have been identified worldwide, and they vary in genotype, antigenic composition, morphology, and infectivity for ticks.  

Another major surface protein, MSP2 is thought to be involved in antigenic variation to evade the mammalian host immune response, and it is also involved with infection and survival in the tick vector, thus contributing to maintenance of persistent infections in both hosts.  

Yet another protein, MSP4 is a stable marker for the genetic characterization of strains and does not undergo antigenic variation when cycling between tick and mammalian hosts.  

As for *A. ovis* affecting sheep, goats, and some wild ruminants, the MSP4 is also used for genetic characterization and differentiation from *A. marginale* and other rickettsial organisms. Mongolian reindeer are also affected.  

**EPIDEMIOLOGY**

**Geographic Occurrence**

Anaplasmosis in cattle is common and worldwide in distribution, being present on all six continents, but at varying degrees even within countries. It is transmitted through tick bites or by the mechanical transfer of fresh blood from infected to susceptible cattle from biting flies or by blood-contaminated fomites, including needles, ear-tagging, dehorning, and castration equipment. Infection in cattle is endemnic in tropical and subtropical areas that support large populations of these vectors, and prevalence rates as high as nearly 80% have been reported in cattle and 40% in buffalo.  

Infection occurs more sporadically in temperate-climate areas where vectors are seasonal; prevalence rates can be as low as 15% in Iowa and 0% to 2% in Canada.  

In the United States and in other countries, the disease has occurred beyond the boundaries of tick-infested areas. Whereas anaplasmosis is enzootic throughout the southern Atlantic states, the Gulf Coast states, and many of the midwestern and western states, the disease occurs sporadically in the northern states and extends to the Canadian provinces of Saskatchewan, Manitoba, Ontario, and Quebec.  

In Europe, anaplasmosis is endemic in the Mediterranean countries of Italy, Spain, and Portugal and has been advancing northward in recent years, with sporadic cases in France, Switzerland, the Netherlands, Hungary, and Austria. A clinical case of *A. centrale* infection has been reported in Italy.  

In Australia infection is closely related to the distribution of *Boophilus microplus*, which is restricted to the northern areas. Prevalence rates are negligible in cattle south of the tick line, but above the tick line the rates increase from south to north. Differences in enzootic and epizootic areas in South America and Africa are also largely related to tick distribution and climate.  

In most countries there is wide geographic variation in prevalence rates, and this variability contributes to the development of geographically stable or unstable enzootic regions. There is concern, and some evidence, that the global warming trend will expand the boundaries and movement of host ticks.  

Anaplasmosis of sheep and goats has a distribution similar to that of cattle, and in endemic areas the prevalence rate can be up to 100%.  

**Host Occurrence**

Cattle and buffalo are susceptible to *A. marginale* and *A. centrale* and sheep to *A. ovis*. *A. marginale* will establish in sheep by experimental infection, but *A. ovis* will not infect cattle. A variety of species of wild ruminants can be infected and may have significance as reservoirs for *A. marginale*. In the United States the black-tail deer (*Odocoileus hemionus columbianus*) in the West Coast region is believed to be a reservoir. In Canada, six of six free-ranging mule deer (*Odocoileus hemionus*) from British Columbia tested positive for *A. marginale* by PCR, and in Brazil, 79.3% of free-living and captive brown brocket deer (*Mazama gouazoubira*) and marsh deer (*Blastocerus dichotomus*) tested positive. A number of species of antelope in Africa and deer in Europe play a similar role.  

As for *A. ovis*, potential wildlife reservoirs include the bighorn sheep (*Ovis canadensis*) and the mule deer in western United States, the white-tail deer in Indiana, and the roe and red deer in Europe.  

**Source and Methods of Transmission**

The source of infection is always the blood of an infected animal. Recovery from acute infection results in persistent infection characterized by repetitive cycles of rickettsemia. Persistent carriers are the reservoir for herd infection. The level of parasitemia is often too low for detection by microscopy but can be detected by nucleic acid probe analysis. Transmission is biologically by ticks but can also occur transplacentally. Mechanical transmission is by biting flies or blood-contaminated fomites.  

**Hematophagous Insect Transmission**

Spread from animal to animal occurs chiefly by insect vectors. A variety of arthropods may act as vectors, but significant natural vectors are ticks in the family *Ixodidae* and flies in the family *Tabanidae*. Of the ticks, the one-host *Rhipicephalus (Boophilus)* spp. are of major importance in tropical and subtropical regions, and the three-host *Dermacentor* spp. are of major importance in the western United States.  

The organism undergoes a complex developmental cycle in the gut cells of ticks, and the final infective stage is present in the salivary gland. Transtadial transmission of the organism occurs in ticks, but there is little evidence for transovarial transmission of *A. marginale*; however, it has been reported for *A. platys*. Intrastadial transmission is significant with some species, and transmission occurs as the ticks move from one host to another while they are engorging, including from cow to calf. Male *D. andersoni* can act as effective vectors in this manner for at least 120 days.  

There appears to be no developmental sequence of *Anaplasma* spp. in flying insects. *Tabanids* are efficient mechanical vectors and can transmit infection for 2 hours after feeding. Sucking lice (*Haematopinus* spp. and *Linognathus* spp.) have been identified as potential vectors of anaplasmosis in cattle, goats, and buffalo.  

The sheep keg (*Melophagus ovinus*) and deer keg (*Lipoptena cervi*) are also potential mechanical vectors of *A. ovis* in sheep and deer, respectively. Nevertheless, tick-borne biological transmission is probably most important and is at least two orders of magnitude more efficient than mechanical transmission by flies because the bacteria are able to undergo cyclical development and multiplication only in the tick. Over 20 species of tick have been incriminated as vectors worldwide. In Australia the ticks *Boophilus microplus* and *Rhipicephalus sanguineus* are the vectors, and in South Africa it is *B. microplus*, *B. decoloratus*, and *Rhipicephalus simus*. In the United States *Boophilus annulatus*, *Dermacentor andersoni*, *D. variabilis*, *Argas persicus*, biting flies of tabanid species, and eye gnats (*Hippalates pusio*) also act as vectors. The male ticks of *Dermacentor albipictus* (the winter tick) and *D. occidentalis* (the Pacific Coast tick) parasitize both deer and cattle and have been suspected as vectors. *D. reticulatus* is widely distributed in Europe, from the British Isles to Central Asia, and the males have been shown to be competent vectors.  

**Iatrogenic Transmission**

Anaplasmosis may also be spread mechanically by infected hypodermic needles; by castrating, spaying, tattooing, ear-tagging, and dehorning instruments; and by blood transfusions and embryo transplants. In one study, iatrogenic transmission was detected in 6 of 10 steers sham-vaccinated with a needle fitted to a multiple-dose syringe. The ease with which the infection is spread mechanically may vary with the virulence of
the rickettsial strain, and this method of spread may be more important in some countries than others. Anaplasmosis may also be spread when cattle, used as donors of infected blood for immunization against babesiosis, are carriers of *A. marginale*, with the reaction occurring some 3 weeks later than that resulting from the babesiosis.

**Transplacental Transmission**

Intrauterine infection also occurs in cattle but much less frequently in field cases than in experimental ones. In one study involving beef cattle chronically infected with *A. marginale* in southern Brazil, a transplacental infection rate of 10.5% was obtained from 30 cows with no history of acute anaplasmosis during gestation. Abortion, neonatal infection, and fatal congenital infection have also been reported. In ewes intrauterine infection appears to occur with ease in experimental cases, provided the ewe is exposed during the latter two-thirds of pregnancy.

**Animal and Environmental Risk Factors**

**Breed**

*Bos indicus*, *Bos taurus*, and their crosses have equal susceptibility to infection and show the same age susceptibility, but under field conditions *B. indicus* are not as commonly affected, probably because of their relative resistance to heavy tick infestation. However, the effects of the disease on body weight and clinopathological parameters are the same for the two races of cattle. Breeds with black or red coat color have a higher risk of infection than those with white coats in regions where biting flies are the insect vectors. Dairy breeds may be at greater risk for iatrogenic transmission.

**Nutritional Status**

Clinical disease is less severe in cattle on a low plane of nutrition. Exposure of infected, clinically normal animals to devitalizing environmental influences, particularly short-age of feed, and the presence of other diseases may result in the development of acute anaplasmosis. For example, cattle introduced into feedlots are highly susceptible, and outbreaks among them are not uncommon 2 to 3 weeks after entry.

**Season**

In temperate climates a seasonal occurrence of disease occurs in association with seasonal occurrence of the insect vectors. Winter outbreaks are likely associated with iatrogenic transmission or possibly the winter tick, *D. albigibitus*.

**Age at Infection**

All cattle are susceptible to infection, but age at infection is a major determinant of the severity of clinical disease. Young calves are less susceptible to infection with *A. marginale* than older cattle and, when infected, are less susceptible to clinical disease. The reason for this is not understood, but splenectomy calves are fully susceptible to infection, which may be more severe than in the adult. Infection between 6 months and 3 years of age has increasing risk of clinical illness. Animals infected for the first time after 3 years of age are commonly affected by a peracute and fatal form of the disease. The age-specific incidence of clinical disease recorded in an outbreak in the United States showed 81% of cases in cattle aged between 2 and 4 years, with 94% of cases in cattle 3 years of age or older.

**Geographic Region**

Clinical disease is rare in enzootic areas because the infection pressure is high and cattle are infected at an age when they are age-resistant to clinical disease. The average age at which calves in enzootic areas become infected is 11 weeks (range of 4 to 24 weeks), and the clinical and hematological changes in them are mild and brief. Animals that have become seronegative for whatever reason in an infected environment are fully susceptible to infection. Clinical disease occurs where there is introduction of susceptible animals into endemic areas or the expansion of the vector population into previously free areas or into the interface between endemic and nonendemic regions.

Case-fatality rates are usually high in outbreaks, but the mortality rate varies widely depending on susceptibility and may be 50% or more in cattle introduced to enzootic areas. Case-fatality rates of 29% to 49% are recorded in outbreaks in the United States; recovered animals are emaciated, and there is a prolonged convalescence.

**Pathogen Risk Factors**

Phylogenetic analysis of the MSP1a of *A. marginale* worldwide supports the existence of clades, and their evolution is linked to ecological traits affecting the tick vector performance. Consequently, some strains evolved under conditions that support pathogen biological transmission by *R. microplus*, whereas other strains may be linked to transmission by other tick species or to mechanical transmission in regions where *R. microplus* is currently eradicated.

Australian isolates do not appear to differ significantly in antigenicity or virulence. In contrast, in other countries there can be significant differences between isolates in antigenic composition, the protection afforded against heterologous challenge, and virulence. It has been demonstrated that the phenomenon of infection exclusion occurs with *A. marginale*. Infection of tick cells and bovine erythrocytes with one genotype of *A. marginale* excludes infection with other genotypes. In herds of cattle from endemic areas where many genotypes are detected, only one genotype is found per animal. Furthermore, cattle inoculated with two *A. marginale* isolates become infected with only one isolate. However, concurrent strain infections (superinfections) have been reported. For example, experimental infection with a low-pathogenic strain of *A. marginale* did not prevent infection with a highly pathogenic isolate; instead, it provided clinical protection against the highly pathogenic strain. Similarly, *A. centrale*–vaccinated cattle can be superinfected with field strains of *A. marginale* because they differ in their MSP2 genes. Furthermore, superinfection with *A. marginale* is associated with a significant increase in variant diversity, and high levels of endemicity also drive pathogen divergence toward greater strain diversity.

**Economic Importance**

Costs are from death and abortion in clinical cases, loss of production in sick and recovered animals, and costs associated with preventive measures such as tick control. There have been no recent estimates of cost, but anaplasmosis was estimated to cost $875 million in Latin American nations in 1977 and $300 million per year in the United States in 2003.

In developed countries with the disease, exports of cattle to countries that do not have it are constrained. A major cost in developing countries is the constraint on efficient production and the limit to the introduction of susceptible cattle breeds with superior genetics.

**Experimental Reproduction**

Anaplasmosis can be reproduced experimentally by subinoculating infected blood intravenously into intact or preferably splenectomized susceptible animals or by feeding infected ticks on them.

**PATHOGENESIS**

Anaplasma are obligate intraerythrocytic bacteria. They infect mature erythrocytes by an endocytic process that possibly involves the twin-arginine translocation (Tat) pathway, which exports fully folded proteins out of the cytoplasm of the bacteria with the type IV secretion system (T4SS). Inside the erythrocyte, bacterial reproduction occurs by binary fission to produce two to eight infective initial bodies that leave by exocytosis to infect other erythrocytes. The number of infected erythrocytes doubles every 24 to 48 hours, and the infection becomes patent 2 to 6 weeks after infection, with the time frame influenced by the initial challenge dose. Depending on the strain and the susceptibility of the host, from 10% to 90% of erythrocytes may be infected in the acute stage of the disease. At least 15% have to be infected before there is clinical disease. Infected erythrocytes are removed by phagocytosis in the reticuloendothelial system, with release of acute-phase inflammatory reactants and the consequent development of fever.
Continued erythrocyte destruction occurs, resulting in the development of mild to severe anemia and icterus without hemoglobinemia or hemoglobinurinuria. Anaplasmosis is primarily an anemia, with the degree of anemia varying with the proportion of infected erythrocytes. The first appearance of the bacteria in the blood coincides with a fall in the hematocrit and erythrocyte levels, the appearance of immature erythrocytes in blood smears, and the development of fever. Acutely affected animals may die shortly after this phase is reached. The appearance of anti-erythrocyte antibodies late in the acute stage may exacerbate the anemia.

If the animal recovers from the initial acute attack, the disease goes into the subacute and chronic phase. The degree of anemia varies widely in young cattle up to 3 years of age but is always severe in adults and in splenectomized animals. Cattle that survive the disease become carriers for life and serve as reservoirs of A. marginale because they provide a source of infective blood for both mechanical and biological transmission by ticks. They have lifelong immunity and are resistant to clinical disease on challenge exposure.

Carrier animals have cycles of parasitemia associated with the development of new antigenic variants to allow new cycles of invasion, multiplication, and destruction approximately every 10 to 14 days. In the carrier animal, the concentration of infected erythrocytes varies markedly at bimonthly intervals from 10^2 to 10^6 infected cells/mL of blood, much lower than in the acute phase. Each cycle reflects the emergence of one or more clones that express a unique, hyper-variable region (HVR) of MSP2 and MSP3. These “escape variants” are not recognized by antibody present at the time of emergence. As the new variants replicate, a new variant-specific antibody controls them. This cycle continues unabated, allowing lifelong persistent A. marginale infection. It is believed that IgG-2 antibody is responsible for controlling the initial acute bacteremia and the subsequent peaks of bacteremia that arise during persistent infection, and that the antibody acts either by neutralizing extracellular bacteria in the process of invading new erythrocytes or by opsonizing bacteria that are then targeted for phagocytosis. The process is not sufficient to clear infection, and cattle remain persistently infected for life. Another factor that may contribute to persistence is the rapid deletion of antigen-specific CD4+ T lymphocytes following infection and the failure to establish a strong memory T-cell response during the course of the disease.

**CLINICAL FINDINGS**

**Cattle**

There are few recent reports on clinical findings during outbreaks of bovine anaplasmosis. The incubation period varies with the challenge dose but is generally several weeks with tick-borne infection and 1 to 5 weeks with the inoculation of blood. In most cases, the disease is subacute, especially in young animals. Rectal temperature rises rather slowly and rarely to above 40.5°C (105°F). It may remain elevated or fluctuate with irregular periods of fever and normal temperature alternating for several days to 2 weeks. Anorexia is seldom complete. Death can occur at this stage, but many survive in an emaciated condition, and their fertility is impaired. The mucous membranes are jaundiced and show marked pallor, particularly after the acute stage is passed, but there is no hemoglobinuria.

Peracute cases, with a sudden onset of high fever, anemia, icterus, severe dyspnea, and death, often within 24 hours, are not uncommon in adult dairy cows. Affected animals are often hyperexcitable and tend to attack attendants just before death. Pregnant cows frequently abort. In convalescent bulls, there may be depressed testicular function for several months.

In a recent outbreak in Hungary, two of five acutely affected cattle died, but the herd had concurrent infection with other pathogens. A fatal congenital infection in a 2-day-old calf was associated with bovine viral diarrhea virus infection in South Africa. In another case, clinical anaplasmosis was diagnosed in a 15-year-old cow, 13 years after eradication of the main vector Rhipicephalus microplus in Okinawa, Japan, implying that the cow was a long-time persistent carrier.

**Sheep and Goats**

In sheep and goats, infection is usually subclinical, but in some cases, particularly in goats, a severe anemia may occur, and a clinical picture similar to that found in cattle may be seen. Severe reactions of this type in goats may show hypereexcitability and may bite at inanimate objects. The experimental disease in lambs includes fever, constipation or diarrhea, pale and icteric conjunctivae, and severe anemia 15 to 20 days after inoculation. The anemia is not completely resolved in 3 to 4 months.

**CLINICAL PATHOLOGY**

**Hematology**

Anaplasmosis in cattle, sheep, and goats is characterized initially by normocytic normochromic anemia, which becomes macrocytic normochromic as the disease develops. Erythrocyte destruction may be so severe that the erythrocyte count is reduced to 1.5 million/µL. Immature red cells are common at this stage, and their presence is considered to be a favorable sign. The small dot-like bacteria are discernible at the periphery of up to 10% of the red cells in subacute cases, but in peracute cases more than 50% of the cells may be infected. A. ovis are usually situated at the periphery of erythrocytes, but as many as 40% of infected cells may show submarginal organisms. Reticulocytosis and basophilic stippling are usually evident. Packed cell volume and red blood cell count were found to be the most informative parameters in the routine clinical practice for A. ovis infection in sheep.

Diff-Quik staining of blood smears is as accurate as Giemsa in the detection of A. marginale and can be completed in 15 seconds compared with nearly an hour for Giemsa. There are no diagnostic clinical chemistry findings, but as evidence of oxidative stress, levels of erythrocyte lipid peroxidation (LPO) and plasma nitrate (NO) may be elevated during the acute phase. Concentrations of acute phase proteins (Hp, SAA, ceruloplasmin, and fibrinogen) may also be elevated.

**SEROLOGY**

Several serologic tests have been employed for epidemiologic studies of bovine anaplasmosis, but the two currently preferred for identifying infected animals are the competitive ELISA and the card agglutination test.

The competitive enzyme-linked immunosorbent assay (cELISA) is the most accurate serologic test currently available for anaplasmosis; it uses a monoclonal antibody specific for MSP5. However, it cannot differentiate between A. marginale and some other Anaplasma species, because they all possess the MSP5 antigen. A dot-ELISA with high sensitivity, specificity, and predictive value is also described and could be particularly applicable to field examinations. For further details, please see Aubry.

The card agglutination test (CAT) examines serum or plasma for antibodies against A. marginale. It is cheap, quick, and sufficiently accurate to be used as a herd test. Currently, in most countries, the card agglutination and complement fixation tests are routinely available.

The complement fixation test (CFT) used to be the standard test for the detection of carrier animals. It is satisfactory for use in cattle, goats, and sheep, but the antibody titer is highest during the active phase of the disease and sufficiently low in carrier animals to give a proportion of false-negative results. False-positive reactions can occur because of erythrocyte contamination of the A. marginale antigen and the presence of antibodies to erythrocytes in some cattle sera.

A number of other tests have been developed. A capillary tube agglutination test of comparable efficiency is available, is more economical and faster than the CFT, and is particularly suited to testing in extensive field situations. An indirect fluorescent antibody test (IFAT) is also accurate and particularly suitable for testing blood that has been dried onto paper.
for passage through the mail. It is also an accurate test for selecting recently affected animals.

A rapid lateral flow assay (LFA) has been developed that is a useful tool for screening cattle moving from an area with infection to a disease-free area.67 The assay can be carried out in 10 to 15 minutes, it requires no expensive equipment, and it is comparable to laboratory tests in its performance. Vaccinated animals may react to all of the serologic tests for periods of over 1 year.

**Molecular Methods**

Molecular methods can now be used to detect low levels of bacteremia and to differentiate *A. marginale* from other species.68 The PCR assay is more sensitive than other methods in detecting anaplasmosis, especially in latent infections.68 Nested PCR procedures showed bacteremia with a sensitivity of 50 infected erythrocytes per milliliter or as few as 10 copies of *A. marginale*.69–71 Furthermore, a multiplex PCR assay has been developed for the simultaneous detection of *Theileria annulata*, *Babesia bovis*, and *A. marginale* in cattle,72 and the assay was successfully used to detect *A. marginale*, *Babesia bigemina*, and *B. bovis* during an outbreak of tick-borne diseases in southern Brazil.73 PCR assay can also be used to detect infected ticks.

**Transmission** to splenectomized animals is used to detect carriers and to assess the efficacy of treatment or vaccination. It has been the gold standard for the demonstration of *A. marginale*-free blood, but it is expensive and is now largely replaced by PCR in most countries.

**NECROPSY FINDINGS**

The most obvious findings are emaciation, pallor of the tissues, and thin, watery blood. There is mild jaundice, and the liver is enlarged and orange. The kidneys are congested, and there may be myocardial hemorrhages. The spleen is enlarged, with a soft pulp. The bone-marrow cavity may be reddened by increased hematopoietic tissue in acute cases, but there may be serous atrophy of marrow fat in chronic cases. Postmortem identification of *A. marginale* can be established by staining blood smears with Giemsa or with direct fluorescent stains. Peripheral blood is superior to organ smears. Brain smears are unsatisfactory. The technique is applicable to fetuses suspected of being aborted as a result of infection with *Anaplasma* spp. Nucleic acid–based tests may be used but are rarely needed for routine diagnosis at necropsy.

**Samples for Confirmation of Diagnosis**

- **Clinical pathology**—blood smears from cut surface of an ear (CYTO, FAT)
- **Histology**—fixed spleen, liver, bone marrow

**DIFFERENTIAL DIAGNOSIS**

Other causes of hemolytic anemia

**TREATMENT**

**TREATMENT AND CONTROL**

**Treatment**

- **Oxytetracycline** (6 to 10 mg/kg IM daily for 3 days, or 20 mg/kg IM single dose) (R-1)
- **Imidocarb** (5 mg/kg IM twice, 7 days apart) (R-2)
- **Enrofloxacin** (12.5 mg/kg SC twice, 48 hours apart) (R-1)

**Control**

- Killed *A. marginale* vaccine (2 doses 4 weeks apart, then a booster) (R-1)
- Live *A. centrale* vaccine (single dose, preferentially in yearlings) (R-2)
- Live *A. marginale* vaccine (single dose, yearlings only) (R-3)
- Attenuated *A. marginale* vaccine (R-4)
- Cell-culture live *A. marginale* vaccine (R-2)

Treatment is with tetracyclines, imidocarb, or enrofloxacin.

**Treatment of clinical disease** can be with oxytetracycline, 6 to 10 mg/kg BW daily for 3 days, or a single injection of long-acting oxytetracycline at a dose of 20 mg/kg intramuscularly (IM). The convalescent period is long, and animals remain persistently infected. Concurrent administration of estradiol cypionate (14.3 mg/kg BW IM) appears to improve the rate of recovery by reducing rickettsemia during treatment. Blood transfusions are indicated in animals with a PCV less than 15%. Rough handling must be avoided.

**Imidocarb** (5 mg/kg BW IM twice, 7 days apart) is also an effective treatment for clinical cases but does not eliminate persistence.74 The drug is not approved for use in the United States and Europe because it is a suspected carcinogen.

**Enrofloxacin** (12.5 mg/kg BW SC twice, 48 hours apart) is effective, but it also results in persistent infection. At 7.5 mg/kg BW it provided faster reduction of rickettsemia and PCV recuperation compared with long-acting oxytetracycline at 20 mg/kg BW.75 The risk for infection in the rest of the herd should be assessed and, if necessary, temporary or prolonged protection should be provided. Protection can be provided by tetracyclines or by vaccination.

**Temporary protection** in the face of an exposure risk can be achieved with a single intramuscular injection at 20 mg/kg BW of long-acting tetracycline. The results generally are good except when the cattle are exposed to infection during the 14 days before the treatment. **Prolonged protection** can be achieved by intramuscular injection at 20 mg/kg BW of long-acting tetracycline every 28 days or by chlorotetracycline in the feed at 1.1 mg/kg BW daily.

**Elimination of infection** is difficult but not impossible. A trial testing the ability of chlorotetracycline therapy to eliminate the carrier state examined three doses (4.4 mg/kg per day, 11 mg/kg per day, and 22 mg/kg per day) of oral chlorotetracycline fed for 80 days.76 A negative reverse-transcription PCR assay result was confirmed in all treated groups within 49 days and by cELISA some additional 49 to 88 days later. Subinoculation of splenectomized steers confirmed chemosterilization with oral chlorotetracycline.76

**CONTROL**

Methods for the control of anaplasmosis have not changed greatly over the past several decades. Basically, the control and prevention measures include (1) maintenance of *Anaplasma*-free herds through import and movement control, testing, and elimination of carrier cattle; (2) vector control; (3) prevention of iatrogenic transmission; (4) administration of antibiotics; and (5) preimmunization with live vaccines and immunization with killed vaccines.7 The eradication of anaplasmosis is not a practicable procedure in most countries at the present time because of the wide range of insects capable of carrying the disease, the long period of infectivity of carrier animals, and, in some areas, the presence of carriers in the wild animal population.

In enzootic areas some benefit is derived from the control of ticks and other vectors, and weekly dipping in an acaricide has been used in tropical areas to control this and other tick-borne diseases. However, acaricide use has limited efficacy in reducing tick infestations and is often accompanied by serious drawbacks, including the selection of acaricide-resistant ticks, environmental contamination, and contamination of milk and meat products with drug residues. Consequently, the possibility of vector vaccines that target tick proteins is now being investigated.77 Such vaccines can reduce tick feeding and reproduction, and they also reduce the infection and transmission of pathogens from the tick to the vertebrate host. A recombinant trial vaccine against the tick-protective antigen subolesin has the potential not only to control tick infestation of cattle, but also infection with multiple pathogens such as *A. marginale* and *Babesia bigemina*.58–59

**General Measures**

Prior serologic testing should prevent the introduction of the disease into herds by carrier animals. Attention should also be given to preventing iatrogenic transmission with instruments used for injections or surgical operations by disinfection after use on each animal. This is particularly important in feedlots where introduced groups are often subjected to multiple vaccinations and implantation at a time when their resistance
Movement of Animals

Naive animals that are to be introduced into an enzootic area should be vaccinated. Some advantage can be gained when introducing animals into an enzootic area by limiting the introductions to animals of less than 2 years of age and by bringing them in when the insect population is least numerous.

Elimination of Carriers

Elimination of carriers is feasible in regions that are subject to only periodic incursions of infection and that do not have endemic tick vectors. It can be achieved by serologic testing and culling of reactors or by treating them with oral oxytetracycline over a prolonged period of time as outlined earlier.

Outbreaks

If an outbreak does occur, affected animals should be treated vigorously as described previously and in-contact animals vaccinated and/or placed on a regimen of prolonged tetracycline protection. Subsequently, all exposed animals should be tested serologically and the reactors treated or preferably salvaged. Prolonged treatment regimens can be used to provide protection to cattle in seasonal risk periods of transmission.

Chemotherapy

Chemotherapy for control is more commonly used in the United States than in other areas of the world. It can be of value in feedlot cattle but is not applicable to range cattle. It is expensive and carries the risk of causing selection of resistant strains.

Vaccination

Vaccines for the control of anaplasmosis are either live or killed vaccines. Both types use A. marginale or A. centrale from infected bovine erythrocytes, and although both types induce protective immunity that reduces or prevents clinical disease, neither type prevents cattle from becoming persistently infected with A. marginale. Cattle that have recovered from acute infection or have been immunized with killed vaccines are solidly protected against challenge with the homologous strain but are only partially protected against challenge with heterologous strains.

Most control programs in enzootic areas are based on increasing the resistance of the population by immunization. In any vaccination program, particular attention should be paid to the animals at high risk, particularly animals brought in from nonenzootic areas, those in surrounding similar areas to which infection may be spread by expansion of the vector population under the influence of suitable climatic conditions, and animals within the area that are likely to be exposed to climatic or nutritional stress.

Killed Vaccines

Killed A. marginale are usually in an adjuvant vehicle. The vaccine requires two doses, 4 weeks apart, with the last dose given at least 2 weeks before the vector season. Subsequently, booster doses should be given 2 weeks before the next vector season. The vaccine does not prevent infection but does significantly reduce the severity of the disease. It does have the advantage over the other vaccines of having a relatively short postvaccination period when animals remain positive to serologic tests. The duration of the immunity is at least 5 months.

There is a risk for neonatal isoerythrolysis. The risk can be reduced by vaccinating only empty cows and avoiding unnecessary booster injections. When this vaccine is used in the face of an outbreak, tetracyclines can also be given to provide temporary protection during the period of development of immunity; tetracyclines do not interfere with the development of this immunity.

Preliminary reports of the efficacy of DNA vaccines are not encouraging.

Live Vaccines

A living A. centrale vaccine is used extensively in Australia, Africa, Israel, and Latin America, but not in the United States, and there is some reluctance to introduce it into areas where A. centrale does not already occur.

A. centrale is prepared from the blood of infected splenectomized donor calves and is stored chilled or frozen. The vaccine causes a mild, inapparent disease, but it can cause severe reactions in occasional animals. It is generally safe in young cattle. A single vaccination is used in endemic areas, and the immunity is reinforced by continuous challenge and considered to persist for life in tick areas. A. centrale and A. marginale share immunodominant epitopes and have similar antigenic variation in major surface proteins, both of which play a role in the cross-immunity that occurs.

The immunity induced by the live A. centrale vaccine in cattle does not prevent subsequent infection with A. marginale by the infection exclusion phenomenon because both differ in their MSP2 genes. The efficacy of this vaccine varies geographically. Vaccination with A. centrale reduces the severity of the reaction when infection with A. marginale occurs but does not give absolute protection. Protection against challenge in Australia is adequate in most cases, and certainly sufficiently effective enough to justify its use. In contrast, the use of the same vaccine in countries other than Australia, where there are more antigenically diverse and highly virulent strains, is often inadequate, and better vaccines are required.

Tetracyclines will prevent establishment of infection and immunity by the vaccine and should not be administered for 3 weeks before vaccination.

Living A. marginale has been used as a vaccine but its administration is limited to the relatively resistant age group below 1 year of age, to the winter months when vectors are sufficiently rare to avoid the chance of spread to other age groups, and to circumstances where animals that react severely can be restrained and treated adequately. The method has the serious disadvantage of creating a large population of carrier animals that may subsequently spread the disease.

Attenuated vaccines have been attempted by irradiating strains, by passage of the organism through sheep or deer, and by the use of naturally low-virulence isolates. Although most have been received with initial enthusiasm, some have proved ineffective, and others have been associated with adverse reactions. Some are effective against strains in some geographic regions but give unsatisfactory protection against clinical disease in other regions.

Problems With Live Vaccines

All vaccines currently must be produced in live animals, which is expensive. With noninactivated vaccines, there is a risk of transmitting blood-borne viruses. In Australia, a single calf infected with bovine leukosis virus was unsuspectingly used in the production of A. centrale vaccine. The contaminated vaccine was given to 22,627 cattle in 111 herds and resulted in a high rate of infection with bovine leukosis virus in the vaccinated cattle.

A cell-culture system has been developed for propagation of A. marginale in a continuous tick cell line derived from embryonic Ixodes scapularis. Recently, protective immunity was induced by immunization with a live, cultured A. marginale strain. Vaccinated calves had a stable PCV and low bacteremia following challenge with a virulent strain, whereas A. centrale only afforded partial clinical protection. Important features of this cell-culture candidate vaccine are that it carries no risk of biological transmission, it can be easily distinguished from field strains, and only one dose is required.

Studies are ongoing for the development of safe and effective subunit vaccine containing epitopes critical to effective immunity. Whereas blood-derived whole-outermembrane (OM) preparations and cross-linked surface proteins provide the best protection from high-level bacteremia and anemia, they may not be practical for large-scale production. Recombinant proteins, DNA vaccines, and killed preparations of A. marginale, including inactivated cell-culture-derived organisms, have failed to
The ideal vaccine for anaplasmosis in cattle (as well as in sheep and goats) would be one that prevents infection, induces protective immunity, and possibly blocks biological transmission from the tick to the vertebrate host. However, further research is needed to achieve this goal.

EQUINE GRANULOCYTIC ANAPLASMOSIS (EQUINE GRANULOCYTIC EHRlichiosis, ANAPLASMA PHAGOCYTOPHILUM)

Anaplasma phagocytophilum causes disease in horses, humans, dogs, cattle, cats, and other mammalian species. It is characterized in horses by fever, depression, limb edema, icterus, and ataxia. The disease is described here with emphasis on that occurring in horses. See the next section, “Tick-Borne Fever,” for a description of the disease in other species.

ETIOLOGY

The disease in horses is associated with infection by A. phagocytophilum, the same agent that causes human granulocytic ehrlichiosis (HGE). The organisms Ehrlichia equi, E. phagocytophilum, and the HGE agent are now classified as A. phagocytophilum. The variety of species affected and geographic distribution of the disease suggests strains of A. phagocytophilum of varying pathogenicity and host specificity. A. phagocytophilum is a recognized cause of tick-borne fever in sheep, goats, cattle, horses, dogs, cats, roe deer, reinder, and humans in Europe and elsewhere. Infection of some domestic and wild ruminants, including deer, does not induce clinical signs, which could be a result of host susceptibility, the strain of the organism, or combinations of both. There are multiple strains of A. phagocytophilum, and each has a distinct host tropism (reservoir host and vector), with disease being associated with infection of nonhost species (dogs, horses, and humans) by pathogenic strains of the organism. Strains of A. phagocytophilum that cause disease in dogs and horses in southern Sweden differ slightly in their genetic composition from isolates derived from North America. Similarly, nucleotide sequences of strains of A. phagocytophilum from the West Coast of the United States differ from those of strains originating from the East Coast. Strains of A. phagocytophilum in the western United States varying in their pathogenicity in horses, with strains isolated from horses with the disease (and from chipmunks and tree squirrels) producing severe disease in horses, whereas a strain derived from woodrats does not cause disease in horses. There is genetic variability in strains capable of causing disease in horses demonstrated in Germany and the Czech Republic. The organism can be isolated from lizards, which are believed to be the host in a reptile–tick–reptile cycle.

A. phagocytophilum is an obligate intracellular bacterium that replicates in cells derived from the bone marrow.
There is extensive evidence of exposure of dogs to *A. phagocytophilum* and of disease consistent with granulocytic ehrlichiosis; the 47% of dogs in endemic areas in California have antibodies to *E. equi* (*A. phagocytophilum*), and some show clinical signs consistent with the disease. There is evidence of widespread infection of other species with the organism; 0.2% of 2725 serum samples from cattle in California had detectable antibodies to *A. phagocytophilum*, and 43% to 96% of deer and moose, respectively, in Norway are seropositive. Serologic evidence of infection is widespread in Europe. However, demonstration of antibodies in serum by surveys does not provide information on the pathogenicity of the infecting strains of *A. phagocytophilum* (which can vary widely in their capacity to produce disease).

**Anaplasma and Ixodes Ecology**

*A. phagocytophilum* is maintained by a cycle of infection of particular host species, including wild cervids or, in apparently separate cycles, small mammals such as the white-footed mouse and dusky-footed woodrat in the United States and hedgeshogs in Europe, and specific vector species of ticks. The tick–host–tick sylvatic cycles are now being identified, and there appears to be multiple such cycles, with more than one cycle (i.e., different host) being possible in a geographic area. Infection of horses, dogs, and humans, which are not part of the natural cycle of the organism, occurs through the bite of *A. phagocytophilum*-infected ticks. The organism is transmitted by hard ticks that are members of the *Ixodes persulcatus* complex, which includes *Ixodes pacificus*, *Ixodes scapularis*, and *Ixodes ricinus*. Transovarial, but not transstadial, transmission occurs. The tick vectors of *A. phagocytophilum* pass through four stages in their life cycle: egg, larva, nymph, and adult. Maturation from larva to nymph, maturation from nymph to adult, and egg laying all require the ingestion of a blood meal. Because transovarial transmission of infection does not occur, larvae or uninfected nymphs become infected by feeding on an infected mammal. The engorged and infected immature tick then dismounts and matures to the next life stage away from a mammalian host. When the immature tick reaches the nymph or adult stage, it again seeks a mammalian host. Transmission of the infection from the tick to a mammal occurs through feeding on an infected nymph or adult on a susceptible host.

Environmental factors that affect the type of host species, its density in a particular area, and the number and activity of ticks are likely important in determining risk of infection of nonhost species (e.g., horses). Changes in local vegetation, such as that produced by clearing of forest and subsequent regrowth, can influence host and vector population densities and hence risk of transmission of the agent to nonhost species.

**Animal Risk Factors**

Horses that have not been exposed to *A. phagocytophilum* are susceptible to infection and disease. There is a marked seasonality of the disease in California, with most cases occurring in late autumn, winter, and spring. This seasonality likely correlates with the well-documented changes in populations of various stages of the vector ticks and host mammals. Horses of any age are susceptible, and there is no apparent breed or sex predisposition.

Infection in horses is followed by a solid immunity, and recovered animals are resistant to the disease for at least 20 months, although it is suggested that reinfection and disease can occur. Serum antibodies persist for at least 300 days after infection in some horses but decrease to low levels in most horses by 200 days after infection.

**Transmission**

As discussed previously, transmission is through the bite of an infected tick. Transmission through use of blood-contaminated veterinary equipment or by blood transfusion is possible, with the latter being used to induce disease in experimental challenges. Perinatal transmission of *A. phagocytophilum* is reported in humans.

**Morbidity and Mortality**

The case-fatality rate is low, approximately 4%, and deaths of horses with uncomplicated disease are rare.

**Zoonotic Potential**

There is no evidence that infection spreads directly from infected horses or dogs to humans. However, dogs have been suggested to be sentinel animals, in that humans in areas in which dogs have a high prevalence of antibodies in serum to *A. phagocytophilum* might be at increased risk of infection from bites of infected ticks.

**PATHOGENESIS**

Following experimental infection, horses have organism detectable by PCR beginning 5 days after infection, with development of fever and depression 7 to 8 days after infection. Inclusions in granulocytes are detectable beginning 9 days after infection, at which time there is edema of the limbs. The organism incites a proinflammatory cascade after infection; administration of dexamethasone, which inhibits this inflammatory cascade, diminishes the severity of the disease in experimentally infected horses.

The disease in horses is associated with rapid changeover of expressed p44 genes such that there is marked antigenic variation in the major surface protein, p44, during infection in an animal. The rapid changeover of expression of p44 is attributed to development of specific antibody to the hypervariable region of p44. Infection in sheep results in immune suppression secondary to granulocytic and lymphocytic leukopenia, impaired antibody production, reduced lymphocyte response to mitogens, and a decreased oxidative burst activity of neutrophils. The prominent clinical sign of edema is likely related to the vasculitis that is characteristic of the disease.

**CLINICAL SIGNS**

The incubation period for the spontaneous disease is less than 2 weeks. Subclinical infections are believed to be common, based on the number of horses with serologic evidence of infection but no history of disease. Clinically there is high fever of 40° to 42° C (104° to 107° F) followed by mucosal pallor, jaundice, anoxia, depression, increased respiratory movement, incoordination and reluctance to move, and, after 3 to 4 days, edema and heat of the extremities. There can be petechial hemorrhages on mucosal membranes and pleural or peritoneal effusion. Edema persists for 7 to 10 days, and clinical signs resolve in 14 days. Clinical disease is more severe in horses over 3 years of age and is minor in young horses. Severely affected horses can have signs consistent with neurologic disease, including ataxia, defects in conscious proprioception, and recumbency.

Arrhythmias can occur during the acute phase of the disease. Chronic infection and disease is not recognized.

Death of an experimentally infected horse within 2 days of development of clinical signs was associated with disseminated intravascular coagulation.

**CLINICAL PATHOLOGY**

There is commonly mild anemia and leukopenia. *Thrombocytopenia* is common in the acute stage of the disease. There are no consistent serum biochemical abnormalities.

Positive identification of the disease is made on the presence of inclusion bodies (morulae) in the cytoplasm of neutrophils and eosinophils. Careful and protracted microscopic examination of a blood smear, stained with Giemsa, may be necessary to identify the inclusions (morulae). The inclusions are apparent as pleomorphic bodies that stain as onegray color, often in a spoke-wheel formation, in the cytoplasm of granulocytes. The number of infected cells can be quite small, and examination of a buffy-coat preparation may increase the sensitivity of the test.

**Diagnosis** is achieved through use of a PCR test to identify *A. phagocytophilum* DNA in blood samples of infected horses and by demonstration of an increase in antibody titer detected by indirect fluorescent antibody staining. However, antibody titers are low to undetectable in approximately 44% of horses at the onset of clinical signs, and they
reach a maximum within 1 month of infection.
An ELISA that detects antibodies against the p44 surface antigen of A. phagocytophilum is suitable for use in dogs and horses. Evaluation of one commercial version of this test did not support its clinical use.24

NECROPSY EXAMINATION
At necropsy there are petechiae and edema of the legs, and at histologic examination there is vasculitis. There are often inflammatory lesions in the brain, heart, and kidneys.

DIFFERENTIAL DIAGNOSIS
Differential diagnoses include the following:
- Equine infectious anemia, which has a much more protracted course and does not respond to treatment
- Purpura hemorrhagica, which is often associated with infectious upper respiratory tract disease
- Liver disease
- Viral encephalitis
- Equine herpesvirus-1 myeloencephalopathy
- Rabies
- Botulism
- Equine viral arteritis

TREATMENT

<table>
<thead>
<tr>
<th>TREATMENT</th>
<th>Treatment of equine granulocytic anaplasmosis:</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Oxytetracycline 7 mg/kg q 12 to 24 hours for 5 to 7 days (R1)</td>
</tr>
</tbody>
</table>

The specific treatment is oxytetracycline (7 mg/kg BW IV, every 24 hours) for approximately 5 to 7 days. Penicillin, streptomycin, and chloromycetin are not effective. The response to treatment with oxytetracycline is rapid; the fever is reduced or eliminated in 12 to 24 hours, and signs of the disease resolve within 5 to 7 days in most horses. Inclusion bodies are difficult to find 24 hours after beginning treatment. Without treatment the disease is usually self-limiting to 2 to 3 weeks.

CONTROL
There is no vaccine, and specific control measures cannot be recommended at this time, although minimizing access of ticks to horses would appear prudent. There is no need to isolate infected horses.

EPISTHENZOOZONOSIS

SYNOPSIS
Etiology Hemotrophic mycoplasmas (previously Eperythrozoon species)
Epidemiology Subclinical infection common; clinical disease precipitated by stress. Horizontal transmission by blood. Vertical transmission important in swine.
Clinical findings Acute icterohaemorrhagic or chronic ill-thrift in sheep and swine. Reproductive inefficiency and neonatal anemia in swine. Syndromes in cattle less defined.
Treatment Tetracyclines, organic arsenicals.
Control Nonspecific. Prophylactic administration of tetracyclines.

ETIOLOGY
The disease is associated with hemotrophic mycoplasmas, formerly thought to be rickettsial parasites and classified as Eperythrozoon. They infect a range of mammalian species and cannot be grown in culture. Species in farm livestock that have been associated with disease are Mycoplasma (Eperythrozoon) ovis in sheep, M. suis in swine, and M. wenyonii in cattle. Additional forms have been identified in sheep and cattle, designated Candidatus Mycoplasma haemobovis and Candidatus Mycoplasma haemoviris, respectively, and the taxonomy of the hemotrophic mycoplasmas is a work in progress.

EPIDEMIOLOGY
Occurrence Eperythrozoonosis occurs in sheep, swine, cattle, and llamas, with the greatest clinical occurrence and importance in swine and sheep. Latent eperythrozoonosis also occurs in several species of deer, elk, and goats. The organisms appear species specific, although M. ovis has been transmitted from sheep to goats, identified in a number of species of farmed and free-ranging deer,1,2 and detected by PCR of the blood of a Texas veterinarian.3 Three distinct species of hemotrophic mycoplasmas, including two novel species, have been identified by PCR in white-tailed deer in the United States.24 The distribution is as follows:
- Sheep. Eperythrozoonosis of lambs associated with M. ovis is recorded in Africa, Iran, the United States, Canada, Great Britain, France, Norway, Germany, Poland, Eastern Europe, Australia, and New Zealand.
- Pigs. Also known as infectious anemia of pigs, the disease is recorded mainly in the United States, Canada, Great Britain, and continental Europe.
- Cattle. Eperythrozoonosis in cattle is widely distributed, with reports from North and South America, Africa, Australasia, the British Isles, continental Europe, and the Middle East.
- Llamas. Infection with Eperythrozoon spp. is reportedly widespread in llamas in the United States. Infection has been detected in animals that also had other disease problems or as the result of specific survey studies, and it is likely that the organism acts primarily as a secondary opportunistic pathogen in llamas.

Source and Transmission
The reservoir of infection is the persistently infected animal, and the disease can be transmitted by any mechanism that transfers infected blood. In sheep it is thought that the minimal infective dose is one parasitized erythrocyte. Horizontal and vertical transmission are possible.

Sheep
The method of natural spread of the infection in sheep is probably via biting insects. Serologic studies in Australian sheep show that the prevalence of farms with infection is high and that spatial differences are probably a result of differences in vector occurrence. In an infected flock or herd, the disease can also be spread by management practices that transfer infected blood. In sheep, these include vaccination, ear-tagging, shearing, and mulesing, although these risk factors have not been associated with infection in any epidemiologic studies.
Pigs
Skin parasites and blood-contaminated needles and instruments have been shown to transmit disease in swine. Transplacental transmission is also important in swine.

Host and Pathogen Risk Factors
Seasonal differences in disease prevalence occur, being more common in the summer and autumn. This corresponds to increased vector populations but also to weaning of lambs and management procedures that may encourage spread, such as the multiple use of needles for vaccination. Regional differences in the clinical severity of the disease has led to postulations of differences in virulence between strains of the organism. There may also be genetic difference in host susceptibility, and field observations are that the Merino is more susceptible to infection and disease. The increased scrutiny of isolates using PCR has identified novel strains of hemotrophic Mycoplasma in many animal species, some of which are yet to be confirmed as new species.

Many studies suggest that subclinical infection is common and that the development of clinical disease requires the presence of some other debilitating factor or stress for disease to occur. In Merino sheep this may be the stress of weaning, suboptimal nutrition, and intercurrent gastrointestinal nematicode infections. Viral infections with porcine reproductive and respiratory syndrome (PRRS) and swine influenza appear to predispose its occurrence in swine.

Intercurrent infections of hemotrophic Mycoplasma with other blood parasites, such as Anaplasma, are recorded in association with severe disease in sheep and cattle. However, a phenomenon known as interference, in which infection with one blood parasite protects against another, has been noted with Theileria and hemotrophic Mycoplasma in cattle.

PATHOGENESIS
Following experimental infection there is a variable prepatent period, usually 1 to 3 weeks, which is followed by a period of intense parasitemia. Ring-form, coccoid, and rod-shaped organisms are evident in stained blood smears. The organism is epilucent, infecting the surface and periphery of erythrocytes, and is also found free in the plasma in blood examinations. There is a profound hypoglycemia during the parasiticemic phase, which is believed to be a result of direct consumption of glucose by the parasite. The period of intense parasitemia lasts for a period of 5 to 10 days, following which visible organisms in the blood become much less frequent and anemia develops. Parasitized erythrocytes are removed from the circulation by the spleen. It is believed that the parasite alters the erythrocyte membrane, exposing new antigenic determinants and stimulating the development of anterythrocyte antibodies. The severity and duration of the anemia vary between individuals, but the disease commonly lasts from 1 to 2 months. Upon recovery there may be further cycles of parasitemia and anemia, which are less severe. Sheep that develop a high antibody titer tend to rapidly clear the Parasitemia, whereas sheep that have a poorer antibody response tend to show persistent parasitemia and recurrent episodes of anemia. Once an animal is infected, it is probably infected for life.

CLINICAL FINDINGS
Sheep
Sudden death and deaths associated with exercise, accompanied by hemoglobinuria and icterus, may be a feature in some sheep and some outbreaks, but, more commonly, the disease is manifest with fever and depression followed by the development of anemia, exercise intolerance, and ill-thrift. In some cases, it may be the principal cause of ill-thrift in lambs. There is reduced wool growth, and in the experimental disease in lambs at pasture, a retardation of growth of up to 2 kg has been recorded 5 weeks after infection. Lambs suckled by infected ewes are passively immunized via the colostrum until weaning.

Pigs
Acute icteroaemia is the classical syndrome and occurs in feeder pigs. It is characterized by weakness of the hind legs, mild fever (40°C; 104°F), increased pulse rate, pallor of the mucosae, and emaciation. Jaundice is a frequent but inconsistent feature of the disease. Case fatality is high, and death occurs 1 to 5 days after the onset of clinical signs. Although once quite common, the prevalence of this form has decreased, possibly as a result of the use of feed additives containing arsenicals and effective ectoparasite control.

Another manifestation includes anemia and weakness in neonatal pigs accompanied by low piglet viability, affecting several litters. Affected pigs are pale and lethargic, and there is marked variation in birth weight within affected litters. Low-birth-weight piglets die shortly after birth. The anemia increases in severity between birth and weaning age, the pigs have skin pallor and exercise intolerance, and there is considerable variability in weaning weights. The syndrome may or may not be accompanied by reproductive inefficiency characterized by delayed estrus cycles and embryonic death. Anemia, jaundice, and poor growth rate can also present primarily in weaner pigs.

Subclinical infections associated with subclinical anemia are reported to result in reproductive failure, anestrus and delayed estrus, reduced sow body condition, increased susceptibility to enteric and respiratory disease, and failure of feeder pigs to gain weight at the expected rate.

Cattle
Clinical disease has been considered uncommon and has largely been a problem in cattle that have been splenectomized for experimental use, with disease occurring 1 to 4 weeks after the splenectomy. However, clinical disease is recorded in adult commercial dairy cattle manifest with lassitude, stiffness, pyrexia, diarrhea, hindlimb and udder edema, and a fall in milk production, with one reported case clustered 5 days on either side of vaccination against bluetongue virus.

Eperythrozoonosis has also been associated with a syndrome occurring in heifers in early to midlactation, during late summer and early autumn, in which there was fever, swelling of the teats and the hindlimbs, lymph node enlargement, and a fall in milk production. Signs of infection resolved in 7 to 10 days, regardless of treatment. A similar transient disease occurring in the spring and summer months, and manifest with scrotal and hindlimb edema and infertility, has been associated with eperythrozoonosis in young bulls.

CLINICAL PATHOLOGY
Blood Smears and Hematology
The presence of the organism can be established by examination of a blood smear taken during a clinical episode and when the animal has fever. In countries where there is no serologic test available this may be the only method of diagnosis. Parasitemia is most intense before the development of clinical anemia and appears as 0.5- to 1.0-mm, coccoid, rod- or ring-shaped basophilic particles on red cells or free in plasma. Parasitemia is difficult to detect once clinical signs of disease are evident and very difficult in chronic disease. It is recommended that blood samples from a number of animals in the group be examined if eperythrozoonosis is suspected.

Lowered values for hemoglobin and packed cell volume (PCV) are evident on hematological examination of clinically affected animals, and there is marked red cell anisocytosis and polychromasia with basophilic stippling and the presence of many Howell–Jolly bodies in sheep. A profound hypoglycemia may be demonstrated, and there are elevated concentrations of unconjugated and total bilirubin.

Polymerase Chain Reaction
The development of conventional and real-time PCR assays now offers a more precise, sensitive, and efficient diagnostic method, with many animals negative on blood smears being positive on the PCR test.

Serology
Sheep
The complement fixation test and indirect fluorescent antibody test (IFA) have been used. With the complement fixation test, sera...
from affected animals give positive reactions on the third day of clinical illness, remain positive for 2 to 3 weeks, and then gradually revert to negative. Chronic carriers of the disease are usually negative reactors. The IFA or ELISA tests are more suitable for serologic studies because infected animals remain seropositive for significantly longer periods.

**Pigs**
The indirect hemagglutination test and ELISA test can be used in swine and are of value in herd diagnosis but may not detect infection in an individual pig, especially those under 3 months of age. Experimental challenge of splenectomized piglets may be used to determine the presence of infection. PCR may resolve laboratory diagnostic problems.

**TREATMENT**
A single intramuscular injection of tetracycline or oxytetracycline (3 mg/kg BW or more) is an effective treatment in sheep, with clinical improvement occurring in 24 hours in the early stages of the disease. Chronic infections are less responsive. Treatment of affected lambs with neaersphenamine (30 mg/kg BW) or Antimosan (6 mg/kg BW antimony) is effective in relieving clinical illness but does not completely eliminate the parasite. Imidocarb dipropionate also is effective in treatment, but recrudescence does not occur for 2 weeks is common.

**CONTROL**
Control of disease in sows and neonates has been reported with the inclusion of chlorotetracycline in the sow feed at 300 g/ton or by intramuscular administration of oxytetracycline to sows at 14 and 7 days before the expected farrowing date. Tetracyclines also can be used in feed or by in-line water medication in feeder pigs. With large flocks of sheep in enzootic areas, reinfection or recrudescence occurs so quickly that control by treatment may be an unwarranted expenditure.

In confined swine operations, the detection of carrier pigs by PCR, and their subsequent removal, has been proposed as a possible control procedure.

**BOVINE PETECHIAL FEVER (ONDIRI DISEASE)**

Bovine petechial fever is a rickettsiosis of cattle caused by *Ehrlichia (Cytoecetes) ondiri*. The disease occurs in the highlands of *Kenya* and *Tanzania* at altitudes of 1500 to 3000 m, although it is considered likely to occur in neighboring countries with similar topography. Characteristically, bovine petechial fever occurs in cattle that break out from fenced pastures and graze adjacent forest or bushland areas, or when they are grazed on these areas at the end of the dry season. It also occurs in cattle that have been recently introduced to these areas, and indigenous cattle appear to acquire resistance. Epidemics occur in cattle imported to infected areas and last 1 to 2 months, involving 60% to 80% of the group and resulting in significant losses. However, no outbreak has been reported for over a decade.

Infection can be experimentally transmitted to cattle, sheep, goats, wildebeest, impala, duiker, bushbuck, and other wild ruminants, but natural disease is seen only in cattle. *E. ondiri* infection is believed to be endemic in wild ruminants, especially bushbuck and duiker, and the disease sporadically spills into cattle grazing forest edges or bushland. The vector is not known, although epidemicologic findings suggest a tick vector of restricted distribution.

The disease in cattle is characterized by high fever and widespread petechial hemorrhages in mucous membranes for periods up to 10 days; epistaxis, melena, and unilateral conjunctivitis occur in more severely affected animals. The eyeball is tense, protruding and is likely to be distorted. This is a “pachy-egg eye.” Pregnant animals may abort, and there is a fall in milk production for several weeks in lactating animals. Anemia may be severe enough to result in death 3 to 4 weeks after infection. There is a profound lymphocytopenia by the second day of infection, followed by leukopenia and thrombocytopenia. The organism can be demonstrated in granulocytes and monocytes in Giemsa-stained blood smears during the febrile period, but it cannot yet be cultured. Serology (indirect fluorescent antibody test) can be carried out to detect antibodies against *E. ondiri*.

Grossly, the main lesions of ondiri disease are widespread petechial hemorrhages and enlarged, congested lymph nodes. In severe cases, death is often a result of severe hemorrhages into the lungs and airways. Abomasal mucosa is edematous, and the contents of the ileum and colon are tarry. Differential diagnosis includes other hemorrhagic diseases of cattle, such as acute trypanosomiasis, acute theileriosis, hemorrhagic septicemia, bracken fern poisoning, Rift valley fever, and heartwater.

Tetracyclines are effective in treating early experimental cases but are ineffective in advanced cases. Recovered animals may be latently infected and are immune to reinfection for at least 2 years. Control is by avoiding grazing cattle in forest edges and in paddocks with patches of thick scrub.

**MYCOPLASMA SUIS INFECTION IN PIGS**

*Mycoplasma suis* causes anemia, fever, and icterus in pigs and was formerly called *Eperythrozoon suis*; it is a member of the *Mollicutes* family. The classical disease is now called infectious anemia of pigs. The original descriptions of the condition had two possible causes, *E. suis* and *E. parvum*. Currently, on the basis of 16S rRNA, *E. suis* is classified as *M. suis* within the *Mycoplasma* genus. Pigs infected with *E. parvum* have only mild disease. In a recent study in Brazil, a novel species was discovered, and by PCR this showed 98% to 99% matched identity to *Candidatus M. haemominutum* and is likely to be *E. parvum*.

This disease is probably greatly underdiagnosed because of the difficulties in diagnosis. A recent study in China showed a heavy infection rate in swine workers (32/65), and it is now being isolated from diseased humans. Outbreaks of hemotropic mycoplasma infection have been recorded in Mongolia. It can cause acute and chronic infections.

**ETOLOGY**

*M. suis* is a rod-shaped, coccoïd, or ring-like bacterium, about 0.2 to 2.0 μm in diameter. It is seen attached to the surface of red blood cells (RBCs), but recent studies have shown that it can also invade RBCs and live in vacuoles or free in the cytoplasm. It has not yet been cultured, but the genome has been sequenced. It exists in two clusters, a North American/European form and a Chinese form, and these were also found in wild boar in Germany. 1
Epidemiology
The disease can be found in all ages of pigs. Maternally derived antibody may play a part in preventing or delaying infection. It is probably found worldwide in pigs, but few surveys have been carried out. It has been found in Brazil and has also been found in deer. In affected herds, it is usually widespread and may cycle in waves through the herd. It was found in 13.9% of feeder pigs, and 40.3% of pig farms were positive in Germany. The morbidity can be 10% to 60%, and the mortality can reach 90% in an acute outbreak in very young pigs.

Transmission is via blood and blood components by licking, biting, cannibalism, urine discharges, and other biological components containing blood. It is probably transmitted by biting flies, mosquitoes, and hypodermic needles. Transplacental infection has been suggested but not proven. The carrier state probably also exists.

Predisposing factors may include immune-modulating viruses such as porcine reproductive and respiratory syndrome (PRRS) virus, porcine circovirus type II (PCV-2), and possibly simian immunodeficiency virus (SIV). Other factors may include increased arthropod activity and periods of stress, such as farrowing and weaning.

Pathogenesis
Initially, there is a heavy bacteremia, with colonization of the surface of the RBCs aided by a surface protein of the M. suis. The RBCs are then recognized as abnormal by the spleen and removed from circulation, adding to the anemia. The degree of anemia is closely related to the load of M. suis on the RBCs. The bacteria are also capable of penetrating the cell by an unknown method, and this may be the means of their persistence as an infection because they can then evade host defense mechanisms, increase virulence, and reduce antimicrobial efficacy.

It is thought that the M. suis uses the erythrocyte glucose for its own metabolism and by damaging the cell membrane induces production of auto-agglutinins favoring removal of these cells by the phagocyte system, thereby increasing extravascular hemolysis.

Any immune response may occur not only as a result of the M. suis but also in response to the infected RBCs, thereby increasing the hemolysis and anemia and subsequent jaundice. The infection itself may affect T cells and cause immunosuppression. In many instances the immunosuppression caused by concurrent infections with PRRS, PCV-2, and SIV will also complicate the pathogenesis and clinical signs. The rate of destruction of RBCs may be so great that the demand for glucose by the M. suis outstrips the gluconeogenesis, and hypoglycaemia may result, especially in pigs of 0 to 7 days of age, which are already low in glycogen.

Endothelial cell activation, widespread endothelial damage, and adherence of RBCs to the endothelium is evident in M. suis infections. The suggestion is that M. suis has a tropism for endothelial cells, and this interferes with the protective function of the endothelium, resulting in hemorrhagic diatheses.

Clinical Pathology
In acute cases there is a peak bacteremia 7 to 14 days following infection, with bacteria in blood smears and variable types of anemia. Decreases in packed cell volume, total red cell count, and hemoglobin concentration occur because of massive red cell parasitism. Anemia and bilirubinemia results from the RBC destruction, with hypoglycaemia and acidosis sometimes occurring.

Clinical Signs
In natural acute cases, which are most common in postweaned pigs, there is lethargy, pyrexia, anorexia, variable icterus, cyanosis of the extremities, petechial bleeding and ecchymoses, and often death within several days.

In chronic cases there is pyrexia; anorexia; reproductive failure; mastitis, metritis, and agalactia (MMA); reduced birth weights; weakness and anemia of neonates; poor growth rates; and ill-thrift, with a predisposition to secondary infections.

In experimental splenectomized pigs the incubation period is 3 to 10 days. It is particularly acute in the pig under 7 days of age, in which the signs include pallor, fever, occasionally icterus, and cyanosis of the extremities, particularly the ears. More commonly there is a mild anemia and a reduced growth rate. There may be increase of bleeding and in some cases navel bleeding in young pigs. The bleeding was shown to resolve with the use of tetracyclines, suggesting that M. suis may be associated with navel bleeding. Recovered pigs may show a reduced growth rate and unevenness in the litter. Skin hypersensitivity, pallor, and unthriftiness may be seen in the chronic infection. In sows, there may be fever, anorexia, lethargy, and agalactia, particularly around farrowing. A severe outbreak of dysgalactia was described in the United States starting 1 day after parturition and lasting 4 to 6 days.

Pathology
In acute cases there is anemia, jaundice, splenomegaly, and serous effusions in the body cavities. In the chronic cases, secondary infections often mask any primary lesions from the M. suis.

Diagnosis
The diagnosis is complicated because there is no culture available for the organism. It is therefore dependent on the clinical signs, the direct demonstration of the organism in blood smears (stained by Romanowska-type stains, Giemsa, or acridine orange) taken at the time of collection of the blood sample and the hematology results of anemia and bilirubinemia.

The position has been improved by the development of PCR techniques. The first qPCR for M. suis was developed in Germany and was shown to be much more sensitive than the blood smear test. The blood test is entirely dependent on the number of organisms present. The test used on 120 samples from clinically normal, healthy pigs on 11 farms found M. suis on 6 farms and M. parvum on 18 farms, with 3 positive for both, using qPCR.

Antibodies can be detected by ELISA tests. These tests have been developed using recombinant antigens, and initially these were of high sensitivity but low specificity. Because the antibodies may only last 2 to 3 months, t false negatives were common. The blood ELISA described is more efficient. A new ELISA was shown to be 98.5% specific and 96.9% sensitive and much more efficient than an IHA test.

Treatment
Usually a course of oxytetracycline at 20 to 30 mg/kg given daily parenterally will prevent the clinical signs. Pigs affected will not usually feed or drink properly, so administration in the feed is only effective as a prophylaxis. If given in the feed, it needs to be fed for a minimum of 14 days. Often it prevents anemia, but it does not prevent outbreaks.

Control
Usually on an infected farm an equilibrium is reached between the organism and the host, but it can be overcome by concurrent infections, bad management, and a poor environment, and thus these should be rectified. The complicating factors should be removed, such as secondary infections by vaccination (PRRS, SIV, PCV-2). Excessive use of vaccines should be avoided because they involve the use of needles. There is no specific vaccine.

EPIZOOTIC HEMORRHAGIC DISEASE (BLACKTONGUE)

SYNOPSIS

Etiology Epizootic hemorrhagic disease virus (EHDV), an arthropod-borne, double-stranded RNA virus of the family of Reoviridae, genus Orbivirus

Epidemiology Infectious but noncontagous disease transmitted by biting midges. Wild ruminants, particularly white-tailed deer, develop severe clinical disease with high mortality. Historically, cattle were believed to be resistant to clinical disease, but recent outbreaks of EHD primarily affecting cattle have been reported. Small ruminants may seroconvert but do not develop clinical disease. Occurrence is dependent on the presence of competent vectors. In temperate regions the highest disease incidence is in late summer and fall; in tropical regions EHD occurs throughout the year.

Clinical findings In white-tailed deer, rapid edema development on the neck and head; swelling of the tongue and conjunctivae. Hemorrhagic diathesis with bloody diarrhea, hematuria, and dehydration. More chronic presentation with erosions or ulceration in the buccal cavity. In cattle, sudden anorexia, decreased rumination, drop in milk production, weakness, short-term low fever, stiff gait. Morbidity rate dependent on infectious pressure in the herd; low mortality rate.

Necropsy findings In white-tailed deer. cyanosis and petechial ecchymotic hemorrhages of oral mucosa and tongue. Ulceration and necrosis of oral mucosa in more chronic cases. Pulmonary edema; serosanguinous fluid in thorax, pericardial sac. and abdomen. Rarely fatal in cattle.

Diagnostic confirmation Virus isolation and detection from blood or tissue (whole blood, spleen, lungs, lymph node, liver). Serologic tests (agar gel immunodiffusion test [AGID], enzyme-linked immunosorbent assay [ELISA], serum neutralization assay).

Treatment Supportive treatment; no specific treatment is available.

Control Culicoides vector control (insecticides, larvicides, insect repellents, management of culicoides breeding areas). Commercial vaccines are not available; autogenous inactivated vaccines have been used.

ETIOLOGY

Epizootic hemorrhagic disease (EHD) virus is an arthropod-borne virus of the family of Reoviridae, genus Orbivirus, closely related to bluetongue virus. At least seven different serotypes (serotype 1 through 8, with serotype 3 considered to be similar to serotype 1) exist, which have been regrouped in recent years. Some of these have antigenic relations with serotypes of bluetongue virus. The EHD virus (EHDV) can infect most domesticated and wild ruminants naturally; pigs are not susceptible to infection. Clinical disease is primarily observed in wild ruminants. White-tailed deer are most severely affected, followed by mule deer and pronghorn antelope. In recent years several disease outbreaks in cattle herds have been reported.

EPIDEMIOLOGY

Occurrence

Because EHD is a vector-borne viral disease, occurrence of infection depends on the presence of competent vectors. Clinical disease or serologic evidence for infection has been reported from North and South America, Africa, Asia, Australia, and, more recently, from the region surrounding the Mediterranean Basin, including Morocco, Algeria, Tunisia, Israel, Jordan, and Turkey. Although the geographic occurrence of EHD was similar to that of bluetongue during the last century, the recent northward progression of bluetongue from the Mediterranean Basin far into the European continent was not observed for EHD.

Historically, two serotypes (EHDV-1, EHDV-2) were predominant among the wild ruminant population throughout the United States, except in the Northeast and the arid Southwest, and southern Canada. Between 2006 and 2009, EHDV-6 was recovered from clinical cases in Indiana, Illinois, Missouri, Kansas, Michigan, and Texas. In Australia, six serotypes (1, 2, 5, 6, 7, and 8) have been isolated, predominantly from sentinel cattle in the north. Three serotypes have been recognized in Africa: EHDV-3 (considered to be identical to EHDV-1), EHDV-4, and EHDV-6. Two major outbreaks of EHD mainly affecting cattle that were associated with a genetically distinct strain of EHDV-2, called Ibaraki disease, occurred in Japan, Korea, and Taiwan in the 1960s and again 30 years later. The first epidemic of Ibaraki disease resulted in 39,000 sick cattle and 4000 deaths. In Europe and the Mediterranean Basin numerous outbreaks of EHD, primarily affecting cattle instead of wild ruminants, have been observed since the beginning of the millennium. In 2001 clinical cases associated with EHDV of unspecified serotype were reported in Israel. Between 2004 and 2007, outbreaks caused by EHDV-6 were reported in Morocco, Algeria, Tunisia, and Turkey. In 2006 an epidemic associated with EHDV-7 and affecting dairy and beef herds was reported in Israel. In 2008 EHD was added to the list of notifiable diseases of the World Organization of Animal Health (OIE) and is now considered an emerging disease in cattle.

Host Occurrence

Under natural conditions infection occurs in sheep, cattle, and wild ruminants. Natural infection does not appear to occur in goats. Historically, clinical disease was primarily observed in wild ruminants, whereas cattle and to a lesser extent sheep were considered as reservoir hosts for the virus. In recent years, outbreaks of EHD affecting cattle have been reported in different parts of the world. Among wild ruminants, white-tailed deer and to a lesser degree mule deer and pronghorn antelope are most susceptible to clinical disease.

Method of Transmission

The disease is not contagious and is almost exclusively transmitted biologically by specific species of Culicoides. Epidemiologic data suggest that Culicoides species transmitting EHDV are similar, although not necessarily identical, to species transmitting bluetongue virus (BTV), but the vector competence of involved Culicoides species may differ for both viruses. Possible differences in the environmental temperature and number of days at or above a specific environmental temperature required for effective virus replication within the vector for BTV and EHDV may have contributed to the differences in geographic progression of these two viruses observed in recent years in Europe.

Culicoides breed in damp, wet areas, including streams, irrigation channels, muddy areas, and fecal runoff areas around farms. Habitats for them exist on the majority of farm environments. Only female Culicoides are hematophagous and feed on their main or preferred host species, requiring at least one blood meal for the completion of the ovarian cycle. They feed nocturnally on animals in open pens and fields, and the optimal temperatures for activity are between 13° (56°F) and 35°C (95°F). In temperate areas the disease is seasonal because Culicoides do not tolerate low ambient temperatures, resulting in a vector-free season during late fall and winter.

Culicoides Species

Different Culicoides species have different geographic occurrence, and their distribution in a country is determined by climatic factors and the presence of a preferred host. In the United States C. sonorensis is the predominant vector throughout much of the country, except in the Southeast, where C. insignis predominates. C. imicola is a predominant vector; in the Middle East and Asia, C. micola has been involved in the recent expansion of EHD, but C. obsoletus and C. pulicaris have been implicated as new vectors associated with recent EHD outbreaks.

Other Vectors

Other vectors may transmit the disease mechanically but are unlikely to be of major significance in disease epizootics.
Other Methods of Transmission

The Ibaraki strain (EHDV-2) was isolated from the internal organs of aborted fetuses, which proves that transplacental virus transmission is possible. The incidence of congenital infection and thus the epidemiologic relevance of this route of virus transmission has not been quantified. No reports of isolation of EHDV in the semen of infected animals are available.

Although oral and fecal shedding of EHDV-1 was reported in white-tailed deer, the epidemiologic importance of oro-fecal transmission has not been ascertained.1

Host Risk Factors

Although most ruminant species are susceptible to infection with EHDV, clinical disease primarily is observed in white-tailed deer and, in recent years, also in cattle.

Wild Ruminants

In North America, EHD is considered one of the most important diseases of deer, particularly of white-tailed deer (Odocoileus virginianus) but also mule deer (O. hemionus) and pronghorn antelope (Antilocapra americana). There are areas of enzootic stability, where seroprevalence in deer is high but the clinical disease rare, and areas with low seroprevalence where clinical disease is severe.

Cattle

Historically, cattle were believed to function as reservoir hosts for EHDV by being susceptible to infection but resistant to clinical disease. The first reports of clinical disease related to EHDV in cattle date from 1959, when an epizootic disease called Ibaraki disease occurred in Japan. Disease outbreaks caused by the Ibaraki strain (EHDV-2) were subsequently observed in other Asian countries. Since 2001 a number of disease outbreaks have occurred in the Mediterranean Basin and also in the United States that have been linked to EHDV serotypes 6 and 7. EHD is now considered an emerging disease of cattle.5 Morbidity rates in cattle herds can be considerable, depending on the infectious pressure, but clinical signs are much less severe than in white-tailed deer, and mortality is low.7

Small Ruminants

Sheep are susceptible to infection with EHDV but do not develop clinical disease. Although this species has been incriminated as a potential reservoir host for EHDV, more recent experimental studies do not support the assumption that sheep may play a relevant role in the epidemiology of EHDV.7 In goats, thus far only the presence of EHDV antibodies but not the presence of virus or viral DNA has been documented. It is therefore assumed that goats are resistant to infection.

Morbidity and Case Fatality

Wild Ruminants

Morbidity and case-fatality rates of EHDV in wild ruminants are difficult to determine. Among the Cervidae, white-tailed deer are the most severely affected, and case-fatality rates in this species are much higher than those in other commonly affected species, such as mule deer, black-tailed deer, and pronghorn antelopes. In the Northeast and Midwest of the United States EHD typically recurs every year in late summer and early fall, but mortality and case-fatality rates can vary greatly from year to year. Morbidity and mortality rates may be as high as 90%, although in most instances cases are mild and mortality is low. This variability is thought to be caused by a number of factors, such as the abundance of biological vectors, the ambient temperature, the serotype of EHDV that is circulating, herd immunity (based of previous exposure to a similar strain), and the genetic variation in the susceptibility of the host.7

Cattle

Outbreaks of EHD in cattle herds have been reported in Asia, the United States, and the Mediterranean Basin. Although in rare instances considerable morbidity and case-fatality rates have been reported, as in the case of Ibaraki disease outbreaks in Japan and Korea, in most cases morbidity rates do not exceed 5%, and deaths are uncommon. During an EHDV outbreak in Israel, within-herd morbidity rates between 5% and 80% were observed in dairy herds, but the mortality rate remained below 1%.1

Economic Importance

Until outbreaks of EHD affecting cattle occurred, EHD was considered a disease primarily affecting wild ruminants and thus of minor economic importance. Following the most recent outbreaks in North Africa, Turkey, and Israel, the economic importance of EHD had to be reconsidered. Since 2008 EHD has been listed as reportable disease by the OIE, and EHD is now considered a potentially emerging disease of cattle.5 Because the increased virulence of EHDV for cattle has only been observed in recent years, not many studies investigating the economic impact of this disease are available. Losses result from decreased productivity, increased involuntary cull rates, abortion, and, in some instances, death. In infected herds in Israel EHD was found to cause an average loss in production of 125 kg/cow per year, an effect that was highly dependent on the season of the year the outbreak occurred and the seroprevalence of the herd. The highest losses were observed when outbreaks occurred in September and in herds with the highest seroprevalences.5 With losses related to increased mortality added to the production losses, the total cost for the dairy industry in Israel was estimated to range between US$ 1,600,000 and 3,400,000, which is equivalent to an average loss of US$ 26.50 per cow.5

PATHOGENESIS

The incubation period for EHD in deer is 5 to 10 days. After infection with EHDV, initial viral replication occurs in endothelial cells of the lymphatic vessels and lymph nodes draining the site of infection.1 A viremic phase ensues during which the virus is disseminated to other sites of virus replication, such as the lymph nodes and spleen, causing secondary infection of the endothelial cells of arterioles, capillaries, and venules throughout the body. In blood, EHDV is associated with erythrocytes and to a lesser extent with lymphocytes. This cell association permits prolonged viremic periods and the concomitant presence of virus and antibodies in blood.

Endothelial damage results in leakage of blood vessels and ensuing disseminated intravascular coagulopathy. Fibrin thrombi occluding small blood vessels cause congestion, hemorrhage, and edema of surrounding tissue. Ischemic necrosis occurs in tissue where blood perfusion is interrupted as a result of thrombosis.

Occurrence of viremia in relation to EHDV infection was studied in cattle and deer. The virus could be detected from 2 days following infection, and all animals were viremic 4 days after infection. After experimental infection virus could be isolated up to 28 days following infection and in rare instances up to 50 days following infection.1 Neutralizing antibodies can be detected from 10 to 14 days following infection but do not prevent or interrupt viremia. The concomitant presence of virus and homologous antibodies is commonly observed in EHD during the first weeks following infection. Maternal antibodies were identified in fawns born to dams infected with EHD for up to 18 weeks. Passive immunity was not able to prevent infection or viremia in fawns exposed to EHDV but alleviated clinical signs of the disease.1

CLINICAL FINDINGS

Deer

In deer, EHD may occur in a peracute, acute, or chronic form. Peracute disease is characterized by high fever, anorexia, respiratory distress, and severe and rapidly developing edema of the neck and head. Conjunctivae and the tongue are commonly swollen. Affected animals may be found dead or die within 2 days of the first clinical signs.7 The acute form is the classical presentation of EHD in deer, in which extensive hemorrhage affecting the skin, gastrointestinal tract, and heart is the hallmark sign. There is often hyperemia of the conjunctivae and mucosal membranes of the mouth. Ulcers and erosions may develop on the tongue, dental pad, palate, rumen, and
abomasum. Excessive salivation and nasal discharge, which can be tinged with blood, have been observed. Bloody diarrhea, hematuria, and dehydration can occur. The mortality rate for both the peracute and acute forms is generally high.

Deer with the chronic form of EHD are sick for several weeks but recover gradually. Cracks in the hooves resulting from the interrupted horn growth resulting from the disease may cause lameness. Chronic lesions of the mucosa of the rumen, with erosions, ulcers, and scarification, can cause emaciation.

**Cattle**
Most infections in cattle are unapparent. Occasional disease associated with infection with EHDV is recorded in cattle in the late summer in the United States and has been reported in recent outbreaks in the region around the Mediterranean Basin. Common clinical signs are anorexia, reduced rumination, weakness, decreased milk production, stiff gait, and short episodes of pyrexia. Reddening and swelling of the oral mucosa with necrotic ulceration of the dental pad and behind the incisor teeth, cracking and sloughing of the skin of the muzzle, and hyperemia of the skin of the teats and udder may occur in some cases.

**Ibaraki disease** is characterized by fever, hyperemia and edema of the mucosae, hemorrhages, ulcerative stomatitis with laryngeal and pharyngeal paralysis, salivation, and dysphagia. At postmortem there were hemorrhages in the pharynx and esophagus, and animals commonly died with aspiration pneumonia. Infection of pregnant cattle with Ibaraki virus can also result in abortion and stillbirths, and currently this seems a more common clinical manifestation. Fetuses infected between 70 and 120 days of gestation may develop hydroencephaly.

**Clinical Pathology**
Specific diagnosis is either by isolation of the virus, detection of viral antigen or nucleic acid, or detection of specific antibodies in serum. Serologic assays can detect prior exposure to EHDV but cannot establish if the animal is viremic and thus infectious. Serologic tests may be of limited values in regions where EHDV is endemic and seroconversion is common in the affected population.

Materials that can be used for virus isolation include heparin or EDTA in the blood, biopsies, or postmortem tissue samples of the spleen, lung, lymph nodes, or liver.

**Virus Isolation**
Virus isolation commonly is carried out by tissue culture or culture in embryonated chicken eggs (ECEs). Cell lines used for this purpose can be of insect origin, such as the KC cell lines derived from *Culicoides sonorensis*, or mammalian cell lines, such as baby hamster kidney cells (BHKs), calf pulmonary artery endothelium cells (CPAEs), or African green monkey kidney cells (Vero). The cytopathic effect produced by EHDV is only observed on cell lines of mammalian origin and becomes apparent between 2 and 7 days after inoculation. Virus identification from cell cultures is based on a serum neutralization or plaque inhibition test using reference antisera. Virus isolation is the most reliable confirmation of EHDV infection because there are difficulties with the interpretation of serologic test results. However, traditional isolation methods require 2 to 4 weeks.

**Detection of Antigen or Nucleic Acid**
Immunohistochemical tests, including immunofluorescence, or molecular techniques such as in situ nucleic acid hybridization, reverse-transcription polymerase chain reaction (RT-PCR), or the dot blot test can be used for rapid sensitive and specific detection of antigen. Use of RT-PCR has proliferated because of its simplicity, rapidity, reliability, reproducibility, sensitivity, and specificity. However, tests that detect viral RNA prove exposure to the virus but do not necessarily indicate that infectious virus is still present. An antigen-ELISA and sandwich-ELISA have also been used for EHDV identification but are less sensitive than the PCR.

**Serologic Tests**
A number of serologic tests for detection of either group-reactive antibodies or serotype-specific antibodies are available. The commonly available tests include the complement fixation test (CFT), the agar gel immunodiffusion test (AGID), a number of different ELISA tests, and serum neutralization (SN). The AGID test is easy to perform and inexpensive but is also relatively insensitive and detects cross-reacting antibodies to other orbiviruses, such as bluetongue virus. Over the last decades the CFT and AGID have been replaced in many laboratories by the more rapid, sensitive, and specific competitive ELISA.

A number of ELISA tests have been developed that use group-specific monoclonal antibodies, and these present valuable alternatives to the AGID for routine diagnosis and international trade. The competitive ELISA (cELISA), which is the most sensitive and highly specific group-specific test, is the preferred test for serodiagnosis of EHD. The **serum neutralization test (SNT)** is serotype specific and thus allows for differentiation between antibodies against specific EHDV serotypes. The biological detection system (either ECEs or cell cultures) is reacted with a reference serum for specific EHDV serotypes, and the amount of virus neutralization is determined. Although the SNT is highly sensitive and specific, it is also expensive and time-consuming and is therefore not used as a routine diagnostic procedure.

**Necropsy Findings**

**Deer**
Lesions in white-tailed deer and related species are similar to those described for bluetongue in sheep and cattle. In acute cases, there may be cyanosis of the oral mucosa and tongue, along with widespread petechial to ecchymotic hemorrhages. In more chronic cases, there may be ulcers and necrotic debris in the oral mucosa and severe hoof lesions, including fissures and sloughing. Lesions in yaks include swollen conjunctive, ulcerated dental pads, mucoid sanguineous nasal discharge, and petechial hemorrhages in multiple organs; others are pulmonary edema and serosanguinous fluid in the thorax, abdomen, and pericardial sac.

**Cattle**
The disease is usually subclinical and nonfatal in cattle.

**Samples for Confirmation of Diagnosis**

- **Histology**—fixed oral and mucocutaneous lesions, abomasum, pulmonary artery, skeletal muscle from a variety of sites, left ventricular papillary muscle, brain from aborted fetus (LM, IHC)
- **Virology**—chilled lung, spleen, CNS tissues, thoracic fluid from aborted fetus (ISO, PCR, in situ HYBRID, ELISA, etc.)

**Differential Diagnosis**

- Foot-and-mouth disease
- Bluetongue (wild ruminants)
- Bovine viral diarrhea/mucosal disease (cattle)
- Malignant catarrhal fever (cattle)
- Bovine ephemeral fever (cattle)

**Treatment**
There is currently no specific treatment available for EHDV.

**Control**

Reduction of Infection Through Vector Abatement
Attempts to control EHD through a reduction of infection consist of reducing the risk of exposure to infected *Culicoides* and reduction in *Culicoides* numbers. Neither are particularly effective. Widespread spraying for *Culicoides* control is not usually practical and has only a short-term effect.

To address recent EHD outbreaks in cattle herds, several affected countries have introduced control measures such as monitoring of wildlife reservoirs, quarantine, vector control programs on farms, and awareness campaigns for veterinarians and farmers.

**Vaccination**
There is no commercially available vaccine against EHD. Autogenous inactivated
vaccines produced from virus isolates from ill or diseased herdmates have been used in the United States to control EHD outbreaks in captive wildlife deer. In Japan, both a modified live and an inactivated vaccine derived from the Ibaraki-2 strain have been developed to control Ibaraki disease. This vaccine, which is administered once during the low-vector season, was found to be safe and effective in controlling the disease.1

BOVINE IMMUNODEFICIENCY-LIKE VIRUS

ETIOLOGY
Bovine immunodeficiency-like virus (BIV), also known as bovine lentivirus-1, is a lentivirus, within the larger family of Retroviridae. The virus shares structural and genomic similarities with other lentiviruses, such as equine infectious anemia virus, caprine arthritis-encephalitis virus, maedi-visna virus, and the feline, simian, and human immunodeficiency viruses. BIV was first described in cattle in the United States in 1972. These viruses replicate primarily in the cells of the host’s immune system following their insertion as provirus into the genome of these target cells, thus establishing a chronic, lifelong infection. The lentiviruses are usually associated with specific diseases. However, a clear involvement of BIV in the development of a clinical syndrome is not well established.

EPIDEMIOLOGY

Prevalence of Infection
Seroepidemiological evidence indicates that BIV infection has a worldwide distribution. Seropositive cattle have been identified in the United States, the Netherlands, New Zealand, Australia, Bali, Indonesia, Brazil, and Canada, with estimates ranging from 1% to 5% of cattle being infected. In Italy, the prevalence is 5.8% in dairy cattle and 2.5% in beef cattle. In individual herds the prevalence of infection may be much higher. In the United Kingdom, the seroprevalence was found to be 5.9% in dairy cattle and 5.0% in beef cattle. The dairy and beef herd prevalence rates were 60% and 59%, respectively. Although the prevalence of BIV infection in the United Kingdom is low, it is widespread. Recent studies, using DNA derived from semen and buffy-coat samples, analyzed by nested PCR, found no evidence of BIV infection in western Canadian cattle.

A seroprevalence of greater than 50% was present in a dairy herd at a university in the southeastern United States, which is an area with a high prevalence of infection in the cattle population. There is some evidence that in some cattle herds with a high incidence of unthrifty animals, the prevalence of seropositive animals may be as high as 95%. The prevalence of BIV infection among dairy cattle in Ontario is low and may be associated with an economically important decrease in milk production. Cases of dual infection with BIV and BLV have been reported in Mississippi dairy cattle.

The virus has been found in the seminal leukocytes of 82% of randomly selected semen samples from a bovine stud semen repository, suggesting the possibility that artificial insemination of dairy cows may have a major role in the transmission of the virus. BIV may be involved in the pathogenesis of mastitis in cattle as a result of its immunosuppressive effects, but no clear evidence is available. Retroviruses are heat labile and readily inactivated at 56°C (133°F), and pasteurization of milk for human consumption should provide an adequate safeguard. Feeding milk seeded with the virus and pasteurized before inoculation into calves is effective in inactivating the virus and preventing transmission. There is no evidence that the virus is a major human pathogen.

Methods of Transmission
The virus is strongly cell-associated and may be transmitted with infected blood, colostrum, and milk that contains lymphoreticular cells. There is some evidence of transplacental infection of the virus in cattle. In dairy cows naturally infected with BIV and seropositive at parturition, 40% gave birth to calves that were BIV seropositive before receiving colostrum, whereas seronegative cows did not. Calves born with anti-BIV antibodies or infected with BIV were more likely to be infected with BIV than were seronegative cows. Conversely, seronegative cows that were BIV seropositive before the birth of their calves were more likely to transmit the virus to their offspring than were seronegative cows.

Infection of calves with BIV is associated with lymphoproliferation, lymphadenopathy, immunosuppression, neuropathy, and progressive emaciation. The virus was initially isolated from a cow with persistent lymphocytosis, lymphadenopathy, neuropathy, and progressive emaciation. However, overt clinical disease in seropositive calves is rare, and experimentally induced infection in calves has resulted in only mild clinical consequences.

Early studies of inoculation of calves with the virus resulted in lymphoproliferative disease, lymphocytosis, and persistence of the virus. Later studies have failed to reproduce significant clinical disease, which may in part be a result of the long incubation period. It is also possible that the lentiviruses have variable virulence because genetic variation produces viruses with both antigenic and biological heterogeneity in pathogenesis. Experimental infection of an 11-month-old calf with the virus was followed by the development of a T-cell lymphosarcoma, and the bovine leukosis virus was not present.

The virus and its DNA have been detected in the blood and semen of experimentally infected bulls. However, the virus has not been detected in the semen, blood leukocytes, or semen leukocytes of samples supplied by artificial insemination centers.

Retroviruses, including the lentiviruses, are characterized by the expression of the unique enzyme, reverse transcriptase, that facilitates the transcription of the RNA of an infectious virus to a complementary DNA copy. The viral DNA has the ability to become incorporated into the host’s cell nucleus as a “provirus.” Proviruses are noninfectious, can remain latent for many years, and persist in the presence of antibody. A change in the virus from its latent form to an infectious RNA virus can occur and depends on activation of the latently infected cells. The stimuli for activation can include concurrent
infection and stress, or both. Although other lentiviruses such as equine infectious anemia virus can cause severe clinical disease, the cause-and-effect relationship between BIV infection in cattle and clinical disease has not yet been documented.

**CLINICAL FINDINGS**
In the United States, naturally occurring BIV infection in Holstein dairy cattle in Louisiana has been described. Progressive weight loss was common, and concurrent infections included metritis, subcutaneous abscesses, purulent arthritis, laminitis, and infectious pododermatitis, fascioliasis, and mastitis. Reduced vitality, dullness, and stuper were also common.

The course of the disease varied from 3 to 40 weeks.

**CLINICAL PATHOLOGY**
_Detection of Virus._ A PCR test has been used to detect BIV in the blood and milk of BIV-seropositive cows. The virus can be detected in experimentally infected calves using PCR in peripheral blood mononuclear cells.

_Serologic Tests._ With the BIV ELISA, naturally occurring cases in dairy cattle are serologically positive. An indirect immunofluorescent antibody test has been used to detect seroconversion in experimentally infected bulls by 17 days after infection. The sensitivity and specificity of the indirect fluorescent-antibody assay (IFA) and the nested-set PCR have been compared using Bayesian techniques. The PCR is the more sensitive assay.

**NECROPSY FINDINGS**
Moderate to marked enlargement of hemal lymph nodes has been described. Lymphoid depletion is common and characterized by an absence of follicular development in nodes draining regions with secondary infections. Encephalitis characterized by meningeal, perivascular, and parenchymal infiltration with lymphocytes, plasma cells, and macrophages with perivascular edema has been observed. Several secondary infections have been observed in cattle with BIV infection, but the role of BIV as a predisposing pathogen is uncertain.

</table>

(EBL) is an exogenous C-type oncovirus in the Retroviridae family.

**Epidemiology** Infection is widespread in all continents, although several countries have successfully implemented BLV eradication programs. Prevalence of infection varies between countries. Persistent aleukemic (AL) infection is most common, followed by infection with persistent lymphocytosis (PL) in 30% of infected animals. Less than 5% of infected animals develop lymphosarcoma, the only clinically apparent form of EBL. Clinical disease is most common in mature cattle. Infected animals are the only source of the virus, which is transmitted horizontally by transmission of infected lymphocytes from parturition, contaminated surgical instruments, rectal palpation, and blood-sucking insects. Congenital infection in 4% to 8% of calves born to infected cows. Genetic makeup of animal determines risk of developing PL or lymphosarcoma. Economic losses as a result of loss in milk production traits, premature culling, carcass condemnation, and restrictions of international commerce. EBL is currently not considered a zoonosis.

**Etiology**
The causative agent enzootic bovine leukosis is bovine leukemia virus (BLV), an exogenous C-type oncovirus in the Retroviridae family that is highly homologous to human T-cell lymphotropic virus 1 and 2. Infection occurs by transfer of infected lymphocytes from one individual to another and is followed by a permanent antibody response and, less frequently, development of persistent lymphocytosis (PL) or lymphosarcoma. It has leukemogenic activity, can be grown in tissue culture, and produces specific antibodies in calves and sheep.

**EPIDEMIOLOGY**
_Prevailing of Infection_ Leukosis in cattle was originally described in Germany in 1871. Reports of the disease in cattle became common following World War II, and most countries that raise cattle have reported the occurrence of the disease. The main presumed routes of transmission having led to this epizootic during the first part of the last century in Europe were close animal contact and the use of whole blood vaccination, a procedure used at that time to protect cattle from developing babesiosis.

For this purpose young cattle susceptible to babesiosis were injected with 2 to 3 mL of citrated blood drawn from donor cows with a history of babesiosis before going on pasture. Live animal transports across the Atlantic Ocean brought BLV to the Americas, where it primarily spread by close contact between infected and susceptible animals. The infection is now common in cattle in Canada, the United States, and many countries in eastern Europe and South America and some Asiatic and Middle Eastern countries.

Today large parts of Europe and New Zealand are officially free of EBL after successful implementation of EBL-eradication programs. In Australia the National Dairy Enzootic Bovine Leucosis Eradication Program (NDEBLEP) was established in 2008 and eradicated BLV from dairy cattle by 2012. The prevalence of BLV infection in adult beef cattle in Australia is assumed to be very low. In the United States a serologic survey conducted in 2007 reported a herd prevalence of 83.9% of BLV seropositivity among dairy herds. A similar census from 1996 revealed a within-herd prevalence of 25% or higher in BLV-positive herds in the United States. Recent epidemiologic surveys from different Canadian provinces reported herd prevalence rates reaching up to 89% and individual animal prevalence rates between 20.8% and 37.4%. In Argentina a marked increase of the prevalence was reported for dairy herds in the last decades.
The individual animal seroprevalence was estimated with 33%, and the percentage of infected herds with one or more infected animals was 84%.

The seroprevalence of BLV infection in breeding beef bulls under 2 years of age offered for sale in Kansas was 8.5%. This indicates that young bulls purchased for entry into recipient herds could be infected with the virus. The infection occurs in water buffalo in Brazil and in draught animals in Cambodia.

An outbreak of enzootic bovine leukosis in Egypt was associated with the importation of Holstein–Friesian heifers and bulls from Minnesota in 1989 to form a closed dairy herd in upper Egypt. In 1996 clinical evidence of EBL occurred, and ELISA testing revealed a BLV seroprevalence of 37.7% in cattle under 2 years of age and 72.8% in animals over 2 years of age.

Occurrence of Clinical Disease
The occurrence of clinical lymphosarcoma in countries where the infection occurs has been estimated to be 1 per 1000 per annum; it has been estimated at 1 per 50,000 per annum in infection-free countries. Even in countries or areas where the infection and the disease are common, there are many herds that remain uninfected. Dairy cattle are much more commonly infected than beef cattle, and they have a much higher incidence of lymphosarcoma. In severely affected dairy herds, an annual mortality rate of 2% is unremarkable, and it may be as high as 5%.

All breeds of cattle are susceptible to BLV infection. It occurs rarely in animals less than 2 years of age and increases in incidence with increasing age. The prevalence of infection is higher in large herds than in smaller herds.3 The higher prevalence in dairy herds compared with beef herds is probably a result of their closer confinement and the higher average age of the herds.

There are a number of forms taken by the disease, as follows:
- Aleukemic enzootic bovine leukosis (AL) infection
- Enzootic bovine leukosis with persistent lymphocytosis (PL)
- Enzootic bovine leukosis with tumors—the common form in adults

Methods of Transmission
Direct Contact
Horizontal transmission is the usual method by which the virus is spread under natural conditions. It appears that close physical contact and exchange of contaminated biological materials are required for transmission. The virus is present mostly in lymphocytes and can be found in blood, milk, and tumor masses. Most susceptible cattle become infected by exposure to infected lymphocytes, and not by cell-free virus. Either 10 μl (45,240 lymphocytes) or 1 μl (4524 lymphocytes) of whole blood from a BLV-seropositive cow when injected into calves resulted in infection and seroconversion. It is likely that a threshold number of approximately 100 BLV-infected cells is required to establish infection in the recipient. Therefore any means by which BLV-infected lymphocytes can be transmitted from one cow to another is a potential means of transmission. Natural transmission occurs mostly in cattle more than 1.5 years of age with an apparently increased risk of infection during the periparturient period and after entering the milking herd.3 This suggests that vaginal secretions, exudates and placental fluids from cows, and contaminated calving instruments may serve as sources of infected blood cells.

A considerable number of newborn calves were found to contract BLV infection around parturition or during the first hours and days of life.4 5 Intrauterine infection occurs in 4% to 8% of calves born from BLV-seropositive cows in naturally infected herds. These cases probably occur as a result of transplacental exposure to the virus during gestation.

The virus has been found in the nasal secretions of infected cattle for 2 to 4 years, but there is no evidence that transmission to other animals occurred. Transmission experiments suggest that the virus is not present in saliva, but it does appear intermittently in urine. It is present in nasal and tracheal washings but only in cells, not as a free virus.

Semen, Artificial Insemination, and Embryo Technology
Most workers have failed to find the virus in semen and artificial insemination (AI). However, the virus has been found in semen collected by massage of the donor's urethra and accessory glands per rectum, a procedure that is associated with contamination of semen with blood. Although transmission by AI has not been demonstrated, it is possible that semen containing infected lymphocytes transmission could serve as a source of the virus. Thus bulls at AI centers will be required to be serologically negative for BLV virus. Properly collected semen from BLV-seropositive bulls will not contribute to dissemination of viral infection. More recent studies found that natural service breeding of heifers, and to a lesser extent, cows, was associated with an increase in BLV prevalence.5 Fertilized embryos from donors infected with BLV have been transferred without infection of the fetus. It is possible to produce transferable-stage in vitro fertilized embryos that are free of the integrated BLV provirus, from oocytes that had been exposed to BLV during maturation.

Iatrogenic Transmission
Transmission can occur via infected blood that contaminates surgical instruments, such as dehorning gouges, ear tattooing pliers, and hypodermic needles used on infected and then susceptible animals without disinfection. Transmission can also occur during blood transfusions and vaccines containing blood, such as those for babesiosis and anaplasmosis. Amounts of blood as small as 0.1 μl are capable of transmitting the infection. Thus the infection can be transmitted via the tuberculin intradermal test. However, although some studies have found that use of common needles for blood sampling of infected and noninfected cows at the same time poses a great risk of transmission of the virus to noninfected cows, other studies suggest that the quantities of infective blood passed during injection with common needles is too small to induce infection. The routine practices of brucellosis vaccination, ear-tagging, and tattooing in dairy herds did not seem to be associated with the spread of the disease, but infection could be reduced from 80% to 4% in heifers between the time of weaning to calving by altering dehorning methods. Transmission via infective milk is possible by the passage of infected lymphocytes through intestinal mucosal epithelium during the first few hours of life. However, the risk of infection via this route appears to be greatly reduced because of the presence of maternal antibodies in colostrum and milk.6

Rectal Palpation
The virus can be transmitted by rectal inoculation of infected blood into cattle and sheep. Using blood-contaminated sleeves from palpat ing seropositive heifers to palpate seronegative cows resulted in transmission of infection, as evidenced by antibody formation. This poses the possibility that the virus can be transmitted by rectal examination of cattle, particularly in dairy herds, when a single rectal palpation sleeve is used repeatedly during reproductive tract examinations. Field studies examining the use of the same sleeve for more than one animal or an individual sleeve for each animal indicate that rectal transmission is a potential route of spread of BLV, but that it is related to frequency of palpation and age of cattle. Controlled studies of rectal palpation of cows in a dairy herd over a period of 22 months, using a single sleeve per animal or not changing the sleeve between an infected animal and seronegative animals, resulted in a 2.8-fold increase in the risk of BLV infection. Thus rectal examination without a change of sleeve may be a risk factor in some herds.

Insects
Blood-sucking insects may be involved in transmission of the virus. Evidence implicating arthropod vectors in BLV transmission is indirect, involving experiments in which virus-carrying arthropods or parts of them were transferred to uninfected cattle. In several experiments, infected tabanids, other biting flies, and ticks were placed by hand on cattle and sheep. Minced mouthparts or hematophagous insects previously fed on
BLV-infected cattle also were injected into hosts. In some countries there is empirical evidence that the incidence of seroconversion is higher after the tabanid fly season. A space–time study found a significant positive geographic correlation between the rate of incidence of BLV infection and the density of the horse-fly population. Seasonal variations in the incidence rates also occur; the highest rates are generally observed during summer and the lowest during winter, spring, and early summer. There is also a time link between the rate of seroconversion and the variations in activity of the horse-fly population. Experimentally, the virus has been transmitted by horse flies, Tabanus fuscoicostatus, from a seropositive cow to recipient calves and goats. Horse flies take relatively large blood meals, have a painful bite, and are often interrupted in feeding and must finish feeding on other animals. This behavior, the large number of flies, and the low volume of blood and small number of lymphocytes required to transmit BLV make tabanid flies candidates for mechanical vectors of the virus. The stable fly, Stomoxys calcitrans, has an insufficient mouthpart volume to carry enough blood lymphocytes to transmit the virus.

Congenital Infection
Intrauterine infection has been estimated to occur in 4% to 8% of calves born from BLV-seropositive cows in naturally infected herds and thus is considered to play a minor role in the epidemiology of EBL. Infection of the fetus probably occurs as a result of transplacental exposure to the virus during gestation. Calves born from seropositive cows acquire colostral antibodies if they ingest colostrum, which appears to have a protective effect against BLV infection during the first days of life. Antibody levels decline during the first 6 to 7 months of life. In one study the minimum and maximum duration of colostral antibodies were 14 and 147 days, respectively, with a half-life of 36 days. The decay of colostral antibodies and the age at which a calf can be expected to become seronegative is a function of the quantity of BLV antibodies absorbed by the calf and the infection status of the calf.

Interspecies Transmission
Cattle are the only species infected naturally, although sheep and goats can be infected experimentally. The infection does not spread from cattle to commingled sheep or between experimentally infected and noninfected sheep. However, horizontal transmission of a naturally occurring lymphosarcoma in sheep is associated with an antigenically similar virus to the BLV. It is assumed that horizontal spread of the BLV from cattle to sheep does not occur. The experimental transfer of infection from cattle to sheep is effected so readily that it has become a preferred technique for testing for the presence of a virus.

Source of Infection
In cattle, infection with the virus is permanent, spontaneous recovery has not been documented, and the proviral DNA is maintained in infected lymphocytes. The virus is located in lymphocytes initially in a covert nonproductive state, resulting in an inability of antibodies to arrest the infection, and multiplication of the virus is not necessary for survival or transmission. The virus is also capable of periodic antigenic change and circumventing control by immune mechanisms; thus, the infected animal remains a source of infection for life, regardless of the simultaneous presence of specific antibodies. This virus–host system is the same as that of other retroviruses, especially equine infectious anemia (EIA) and maedi-visna of sheep. In most circumstances, infection occurs when animals are in close physical contact and are more than 12 months old. Infection is established readily by subcutaneous injection, intradermal injection, and intratracheal application, but it does not occur after oral administration, with the exception of neonatal calves.

Experimental transmission of the infection using tumor material, infected blood, or tissue culture virus can be achieved in cattle, sheep, and goats, and apparently also in chimpanzees, but the tumors are produced only in the three ruminant species. A sheep bioassay can be used to determine the presence of the virus in infected cattle.

Risk Factors
Animal Risk Factors
The prevalence of infection based on seroreivalence is positively associated with increasing age in both dairy and beef cattle. The prevalence of infection in dairy cattle under 17 to 24 months of age is much lower than in adult cattle and increases sharply after 24 months of age when heifers join the milking herd and are in close contact with older cattle. The rate of spread may also be associated with the prevalence of infection; in herds with a prevalence of 13% to 22% when first tested, the spread was slow; in a herd with a prevalence of 42%, the spread was much more rapid.

Genetic Resistance and Susceptibility
Infection with BLV is not synonymous with clinical disease. Most animals that become infected do not develop neoplastic disease. Once infection has occurred, the subsequent development of only an antibody response, or antibody plus persistent lymphocytosis (PL), or antibody plus lymphosarcoma, with or without PL, is determined by the host’s genetic makeup. Lymphosarcoma, the clinically apparent form of BLV infection involving the clonal transformation of infected B cells, occurs in about 1% to 5% of BLV-infected cattle and seems to be under genetic control of the host.

Immune responsiveness and heritable resistance or susceptibility to infection are influenced by the host major histocompatibility complex (MHC). In cattle this MHC refers to the so called bovine lymphocyte antigen (BoLA). The earliest studies linked the presence of two class I BoLA-A alleles to the resistance to PL, an association that could not, however, be confirmed at the population level.

A complex relationship exists among genetic merit, milk production, BoLA genotype, and susceptibility to PL. Cows with high genetic potentials for milk and fat yields may be more susceptible to PL than cows with lower genetic potentials, but cows with PL do not produce yields of milk or fat according to their predicted genetic values. The major histocompatibility gene BoLA-A was found to be not only associated with resistance to persistent lymphocytosis, but also with the individual’s production potential. It was therefore hypothesized that genetic selection for increased milk production may have increased the susceptibility to BLV infection of dairy cows over the past decades.

Early attempts to quantify the economic impact of subclinical infection emphasized differences in milk production between seropositive and seronegative cattle. This approach, however, is likely to be confounded by age differences and ensuing differences in the stage of the disease complex. Antibodies to BLV may be present in recently infected cows without other abnormality, in cows over 3 years of age with PL, and in animals older than 6 years of age with tumors.

Susceptibility to Other Diseases
A highly significant correlation was shown between BLV infection and the persistence of Trichophyton verrucosum infection, which suggests that the immune system may be impaired in BLV-infected cows. Observations in Sweden indicate many significant associations between BLV infection status and measures of incidence, reproduction, and production, but most were of low magnitude. The risk for other infectious diseases seemed to be greater among BLV-infected herds, whereas the risk for noninfectious diseases did not differ.

Immune Mechanisms
Both humoral- and cell-mediated immunity are induced in natural BLV infection. Although BLV is primarily associated to B lymphocytes, BLV provirus has been detected in the DNA of CD2+ T cells, CD3+ T cells, CD4+ T cells, CD8+ T cells, monocytes, and granulocytes of infected but clinically healthy
BLV infection was reported to disrupt the equilibrium between B and T lymphocytes not only in PL but also in AL BLV-infected cattle. Studies of cytokine profiles in healthy and BLV-infected cows suggest that type I and II cytokines are altered with increases in IL-10 and IL-4 concentrations and declines in IL-2, IL-12, and interferon-γ concentrations. Following infection, a persistent antibody response occurs primarily to the envelope glycoprotein gp51 and the major core protein p24 of the BLV virions. The time from infection to development of antibodies can be as long as 14 weeks. Experimental infection of calves with the virus results in seroconversion, which can be demonstrated with the ELISA in 4 to 5 weeks after infection. Lymphocytosis can occur at about the same time after infection.

Environmental and Management Risk Factors
Lack of Biosecurity
The introduction of infected animals into a herd has a significant positive effect on the subsequent prevalence of infection and clinical disease. The appearance of new outbreaks of leukosis is almost always the consequence of the introduction of BLV-infected animals in farms or areas previously free of the infection.

Calf Management
The level of calf management in dairy herds is also a major risk factor. Any environmental factor or management practice that allows newborn calves access to infective blood will increase the level of infection in the calves, including prolonged close contact between the cow and calf immediately after parturition or the use procedures or instruments such as the following:

- Gouge dehorners and ear-tagging equipment
- Tattooing equipment
- Instruments used for castration or the removal of supernumerary teats
- Use of single needles for vaccination
- Instruments for control of excessive fly population in calf barns

Feeding colostrum of infected dams to newborn calves has been incriminated as potential route of infection in the past. More recent research indicates that administration of maternal colostrum to calves born from BLV-positive cows greatly decreased the risk of infection in early life compared with calves born to BLV-positive dams but not receiving colostrum from their mothers. These results suggest that exposure to BLV occurs around birth and is not dependent on ingestion of colostrum but that ingestion of colostrum-containing BLV antibodies lessens the risk of contracting BLV infection.

Some observations have found positive associations between BLV status of dairy herds and weaning age, housing preweaned calves in hutches or separate calf housing, and contact between young stock and older animals during the winter housing period.

Pathogen Risk Factors
BLV is highly cell associated and persists in a subpopulation of peripheral B lymphocytes and to a much lesser extent in subpopulations of T lymphocytes. Free virus is rarely or never found in the blood of infected cattle. EBL is therefore not highly contagious. Once an animal is infected, the virus DNA persists for life, incorporated into the DNA of infected lymphocytes.

Economic Importance
Economic losses resulting from BLV infection are associated with morbidity and mortality as a result of malignant lymphosarcoma. BLV decreases productivity and longevity in clinically and subclinically infected cattle, BLV eradication or control measures, and restrictions of international trade.

Loses associated with clinical disease can be economically significant at a herd level in high-prevalence herds but are generally not significant in herds with low BLV seroprevalence because only 0.1% to 5% of seropositive cows and 10% to 50% of cows with persistent lymphocytosis develop lymphosarcoma. Economic losses per case of lymphosarcoma in the United States were estimated to be $412.00 in a 2003 survey. In addition, malignant lymphosarcoma was found to be the largest single reason for carcass condemnation during postmortem inspection at slaughter plants in the United States, accounting for over 21% of all condemnations.

The nature and extent of the economic losses associated with subclinical BLV infection have been controversial because the evidence has been conflicting and because the costs incurred by subclinical infection are difficult to assess. The effects of subclinical BLV infection on milk production, reproductive performance, longevity, and culling rate are variable. In some observations, a BLV-seropositive cow had a shorter life span than both its seronegative counterpart and the entire milk cow population in the United States, accounting for over 21% of all condemnations.

The cost of clinical disease and subclinical infection varied substantially with the prevalence of infection, whereas the cost of control varied with herd size. A basic BLV control program is considered economical in herds in which the prevalence of infection is greater than or equal to 12.5%.

Trade Restrictions
A major economic effect of the disease lies in import restrictions placed by countries free of EBL on infected cattle and on semen either from infected bulls or from noninfected bulls from a positive herd. It is the practice, particularly in countries that are recognized as free of EBL by the World Organization of Animal Health (OIE), to require proof of freedom from infection with the virus from animals about to be imported into the country. This is a matter of major importance when the cattle are purebred and are sold at high prices as breeding animals. Some countries are already demanding a negative blood test for all cattle and meat to be imported, and this could represent a loss of export markets for some countries.

Zoonotic Implications
The possibility of transmission of the virus from cattle to humans is a real one; the virus is commonly present in the milk of infected cows, and the disease has been transmitted to chimpanzees in this way. Using an immunoblot test, a serologic survey of 257 humans in California found that one antibody isotype reactive with BLV in 74% of the sera tested. However, this does not necessarily mean that humans are actually infected with BLV. The antibodies could be a response to...
heat-denatured BLV antigens from consumed milk or meat. Only 9% of the subjects indicated any direct contact with cattle or their biological products.

There is an ongoing scientific debate on the possible association of leukemia in humans with exposure to BLV, either through direct contact with animals or carcasses or through consumption of dairy or meat products. A number of retrospective and prospective epidemiological studies have explored the risk of leukemia among specific occupational groups, such as farmers and people working in food production or meat processing. Several of these studies reported a significantly increased risk of developing leukemia for workers in livestock farming or meat processing, whereas others failed to identify such an increased risk. Increased risk of developing leukemia in occupational groups having contact with cattle does not create an automatic association with exposure to BLV because people in these groups would share exposure to other chemical, biological, or environmental agents possibly causing or contributing to this risk. To this date in vivo studies have not provided any evidence that BLV increases the risk of disease in humans.

Other Species
Lymphosarcoma occurs sporadically in all species, but natural infection with the BLV virus has been demonstrated only in sheep and capybaras.

Although there is no evidence of a relationship between bovine viral leukemia and any disease of pigs, there is a record of enzootic leukemia in that species, which is inherited.

PATHOGENESIS

Virus and Lesion
Infection with BLV virus may occur in utero, at the time of birth, or at a later stage of life and requires exposure of a susceptible individual to infected lymphocytes. The virus primarily establishes a persistent infection in a subpopulation of B lymphocytes by integrating proviral DNA into the host cellular DNA. Other cells that were found to carry proviral DNA, although to a much lower extent, are CD2⁺ T cells, CD3⁺ T cells, CD4⁺ T cells, CD8⁺ T cells, γ/β T cells, monocytes, and granulocytes.11

The four possible outcomes after exposure of cattle to BLV are outlined in Fig. 11-7 and are as follows:

1. Failure of the animal to become infected, probably because of genetic resistance
2. Establishment of a permanent infection and the development of detectable levels of antibodies without clinical or hematological abnormalities (aleukemic infection)
3. Establishment of a permanent infection; the animal becomes seropositive and also develops PL, a benign lymphoproliferative process. It is not a preclinical stage of lymphosarcoma.
4. Infected, seropositive animals that may or may not have been through a stage of persistent lymphocytosis and that develop neoplastic malignant tumors—lymphosarcoma

After infection, seroconversion occurs within 2 to 12 weeks, a time frame that, among other factors, is determined by the infective viral dose. Antibodies against BLV are not protective against tumor development. Whether or not the animal becomes infected or develops any of the other forms of the disease depends on the recipient's genetic constitution. The outcome may also be influenced by the animal's immune status and the size of the infective dose of virus.

A subset of animals develops a persistent increase of lymphocytes that can become apparent any time after the infection but rarely occurs before 2 years of age. Persistent lymphocytosis in affected animals persists for several years if not for life and may or may not precede the development of malignant lymphosarcoma. Persistent lymphocytosis in contrast to the malignant lymphosarcoma is the result of polyclonal proliferation of B lymphocytes and therefore presents a benign lymphoproliferative process. The increase of lymphocytes also involves an increase of the T lymphocyte count and a concomitant increase of the BLV antibody titer.

Development of lymphosarcoma, a neoplasm of the lymphoreticular system, occurs in less than 5% of infected cattle and is the only clinically apparent form of EBL. This neoplasm is usually derived from a single cell clone and is never benign. Lymphosarcoma usually occurs in BLV-infected cattle 5 to 8 years of age. Lesions develop at varying rates in different animals so that the course may be quite short or protracted over several months. The outcome is invariably fatal.

Lesions and Clinical Disease
In adult cattle, almost any organ may be the site of lesions, but the abomasum, heart, and visceral and peripheral lymph nodes are most commonly affected. Depending on the organ that is most involved, several clinical syndromes occur. Involvement of the abomasal wall results in impaired digestion and persistent diarrhea. When the atrial wall is affected, congestive heart failure occurs. In nervous tissue, the primary lesion is in the roots of peripheral nerves and spreads along the nerve to involve meninges and cord. Involvement of the spinal meninges and nerves results in the gradual onset of posterior paralysis. The skin, reproductive tract, and peribital tissues are commonly affected. In the cutaneous form, intradermal thickenings develop, which persist but do not cause discontinuity of the epithelium. They are composed of aggregations of neoplastic lymphocytes. Invasion of peribital tissues commonly results in exophthalmos. Esophageal obstruction may result from mediastinal lymph node involvement in calves.

The tumors consist of aggregations of neoplastic lymphocytes, but in many cases they may be more accurately described as reticulosarcoma. They are highly malignant and metastasize widely. The hemogram is variable, and although there may be an accompanying lymphocytosis, the presence of large numbers of immature lymphocytes in the blood smear is a more reliable indication of the presence of the disease. Some degree of anemia is common.

CLINICAL FINDINGS
This disease is characterized by tumors developing rapidly in many sites with an accompanying great variation in clinical signs and syndromes. An approximate indication of the frequency with which individual signs appear is set out in Figure 11-8.

The usual incubation period is 4 to 5 years. This form is rarely seen in animals under 2 years of age and is most common in the 4- to 8-year-old age group. Persistent lymphocytosis without clinical signs may occur earlier but rarely before 2 years of age. Many cows remain in the preclinical stage for years, often for their complete productive lifetime, without any apparent reduction in performance, but clinical disease appears in a small subset of these cows. The clinical signs and the duration of the illness vary with the number and importance of the sites involved and the speed with which the tumor masses grow.

In 5% to 10% of clinical cases the course is peracute, and the affected animals often die suddenly or unexpectedly without any prior evidence of illness. Involvement of the adrenal glands and rupture of an abomasal ulcer or an affected spleen, followed by acute internal hemorrhage, are known causes. These animals are often in good bodily condition.

In most cases the course is subacute (up to 7 days) to chronic (several months) and initiated by an unexplainable loss of body condition and appetite, pallor, and muscular weakness. The heart rate is not increased unless the myocardium is involved, and the temperature is normal unless tumor growth is rapid and extensive, when it rises to 39.5° to 40°C (103° to 104°F). Although the following specific forms of the disease are described separately, any combination of them may occur in any one animal. In many cases, clinical illness sufficient to warrant the attention of the veterinarian is not observed until extensive involvement has occurred and the possibility of slaughter of the animal for beef purposes cannot be considered. On the other hand, many cases are examined at a time when diagnostic clinical signs are not yet evident. Once signs of clinical illness and tumor development are detectable the course is rapid, and death occurs in 2 to 3 weeks.

**Enlargement of the Superficial Lymph Nodes**

Enlargement of the superficial lymph nodes occurs in 75% to 90% of clinical cases and is often an early clinical finding. This is usually accompanied by small (1 cm in diameter) SC lesions, often in the flanks and on the perineum. The skin lesions are probably enlarged hemolymph nodes and are of no diagnostic significance, often occurring in the absence of other signs of the disease. In many cases with advanced visceral involvement, peripheral lesions may be completely absent. Enlargement of visceral lymph nodes is common, but these are usually subclinical unless they compress other organs such as intestine or nerves. They may be palpable on rectal examination, and special attention should be given to the deep inguinal and iliac nodes. In advanced cases, extensive spread to the peritoneum and pelvic viscera occurs, and the tumor masses are easily palpable.

Although the enlargement of lymph nodes is often generalized, in many cows only a proportion of their nodes are involved. The enlargements may be confined to the pelvic nodes or to one or more SC nodes. Involvement of the nodes of the head is sometimes observed. The affected nodes are smooth and resilient and in dairy cows are easily seen, and their presence may be marked by local edema. Occasionally, the entire body surface is covered with tumor masses 5 to 11 cm in diameter in the SC tissue.

**Digestive Tract Lesions**

Digestive tract lesions are common. Involvement of the abomasal wall results in a variable appetite, persistent diarrhea, not unlike that of Johne’s disease, and occasionally melena as a result of bleeding of an abomasal ulcer. Tumors of the mediastinal nodes may cause chronic, moderate bloating.

**Cardiac Lesions**

Lesions in the heart usually invade the right atrial wall primarily, causing right-side congestive heart failure. There is hydropericardium with muffling of the heart sounds, hydrothorax with resulting dyspnea, engorgement of the jugular veins, and edema of the brisket and sometimes of the intermandibular space. Tachycardia as a result of insufficiency and arrhythmia as a result of heart block are common. A systolic murmur is also common, along with an abnormal jugular pulse. The liver may be enlarged and palpable caudal to right costal arch, and passive congestion of the liver and visceral edema results in persistent diarrhea.

**Nervous System Involvement**

Neural lymphomatosis is usually manifested by the gradual onset over several weeks of posterior paralysis. Knuckling of the fetlocks of the hindlegs while walking is common, and one leg may be more affected than the other. This is followed by difficulty in rising, and finally by clinical recumbency and inability to stand. At this stage, sensation is retained, but movement is limited or absent. There may be a zone of hyperesthesia at the site of the lesion, which is usually at the last lumbar or first sacral vertebra. Appetite and other functions, apart from the effects of recumbency, are usually normal. Metastases in the cranial meninges produce signs of space-occupying lesions with localizing signs referable to the site of the lesion.

**Less Common Lesions**

Less common signs include enlargement of the retropharyngeal lymph nodes, which may cause stertor and dyspnea. Sometimes clinically detectable lesions occur in the periorbital tissues, causing protrusion of the eyelid (exophthalmos), and in the limb muscles, ureter and kidney, and genitalia. Involvement of the uterus may be detectable as multiple nodular enlargements on rectal examination. Severe bilateral exophthalmos may occur, along with generalized lymphadenopathy. Perireteral lesions may lead to hydronephrosis with diffuse enlargement of the kidneys, whereas tumors in renal tissue cause nodular enlargements. In either case terminal uremia develops.

BLV particles have been detected by electron microscopy around lymphocytes in the mammary tissue of BLV-antibody-positive cows affected by subclinical mastitis. Whether the virus is a causative agent or an immunosuppressant in bovine mastitis is unknown.
Other Species

Outbreaks of lymphosarcoma in sheep have been observed with clinical, epidemiologic, hematological, and necropsy findings similar to those of enzootic bovine leukemia. B-cell leukemia has been described in sheep.

Infection of other species with BLV has not been demonstrated, but epidemic occurrences of lymphosarcoma have been observed in pigs, but only sporadic cases in horses.

CLINICAL PATHOLOGY

A definitive ante-mortem diagnosis depends on the clinicopathological examination of the animal. Several diagnostic techniques are available, and it is important to make the appropriate selection for the particular stage of the disease that is being considered, as follows:

- Diagnosis of the viral infection is made by serologic or virological techniques.
- Persistent lymphocytosis is identified by hematology but is not pathognomonic for BLV infection.
- Neoplastic tumors are identified by histologic examination of a biopsy specimen.

Because of the increasing economic impact of BLV infection in the cattle industry, the availability of a highly sensitive and specific assay for the identification of BLV-infected animals is of critical importance. Such an assay is needed for the selection of BLV-free cattle for commercial sale, purchase testing of breeding animals and import or export testing, and control and eradication programs. Ideally, the assay should be practical, inexpensive, and able to be adapted for large-scale use.

Diagnosis of the Presence of Infection With BLV

Serologic Tests

Seroconversion occurs between 3 and 16 weeks postinfection. Virtually all cattle infected with BLV will continuously have antibodies against the major internal (p24) and envelope (gp51) virion proteins in their serum, and serologic tests are commonly used for the diagnosis of BLV infection in cattle over 6 months of age. Maternally derived antibodies may be detectable until 7 months of age and are indistinguishable from antibodies resulting from infection. BLV antibodies tend to decline in the periparturient period as a result of the shift from the dam's circulation to the mammary gland, and titers may drop below the detection limit from 2 to 6 weeks before to 2 weeks after calving.22

A number of diagnostic tests are available to diagnose seroconversion in individual animals and on a herd level, as discussed in the following sections.

Enzyme-Linked Immunosorbent Assay in Serum or Milk. In the last decade ELISA-based testing has replaced the AGID in eradication programs in several countries and is one of the prescribed diagnostic tests for international trade. It is more sensitive than other serologic tests and can be used on milk. The ELISA can detect antibody titers 10- to 100-fold below the detection limit of the AGID. The superior sensitivity of the ELISA allows detection of antibodies in pooled serum samples of herds with a prevalence of less than 1%, whereas the AGID test detected only 50% of the herds detected by the ELISA. Two commercially available ELISAs and the PCR were evaluated and compared with the AGID to detect antibodies to BLV or its nucleic acid. The ELISA tests detected about 10% more reactors than the AGID and the electrophoretic immunoblotting results. Some ELISA-positive animals were not detected by the PCR.

Four commercially available BLV-ELISA kits from Europe and the United States were compared with the AGID test officially approved by the Canadian Food Inspection Agency. The ELISA tests were more sensitive than the AGID test kits. A highly sensitive and specific blocking ELISA comparable to the radioimmunoprecipitation assay for the detection of BLV antibodies in serum and milk samples has been developed.

The milk ELISA has been adopted for testing milk from individual cows and pooled milk samples. A comparison of the ELISA and AGID tests for the detection of BLV antibodies in bovine serum and milk found a high level of agreement. The bulk-tank milk ELISA is useful for identification of herds that are negative for BLV infection and to monitor BLV-negative herds. The antibody level in milk is lower than in serum but the sensitivity of the ELISA is as effective as for sera. Testing of bulk milk is a useful and practical method for large-scale epidemiologic studies and initial eradication programs. Heifers, bulls, and dry cows and youngstock over 1 year of age that are not included when bulk milk is tested need to be sampled individually before a herd is declared free of the virus. The sensitivity and specificity of the milk ELISA is estimated to be adequate until the prevalence of BLV-infected individuals in the country is less than 1%. Herds identified as positive by the milk ELISA would require further testing at the individual or herd level to definitively establish their BLV status.

Agar Gel Immunodiffusion Test. The AGID is a specific but not very sensitive diagnostic test for BLV. It has, however, been proven to be highly useful and efficient as a basis for eradication or control programs because it is simple, easy to perform, and inexpensive.22 It remains one of the prescribed tests for international trade. Most commercial AGIDs test for the presence for both antibodies against p24 and gp51 but are not standardized for the demonstration of antibodies against gp51.

Radioimmunoprecipitation Assay. The radioimmunoprecipitation (RIP) assay, which uses gp51 or p24 as antigen, is a highly sensitive and specific method for serologic diagnosis of BLV infection. The RIP assay has been used as the criterion-referenced standard to critically evaluate the performance of other diagnostic tests for BLV infection. Detailed comparisons of various BLV assays in a large number of cattle of various origins and ages found that the RIP assay is the most sensitive and specific test. However, its major disadvantage is that it requires a gamma counter and radioisotopes, which are expensive.

Radioimmunoassay. Radioimmunoassay (RIA) is suitable for individual cow testing because of its accuracy. There are several versions of this test, and the one using the virion gp antigen is preferred. It is one of the most sensitive tests and is useful for the detection of BLV antibodies in cattle exposed no longer than 2 weeks, in milk samples, and in serum samples from periparturient dams.

Detection of Virus

Polymerase Chain Reaction. The PCR is a sensitive and specific assay for direct diagnosis of BLV infection in peripheral blood lymphocytes. The test is useful for the early detection of BLV infection even before antibodies are present. It is more sensitive than the ELISA or AGID in detecting infected cattle where the prevalence of infection is less than 5%. The test can identify proviral DNA of BLV in the lymphocytes of calves at birth in calves born to infected cows. At birth, the presence of an antibody titer can result from passive transfer of immunity or perinatal infection, and the PCR test can differentiate uninfected newborn calves with colostral antibodies from BLV-infected calves and detect the presence of the virus in the presence of antibodies. The PCR has a practical application in the identification of BLV-infected calves, regardless of colostral antibody, which allows immediate removal of the source from the herd. In a dairy herd with a high prevalence of BLV, a positive PCR assay result provided definitive evidence that a cow was infected with BLV. However, sensitivity and specificity were 0.672 and 1.00, respectively. The predictive value of a positive test was 1.00, and the predictive value of a negative test was 0.421. Thus PCR assay alone is unreliable for routine detection of BLV in herds with a high prevalence of BLV infection.

The PCR can also be used to ensure that cattle used in the production of a whole-blood vaccine for tick-borne disease are free from BLV infection. The sheep bioassay, currently in use, requires 4 months of serologic testing to ensure that donor animals are not infected. Replacement of the sheep bioassay with the PCR could result in considerable saving of time and effort. Use of the PCR
The association between the strength of serologic recognition of BLV by the use of ELISA and lymphocyte count in BLV-infected cows has been examined. The sample-to-positive ratio, which is the ratio between the test sample and a positive control sample, was compared among lymphocytic and nonlymphocytic cows. The sample-to-positive ratio and lymphocyte count were related, but cows with high sample-to-positive ratio were not always lymphocytic. Culling cows on the basis of sample-to-positive ratio will reduce culling of ELISA-positive cows; however, culling on the basis of lymphocyte count will eliminate a greater proportion of the reservoir of infection.

Diagnosis of Lymphosarcoma
Lymphosarcoma can only be diagnosed by histopathological examination of a section of tumor material obtained by biopsy or necropsy. A needle aspirate of an enlarged peripheral lymph node may provide a rapid and inexpensive diagnosis. Enlarged lymph nodes or hemolymph nodes are the usual sources, but when the genital tract is involved an exploratory laparotomy is usually performed so that a sample can be obtained. The lymphocyte count may increase to 20,000 to 30,000/µL and in some cases may reach values of 50,000 to 100,000/µL, and even 400,000 to 500,000/µL. Conversely, in some cases, the lymphocyte count decreases. Chromosomal changes may be detectable in cells from lymph nodes or in leukocytes from peripheral blood of affected animals. When there is myocardial involvement there may be obvious changes in the electrocardiogram, but these are unlikely to be of value in differential diagnosis.

Diagnosis of Persistent Lymphocytosis
Approximately 30% of animals infected with BLV develop PL, which is defined as a benign increase in the absolute lymphocyte count of three or more standard deviations above the normal mean as determined for that respective breed and age group of animals in leukemia-free herds. The PL is an increase in peripheral B lymphocytes. It has been suggested that one additional criterion for PL should be that it persists for more than 3 months. When PL was first recognized in herds that experienced malignant lymphosarcoma, it was considered a subclinical expression of the tumor stage of the disease. Although persistent lymphocytosis is not pathognomonic for BLV infection, it became an important diagnostic criterion in control and eradication programs until BLV was identified as causative agent and serologic tests became available to more accurately identify infected animals. The majority of cells involved in PL are normal lymphocytes, but atypical and abnormal forms have been described and are considered as indicative of preleukemic condition. The total count increases from a normal of 6000 to as high as 15,000/µL. An increase in the percentage of lymphocytes in the total white blood cell count from the normal of 50% to 65% is considered a positive result. The presence of 25% or more of the total lymphocyte count as atypical immature cells is also considered a significant aberration. The PL may or may not subside in animals that subsequently develop lymphosarcoma.
Enzootic bovine leukemia was eradicated from Finland in 1996. The disease was first recognized in 1966, and it required 30 years of use of the key principles of test and slaughter policy to achieve eradication. The infection status was monitored at meat inspection, hematologically between 1970 and 1977, and serologically between 1978 and 1989. Annual surveys including all dairy herds and samples from beef animals were conducted from 1990 to 2001. Bulk-tank samples represented the dairy herds in the surveys; beef animals were sampled individually at slaughter. The maximum positive herd-level percentage in the survey was 0.03%. The herd level prevalence of infection never exceeded 5%.

Considering the animal-health aspects and possible consumer reactions against having a widespread retrovirus infection in food-producing animals, and the requirements for exporting cattle and semen, Sweden introduced a national program for the eradication of BLV in 1990. An ELISA test was evaluated for detection of antibodies to BLV in individual and bulk milk and serum samples.

In the meantime, a total of 17 countries of the European Union are officially free of BLV. Similarly, since 2010 New Zealand, after having implemented a BLV eradication program, is free of evidence of EBL, and Australia expects to have eradicated the disease. In Canada and the United States, it is considered cost prohibitive to cull and slaughter all seropositive cattle because of the high prevalence of infection. Many seropositive cows are valuable pedigreed animals, and there are no indemnity programs available. Thus all control and eradication programs in these countries are herd based and strictly voluntary. Livestock producers are willing to adopt control programs because of the economic losses associated with export restrictions if their cattle are infected and the losses resulting from the occasional clustering of cases of lymphosarcoma.

**Eradication Programs**

Enzootic bovine leukemia can be eradicated only by the following methods:

- **Test and slaughter of cattle infected with the virus**—programs based on the culling of seropositive cows are effective.
- **The maintenance of a closed herd**, which permits the entry of only those animals free of infection.

The efficiency of such a program depends on the accuracy of the test used to identify the infected animals and the repetition of the test at an appropriate interval so that animals that were in the incubation stages of the disease at the time of the first test will have had time to seroconvert. The recommended procedure is as follows:

1. Identify infected animals using the serum or milk ELISA or AGID test.
2. Cull and slaughter seropositive animals immediately.
3. Retest the herd 30 to 60 days later.
4. Use the PCR assay to test young calves and as a complementary test for clarifying doubtful test results in herds with a low prevalence of infection.

Testing is repeated until the herd has a negative test. When the herd is negative, testing is repeated every 6 months and the herd declared free when there have been no positive reactors for 2 years. Future introductions into the herd are managed most safely by artificial insemination or fertilized ovum transfer, or importations of animals that have been tested and are seronegative on two tests carried out 30 and 60 days before arrival.

In herds where the prevalence is high, a two-herd scheme can be successful. Newborn calves are removed from seropositive cows and raised in isolation. The cattle are tested serologically between 1978 and 1989. Annual testing is repeated every 6 months and seropositive animals culled. The parent herd is eventually disposed of as negative replacement animals become available. Only those bulls that are seronegative may be used, and they must be tested every 3 months.

Although eradication is biologically feasible, it is unlikely that area eradication programs will be implemented on an extensive scale because losses from the disease are not sufficiently high, and there is a high risk of insect vectors reintroducing it, which poses a real threat to maintenance of a BLV-free herd. The cost-effectiveness of an eradication program on a national basis would be a major consideration. For an individual herd, it is feasible, provided some steps are taken to increase the genetic resistance of the residual stock and to reduce the chances of contact infection occurring.

**Limitation of Spread of Infection**

In herds with a high prevalence of infection, the test and slaughter method of eradication is not economically viable if the animals have a high economic value because of superior genetic potential. Control of infection in these herds is possible using embryo transfer from infected dams to negative recipients and isolation of newborn calves, but these are not practical on a country-wide basis. An alternative method is segregation of BLV-infected and noninfected animals based on the serum/milk ELISA or AGID test. This is known as the test and segregation method, which is based on the evidence that the spread of infection between animals is relatively slow and that the virus is spread by movement of infected animals from one herd to another and within a herd. Following the initial testing of the herd, the herd is divided into two groups, BLV-positive and BLV-negative animals, and kept at least 200 m apart. A third separate location is used for quarantine of replacement animals.
Chapter 11  ■  Diseases of the Hemolympathic and Immune Systems

Replacement animals must be found negative in two consecutive serum antibody tests, the first within 30 days before purchase and the second after 60 days of isolation, before being moved into the negative group. The serologic tests are conducted every 3 months, and the reactors removed to the positive group location until the remaining animals in the herd have attained BLV-negative status by the test. Thereafter, the tests are done every 6 months and continued until at least four consecutive negative tests are obtained for each herd. Variations of this method of test and segregation with subsequent removal of seropositive animals in the routine culling program have been successful.

The colostrum and milk fed to calves in the BLV-negative group must be from seronegative cows or be pasteurized to inactivate the virus. In Canada, cattle owners may enroll in the Canada Health Accredited Herd program to declare freedom from EBL. All reactors must be removed from the herd. If a large number of reactors are detected, two herds on two separate farms can be established: one herd comprised of the reactors and the other of cattle that are seronegative. Calves from the reactor herd can be added to the accredited herd in accordance with strict isolation and testing procedures. To qualify for accredited certification, a herd must have two consecutive negative herds tests, at least 4 and less than 12 months apart. The tests must include all cattle in the herd. The first annual renewal test must occur no more than 12 months following the second qualifying test for certification, and must include all cattle in the herd. Subsequent renewal tests must occur within the same 12-month interval. Only calf 24 months of age and older must be tested, but a herd inventory and audit must be performed on the whole herd. In herds with reactors, the two qualifying tests do not begin until at least 4 months after the removal of the last reactor uncovered during any test. Herd additions can be made during the qualifying test period or after certification has been achieved. Each animal must be accompanied by a health certificate, and depending on the enzootic bovine leukosis status of the originating herd, certain testing and isolation procedures could apply. Owners wishing to have their animals attend exhibitions can do so providing they adhere to certain conditions. Properly processed semen and embryos can be introduced without restrictions. Owners are encouraged to follow preventive health management practices to augment the eradication of enzootic bovine leukosis from their herds. These include all areas where blood transfer could occur (needles, dehorning, castrating, extra test removal, ear-tagging, tattooing, hoof trimming, rectal palpations, drenching) and other procedures that transfer leukocytes, in addition to routine insect control.

Prevention of Infection in Calves and Young Stock
Several management techniques can be used to prevent infection in calves from birth until they become herd replacements. Immediate removal of newborn calves from the maternity pen and feeding of colostrum and milk from seronegative cows is widely accepted as effective in preventing infection in calves. Postnatal infection in calves can also be minimized by feeding milk replacer and/or whole milk from noninfected cows. The use of colostrum and milk from noninfected cows permits early serologic detection of infected calves. However, feeding colostrum from seropositive cows to newborn calves can provide significant protection from infection during the first 3 months of life. Field studies indicate that colostrum-derived BLV antibodies may prevent as much as 50% of the infection during the first 3 months compared with calves that did not receive colostrum with BLV antibodies. Further reduction in the risk of infection via colostrum can be achieved by pasteurization of the colostrum at 63°C (147°F) for 30 min. The colostrum-derived BLV antibodies will, however, delay early detection of infection in calves. The replacement of whole-milk feeding with high-quality milk replacer may also be considered.

Transmission to newborn calves can also be reduced by avoiding exposure to maternal blood at the time of parturition, housing calves in individual hutches with individual feeders and waterers, and management techniques to avoid intrauterine transmission. When handling a group of calves, the youngest ones should be handled first and the older and sick calves last. Equipment that could act as a fomite in transferring blood should be disinfected with chlorhexidine when used between calves. These instruments include the following:
- Nose tongs
- Scissors
- Forceps
- Dehorning instruments
- Esophageal tubes
- Bailing guns
- Tattoo equipment
- Ear taggers

Dehorning of calves with the electrocautery method before 2 months of age can reduce the prevalence of infection compared with gouge dehorning, which allows the transfer of infected blood between calves. Handling facilities that become contaminated with blood should be cleaned between calves. Fly control should be instituted as necessary. Single needles should be used for vaccination, and calves should be tested serologically for BLV infection at about 6 months of age.

A marked reduction in the prevalence of infection within the heifer age groups of a dairy herd with a high prevalence can be achieved by the following practices:

1. Use of single needles and individual sleeves for rectal examination
2. Disinfection of tattoo equipment before use
3. Dehorning by use of electrocautery

Biosecurity
Prevention of entry of infection into herd can be achieved by ensuring that all imports into the herd have been tested at least 30 days before arrival and are seronegative. Control of insect vectors is highly desirable. Blood transfusions and vaccines containing blood, such as those used for babesiosis and anaplasmosis, are particularly potent means of spreading the disease, and donors must be carefully screened to ensure that they are free of the disease. In the future, the selection of cattle with inherent resistance to BLV may be a possibility. Embryo transfer from valuable pedigreed seronegative cows may aid in reducing prenatal infection. Insemination is not a method of transmission, and thus artificial breeding programs are not disrupted.

Vaccine
The possibility of a vaccine for BLV has been explored extensively. Thus far inactivated virus vaccines, cell-derived vaccines, viral vectors, subunit vaccines, recombinant vaccinia virus vaccines, and synthetic peptides have been examined, without much success.10

REFERENCES
**EQUINE INFECTIOUS ANEMIA (SWAMP FEVER)**

**SYNOPSIS**

**Etiology** Equine infectious anemia virus, a retrovirus (lentivirus).

**Epidemiology** Worldwide distribution. Affects all species of Equidae. Transmission of disease is by contaminated blood of clinically affected or inapparently infected horses during interrupted feeding of blood-feeding insects or iatrogenically. Horses are infected for life.

**Clinical signs** Fever, depression, edema, petechial hemorrhages, abortion, chronic weight loss, splenomegaly.

**Clinical pathology** Anemia, thrombocytopenia, hypergammaglobulinemia, positive agar gel immunodiffusion (AGID) or competitive enzyme-linked immunosorbent (cELISA) test.

**Diagnostic confirmation** AGID or cELISA test.

**Differential diagnosis list:**
- Acute disease:
  - Purpura hemorrhagica
  - Babesiosis
  - Equine granulocytic ehrlichiosis
  - Equine viral arteritis
  - Autoimmune hemolytic anemia
  - Leptospirosis
  - Parasitism
  - Idiopathic thrombocytopenia

- Chronic disease:
  - Neoplasia
  - Internal abscessation
  - Liver disease

**ETIOLOGY**

The equine infectious anemia virus (EIAV) is a retrovirus, a member of the subfamily Lentivirinae of the family Retroviridae. It is an RNA virus that uses a reverse transcriptase enzyme to generate proviral DNA, which is spliced into the host's genome. The virus infects only Equidae, and there is no evidence that it infects or causes disease in humans. EIAV shares antigenic cross-reactivity with the human and feline immunodeficiency viruses but not with the viruses causing caprine arthritis–encephalitis or maedi–visna of sheep. The EIAV genome is composed of three major genes: gag—encoding matrix and capsid proteins; pol—encoding proteases, reverse transcriptase, and integrase; and env—encoding envelope glycoproteins. Antibodies against gag-encoded proteins (e.g., p26) are used commonly for diagnosis of equine infectious anemia (EIA) by AGID or ELISA testing.

Analysis of the genome of the gag gene has revealed a strong geographic localization of clades of EIAV that are clearly related to the evolutionary history of modern horses. Both horses and EIAV appear to have a Eurasian origin that might have differentiated as a consequence of horse movement associated with human migration. Analysis of the gag genome reveals that EIAV strains from the Americas form a distinct group with a potentially single common origin temporally associated with European colonization of North America. The close geographic structuring of EIAV is a result of the insect-borne nature of the infection, which favors transmission over short distances as opposed to long distances, and the limited mobility, until very recently, of equids. There are three distinct monophylegetic groups, two of which (EIAV-1 and EIAV-2) contain only European strains and the third of which (EIAV-3) contains European, Asian, and American strains. This third group has three clades including European, Asian, and all American strains. The two Japanese strains in this group are of American origin.

Genomic characterization of EIAV enables a more complete understanding of the geographic origin of virus strains and the epidemiology and pathogenesis of the disease. For instance, analysis of strains of the virus isolated in Belgium in 2010 confirmed that the source is Romanian, that Japanese strains V70 and V26 are of Japanese origin, that there exists a distinct Japanese strain, and that the virus that caused the 2006 outbreak in Ireland was of European strain origin. There is considerable antigenic drift in the surface glycoproteins (gp45, gp90), and the emergence of novel antigenic strains within an individual horse is associated with the relapsing febrile reactions characteristic of the disease. Examination of variations in the viral regulatory protein, Rev, and the transmembrane protein, gp90, demonstrates the existence of viral quasispecies such that genetically distinct viral subpopulations of differing phenotype exist within a chronically infected, often asymptomatic, animal. Mutations in gp90 are driven by the host immune response and can cause relatively large insertions or deletions in the gene.

EIAV, like all retroviruses, integrates into the genome of the host by insertion of viral cDNA into the host DNA. This process involves nonrandom insertion of viral cDNA, as a provirus, into the host genome in the form of preintegration complexes. This integration of viral DNA into the host genome is lifelong. The sites of EIAV insertion into the genome of infected horses have been described.

**EPIDEMIOLOGY**

**Occurrence**

EIA has been diagnosed on all continents except Antarctica, and there is increasingly detailed information on distribution of the virus and infection rates in many countries and localities, including Turkey, Brazil, Oman, Ethiopia, Pakistan, Costa Rica, Romania, Taiwan (where the disease is not currently present), Greece, India, Italy, and Mongolia, among others. In Europe it is most prevalent in the northern and central regions. It has appeared in most states of the United States and the provinces of Canada, but the principal enzootic areas are the Gulf Coast region and the northern wooded sections of Canada.

Extensive serologic surveys using the AGID (Coggins) test have shown rates of infection of 1.5% to 2.5% in the United States, 6% in Canada, a low level in France, 1.6% in West Germany, and 15% to 25% in Argentina. Within a geographic area, the prevalence of infection (positive AGID) varies depending on the density of the population, the proportion of carrier animals, and the density of the population of insect vectors. Under ideal conditions the incidence of infection can approach 100% over a period of weeks, but this rapid spread is unusual.

The morbidity varies considerably and depends on the strain of the virus and the inoculum delivered by the biting insect. Some horses become acutely ill and die after infection, whereas in others the infection is clinically inapparent. Outbreaks of disease associated with EIAV in horses of developed countries are rare.

**Animal Risk Factors**

Horses and ponies are susceptible to infection by EIAV and characteristically develop signs of the disease within days to weeks of infection. Mules also become infected and develop clinical signs similar to those of horses and ponies when infected with strains of the virus pathogenic to horses, but donkeys do not subsequently develop signs of the disease despite persistent infection with the horse-derived virus. The resistance of donkeys to horse-derived strains of EIAV is not definitive evidence that donkeys do not develop equine infectious anemia, and there is suspicion that strains of the virus pathogenic to donkeys exist.

**Methods of Transmission**

The source of all new infections with EIA is an infected horse, donkey, or mule. Horses are persistently infected, and clinically normal infected horses are a source of the virus. The virus can also be spread from clinically affected animals, which, because of the high concentration of virus in their blood, are a potent source of infection and important in the rapid spread of infection. Transmission of EIAV occurs almost exclusively through the transfer of contaminated blood or blood products. In field conditions this usually occurs through the mechanical transmission of contaminated blood from an infected horse to an uninfected horse by biting insects.
Insect Vectors

The insect vectors responsible for the transmission of EIAV between horses are all large biting flies, including Stomoxys calcitrans (stable fly), Chrysops spp. (deer fly), and Tabanus spp. (horse flies). Mosquitoes are not recognized as an important vector. **Transmission is mechanical** because the virus does not replicate in insects and is related to the large quantity of blood (10 mL) that the biting insects are capable of holding in their mouths. Infection occurs only if the feeding of the insect is interrupted. If this occurs the insect may attempt to feed again on the initial host or may seek another host that is close by. If the initial host is infected, the insect can carry blood from this animal to the second host and spread the infection. Tabanid flies can travel a distance of over 6 km, but when feeding is interrupted, the flies usually attempt to complete the meal on the initial host or a nearby animal and rarely travel more than 200 m to complete the meal.

**Insect factors** that influence the likelihood of spread include the following:

- Climate and season—tabanids prefer hot and humid conditions for feeding and breeding, and their activity is much reduced or absent in winter months.
- Attractiveness of the host—foals are less likely to be bitten.
- Proximity of hosts to woodlands—tabanids prefer treed or sheltered habitat.
- Host housing—tabanids do not enter closed shelters.
- Distance between horses—as noted earlier, tabanids prefer to complete an interrupted meal on the initial host or a nearby host.

Other Means of Transmission

**Intrauterine infection** can occur, although not invariably, and result in abortion or the birth of infected foals that often die within 2 months. Mares can be infected by insemination with semen containing the virus.

Iatrogenic spread of infection can be important in some outbreaks. Infection can be readily achieved by the use of **contaminated surgical instruments** or needles or by the injection of minute quantities of virus, and the use of a common needle when injecting groups of horses can cause an outbreak of the disease. In enzootic areas, outbreaks have been caused by the use of untreated **biological preparations** of equine origin. This mode of spread is exemplified by the 2006 outbreak of the disease in Ireland. The virus was introduced in plasma illicitly imported into the country from Italy. The virus was introduced in plasma illicitly imported into the country from Italy. 25 The virus was introduced in plasma illicitly imported into the country from Italy. 25,26 The virus was introduced in plasma illicitly imported into the country from Italy. 25 The virus was introduced in plasma illicitly imported into the country from Italy. 25,26 The virus was introduced in plasma illicitly imported into the country from Italy. 25

**Immune Reaction**

The immune response to EIAV is responsible for controlling replication of the virus and also plays an important role in the pathogenesis of the disease. The major clinical signs and lesions of equine infection anemia are attributable to the host response to the virus and not direct viral damage to tissue. Replication of EIAV stimulates a strong immune response that is detectable in horses and ponies within 7 to 10 days of infection. The initial infection is likely controlled by **cytotoxic T-lymphocytes** before the appearance of neutralizing antibodies. Antibodies to the p26 core protein are detectable by AGID test in almost all horses 45 days after infection; by 60 days after infection, antibodies to gp45 and gp90 are present. The neutralizing antibodies are specific to the phenotype of the virus causing the viremia, and this phenotype can change over time, as discussed earlier. Hypergammaglobulinemia develops. The immune response includes the production of virus-neutralizing antibodies, complement-fixing antibodies, and cytotoxic T-lymphocytes. The immune responses are responsible for the termination of viremia, although this effect is not mediated by antibody-dependent cellular cytotoxicity against EIAV-infected macrophages, but rather by development of neutralizing antibody and cytotoxic T-lymphocytes. The importance of neutralizing antibodies in control of the disease within an animal is indicated by the observation that viremia is never associated with a virus with a neutralizing phenotype already recognized by the horse.

Most viruses in viremic horses consist of a complex of virus and antibody. The **virus–antibody complex** is readily phagocytosed by cells of the reticuloendothelial system, including tissue macrophages, and is involved in the development of the fever, depression, thrombocytopenia, anemia, and glomerulonephritis characteristic of the disease.

**Neurologic** disease in horses with EIAV infection is attributable to viral infection of neural tissue but not necessarily neurons.

**Anemia and Thrombocytopenia**

The anemia characteristic of horses experiencing several febrile episodes of EIA is attributable to the shortened life of RBCs and decreased RBC production. Infection with EIAV shortens the life span of circulating RBCs by about 48 days, compared with the normal value of 130 days. The reduction in RBC life span is likely a result of the presence of virus–antibody complexes on the surface of RBCs with subsequent clearance of such cells by the reticuloendothelial system, as evidenced by the presence of sideroleukocytes in the peripheral blood of infected horses. EIAV also has a suppressive effect on erythroid series cells in bone marrow. Anemia occurs in Arabian foals with severe combined immunodeficiency infected with...
Enzootic Bovine Leukosis (Bovine Lymphosarcoma)

8 ELAV, indicating that the anemia is not wholly a result of the adaptive immune response of the host. Anemia of chronic disease, which is in part a result of the limited availability of iron stores, likely contributes to the lack of bone-marrow response.

Thrombocytopenia is a consistent feature of the acute, febrile episodes of ELAV and has been attributed to the deposition of virus–antibody complexes on platelets, with subsequent removal of affected platelets by tissue macrophages. However, others have identified a primary production deficit resulting from an indirect, noncytocidal suppressive effect of ELAV on megakaryocytes. ELAV does not infect megakaryocytes, and the suppressive effect of infection is at least in part a result of tumor necrosis factors alpha and beta. Another explanation for the thrombocytopenia is increased removal of platelets because of increased in vivo activation and formation of platelet aggregates, a form of nonimmune-mediated platelet destruction. This was associated with increased thrombopoesis and an increase in the proportion of young platelets in blood. The precise mechanisms underlying the thrombocytopenia associated with acute ELAV infection of horses is unclear.

Platelets of ELAV-infected horses with clinical signs of disease have diminished function in vitro. Platelets from infected horses had greater amounts of fibrinogen bound to their surface, ultrastructural abnormalities consistent with activation, and diminished in vitro aggregation responses.

Persistence of Infection

The cell reservoir of the virus in persistently infected horses is unknown, as are the mechanisms underlying latency. However, the ability of retroviruses to splice a DNA copy of their genome into the genome of the host is probably important in the persistence of viral infection. The viral genome is detectable in clinically normal but persistently infected horses. Presence of viral DNA in host tissue is indicative of infection, whereas the presence of viral RNA in blood is suggestive of viral replication. This viral strategy allows the virus to escape immune surveillance of the host. Factors triggering a relapse of virus production from the latent genome are unknown, but relapse is associated with antigenic drift that enables the virus to evade host immune responses.

Summary of Pathogenesis

A likely scheme of pathogenetic events is as follows:

- Formation of antigen–antibody complexes, which induce fever, glomerulitis, anemia, thrombocytopenia, and complement deposition
- Hemolysis or phagocytosis caused by specific complexes activating the reticuloendothelial system
- Temporary iron-deficient erythropoiesis caused by delayed release of iron from macrophages
- Subsidence of pathologic processes as virus-neutralizing antibody restrains viral multiplication in macrophages—the virus is incorporated into the host genome and becomes latent.
- Appearance of a new antigenic variant of the virus and commencement of a new cycle of viral replication in macrophages and a new clinical episode—the antigenic variation results from changes in the surface glycoprotein of ELAV.
- Less frequent recurrence of these episodes, with the horse becoming permanently asymptomatic—the animal can be said to have achieved an appropriate level of immune response sufficient to protect it against antigenic epitopes that are common to all ELAV strains.

CLINICAL FINDINGS

An incubation period of 2 to 4 weeks is usual in natural outbreaks of equine infectious anemia. Outbreaks usually follow a pattern of slow spread to susceptible horses after the introduction of an infected animal. On first exposure to infection, horses manifest signs of varying degrees, classified as acute or subacute. Occasionally the initial attack is mild to inapparent and may be followed by rapid clinical recovery. As a rule, there is initial anorexia, depression, profound weakness, and loss of condition. Ataxia, behavioral changes, hyperesthesia, and blindness occur, and in some horses is recorded as the only clinical abnormality. There is intermittent fever (up to 41°C; 105°F), which may rise and fall rapidly, sometimes varying as much as 1°C (1.8°F) within 1 hour. Jaundice; edema of the ventral abdomen, prepuce, and legs; and petechial hemorrhages in the mucosae, especially under the tongue and in the conjunctivae, may be observed. Pallor of the mucosae does not occur in this early stage, and they tend to be congested and edematous. There is a characteristic increase in the rate and intensity of the heart sounds, which are greatly exacerbated by moderate exercise. Respiratory signs are not marked, and there is no dyspnea until the terminal stages, but there may be a thin serosanguineous nasal discharge. There is considerable enlargement of the spleen, which may be detectable per rectum. Pregnant mares may abort. Many animals recover from this acute stage after a course of 3 days to 3 weeks. Others become progressively weak and recumbent, and they die after a course of 10 to 14 days of illness.

Animals recovering from the acute disease may appear normal for 2 to 3 weeks and then relapse, with similar but usually less severe signs. Death may occur during such a relapse. Relapses continue to occur at intervals of as little as 2 weeks but usually cease after about a year. If they recur, they are usually associated with periods of stress and characterized by fever, increasing emaciation, weakness, ventral edema, and the development of pallor of the mucosae, a late sign of this disease. In this chronic stage, the appetite is usually good, although allotriophobia may be observed. Some affected animals appear to make a complete recovery, but they remain infected and can suffer relapses as many as 11 years later.

Prolonged therapy with corticosteroids can cause such a relapse. Even in the absence of clinical illness, infected animals often perform less efficiently than the uninfected. Most deaths occur within a year of infection. Survivors persist as asymptomatic carriers.

CLINICAL PATHOLOGY

Hematological examination of horses with the acute disease reveals moderate to marked thrombocytopenia and anemia, which can be severe. Thrombocytopenia occurs during the initial episode, and can precede horses becoming serologically positive, and during relapses of the disease, is most severe during the febrile episodes, and can be sufficiently low that it allows petechial hemorrhages to develop. The anemia can become more severe with relapse (14% to 20%, 0.14 to 0.20 L/L) and is normocytic and normochromic. During the 2006 outbreak in Ireland, anemia was an inconsistent feature of the disease (40% of cases). The presence of sideroleukocytes (leukocytes containing hemosiderin) is considered highly suggestive of ELAV. There are no characteristic changes in the white blood cell count, although presence of band neutrophils is common in the early stages of the clinical disease.

Hyper gammaglobulinemia may be present. Serum biochemical examination might reveal an increase in bilirubin concentration, a decrease in serum iron concentration, and increased glutamate hydrogenase (GLDH) activity in serum.

DIAGNOSTIC CONFIRMATION

Diagnostic confirmation cannot be made based on hematologic or serum biochemical analysis and is achieved through detection of antibodies to the p26 core antigen of ELAV. Two tests are in general use: the AGID test (Coggin's test), which is standardized using recombinant reagents, and a number of ELISAs, including a cELISA test. Results of AGID testing are available in 24 hours, whereas those of ELISA testing can be
available in as little as 1 hour. Commercially available ELISA tests detect antibody to the p26 antigen, antibody to the gp45 transmembrane protein, or both.29 The ELISA tests inherently have greater sensitivity (detect lower concentrations of antibody) than does the AGID, but often the characteristics of the commercial ELISA assays are modified to decrease the sensitivity (increase the lowest concentration of antibody detected by the kit) so that results obtained with these kits are concordant with those obtained by AGID.30

An advantage of an ELISA that detects antibodies to gp45 antigen is that, when combined with testing for antibodies to p26, the ability to detect infected horses with equivocal test results on a single test is increased. This is similar to the technique of using a Western blot test to demonstrate the presence of antibodies to more than one antigen, especially those against the gp45 and gp90 antigens, when equivocal AGID or ELISA results are obtained.

False-negative reactions for either test occur because the horse lacks antibodies to the p26 antigen. The AGID and cELISA tests do not detect a recently infected horse that has yet to develop antibodies. Some horses do not develop anti-p26 antibodies for 45 days after infection. False-positive reactions can occur in foals born to infected mares. Colostral transfer of anti-p26 antibodies to the foal will be detectable up to 6 months after birth.

Positive reactions to ELISA testing (to the p26 antigen) in samples that are negative by AGID testing can be the result of interspecies determinants. It is suspected that horses exposed to related lentiviruses produce antibodies to structural proteins that cross-react with the EIAV p26 antigen in ELISA, but not AGID, testing.

An algorithm for testing of equine samples for EIAV is provided in Table 11-8. Tests to detect proviral DNA or viral RNA in blood and tissue have been developed and are useful in detecting the presence of virus when viral concentrations in blood and/or tissue are low. The identification of proviral DNA in the blood of infected horses is as specific and apparently more sensitive than the AGID in detecting infected horses.

Experimental transmission of the disease to susceptible horses by the SC injection of 20 mL of whole blood or Seitz-filtered plasma is also used as a diagnostic test and is a valuable, although expensive and archaic, supplement to other tests. The donor blood should be collected during a febrile episode when the viremia is most pronounced, and the recipient animals should be checked for increases in body temperature twice daily.

Molecular diagnostic tests offer the advantage of detection of viremia, but currently are limited because available primers for PCR do not reliably detect all strains of the virus.29,30

| Tier 1 | Test sample using ELISA. If negative, report the results. If positive, continue to Tier 2. |
| Tier 2 | Test with both same and at least one other ELISA format. If negative, report as negative. If positive in only one ELISA—report as negative. If positive in two or more ELISAs from different manufacturers, perform AGID test. If negative, report as negative. If positive, forward to Tier 3. If inconclusive, forward to Tier 3. |
| Tier 3 | Test in all formats to confirm results. If confirmed, test by immunoblot. If gp90, gp45, and p26 positive (recognized), report as positive. If 2 major proteins are positive (recognized), report as positive. If only p26 is recognized, report as negative. |

**Differential Diagnosis**

**Acute disease**
- Purpura hemorrhagica
- Babesiosis
- Equine granulocytic ehrlichiosis
- Equine viral arteritis
- Autoimmune hemolytic anemia
- Leptospirosis
- Parasitism
- Idiopathic thrombocytopenia

**Chronic disease**
- Internal abscessation (metastatic Streptococcus equi infection)
- Chronic inflammatory disease, neoplasia, and chronic hepatitis

**TREATMENT**

No specific treatment is available. Supportive treatment, including blood transfusions and hematinic drugs, may facilitate clinical recovery, but it is important to remember that recovered horses are persistently infected and infectious for life.

**CONTROL**

Control of EIA is based on identification and eradication or lifelong quarantine of infected animals, quarantine and testing of new stock, compulsory testing of imported horses, and efforts to prevent spread of the virus by controlling insect access to horses and use of strict hygiene when vaccinating or collecting blood samples from horses.28

The control of equine infectious anemia is still universally based on the eradication of the disease by identifying the infected, clinically normal animals with a serologic test and then destroying them. Identification is by means of the AGID or cELISA tests. The ability of a program of test and eradication to eliminate the disease is evidenced by the eradication of EIA from Hong Kong. An effective control program is described for Kentucky in the United States that permits the maintenance of infected horses with indelible identification and prescribed restrictions on housing.

Control programs based on this test-and-slaughter policy are under fire because of the view of horse owners that many asymptomatic horses, with very low infectivity, are being destroyed unnecessarily.41 A decision on the matter depends on whether the objective is eradication or containment, and if the latter, at what level. Until now the policy has been eradication, and it is obvious that another attitude is possible. Some flexibility in official attitude is desirable because of the
fallibility of the recommended control procedures and the devastating losses that can occur when the optimum environment for the spread of the disease is encountered.

Foals from infected mares can be raised free of infection. Such foals have detectable antibodies to EIAV for up to 330 days on immunoblot and 260 days on ELISA testing because of transfer of maternal immunoglobulins in colostrum during the neonatal period. However, foals that are ultimately free of infection do not have detectable viral RNA in blood and have declining concentration of antibodies to EIAV. Foals should be isolated from infected horses as soon as feasible after diagnosis of EIAV infection in the dam.

Restriction of introduction of infected horses into clean herds or areas is important to prevent introduction of the disease. Horses should be tested before introduction to the herd, and perhaps again in 1 to 2 months. If suspect horses are to be introduced, they should be kept under close surveillance for at least 6 months before being admitted. Horses known or suspected to be infected should be separated from all other uninfected horses, donkeys, and mules by a distance of at least 200 m. This recommendation is based on observations of the feeding behavior of tabanids, which are very unlikely to fly more than 100 m after an interrupted feeding. Suspect positive horses should be retested after at least 1 month and probably at regular intervals thereafter. Operators of open stud farms and rest farms can also insist on proof of a negative test before admitting each horse. One deficiency of this policy is the long period of incubation of up to 45 days between infection and seroconversion to a positive test.

In countries where the incidence is high, it is usual to control horse movement by a system of permits and certificates of freedom from the disease and to insist on skin-branding or lip tattooing of all horses. Horses with a positive AGID or ELISA test should be allowed to move only under specified conditions.

Draining of marshy areas and the control of biting insects may aid in limiting spread of the disease. A degree of protection may be obtained by the use of insect repellents and by stabling in screened stables. Great care must be taken to avoid transmission of the disease on surgical instruments and hypodermic needles, which can only be sterilized by boiling for 15 minutes or by autoclaving at 6.6-kg pressure for a similar period. Chemical disinfection of instruments and tattoo equipment requires their immersion for 10 minutes in one of the less corrosive phenolic disinfectants. All materials to be disinfected need to be cleaned of organic matter first. For personal disinfection, sodium hypochlorite, ethanol, or iodine compounds are safe, and for materials where organic matter is not removable, agents such as chlorhexidine or phenolic compounds combined with a detergent are satisfactory.

There are considerable problems associated with development of vaccines against EIA because only neutralizing antibodies are capable of causing sterile immunity and preventing infection. Neutralizing antibodies are specific for the homologous virus, but the large variation in phenotypes of the wild virus means that it will be difficult to stimulate neutralizing antibodies protective against all of the possible infecting phenotypes. Vaccines are available in parts of the world but are not in general use. Killed, whole-virus vaccines are safe, but subunit vaccines may actually enhance the occurrence of the disease. An experimental live attenuated EIAV DNA prophage vaccine affords complete protection in experimentally infected horses and has been widely used in China. The use of attenuated vaccines is associated with risk of introduction to virulence and lack of sterilizing immunity against heterologous virus challenge.

TICKS THAT TRANSMITPROTOZOA NDISES

Ticks are the most important vectors of many protozoan diseases, the protozoan in most instances surviving from generation to generation of ticks by infecting their eggs. Where control of these diseases is to be undertaken, it is necessary to know which ticks are vectors, how many hosts the tick parasitizes during a life cycle, and which animals can act as hosts. Much of the information on these points is fragmentary and only a summary is presented in Table 11-9. Additional information on the control of ticks is provided in Chapter 17.

BABESIOSIS (TEXAS FEVER, REDWATER FEVER, CATTLE TICK FEVER)

* Babesia* spp. are a diverse group of tick-borne, obligate, intraerythrocytic apicomplexan parasites infecting a wide variety of organisms. Infection of a vertebrate host is initiated by inoculation of sporozoites into the bloodstream while the tick takes a blood meal. Most babesial sporozoites directly invade circulating erythrocytes without a tissue stage of development. A few, notably, *Babesia equi* and *Babesia microti*, first invade lymphocytes, where they form motile merozoites, which then invade erythrocytes. Once an erythrocyte invasion occurs, a seemingly perpetual cycle of asexual reproduction is established, despite a rapid development of a strong immune response.

SYNOPSIS

**Etiology** Babesia spp.

**Epidemiology** Disease of tropical and subtropical countries. Occurs in cattle, sheep and goats, horses, cervids, and pigs. Transmission by blood-sucking ticks. Young calves have innate resistance. Endemic stability occurs in herds with a sufficient inoculation rate to immunize a high percentage of animals.

**Zoonotic implications** Babesia bigemina and *B. microti* occurs in humans where suitable ticks are found. Human donor blood may be infected.

**Clinical signs** Anemia, hemoglobinuria, jaundice, fever, high case-fatality rate.

**Clinical pathology** Parasites in stained blood smear, positive serology. Polymerase chain reaction (PCR) for detection of parasite in blood.

Continued
Necropsy lesions Thin, watery blood; pallor; jaundice.
Diagnostic confirmation Parasites in blood smear; vector present in environment.
Differential diagnosis list A syndrome of acute hemolytic anemia should suggest the following alternative diagnoses:
Cattle Theileriosis Postparturient hemoglobinuria Bacillary hemoglobinuria S-methyl-L-cysteine-sulfoxide (SMCO) poisoning Leptospirosis
Treatment Diminazene aceturate and imidocarb.
Control Tick control, vaccination with live vaccine, chemoprophyaxis with imidocarb.

ETIOLOGY
The nomenclature of these intraerythrocytic parasites is still subject to change; species in livestock include the following:
- Cattle: species include Babesia bovis (B. argentina), B. bigemina, and B. divergens.1,2
- Sheep and goats: B. motasi, B. ovis
- Pigs: B. trautmanni, B. perroncito

EPIDEMIOLOGY
Geographic Occurrence
The distribution of the causative protozoa is governed by the geographic and seasonal distribution of the insect vectors that transmit them (Table 11-10).

Host Occurrence
Bovine Babesiosis
Babesiosis caused by B. bigemina and B. bovis is an important disease mainly in tropical and subtropical regions of the world.1,2 Both species are transmitted transovarially by Boophilus or Rhipicephalus ticks, but only tick larvae transmit B. bovis, whereas nymphs and adults transmit B. bigemina. Other species of Babesia rely on other ticks, including Haemaphysalis and Hyalomma. B. bigemina and B. bovis occur in the tropical and subtropical regions of Africa, America, Asia, Australia, and Europe (between 40°N and 32°S). B. divergens occurs in Europe and is the principal cause of babesiosis in the United Kingdom. Other species, such as B. divergens and B. major, occur in temperate regions.

Bovine babesiosis is widespread in South Africa, for example, and the distribution of both B. bovis and B. bigemina is determined by the distribution of their tick vectors. The seroprevalence of B. bigemina in nonvaccinated cattle is a result of the high vector-tick population and the endemically stable situation that can be achieved by a tick-control method that allows a reasonable number of ticks on cattle rather than relying entirely on intensive tick control and vaccination.1

Sheep and Goats
In sheep and goats, babesiosis is associated with species such as B. ovis and B. motasi and occurs in Africa, Asia, and Europe. Sheep babesiosis is of considerable economic importance in the areas infested with Rhipicephalus or Haemaphysalis.

Porcine Babesiosis
Associated with B. trautmanni and B. perroncito, porcine babesiosis occurs in Africa and Europe.

Equine Piroplasmosis

In horses, donkeys, mules, and zebras, equine piroplasmosis is associated with *B. caballi* and "*B. equi*":12 The latter parasite is now recognized as *Theileria equi* and will be retained within the context of piroplasmosis (disease caused by *Babesia* or *Theileria*) because the diseases caused by *B. caballi* and *T. equi* are similar clinically (see the section on equine piroplasmosis).13 Equine piroplasmosis occurs in much of southern Europe, Asia, and the Americas. For example, it is widespread in China and a cause for serious concern in northeastern China. In addition, equine piroplasmosis is also widespread in horses, mules, donkeys, and zebras in South Africa.13 Alternatively, Australia is free from equine piroplasmosis, but seropositive horses were temporarily imported into this country for the Sydney Olympic games in 2000. While in Australia, seropositive horses were kept at particular restricted sites.

Wildlife Babesiosis

Among *Babesia* species that infect wildlife, *B. odocoilei* infects cervids, including the whitetailed deer (*Odocoileus virginianus*), American elk, and American woodland caribou (*Rangifer tarandus caribou*).17 Desert bighorn sheep (*Ovis canadensis nelsoni*) and red deer (*Cervus elaphus elaphus*) are also susceptible to infection but do not exhibit classical signs of disease. *B. odocoilei* is transmitted by ticks of the genus *Ixodes*. Various species of *Babesia* have been recorded in reindeer, including *B. divergens* and *B. tarandirangiferis*.

Origin of Infection and Transmission

Viable stages of *Babesia* are present in the bloodstream of animals in the active phase of the infection. Ticks are the natural vectors of babesiosis; the causative parasites persist and pass through part of their life cycle in the invertebrate host. Both *B. bovis* and *B. bigemina* pass through part of their life cycle in the tick *Rhipicephalus australis* (previously *Boophilus microplus*). Other species of *Boophilus* and *Rhipicephalus* are major vectors of babesiosis, but other ticks of the genera *Haemaphysalis*, *Hyalomma*, *Ixodes*, and *Dermacentor* can be involved in transmission.18 *Rhipicephalus australis* is the main vector of babesiosis associated with *B. bovis* and *B. bigemina* in cattle production systems in Australia and Central and South America. *Ixodes ricinus* is a common carrier of *B. divergens* in the United Kingdom.19 *Rhipicephalus* and *Haemaphysalis* spp. are common ticks of sheep and/or goats.20

Knowledge of the life history of the tick is central to implementing effective control strategies against babesiosis or piroplasmosis. When adult animals become infected with *Babesia*, they can act as carriers for variable periods, up to 2 years. If they are constantly reinfected, as they are in an endemic environment, they can act as carriers for life. Ticks that parasitize only one host are easier to eradicate and cause less spread of the disease than those parasitizing multiple hosts. The control of ticks capable of surviving on both domestic and wild animals presents major challenges.

Life Cycle and Development of *Babesia*

The development of *B. bovis* and *B. bigemina* follows similar patterns. *Babesia* spp. do not parasitize any vertebrate host cell other than erythrocytes. Each sporozoite penetrates the erythrocyte membrane with the aid of a specialized structure called the apical complex. Once inside, it transforms into a trophozoite from which two merozoites develop by a process of merogony or schizogony (binary fission) (see Fig. 11-9). The tick becomes infected when ingesting erythrocytes containing piroplasms (gametocytes). They develop into male and female gametes in the tick gut. The microgametes fuse with macrogametes to produce motile zygotes. The zygotes then multiply, and the resultant "vermicules" invade numerous organs of the tick, including the ovaries. Therefore the infection passes through the ovary and the egg to the next tick generation (called transovarial transmission). Usually the female tick becomes infected, and sporogony takes place in the salivary glands of larval, nymphal, and/or adult ticks of the next generation. When the tick attaches to a new host, sporozoites mature. In *B. bigemina*, for example, some development occurs in the feeding larvae, but infective sporozoites take about 9 days to appear, and they therefore only occur in the nymphal and adult stages of the tick. Transmission can occur throughout the rest of the nymphal stage and by adult

| Table 11-10 Major *Babesia* species infective to domestic animals, their tick vectors, and their geographic distribution |
|---|---|---|
| *Babesia* spp. | Major ixodid vectors | Known distribution | Domestic species affected |
| *Babesia bigemina* | *Boophilus microplus* | Africa, Asia, Australia, Central and South America, Southern Europe | Cattle, buffalo |
| *Babesia bovis* | *Boophilus microplus* | As for *Babesia bigemina*, but less widespread in Africa as a result of *B. microplus* competition with *B. decoloratus* | Cattle, buffalo |
| *Babesia divergens* | *Ixodes ricinus* | Northwestern Europe, Spain, Great Britain, Ireland | Cattle |
| | *Ixodes persulcatus* | | |
| *Babesia major* | *Haemaphysalis punctata* | Europe, northwestern Africa, Asia | Cattle |
| *Babesia ovata* | *Haemaphysalis longicornis* | Eastern Asia | Cattle |
| *Babesia ovis* | *Rhipicephalus bursa* | Southeastern Europe, northern Africa and Asia | Sheep and goat |
| *Babesia motasi* | *Rhipicephalus bursa* | Southeastern Europe, northern Africa and Asia | Sheep and goat |
| *Babesia caballi* | *Dermacentor* spp. | Africa, South and Central America, southern United States, Europe, Asia | Horses, donkey, mule |
| | *Hyalomma marginatus* | | |
| | *Hyalomma truncatum* | | |
| | *Rhipicephalus everti* | | |
| *Babesia canis* | *Rhipicephalus sanguineus* | Southern Europe, North America, Asia, Africa, Australia | Dog |
| | *Dermacentor* spp., *Haemaphysalis* spp. | | |
| | *Hyalomma* spp. | | |
| *Babesia gibsoni* | *Haemaphysalis* spp., | Africa, Asia, Europe, North Dog | Pig |
| | *Rhipicephalus sanguineus* | | |
| *Babesia traumanni* | *Rhipicephalus* spp. | Southern Europe, former USSR, Africa | |
females and males. For *B. bovis*, the formation of infective sporozoites usually occurs within 2 to 3 days of larval tick attachment. The host is infected with infected tick saliva. Particular species of *Babesia* can persist for several tick generations, even in the absence of new infections.

Contaminated needles and surgical instruments can transmit the infection physically. The ease with which infection can be transmitted in this way depends largely on the degree of parasitemia occurring for each species. Thus the probability of physical transmission is slight with *B. bovis* and higher with *B. equi* and *B. bigemina*.

**Immunity and Susceptibility to Infection**

The immune responses of cattle to infection with *B. bovis* or *B. bigemina* involve both innate and acquired mechanisms. The response directed against infections with *Babesia* is both humoral and cellular and is T-cell dependent. In addition, an age-related immunity to initial infection with *B. bovis* in cattle is well established, characterized by strong innate immunity in young calves. Mononuclear phagocytes are engaged as the primary effector cells on innate and primary immune responses, and nitric oxide has been identified as at least one babesiacidal molecule produced by activated mononuclear phagocytes. When *B. bovis*-infected erythrocytes grown in culture are exposed to nitric oxide, death of the parasites occurs rapidly within the erythrocyte.

**Innate Immune Mechanisms**

There is an age-related immunity to primary infection of cattle with *B. bovis* and *B. bigemina*. Young calves possess this strong innate immunity against *B. bovis* infection, which lasts for approximately 6 months after birth and is abrogated with the removal of the spleen. Interleukin IL-12 and IL-10 are important immunoregulatory cytokines. The protective innate response in young calves to infection with virulent *B. bovis* involves the early appearance of IL-12 and interferon-gamma transcripts in the spleen. This is followed by a short period of inducible nitric oxide synthase expression. In contrast, IL-12 and IFN-gamma (mRNA) expression in the spleens of adult cattle that died from infection with virulent *B. bovis* involved both protective innate response in young calves to infection with *B. bovis*.

**Acquired Immune Mechanisms**

Following *B. bovis* infection, antibodies directed against protective and nonprotective parasite antigens and host antigens are produced. Hyperimmune serum from cattle infected with *B. bovis* many times, or a mixture of IgG1 and IgG2 prepared from hyperimmune serum from cattle, can be used to passively immunize naïve calves against *B. bovis* infection, and the protection is specific. Splenectomized calves given hyperimmune serum and challenged with *B. bovis* recover as effectively as intact calves.

Strong immunity occurs after natural infection with most *Babesia* spp. There appears to be little relationship between the degree of immunity and the level of
antibodies in serum. If the infection recurs repeatedly, the immunity is permanent. If the illness is treated rapidly and efficiently, and the protozoa are killed before antibodies are produced, no immunity occurs. If the infection is not repeated, the protozoa survive in the host for a variable time (e.g., 6 months), and then disappear. A sterile immunity persists for approximately 6 more months, and the host is susceptible again about 1 year after infection. These periods of latent infection and resistance/protection to reinfection are usually subject to significant variation and to different responses between breeds of cattle and species of Babesia.

Despite the potential severity of the acute infection, individuals that survive generally develop immunity against disease, but not against infection, and could remain persistently infected. In the case of B. bovis, infection can persist for years, and even for the lifetime of the animal. Babesia infections have adapted well to survival in immune hosts. A number of phenomena are known to contribute to parasite survival: rapid antigenic variation, cytoadhesion and sequestration, binding of host proteins to the infected red blood surface, the monoallelic expression of different members of multigene families, and establishment of transient immunosuppression.4,5

The inoculation rate measures the daily probability of infection. This is based on the knowledge that animals exposed to the parasite in the first 9 months of life become infected, immune, and seropositive without showing any clinical signs of disease.1 Inoculation rates of 0.0005 and 0.005 are endemically unstable because a high percentage of animals will reach the age of 9 months without having been exposed to the hemoparasite. This results in a high risk of disease (endemic instability) because primary infections in older animals are usually severe and can be fatal. In situations of endemic instability, the vaccination of calves against hemoparasites can be used to ensure that the herd is immune. Cattle producers can use tick control to break the transmission cycle.

Endemic stability is defined as the state in which the relationship between host, agent, vector, and environment is such that clinical disease occurs rarely or not at all.1 Endemic stability (herd immunity) in bovine babesiosis occurs when the rate of transmission (inoculation rate) of Babesia spp. by the tick vector is sufficient to immunize most susceptible calves before the loss of their resistance. In tropical areas with a large vector population, natural exposure usually occurs at an early age, and cattle are thus immune to subsequent challenges as adults. If at least 75% of calves are exposed to B. bovis infection by 6 to 9 months of age the disease incidence will be very low, and a state of natural endemic stability will exist.

**Immunity.** Cattle develop a durable, long-lasting immunity after a single infection with B. bovis, B. bigemina, or B. divergens. Different species of Babesia do not usually induce cross-protective immunity.4 Immunity to B. bovis and B. bigemina appears to last for at least 4 years. There is evidence that the presence of serum antibodies is not necessarily an indication of immunity. Conversely, the absence of detectable antibodies is not necessarily an indication of a lack of immunity.4

**Risk Factors**

**Host Factors**

**B. indicus** breeds of cattle are considerably more resistant to babesiosis than **B. taurus** breeds.1 This observation is thought to be a result of the evolutionary relationship among **B. indicus**, **Boophilus/Rhipicephalus** spp., and **Babesia**. Zebu and Afrikaner cattle have a higher resistance to B. bovis than British and European breeds; Santa Gertrudis and crossbred cattle occupy an intermediate position. Zebu-type cattle are also relatively free from the disease because of their resistance to heavy tick infestation. In Australia, B. bigemina is usually of lower pathogenicity than B. bovis and rarely lethal even when fully susceptible adult cattle are introduced to an endemic area. Inoculation studies with B. bigemina in Australia have shown that B. indicus and B. indicus cross-bred cattle are more resistant than the B. taurus cattle.

**Age Resistance.** In cattle, there is a variation in susceptibility to infection according to age, and the severity of babesiosis increases with age. Calves and foals from naïve dams are highly susceptible to infection and clinical illness from birth to 2 months of age, at which time they develop resistance that persists to approximately 6 months of age. Calves and foals from immune dams receive antibodies via the colostrum, and this passive immunity persists for 3 to 4 months after birth. The highest infection rate is in animals between 6 to 12 months of age; infection is uncommon in animals of greater than 5 years of age. Animals of less than 1 year of age are infected predominantly with B. bigemina and those of greater than 2 years of age by B. bovis. Calves of up to 1 year of age, although fully susceptible to infection, are resistant to disease. The average age at which calves in endemic areas become infected is 11 weeks (2 to 34 weeks), but clinical signs and pathologic changes are mild and relatively short-lived at this early age. After 6 months of age the number of infected animals in enzootic areas increases.

In **housed cattle**, the level of serum antibodies in cattle are at their lowest when they come out of the barn in the spring, and this level gradually increases as they are exposed to infected ticks.

In **enzootic areas**, cattle most commonly affected by clinical disease are those that are susceptible and introduced for breeding purposes, intended for slaughter, or are “in transit.” Cattle indigenous to endemic areas are rarely affected because of the natural resistance of very young animals, and passive immunity via colostrum from immune dams is gradually replaced by a state of active immunity. Severe clinical cases occurring in cattle in such areas are usually caused by exposure to some stress, such as parturition, starvation, or intercurrent disease. Such breakdowns in immunity are most likely to occur if there is a superimposed infection with a different parasite, such as *Anaplasma marginale*.

**Environmental Factors**

There is seasonal variation in the prevalence of babesiosis, with the greatest incidence occurring soon after the peak of the tick population. For example, in England babsesiosis mainly occurs in spring, summer, and autumn. Of the climatic factors, environmental temperature is the most important because of its effect on tick activity—higher temperatures increase activity. Humidity and rainfall have little effect, and even with temperature, the effect is limited once a threshold of 7° to 100° C (44° to 50° F) minimum temperature is exceeded. The heaviest losses occur in **marginal areas** where the tick population is highly variable in size, depending on the environmental conditions. In seasons when the tick population decreases, infection may die out, and immunity is lost. Under favorable conditions, when ticks multiply, infection can spread rapidly among susceptible individuals within a population or among/between populations. Comparative circumstances may be created artificially when an inefficient dipping or treatment program is used, which reduces the tick population to a low level and is subsequently unable to sustain control.

**Pathogen Factors**

Many intraerythrocytic hemoparasites survive host immune responses through antigenic drift or shift, which has been demonstrated for *Babesia bovis*.5 The molecular basis for antigenic variation in *Babesia* and its possible connection with cytoadherence and sequestration have been examined. There are different “strains” and antigenic variants of both B. bovis and B. bigemina. Babesia infections in cattle can relate to superinfection with antigenically distinct parasite populations. Antigenic change can provide *Babesia* with a temporary respite from attack by the host immune system and thus might prolong the infection period or cause disease relapses. Nonetheless, strain differences and antigenic variation do not appear to be of major importance in relation to the effect of a vaccine because cross-immunity between/among strains of the same *Babesia* species usually provide adequate protection against one another.
Chapter 11 • Diseases of the Hemolymphatic and Immune Systems

Economic Importance
Bovine babesiosis is the most economically important of these diseases because of direct losses of production and because of the restriction of movement of cattle for trade by quarantine laws. Many animals die or undergo a long period of convalescence, resulting in major meat and milk production losses. Incidental costs of immunization and treatment add to the economic burden. With early, effective treatment, the mortality rate can be reduced to 5%.

Zoonotic Implications
Human cases of *B. divergens* infection have been reported in France, Britain, Ireland, Spain, Sweden, Switzerland, the former Yugoslavia, and the former USSR. Geographic, these cases coincide with *B. divergens*-infected cattle populations and areas in which *Ixodes ricinus* occurs, involving inhabitants of rural areas who are exposed to ticks by virtue of their occupation or their recreational activities. Most cases are reported between May and October, during the main season of tick activity.

Cases of human babesiosis have been diagnosed sporadically, mainly in North America and Europe. Traditionally, cases of human babesiosis in Europe have been linked to *B. divergens*, whereas those in North America have been associated with *B. microti*. Autochthonous cases of *B. microti* infections have also been detected in Taiwan, Japan, and Europe. Recently, piroplasms similar to *B. duncani* and *B. divergens* have been implicated in human disease. In addition, *B. venatorum* (a *B. divergens*-like organism), which is probably a parasite of deer, was involved in the first documented cases of human babesiosis in Austria, Germany, and Italy. This evidence indicates that various *Babesia* species known to infect wildlife and domestic animals have the potential to cause human disease. Deer-associated zoonoses have become a particular public health concern, for instance, in the United States because human contact with deer ticks has increased as a result of the proliferation of deer, abandonment of farmland that reverts to thick secondary vegetation, and increased use of coastal sites for human recreation. This explains the increasing frequency of reported human cases of babesiosis, Lyme disease, and human granulocytic ehrlichiosis.

*Babesia* spp. represent a potential threat to the blood supply for transfusion because asymptomatic infections in humans occur, and the spread of these hemoparasites via blood transfusions has been reported from various countries. Using the microaerophilous stationary-phase (MASP) culture technique, the parasites proliferate in a settled layer of blood cells. This provides the opportunity to examine the basic biology of the organism, host–microbe interactions, immune factors triggered by the parasite, factors involved in innate resistance of young animals to infection, and antimicrobial susceptibility. Their in vitro cultivation might also be used to produce parasite antigens and attenuated strains of *Babesia* that could be used for immunization.

PATHOGENESIS
*Babesia* spp. are a diverse group of tick-borne, obligate, intraerythrocytic apicomplexan parasites infecting a wide variety of organisms. Infection of a vertebrate host is initiated by inoculation of sporozoite stage into the bloodstream while the tick takes a blood meal. Most *Babesia* sporozoites directly invade circulating erythrocytes. Once erythrocyte invasion occurs, a perpetual cycle of asexual reproduction is established, despite the onset of a strong immune response.

Acute Cases
When an animal becomes infected, multiplication of the protozoa in the visceral (*B. bovis*) or peripheral (*B. bigemina*) vessels reaches a peak with the development of clinically detectable hemolysis, the principal pathogenic effect, after an incubation period of 7 to 20 days. The hemolysis results in profound anemia, jaundice, and hemoglobinuria. A fatal outcome as a result of anemic shock follows. Surviving animals, there are ischemic changes in skeletal and heart muscles.

In *B. bovis* infection, there is also profound vasodilation and hypotension, resulting from the stimulation of production of vasoactive substances and an associated increase in vascular permeability. Circulatory stasis and shock follow; disseminated intravascular coagulation (DIC) and subsequent fatal pulmonary thrombosis are also features. Cerebral babesiosis is possible. In contrast, *B. bigemina* is an uncomplicated hemolytic agent and does not exert these vascular and coagulation effects.

Susceptibility to infection with *Babesia* spp. decreases with age, but the severity of disease increases. For example, calves of 5 to 6 months of age infected with *B. bovis* show limited clinical signs, cattle of 1 to 2 years of age have a moderately severe disease, and aged cows suffer a severe, often fatal disease. Intranatal infection with *B. bovis* has been reported.

Animals that survive become carriers, a state in which a subclinical infection is maintained by a delicate immunologic balance between protozoa and antibodies. This balance is readily disturbed by the stress of transport, deprivation of food, pregnancy, or intercurrent disease. Carrier animals are resistant to infection with *B. bovis* for up to 2 years. With constant reinfection, such as occurs in enzootic situations, protection is continuous.

The ability of cattle to infect ticks is much longer (1 year) with *B. bovis* than with *B. bigemina* (4–7 weeks). Similarly, the peak incidence is at a younger age for *B. bigemina*, and the reinfection rate is more rapid. Some experiments have shown that merozoites can periodically disappear from peripheral blood in infected cattle. In pregnant cows, there is usually no apparent infection of the calf in utero, but passive immunity is transferred via colostrum to the newborn calf.

Immunology
Calves of less than 9 to 12 months of age are as susceptible as adult cattle to infection with *B. divergens* but are less likely to exhibit clinical disease. This phenomenon, known as inverse age resistance, is the result of an innate resistance in calves and is independent of the maternal immune status. Although offspring of resistant dams acquire specific antibodies (mainly IgG) via colostrom or milk, these immunoglobulins are not required for protection because calves of susceptible dams without specific serum antibodies are equally resistant. Studies of *B. bovis* in vitro have shown that erythrocytes from very young calves were unfavorable for parasite development, possibly because of the inhibitory effect of fetal hemoglobin.

Cattle that recover from acute infection with *B. bigemina* or *B. bovis*, either naturally or following chemotherapy, remain persistently infected and resistant to further disease following reinfection with the same strain. Immunization with dead piroplasms or extracts can induce protection against challenge with homologous or heterologous strains, indicated by low parasitemias and a diminished packed cell volume (PCV).

Immunity does not last indefinitely, and in the absence of a reinfection, the animal becomes susceptible to reinfection. Specific immune responses include both cellular and humoral components. Monocytes and lymphocytes are the main agents of cell-mediated immunity. Experimentally, the exposure of cattle to avirulent and virulent strains of *B. bovis* in a primary infection results in considerable antimicrobial activity in peripheral blood monocytes and neutrophils. This elevated antimicrobial activity coincides with the time that parasite numbers peak in the circulation and occurs before parasite clearance. This information suggests that peripheral blood monocytes and neutrophils are active mediators in the innate immune response to a primary infection with *B. bovis*. In cattle vaccinated against *B. divergens*, protection is associated with elevated mononuclear cell proliferation.

In cattle infected with *B. divergens*, serum antibodies can be demonstrated even before infected erythrocytes appear in blood smears, suggesting that they have no inhibitory effect on merozoite replication. During secondary infection, protection seems to depend on the high specificity of some anti-*B. divergens* serum antibodies, rather than their level, because resistant animals often
have low levels of specific antibodies. The importance of the spleen in the specific immune response is indicated by the fact that the removal of the spleen following recovery may result in a clinical relapse.

Specific serum antibodies produced against the parasites are used for serologic diagnosis. The highest titers are obtained in the sera of cows that have had a series of infections, but the degree of resultant immunity is not related to the specific antibody titer. The antibodies can be passively transferred via serum or colostrum. The immunity to different strain of *B. bovis* is specific. However, when an infection with a heterologous strain of the protozoa occurs, there is an increased immune response. As with cattle, *B. ovis* infection in sheep can produce an acute attack of clinical illness, parasitemia, and the subsequent development of immunity.

**CLINICAL FINDINGS**

**Cattle**

* Babesia Bovis*. The acute disease generally runs a course of 3 to 7 days, and a fever of greater than 40°C (104°F) is usually present for several days before other signs emerge. This is followed by inappetence, depression, polyneuritis, weakness, and a reluctance to move. Hemoglobinuria is often present (known as “redwater” in some countries); urine is dark red to brown in color and produces a very stable froth. Anemia and jaundice develop, particularly in prolonged and severe cases. Diarrhea may occur. Muscle wasting, tremors, and recumbency develop in advanced cases, followed terminally by coma. Many severely affected animals die precipitously at this point, after an illness of only 24 hours. Metabolic acidosis can be present in a significant percentage of cases of bovine babesiosis. During the fever stage, pregnant cattle can abort, and bulls may become sterile for 6 to 8 weeks. Cerebral babesiosis is manifested by incoordination, followed by posterior paralysis or mania, convulsions, and coma. The mortality rate in such cases is high, in spite of chemotherapy.

In those that survive, the febrile stage usually lasts for approximately a week, and the total course about 3 weeks. Cattle that survive recover gradually from the severe *emaciation* and anemia, which are inevitable sequelae.

A *subacute* syndrome also occurs, particularly in young calves, in which fever is mild and hemoglobinuria is absent. The syndrome associated with *B. divergens* is similar to that of *B. bovis*, except that, in addition, there is spasm of the anal sphincter, causing the passage of feces with great force in a long, thin stream, even in the absence of diarrhea; this sign is referred to as “pipe-stem” feces.

* Babesia Bigemina*. Hemoglobinuria is present earlier and more consistently than in *B. bovis* infection, and fever is less of a feature. Acutely affected animals are usually not as severely affected as those with *B. bovis* infection. There is no cerebral involvement, and recovery in nonfatal cases is usually rapid and complete. However, in some cases, disease can develop very rapidly, with sudden and severe anemia, jaundice, and death. Animals that recover from *B. bigemina* remain infective to ticks for 4 to 7 weeks and remain as carriers for only a few months.

**Sheep**

Anemia, fever, icterus, and hemoglobinuria are common.

**Wildlife**

Babesiosis of elk and caribou are characterized clinically by lethargy, hemoglobinuria, icterus, fever, recumbency, and sudden death. Elk infected with *B. odocilis* may not have any clinical signs of disease but may become ill during periods of stress, such as during the rutting season, calving, transportation, or overcrowding.

**Other Species**

In all other species, the syndrome observed is clinically similar to that described for cattle.

**CLINICAL PATHOLOGY**

**Hematology**

Severe anemia with erythrocyte counts as low as 2 million/µL and hemoglobin levels down to 5g/dL occur in clinical cases in cattle, with anemia peaking 9 to 16 days following infection. Significant reduction in platelet numbers and a depression in the fibrinogen content of blood also occur.

**Demonstration of the Presence of Babesia**

**Direct Examination of Blood Smears**

A diagnosis of babesiosis in clinically affected animals depends on the detection of piroplasms (merozoites) in Giemsa-stained smears of capillary blood; venous blood may give a false negative result for *B. bovis* infection. There is no exact correlation between the percentage of erythrocytes containing protozoa and the severity of the clinical signs. Also in *B. bigemina* infection, piroplasms are numerous in peripheral capillaries; *B. bovis* is less readily found. This difficulty can be largely overcome by using thick blood smears for detection. Microscopic examination can detect parasitemia of approximately 10^6 in thin blood films and 10^7 in thick blood smears. Therefore thick blood films are 10 times more sensitive and are more reliable for the detection of low-level *B. bovis* infection. Blood films should be prepared from capillary blood collected after pricking the tip of the tail or margin of the ear; blood from the general circulation may contain 20 times fewer *B. bovis* than capillary blood.

**Transmission Test**

The inoculation of blood from a potentially infected bovine to susceptible splenectomized calves is a highly sensitive technique for the direct detection of *Babesia*. For this test, 50 to 100 mL of blood is injected into the recipient either SC or IV. In the latter case, the incubation period will be shorter. The recipient cattle are examined daily, and the blood is examined for protozoa at the peak of the febrile reaction.

**Carrier cattle** infected with *B. bovis* and/or *B. bigemina* are difficult to detect because of the small number of piroplasms in peripheral blood. Microscopic examination of stained blood smears is not a reliable technique for the detection of *Babesia*-carrier animals. The evaluation of the persistence of *B. bovis* and *B. bigemina* infections can be established by inoculating blood from donor cattle into splenectomized calves and measuring specific anti-*Babesia* serum antibody levels.

**Culture of Babesia**

Some *Babesia* spp. can be cultured in vitro. For instance, *B. divergens* from the blood of carrier cattle can be isolated using an in vitro culture technique in sheep erythrocytes. *Babesia* stages can be isolated 9 months after the acute babesiosis phase and can be successfully subcultured, cryopreserved, and resuscitated using culture medium. This culturing approach allows for detailed studies of the parasite.

**Preservation of live protozoa** can be effected by cryopreservation, by culture in a medium containing infected bovine erythrocytes, and in simple culture media in special apparatus for long periods and in large numbers.

**Methods of Detection and Identification of Babesia spp.**

The accurate diagnosis of babesiosis is an important component of controlling babesiosis. Microscopy detection methods are inexpensive and rapid, but their sensitivity and specificity are limited. Improved methods are being developed, and they offer faster, more sensitive, and more specific options compared with conventional approaches. Methods based the detection of nucleic acids (DNA) and their amplification are the most sensitive and reliable techniques available today. For instance, PCR assays have been developed for the detection and identification of common pathogenic bovine, equine, and rodent piroplasms. Following specific amplification of the parasite DNA by nested PCR, the parasite species can be identified by PCR-coupled sequencing and/or fragment-length polymorphism.

Other combined tests include ELISA using a recombinant *B. bovis* antigen, PCR, and a DNA probe, which can specifically detect even low-level infections. The DNA probe has the added advantage of being able
to detect protozoa in necropsy specimens and in tick tissues. The PCRs are most useful because of their high sensitivity and specificity, which makes them suitable for the detection of carrier animals.

Serology

Diagnosis of past or present infection can be demonstrated by any one of a wide range of serologic tests.7

Cattle

Because of the difficulty in finding piroplasms in smears in animals during the subclinical stages of the disease, particularly in surveillance studies for the detection of the infection in herds or areas, much attention has been directed toward employing serologic tests. Such tests are well established, but most of them have limitations in terms of specificity and sensitivity. Moreover, it is not possible, on an individual animal basis, to distinguish between exposure and infection, or between current and past infections, or to determine the presence of antibodies in a population of animals with particular sensitivity.

Complement Fixation Test. CFT is a commonly used serologic test for bovine babesiosis. Other tests assessed under field conditions include passive agglutination, indirect fluorescent antibody test (IFAT), indirect hemagglutination, ELISA, microplate enzyme immunosassay (EIA), latex agglutination, capillary agglutination, slide agglutination, and card agglutination. These tests have relatively good responsiveness, with EIA being particularly sensitive.

Immunofluorescence Antibody Test. IFAT has been a popular test used to distinguish between Babesia spp. and to demonstrate the presence of antibodies in a population of animals. IFAT differentiates between antibodies against B. divergens and other bovine babesias, but not between B. divergens and B. capreoli from red deer.

ELISA. An ELISA test using a crude antigenic preparation of B. bovis was assessed for the specific detection of IgM serum antibodies and achieved a specificity of 94% and sensitivity of 100%. Specific IgM antibodies against B. bovis have been reported to appear on the 11th day following inoculation in animals by R. australis ticks and on the 19th day after inoculation in animals with infected blood.

A competitive ELISA (cELISA) is another high-throughput method for detecting serum antibodies against hemoparasites. For instance, the gene encoding B. bovis rhoptry-associated protein 1 (RAP-1) was used to develop such an assay. This ELISA approach was reported to differentiate animals with B. bovis–specific antibodies from uninfected animals, and from animals with antibodies against other tick-borne hemoparasites, with high sensitivity and specificity (both ≥ 98.5%).

Sheep

ELISA has been assessed for the detection of B. ovis in sheep.

A latex agglutination test (LAT) using recombinant B. equi merozoite antigen 1 (EMA-1) was developed for the detection of antibodies to T. equi.1 It is a simple, rapid, relatively sensitive, specific, and inexpensive alternative to IFAT or ELISA.

NECROPSY FINDINGS

In acute cases of babesiosis in all species, in which patients die after a brief illness and during an anemic crisis, the typical findings are jaundice; thin, watery blood; pale tissues; enlargement of the spleen, which has a soft, pulpy consistency; and gross enlargement and dark-brown discoloration of the liver. The gallbladder is distended, with thick, granular bile; the kidneys are enlarged and dark; and the bladder contains red–brown urine. Ecchymotic hemorrhages are present under the epicardium and endocardium, and the pericardial sac contains an increased quantity of blood-stained fluid. In cattle, a characteristic manifestation is severe intravascular clotting.

In subacute or chronic cases of relatively long duration, the carcass is emaciated but hemoglobinuria is absent; the other changes observed in acute cases are present but are less pronounced. The microscopic examination of blood smears taken from peripheral blood, from kidney and heart muscle, and, in the case of suspected B. bovis infection, from the brain, is mandatory for clinching the diagnosis. Smears from blood and most tissues must be made within 8 hours of death, within 28 hours for the brain, and stained with Giemsa for the detection of B. bovis.

Direct fluorescent antibody staining of smears permits the use of slightly “older” tissues. Organ smears are still usable 5 days after collection, provided that they are kept at 22°C (72°F). The morphology of B. bigemina changes quickly after the host’s death, so that zoites resemble those of B. bovis. Blood collected after death can also be used for detection of serum antibodies in serologic tests.

Differential diagnosis

Preferably, the presence of the tick vector should be collected and verified before a definitive diagnosis of babesiosis can be made, unless an animal has left a known enzootic area within the preceding month. Clinically, a high morbidity and case-fatality rate in cases displaying jaundice with hemoglobinuria and fever are suggestive, but confirmation of the diagnosis by microscopic examination of stained blood smears, complementary immunologic or molecular tools, and/or by transmission experiments is required. A necropsied animal with splenomegaly, jaundice, hemoglobinuria, swollen and dark kidneys and liver, and/or myocardial ecchymoses is suggestive of babesiosis/piroplasmosis, but the diagnosis needs to be confirmed by traditional or molecular laboratory testing of tissues for the presence of the parasite stages (merozoites/piroplasms).

TREATMENT

Primary treatment is aimed at killing the parasite(s) in the patient. Effective drugs are available for use in cattle, but the initial phase of the disease is acute; if treatment is delayed for too long, the animal may succumb to the anemia, in spite of chemotherapy. If the illness is a consequence of vaccination with live vaccine, care must be taken to avoid a complete sterilization of the blood before sufficient serum antibody is produced against the parasite(s) to elicit a durable immunity. Treatment has no suppressive effect on the protozoa that are residing in the ticks parasitizing the cattle at the time.

Drugs such as diminazene aceturate, imidocarb dipropionate, amicarbalide diisothionate, and phenamidine have been used against Babesia. Parvaquone, buparvaquone, and alovaquone are introductions with good reputations from clinical trials. Tetracyclines have been used extensively, but their use in acutely sick animals has been discontinued. There is some use in the simultaneous administration of live Babesia in a chemosterilant situation; the parasite is controlled and effective immunization is achieved.

infection by chemotherapy are resistant to challenge with the homologous strain of that organism for several years. The presence of infection does appear to be mandatory for protection against heterologous strains.

Although a certain period of antigenic exposure is necessary before treatment to facilitate the establishment of immunity, cattle treated with imidocarb dipropionate ultimately have a solid immunity. Long-term persistence of low-level parasitemia is now considered a disadvantage. Remaining parasites may give rise to recrudescence under adverse conditions, treated cattle may act as a source of infection, and parasites surviving low levels of babesicide may acquire resistance.

Imidocarb provides “protection” from clinical disease for 3 to 6 weeks, but allows a sufficient level of infection for immunity to develop. This strategy is highly effective if the host is assured to be exposed to babesiosis during the period of protection, either through a tick bite in geographic areas where babesiosis is endemic or by inoculation of live parasites. Acquired immunity then takes over from “drug protection,” and the animal passes smoothly to a resistant state without an intermediate clinical stage. However, if infection rates are sporadic or if very high doses of imidocarb are used, a complete inhibition of parasite development will hinder the mounting of an adequate immune response. The major issue associated with this approach is concern regarding drug residues in milk and meat, which has led to the withdrawal of imidocarb in several European countries.

Imidocarb (Imizol)

This and the related drug, amidocarb, are effective babesicides for cattle at the dose rate of 1 mg/kg BW. At 2 mg/kg BW, it eliminates the parasites from the host and maintains some residual activity; noninfected cattle derive a month’s resistance to clinical infection but can be infected subclinically. Therefore, imidocarb can be used to “protect” cattle when vaccination is undesirable (e.g., during pregnancy) or when exposure to infection is short-lived. Conversely, it can be used to temporarily protect animals before vaccination. The drug can be given SC. The hydrochloride form is inclined to be an irritant; propionate is less irritating.

Sheep

Diminazene aceturate is effective as a treatment in sheep (3.5 mg/kg BW on two successive days, or 12 mg/kg BW as a single dose).

Supportive Treatment

In all species, treatment regimens for severely affected sheep should include blood transfusions and antishock preparations. In chronic cases and convalescent patients, hematinsics should be provided.

CONTROL (BOVINE BABESIOSIS)

Prevention and Biosecurity

Preventing the introduction of the disease into a nonenzyotico area depends on effective quarantine to prevent the introduction of the vector tick and laboratory testing to ensure freedom of the importee from infection with the pathogen(s). 1

Control

The control of bovine babesiosis in an area depends on the control the tick vector. Eradication is usually not achievable/practical because of the high cost to local wildlife, some of which can be hosts to ticks. Other challenges encountered include the following:

• The difficulty of getting a complete muster of all cattle on every dipping day
• Multihost ticks, which can be infective but temporarily not resident on an animal on dipping day
• The spread of ticks or infested cattle as a result of environmental issues, such as floods or windstorms
• Illegal movement of cattle without a permit

Other issues include the persistence of Babesia through successive generations of the tick vector and the resistance of ticks to acaricides, which is also a factor relating to the infestation level of cattle.

The effect of different tick (Rhipicephalus microplus) control strategies (none, threshold, and strategic) on endemic stability and the likelihood of babesiosis (Babesia bovis) has been examined in parts of South America using a computer simulation model based on weekly tick counts. The cattle population was in a state of enzootic stability, with an inoculation rate exceeding 0.005 throughout the year. Threshold dipping strategies did not increase the risk of babesiosis. Strategic dipping resulted in an extended period of enzootic instability lasting 30 weeks, which required protection of the herd by vaccination. Therefore strategic dipping is proposed to lead to effective control or eradication of Babesia from tick and cattle populations, but it would not result in an eradication of the tick vector. This situation could lead to subsequent outbreaks if Babesia carrier animals were introduced into the herd. Strategic tick control could be accompanied by concurrent vaccination against babesiosis.

Limitation of Prevalence

To limit prevalence at economically sustainable levels requires different solutions in different circumstances. It is largely dependent on tick control through frequent application of acaricides, chemotherapy to kill Babesia in the cattle host, and, to a lesser degree, by immunization of cattle. 7,9 These measures are only partly effective and are time-consuming and expensive. The reason for the poor performance of vaccination procedures, even after a great deal of research, is that the mechanisms of immunity against protozoa, particularly Babesia spp., have not been explored in great detail. Further investigations need to elucidate how immune responses to these parasites work.

Aspects that need to be considered to limit prevalence are the following:

• Susceptible cattle moving into an enzootic area need prior vaccination.
• Marginal areas abutting enzootic areas in which tick populations vary with climatic change, so that resident cattle lose immunity after some dry years and are then exposed to infection when wet years. Foster an increased prevalence of ticks in these areas. Vaccination before outbreaks are predicted to commence is recommended, if forecasting is possible, and temporary chemoprophylaxis after outbreaks have commenced.
• In enzootic areas where losses are occurring as a result of environmental stress or, particularly, concurrent infection with another pathogen (e.g., Anaplasma marginale), or where the tick population has been decimated by overzealous dipping, chemoprophylaxis and relaxation of dipping are recommended. Exposure of cattle to ticks is important to ensure to maintain a state of infection and immunity.

Vaccination

Vaccination with live and dead whole parasite extracts, and isolated parasite antigens has been used, with varying degrees of success. 6 Several findings support the development of vaccines against babesiosis. First, cattle that recover from a primary Babesia infection or that have been immunized with attenuated parasites are resistant to challenge infection. Second, the immunization of cattle with native Babesia antigen extracts or culture-derived supernatants containing secreted Babesia antigens elicit protective immunity against both homologous and heterologous challenge.

The characteristics of cattle farms on which the exposure of young cattle to tick fever organisms is sufficient to ensure that immunity is high and the risk of clinical disease is low (endemic stability) can be compared with those farms on which exposure is insufficient (endemic instability) to study and understand the relationships between the management of ticks and tick fever. In Queensland, Australia, for example, many cattle herds do not have sufficient exposure to B. bovis, B. bigemina, or A. marginale to confer endemic stability for tick fever. 1 For B. bovis, the major cause of outbreaks of clinical disease in Queensland, less than half of the herds had evidence of endemic stability. The decision to leave some ticks on cattle, in an effort to induce endemic stability, did increase the likelihood of endemic stability to A. marginale. However, it was ineffective, because only 26% of herds
had endemic stability against all three pathogens. Thus, given the low proportion of herds with endemic stability to tick fever organisms and the high likelihood of clinical disease, vaccination is recommended to protect dairy cattle from tick fever throughout tick-infested areas.

**Live Vaccines**

Vaccines incorporating live, attenuated strains of *B. bovis* and *B. bigemina* have been used routinely or experimentally in Australia and a number of other countries. The literature used routinely or experimentally in Australia cattle. Disease from vaccinated to unvaccinated used. There is no reliable evidence to indicate vaccines in most countries where they are the basis for the production of live Australia over many decades have formed quality control essential; unfortunately, such is a concern and makes postproduction contamination of blood-derived vaccines of some major importance. The development of effective live vaccines is restricted to cattle of less than 1 year origin and purifies the strains of the parasites. The risk of contamination of blood-derived vaccines is a concern and makes postproduction quality control essential; unfortunately, such quality control is beyond the means of some endemic countries. Techniques developed in Australia over many decades have formed the basis for the production of live *Babesia* vaccines in most countries where they are used. There is no reliable evidence to indicate that current live vaccines might spread disease from vaccinated to unvaccinated cattle.

**Origin and Purification of Strains.** Since 1990, three strains of *B. bovis* and one of *B. bigemina* (G strain) have been used to produce vaccines in Australia. After testing for virulence, immunogenicity, and purity, suitable strains are preserved as master stabiles in liquid nitrogen.

**Attenuation of Parasites**

*Babesia Bovis*. The most reliable method of reducing the virulence of *B. bovis* is the rapid passage of strains through susceptible, splenectomized calves. Attenuation usually occurs after 8 to 20 calf passages.

*Babesia Bigemina*. Rapid passage in splenectomized calves is not reliable, but the virulence of *B. bigemina* decreases during prolonged residence in latently infected animals. A single *B. bigemina* isolate (G strain) has been used in the Australian and South African vaccines for many years.

**Vaccine Specifications**

Live vaccines have proven very effective and reasonably safe, particularly when vaccination is restricted to cattle of less than 1 year of age, when they still are resistant to disease. Vaccines are derived from splenectomized donor calves infected with attenuated strains of *Babesia*, or from parasites grown in vitro. The vaccines are provided either chilled or cryopreserved. In spite of the costly and time-consuming nature of producing such live vaccines, they have usually provided greater than 95% protection for the life of the cattle vaccinated.

**Frozen Vaccine.** Frozen vaccine is superior to chilled vaccine because of its long shelf-life, which allows postproduction testing of potency and safety before dispatch. Glycerol is used as cryoprotectant in Australia and is preferred over dimethyl sulfoxide because it allows postthaw storage life of the vaccine for at least 8 hours (at temperatures of 4° to 30°C (39° to 86°F)). Frozen vaccines are transported in suitably insulated containers with liquid N₂ or solid CO₂, which limits the ability to supply vaccines to all destinations. To ensure infectivity, the vaccine must be used within 8 hours of thawing, and once thawed should not be refrozen. A frozen bivalent *B. bovis* and *B. bigemina* vaccine and frozen monovalent *B. bovis* and *B. bigemina* vaccines using dimethyl sulfoxide as the cryoprotectant are produced in some countries. If dimethyl-sulphoxide is used, a vaccine should be used within 30 minutes of thawing.

**Chilled Vaccine.** Most of the babesiosis vaccines produced to date have been provided in a chilled form. In Australia, 35 million doses were supplied between 1996 and 2003. It is popular because of ease of production, ease of transportation even with limited resources, ease of use, and low cost. The chilled vaccines used in Australia contained 1 × 10⁷ *B. bovis*, 2.5 × 10⁹ *B. bigemina*, and 1 × 10⁶ *Anaplasma centrale* organisms per 2 mL dose. A chilled vaccine has a very short shelf-life of approximately 4 days, which requires rapid, reliable means of communication and transportation to ensure viability. Chilled vaccines can remain viable for up to a week if stored at 4°C (39°F).

To reduce the risk of neonatal hemolytic disease in calves (alloimmune hemolytic anemia) of vaccinated dams, the vaccine should not be used repeatedly. Most owners vaccinate only young animals, seldom more than twice. A reduction of the vaccine dose and the use of a cell-free diluent have essentially eliminated the problem in Australia.

**Use of Live Vaccine**

**Cattle Born in Tick-Infested Regions.** Any factor affecting the survival of the tick vectors will affect the risk of babesiosis. An increased number of ticks will increase the threat of disease until an endemically stable situation develops. Conversely, reduced tick numbers will increase the longer-term risk of babesiosis because of the reduced natural exposure of calves. Therefore, cattle owners in endemic areas in Australia are advised to supplement natural exposure by vaccinating calves at weaning age. Vaccination is also recommended if cattle are being moved within an endemic area.

**Susceptible Cattle Imported Into Vector-Infested Country or Region.** Large numbers of cattle, predominantly *B. taurus*, are being imported into tropical developing countries to upgrade local livestock industries. This has resulted in significant economic losses from tick-borne diseases, including babesiosis. Vaccination of naive cattle moving from tick-free to endemic areas within Australia is usually very effective. This practice has played a crucial role in making the livestock industries in these countries more sustainable and competitive in meeting market demand with regard to breed.

The K strain of *B. bovis* and G strain of *B. bigemina* from Australia have been shown experimentally to be protective in South Africa and Sri Lanka. Vaccines containing these strains have also been used with beneficial results in parts of Africa, South America, Malaysia, and the Philippines.

**Control of Outbreaks.** Use of a vaccine in the face of an outbreak is common practice in Australia. Superimposing vaccination on a natural infection will not exacerbate the disease but will preempt the development of virulent infections in a proportion of the herd not yet exposed to the pathogens. To
prevent further exposure, the group should also be treated with an acaricide capable of preventing tick attachment from the time of diagnosis to 3 weeks after vaccination. Injectable or pour-on formulations of ivermectin and moxidectin and fluazuron are highly effective acaricides but do not prevent the transmission of Babesia.

Clinically affected cattle should be treated as soon as possible with a suitable babesi-acide. In the case of a severe outbreak, it might be advisable to treat all the cattle with a prophylactic compound, such as imidocarb or diminazene, and to vaccinate them later when the drug residue will not affect the replication of the vaccine parasite(s).

**Hazards and Precautions of Live Vaccine Use**

**Severe Reactions.** The likelihood of vaccine-inducible reactions has been reduced with the development of attenuated strains. However, there is always a risk of such reactions when highly susceptible adult cattle are vaccinated. Calves of 3 to 9 months of age have a high level of natural resistance and a low risk of reactions. In some countries, vaccination is only recommended for calves, whereas in Australia and South Africa, adult cattle can be vaccinated, provided proper precautions are taken. Concurrent infections may increase the likelihood of reactions. In pregnant cows, fever associated with reactions has the potential to cause abortion; in large bulls, there can be a temporary loss of fertility. In the case of valuable cows and bulls, their body temperatures should be monitored if vaccine-induced reactions occur, and those with prolonged fever should be treated with a babesi-acide.

**Lack of Protection.** Since the introduction of a standardized method of production in Australia, live antibabesiosis vaccines have been highly effective. In most cases, a single vaccination provided lasting, probably lifetime immunity against field infections with antigenically distinct strains. However, some failures have occurred and are thought to have been associated with a loss of immunogenicity because of frequent passing of the vaccine strains in splenectomized calves. This was overcome by replacing the vaccine strain. To prevent future recurrences of vaccination failure, the number of passages of vaccine strains of *B. bovis* is limited by frequently reverting to a master stabile with a low passage number. Other failures may be associated with the immune responsiveness of the host and the immunogenicity of vaccine strain subpopulations.

A single inoculation of cattle at 6 to 9 months of age with an attenuated vaccine containing *B. bovis* and *B. bigemina* usually provides good, long-lasting protection. At this age, the risk of vaccine reactions is minimal. Immunity following use of a live *B. bovis* vaccine lasts for at least 4 years, possibly less for *B. bigemina*. It is known to persist even after elimination of Babesia infections, and studies on drug-cured cattle suggest that the degree of acquired immunity relates to the degree of antigenic stimulation (duration of prior infection) rather than the presence of live parasites. There is no evidence of a loss of immunity with time, and revaccination is mostly not required. Revaccination is advisable when there is uncertainty over the reliability of previous procedures, to ensure that all animals seroconvert, or if there has been a change in the strains used in the vaccine.

A cryopreserved vaccine containing in vitro culture-derived (attenuated) stains of *B. bovis* and *B. bigemina* can achieve protection in 90% of vaccinated cattle against the virulent field strains of Babesia. Inherently disadvantaged vaccines derived from the blood of animals include the risk of reactions or contamination with pathogenic organisms, sensitization against blood groups, tick transmissibility of vaccine strains, and the need for a cold chain transportation.

Vaccinated cattle should be housed or kept under close observation for a month in case excessive reactions occur. A major problem in vaccination with live Babesia is the occasional apparent failure to transmit the protozoa. This may be result from the absence of the protozoa from the bloodstream of the donor at the time that the blood is drawn or from the presence of a prophylactic drug—for example, imidocarb dipropionate—or low levels of antibody in the animal’s tissues. Revaccination is necessary in these circumstances, preferably with blood from a donor that is undergoing a severe reaction at the time.

The attenuated organisms used in unfrozen South Africa *B. bovis* and *B. bigemina* vaccines are susceptible for longer periods to the residual effect of the antibabesial drugs diminazene and imidocarb dipropionate compared with the virulent field strains. The waiting periods before administration of the frozen *B. bovis* and *B. bigemina* vaccines in animals that have been treated with diminazene at 3.5 mg/kg BW compare favorably with those of unfrozen vaccines at 4 and 8 weeks. The inhibitory effect of imidocarb dipropionate at 3.0 mg/kg BW on the infectivity of both frozen *B. bovis* and *B. bigemina* vaccines is longer and requires minimum waiting periods before administration of these vaccines of 12 weeks and 24 weeks, respectively.

**Vaccination With Subunit Vaccines**

Subunit vaccines offer an attractive alternative to virulent or attenuated Babesia spp. Such vaccines are based on recombinant antigens derived from cloned complementary DNA from protozoan parasites. Several protective antigens associated with merozoites or merozoite-infected erythrocytes of *B. bigemina* and *B. bovis* were identified as possible molecules.**

### Dead Vaccines

Dead vaccines would overcome many of the inherent difficulties in the production, transport, and use of live vaccines. However, they have not been sufficiently efficacious, and more research is required.

### Vector Control

This approach was first used successfully to control and eventually eradicate the cattle tick *Boophilus annulatus* and *Babesia* from the United States. In 1906, an eradication program began that involved livestock owners, state officials, and U.S. Department of Agriculture specialists. The program involved three tactics. First, some pastures were rendered tick-free by excluding all host animals until the ticks had starved to death. The second, more common tactic was to retain livestock on the infested pastures and to disinfect the animals at regular 2-week intervals by immersion in an arsenic solution, which killed the engorged female ticks. Third, the interstate movement of tick-infested cattle was prohibited through quarantine. The campaign to eradicate cattle ticks from the United States is the most sustained, extensive, coordinated area-wide attack ever made against an arthropod pest. The tick was removed from more than a million square kilometers over a period of 34 years. The tick is confined to the lower Rio Grande River in Texas, where reinfection occurs via animal movement from Mexico. This necessitates continual control of fringe populations of cattle.

In Africa, babesiosis is only part of very important complexes of ticks and tick-borne disease, and intensive government-regulated tick control programs have been used for many years. In other continents, the situation is much less complex; where babesiosis is endemic, disease control (rather than eradication) is more realistic. Eradication of tick vectors is rarely considered practical, environmentally sustainable, or economically justifiable on either a national or a local basis.

### Natural Endemic Stability

Natural endemic stability can seldom be relied upon as a disease control strategy. First, in endemic areas, climatic effects, genetic makeup of hosts, and management strategies inevitably have a major effect on the rate of transmission and, ultimately, on the likelihood of endemic stability developing. Second, endemic stability is an economic concept that incorporates risk management and loss thresholds. The climatic, animal, and management parameters that allow endemic stability can change on a seasonal and annual basis. Third, the model for endemic stability was developed in
Australia and the Americas, where disease/vector interactions are relatively simple. The African situation is much more complex and less predictable, with four main diseases, several vectors, the presence of game reservoirs, and a larger range of susceptibility of bovine breeds.

Control of Babesiosis in Species Other Than Cattle

The principles of the control of babesiosis in other species is similar to those used for control of this disease in cattle. Most attention is focused on controlling the vector tick, identifying infected and carrier animals by an appropriate laboratory test, and sterilizing the positive reactors using a suitable treatment strategy.

EQUINE PIROPLASMOSIS

Piroplasmosis of equids is a tick-borne infectious disease caused by the hemoprotozoan parasites Theileria equi and Babesia caballi.1,2 Babesiosis, also known as equine babesiosis (B. caballi), theileriosis (T. equi), or “biliary fever,” affects all equids, including horses, donkeys, mules, and zebras. Infection with either or both of these obligate intraerythrocytic organisms can cause varying degrees of hemolytic anemia and associated systemic disease. Recently T. equi infection has reemerged in the United States; consequently, questions have arisen as to the tick–vectors–parasite–host relationship required for the development of clinical disease.

SYNOPSIS

Etiology Babesia caballi and Theileria equi.

Epidemiology Occurs in equids. Transmission by ticks.

Clinical signs Anemia, hemoglobinuria, jaundice, fever, often high case-fatality rate for T. equi but not for B. caballi.

Clinical pathology Parasites in stained blood smear, positive serology. Polymerase chain reaction (PCR) can be used for detection of parasite in blood or tissues.

Necropsy lesions Thin, watery blood; pallor; jaundice.

Diagnostic confirmation Parasites in blood smear; vector present in environment.

Differential diagnosis list A syndrome of acute hemolytic anemia should suggest the following alternative diagnoses: Equine infectious anemia Severe myoglobinuria (rhabdomyolysis associated with exercise or hypoglycin A intoxication) Foals with aloimmune hemolytic anemia Cardiac form of African horse sickness

Treatment Imidocarb—drug of choice. (R1)

Aspects of control Tick control; chemotherapy with imidocarb; surveillance of horses and ticks using effective serologic, molecular, and complementary tools.

ETIOLOGY

B. caballi and T. equi (previously Babesia equi) are known to cause infections and disease in equids, including horses, donkeys, mules, and zebras.1,3 For T. equi, molecular studies support previous observations of preerythrocytic stages in lymphocytes. Nonetheless, the taxonomy of T. equi remains controversial.4

EPIDEMIOLOGY

Geographic Occurrence

The distribution of the causative protozoa is governed by the geographic and seasonal distribution of the insect vectors that transmit them (Table 11-10).

Host Occurrence

Babesiosis and theileriosis of equids are known as equine piroplasmosis. In horses, donkeys, mules, and zebras the disease is associated with B. caballi or T. equi.1,4 The diseases caused by B. caballi and T. equi are similar clinically, but the latter species is more virulent.1 Equine piroplasmosis occurs in much of southern Europe, Asia, and the Americas. For example, it is widespread in China and a cause for serious concern in northeastern China. In addition, equine piroplasmosis is also widespread in horses, mules, donkeys, and zebras in South Africa, and has reemerged in the United States.6,7 Australia is free from equine piroplasmosis, but seropositive horses were temporarily imported into Australia for the Sydney Olympic games in 2000. While in Australia, seropositive horses were kept at particular restricted sites. The distribution of equine piroplasmosis coincides with the distribution of tick vectors.7,8 Ixodid ticks of the genera Hyalomma, Dermacentor, and Rhipicephalus have been identified as vectors for the transmission of either T. equi or B. caballi to equids hosts. In tropical countries, Hyalomma species appear to be suitable vectors for transmission of T. equi to horses and donkeys.

Impact

Mortality rates in outbreaks of equine piroplasmosis can be high, but the predominant losses in horses result from the interference with racing and equine competitions and meetings. This is a particular issue now, with the increased movement of horses between or among countries to partake in international equine competitions. Another possible form of loss is the death of foals infected in utero. Although there was early evidence that equine babesiosis might be an emerging disease threatening to be of major importance to the horse industry, this has not been the case. However, disease caused by T. equi appears to be a significant threat. Nonetheless, the use of diagnostic methods to screen horses before, during, and after international travel associated with international competitions or races is an important disease monitoring/prevention approach.

Life Cycle and Transmission

The life cycles of both T. equi and B. caballi involve distinct developmental stages that occur in the host and tick.2 Both parasites progress via three stages: the sporozoite (aexual transmission stage), merozoite (asexual blood stage), and gametocyte (sexual blood stage). Development within the tick varies, depending on the tick species involved. Infective sporozoites are transmitted through tick saliva to the equid host. Once within the equid host, B. caballi sporozoites directly invade erythrocytes, where they multiply and develop into trophozoites, and then into merozoites. After erythrocyte rupture, merozoites are released and invade other erythrocytes. In contrast, T. equi first enters peripheral mononuclear cells (PBMCs), which is part of the reason for its taxonomic reclassification as Theileria. Within PBMCs, T. equi zoites replicate to produce large schizonts; after ~9 days, merozoites are released and invade erythrocytes, where they multiply and develop into trophozoites, and then into merozoites. Merozoites are released and invade other erythrocytes. For both B. caballi and T. equi, asexual replication results in a massive expansion of the population of merozoites and parasitized erythrocytes. Following multiple rounds of replication, some merozoites develop into gametocytes within peripheral blood. Upon ingestion by a competent tick, the parasites undergo sexual reproduction, with gametocytes developing into gametes, which combine to form zygotes within the midgut of the tick. After 6 to 24 days, sporozoites accumulate within the salivary gland of the tick.
Transmission can also occur iatrogenically through inappropriate mixing of the infected and uninfected blood. This can occur during the practice of sharing needles among different horses, but use of any blood-contaminated equipment could result in transmission. Infection can also result when chronically infected horses serve as blood donors to naive horses. The illegal practice of blood doping (prerace blood transusions) was implicated in an outbreak in Florida in 2008. Experimental infection can be induced by the IV and SC injection of infective stages and by infected ticks.

Movement of Horses

The international movement of animals has become a very important matter to the horse industry. These days, groups of pleasure horses are transported around the world to compete in different countries, and valuable horses are transported around the world to compete in different countries, and valuable

PATHOGENESIS

Although some aspects of pathogenesis remain unknown, infection with *T. equi* or *B. caballi* causes the lysis of erythrocytes, resulting in varying degrees of hemolytic anemia. The physical rupture of erythrocytes during the release of merozoites causes intravascular hemolytic anemia. Infected red blood cells are removed from the circulation by splenic macrophages, further contributing to hemolytic anemia. Uniformly, infection with *T. equi* results in more severe clinical disease than *B. caballi*.

Nonparasitized erythrocytes are also removed from circulation, but the reason for this removal is unknown. It appears that the structure of erythrocyte membranes alters substantially during *T. equi* infection, suggesting that this change causes decreased deformability of the red cells, which might lead to a reduced microvascular blood flow. The level of malondialdehyde (marker of lipid peroxidation) in blood is significantly increased, suggesting that an accumulation of oxidative ions also contributes to erythrocyte lysis. *T. equi* and *B. caballi* infections also alter coagulation; *B. caballi*-infected erythrocytes cause microthrombi by clumping within small vessels, leading to venous stasis and vasculitis. Also described are thrombocytopenia and prolonged clotting times during *T. equi* and *B. caballi* infections.

Decreased platelet counts might relate to immune-mediated destruction, splenic sequestration, and/or excess consumption, as seen in disseminated intravascular coagulation (DIC). Severe piroplasmosis often results in hypercoagulability, systemic inflammatory response syndrome, and subsequent multiorgan system dysfunction.

Placental transmission can result in abortion (usually in late gestation), stillbirth, or neonatal infection. Variation in genotypes of host and/or parasite could influence the prevalence of placental transmission. Transmission appears not to be linked to exposure to semen from an infected stallion, but blood contamination during mating might present a transmission risk.

In most cases, horses become persistently infected and become carriers. The inapparent carrier state is life-long with *T. equi* and possibly for *B. caballi*. Persistent subclinical infection might result, in part, from the sequestration and immune-evasion strategies of the parasites. A carrier status represents a delicate balance between protozoa and immune responses; this balance is readily disturbed by the stress of transport, deprivation of food, pregnancy, or intercurrent disease.

After transmission, depending on many factors, including infectious dose and immune status of the host, clinical signs usually develop within 12 to 19 days for *T. equi* and 10 to 30 days for *B. caballi*. The fatality rate of naive horses in geographic regions endemic for equine piroplasmosis appears to be 5% to 10%, but the severity of disease can vary significantly from one geographic region to another. Immunology

The responses of the equine immune system to infection with *T. equi* or *B. caballi* are not yet completely understood but are undoubtedly complex and multifaceted and involve both cellular and humoral components. It is well accepted that infection with either parasite results in carrier status, which confers protection against disease. There is no documented cross-protection between *T. equi* and *B. caballi*, and horses can be infected with both parasites simultaneously.

CLINICAL FINDINGS

Clinical disease can present in different forms. For acute *T. equi* infection, clinical signs usually relate to hemolysis and resultant anemia. Although *B. caballi*-infected horses do become anemic, the rare cases of acute death from *B. caballi* appear to result from multiple-organ dysfunction linked to systemic formation of microthrombi and DIC. In these cases, clinical signs vary depending on the organ system affected.

Horses with acute infection initially develop nonspecific signs, such as high fevers, sometimes greater than 40°C (104°F), lethargy, peripheral edema, anorexia, and/or weight loss. Petechia caused by thrombocytopenia can be observed on mucous membranes, including the nictitating membrane. Signs of hemolytic anemia follow and include icteric or pale mucous membranes, tachycardia, tachypnea, pigmenturia (linked to bilirubinuria or hemoglobinuria), and weakness.

Some horses show gastrointestinal signs, including colic or impactions, followed by diarrhea. Other less common clinical signs include a secondary development of pneumonia, pulmonary edema, cardiac arrhythmia, catarhal enteritis, laminitis, and/or central nervous system signs, characterized by ataxia, myalgia, and/or seizures.

Permanent or temporary infertility has been seen in stallions. Acute renal failure might occur as a result of hemoglobin-induced pigment nephropathy. Systemic responses to severe inflammation (hypotension) can worsen the kidney disease. Severe infections can also culminate in liver failure or DIC.

A fulminate, abrupt onset of signs of (peracute) disease has been described. Sudden death from *T. equi* can occur, and the introduction of naive horses into an endemic region can lead to a rapid onset of a severe disease outbreak.

Neonatal foals infected in utero with *T. equi* might present with severe and acute signs. Such foals can exhibit clinical signs at birth or can become ill at 2 to 3 days of age. Clinical signs, such as decreased suckling and weakness, are often nonspecific, but progress to resemble those of an infected adult horse (icterus, fever, and anemia). Cases of fetal and neonatal *B. caballi* infection have been reported but are rare.

Chronic *T. equi* or *B. caballi* infection usually results only in nonspecific signs, including weight loss, poor performance, partial anorexia, and/or lethargy. Mild anemia might be present, and the spleen might be enlarged. Splenomegaly appears to be caused by an increased rate of extravascular hemolysis within the spleen in less severely affected horses.

Pregnancy in carrier mares can result in abortion or neonatal infection. Because apparent carriers can serve as reservoirs for transmission (via ticks, placentally or iatrogenically), such horses represent the largest challenge in nonendemic areas.

CLINICAL PATHOLOGY

Acute infection is characterized by severe leukocytosis, lymphopenia, and a high absolute neutrophil count. *T. equi* is detected in neutrophils and monocytes in the case of high parasitemia, indicating phagocytosis of the infected erythrocytes. Animals that die of *T. equi* infection show varying degrees of emaciation, hepato- and splenomegaly, and “flabby” kidneys. Petechial hemorrhages are also common in the liver, in the spleen, and on the cortical surface of the kidneys.

Microscopic Examination

Light microscopic examination of Giemsa-stained blood smears can be used to identify piroplasms within erythrocytes. *T. equi* and
B. caballi can be readily distinguished from one another. Within erythrocytes, B. caballi typically appears as two large peariform (pear-shaped) merozoites that measure 2 to 5 μm in length; the percentage of infected erythrocytes is typically less than 1%. T. equi merozoites occur within erythrocytes as small polymorphic piroplasmas, occasionally in a distinct Maltese cross formation; T. equi merozoites usually measure 2 to 3 μm in length. In diseased horses, the percentage of infected erythrocytes is usually 1% to 5%, but it can be greater than 20% in severe cases.

**Serologic and DNA-Based Methods**

Various diagnostic techniques can be used alone or in combination. During an outbreak in a nonendemic region, involvement of the state and national regulatory agencies is essential. Only a few laboratories in the world are authorized to carry out specific testing for equine piroplasmosis; proper handling and dispatch of samples are crucial.

IFAT is used as an adjunct assay to compare CFT results, and it is one of the prescribed tests for equine piroplasmosis recommended by the OIE. Western blot (or immunoblot) has also been used for the diagnosis of T. equi and B. caballi infections in a research setting, but is now increasingly used as a tool for the detection of B. caballi infection. Research is under way to critically validate these serologic/immunologic tests for use in routine diagnosis.

The cELISA is one of the regulatory tests prescribed by the OIE for international horse transport. This test is considered to be the most sensitive means of detection of chronic T. equi infection. A cELISA for T. equi utilizes a recombinant protein (EMA-1; immunodominant, highly conserved surface antigen specific for T. equi) and specific monoclonal antibodies. This test has high sensitivity and specificity compared with all other serologic tests assessed to date. For T. equi, both the sensitivity and specificity of cELISA are greater than 95%. A cELISA using a recombinant protein (RAP-1) was also developed for B. caballi. However, sequence heterogeneity in RAP-1 among parasite strains is linked to an inability of the test to detect infected horses in some regions of the world. Both cELISAs are available commercially, but they are not available to practitioners. ELISA using whole T. equi merozoite antigen has been assessed and appears to be an easy, economical, and reliable test.

Although PCR and cELISA show considerable promise as diagnostic tools, more studies are needed to ensure adequate diagnostic specificity and sensitivity for routine application in different countries. Nonetheless, PCR assay can detect T. equi and B. caballi in the blood of horses that have recovered from acute babesiosis. Nested PCR has been used for the detection of T. equi and B. caballi in the blood samples from horses and infections in ticks. Provided reliable genetic markers are employed, it should be possible to develop a PCR for routine diagnostic testing.

**Necropsy Findings**

In acute cases of equine piroplasmosis, in which patients die after a brief illness and during an anemic crisis, the typical signs include jaundice; thin, watery blood; pale tissues; enlargement of the spleen, which has a soft, pulpy consistency; and gross enlargement and dark-brown discoloration of the liver. The gallbladder is distended, with thick, granular bile; the kidneys are enlarged and dark; and the bladder contains red-brown urine. Petechial or ecchymotic hemorrhages are present under the epidermidum and endocardium, and the pericardial sac contains an increased quantity of blood-stained fluid. A characteristic manifestation is severe DIC.

In subacute or chronic cases of relatively long duration, the carcass is emaciated but hemoglobinuria is absent; the other changes observed in acute cases are present but are less pronounced. The microscopic examination of blood smears taken from peripheral blood and from kidney and heart muscle, and from the brain in the case of suspected disease, is mandatory for clinching the diagnosis. Smears from blood and most tissues must be made within 8 hours of death, within 28 hours for the brain, and stained with Giemsa for the detection of piroplasms.

Direct fluorescent antibody staining of smears permits the use of slightly “older” tissues. Organ smears are still usable 5 days after collection, provided that they are kept at 22°C (72°F). The morphology of piroplasms can change quickly after the host’s death. Blood collected after death can also be used for detection of serum antibodies in serologic tests or parasite DNA by PCR.

**Differential Diagnosis**

Preferably, the presence of the tick vector should be collected and verified before a definitive diagnosis of piroplasmosis can be made, unless an animal has left a known enzootic area within preceding months. Clinically, a high morbidity and case fatality-rate in cases displaying jaundice with hemoglobinuria and fever are suggestive, but confirmation of the diagnosis by microscopic examination of stained blood smears, complementary immunologic or molecular tools, and/or by transmission experiments is required. A necropsied animal with splenomegaly, jaundice, hemoglobinuria, swollen and dark kidneys and liver, and/or myocardial petechia/ecchymoses is suggestive of babesiosis/piroplasmosis, but the diagnosis needs to be confirmed by traditional or molecular laboratory testing of tissues for the presence of the parasite stages (piroplasms).

**Differential Diagnosis List**

A syndrome of acute hemolytic anemia should suggest the following alternative diagnoses (Table 11-1):

- Equine infectious anemia—has a much longer, recurrent course; usually occurs in sporadic cases; and is not associated with protozoa in body fluids and tissues
- Myoglobinuria—red urine is a result of myoglobinuria, always associated with elevation of serum creatine phosphokinase activity
- Foals with alloimmune hemolytic anemia—detectable only upon laboratory examination for evidence of incompatibility between the serum of the dam and the foal’s erythrocytes
- Other immune-mediated disorders
- Cardiac form of African horse sickness (AHS)—edematous lesions that occur are similar to those of babesiosis, but there is no evidence of hemoglobinuria or jaundice
- Equine viral arteritis virus, equine anaplasmosis, purpura hemorrhagica, and red maple leaf toxicity

**Treatment**

**Chemotherapy**

For the alleviation of clinical signs, several drugs have been used with success, yet imidocarb, in its diproprionate salt form, is considered to be the most effective. Imidocarb, a carbamidine derivative, is typically administered to horses intramuscularly. The alternate form of this drug, a dihydrochloride salt, causes more severe muscle damage at the site of injection. Reported dosages of imidocarb for the alleviation of clinical signs vary, but 2.2 to 4.4 mg/kg given IM once is effective. If necessary, lower dosages can be repeated at 24- to 72-hour intervals for two to three treatments.

In nonendemic regions, where chemotherapeutic clearance is desired, T. equi and B. caballi should be treated with 4.4 mg/kg of imidocarb IM every 72 hours (four times). Donkeys and mules are very sensitive to imidocarb; therefore, its use in these species is not recommended. Imidocarb has anticholinesterase activity, such that reactions to the drug might present as sweating, signs of agitation, colic, and/or diarrhea. Typically, these signs are transient and rarely life-threatening. Effects can be prevented with an IV dose of glycopyrrolate at 0.0025 mg/kg once, or reversed with a single IV dose of atropine at 0.2 mg/kg. Horses undergoing treatment should be monitored for complications and transient elevations of liver enzyme activities (aspartate aminotransferase [AST], alanine aminotransferase [ALT], alkaline phosphatase [ALP], and sorbitol dehydrogenase [SDH])—usually, these issues resolve following imidocarb treatment.

Diminazene aceturate and diminazene diacetate have also been used against T. equi and B. caballi at a dose of 3.5 mg/kg IM every 48 hours (two treatments).
Diminazene aceturate is more effective than diminazene diaceturate; both drugs have been reported to cause damage at the injection site. Efficacy of both drugs increases with the second dosage; no chemosterilization has been reported. Signs of toxicity include respiratory distress and lethargy. The antibiotic oxytetracycline when administered IV at a dose of 5 to 6 mg/kg, once daily for 7 days, is effective against T. equi but not against B. caballi. Other drugs reported to have efficacy in the treatment of babesiosis include amicarbilade isethionate, efluvaine, artesunate and arteether (artemisinin derivatives), buparvaquone, and atovaquone, but these drugs are no longer used in practice.

Supportive Treatment
In addition to the use of antiprotozoal drugs, acutely infected horses often require supportive treatment, including, but not limited to, intravenous fluids, NSAIDs, pain management, and blood transfusions. Adequate hydration is essential during treatment with imidocarb.3

CONTROL
The principles of the control of piroplasmosis are similar to those used for the control of babesiosis in cattle. Most attention is focused on controlling the vector tick, identifying infected and carrier animals by an appropriate laboratory test, and the use of a suitable treatment strategy for test-positive animals. The control of ticks in pleasure animals is a practical proposition when horses are detected, a safe chemotherapeutic strategy for test-positive horses by periodic spraying/treatment and animals. The control of ticks in pleasure animals. The control of ticks in pleasure animals.

Nutritional Deficiencies
IRON DEFICIENCY
SYNOPSIS
Etiology Dietary deficiency of iron.
Epidemiology Young animals on milk diet; most commonly nursing piglets that have not received supplemental iron. Housed nursing lambs. Occurs in veal calves fed milk with limited quantities of iron. Continued blood loss as a result of hemorrhage (lice, blood-sucking helmithins). Subclinical iron deficiency occurs in calves and foals but is of doubtful significance. May be more susceptible to infectious diseases.
Signs Pale white skin of well grown nursing piglets, dyspnea, pallor of mucosa, sudden death may occur. Stillbirths if sows iron deficient. Secondary infectious diseases.
Clinical pathology Subnormal levels of hemoglobin and serum iron; microcytic hypochromic anemia.
Necropsy findings Pallor; thin, watery blood; anasarca; dilated heart; enlarged liver.
Diagnostic confirmation Low serum hemoglobin and serum iron with microcytic hypochromic anemia. Response to iron therapy.
Differential diagnosis Other causes of anemia (Table 11-3).
Treatment Parenteral and oral iron salts.
Control Ensure adequate iron intake. Parenteral iron-dextran to nursing piglets and lambs.
ETIOLOGY
Iron deficiency is usually primary and most likely to occur in newborn animals whose sole source of iron is the milk of the dam because milk is a poor source of iron. Deposits of iron in the liver of the newborn are insufficient to maintain normal hemopoiesis for more than 2 to 3 weeks and are particularly low in piglets.
EPIDEMIOLOGY
Iron-deficiency states are not common in farm animals except in the very young confined to a milk diet.
Iron-deficiency anemia occurs in nursing piglets for three reasons:

1. They do not have access to soil, which is a main source of iron for young farm animals.
2. They grow rapidly, and thus their absolute requirements for iron are high.
3. Milk is a poor source of iron.

The administration of iron dextran to the piglets at a few days of age is preventive and is a routine health management strategy in modern pig production. If they do not receive supplemental iron dextran, clinical disease occurs usually when the piglets are 3 to 6 weeks old. The losses that occur include those resulting from mortality, which may be high in untreated pigs, and to failure to thrive. Under modern pig production systems, piglets do not have access to sufficient dietary iron until they are weaned to a dry diet containing supplemental iron, thus the need for administration of parenteral iron dextran to all piglets at a few days of age. Even piglets raised outdoors with access to soil perform better when supplemented with iron. Iron-injected piglets raised outdoors are heavier at weaning, there is less preweaning morbidity and mortality, and they have higher blood hemoglobin concentrations compared with nonsupplemented piglets.1 Larger piglets in a litter appear to be at greater risk of developing iron deficiency at weaning.2

Iron deficiency in pigs increases the severity of Trichuris suis and Ascaris suum infections.

Iron-deficiency anemia occurs in nursing lambs that are housed and do not have access to soil, do not consume much feed other than their dam’s milk for the first 7 to 10 days of life, and grow at 0.4 kg/d. The parenteral administration of iron dextran at 24 h of age prevents the anemia. Abomasal bloat occurs in these lambs with lower serum iron concentration, and iron-dextran injections are preventive and also have a significant effect on weight gain and red blood cell and iron parameters.

Continued blood loss by hemorrhage in any animal may result in subclinical anemia and iron deficiency. Cattle heavily infested with sucking lice may develop serious and even fatal anemia. The chronic form is characterized by a nonregenerative anemia with subnormal levels of serum iron, and treatment with iron is necessary for an optimal response. Horses carrying heavy burdens of bloodsucking strongyloid worms often have subnormal hemoglobin levels and respond to treatment with iron. Occasionally veal calves, and possibly young lambs and kids, may also suffer from an iron deficiency.

Good-quality veal is traditionally pale in color and is produced by feeding calves an all-liquid milk replacer diet with a low concentration of available iron. The pallor of veal is largely a result of low concentrations of myoglobin and other iron-containing compounds in muscle. Use of milk replacers containing only 10 mg iron/kg DM results in marked anemia and reduced growth performance. Feeding milk replacers with 50 mg iron/kg DM is considered, physiologically,

REFERENCES
the optimum amount of iron for veal calves but may be too high for acceptable carcass yield in some countries. A severe iron deficiency with reduced growth rate in veal calves may be associated with a higher incidence of infectious disease because of an impaired immune system. The objective in veal calf management is to walk the narrow line between the maximum production of white meat and a degree of anemia insufficient to interfere with maximum production.

Subclinical iron-deficiency anemia also occurs in newborn calves and kids, but there is debate as to whether the condition has practical significance. Supplementation of dairy calves with iron, or iron and copper, increases growth rate. In newborn calves affected with a normochromic, normocytic, and poikilocytic anemia, the levels of serum iron are not significantly different from those of normal calves. It has been proposed that severe poikilocytosis in calves is associated with abnormalities of hemoglobin composition and protein 4.2 in the erythrocyte membrane, and iron deficiency is the cause of moderate poikilocytosis in calves.

Anemia, without clinical signs, is most likely to occur when calves are born with low hemoglobin and hematocrit levels, a relatively common occurrence in twins. It is possible that suboptimal growth may occur during the period of physiologic anemia in early postnatal life. There is some evidence for this in calves in which hemoglobin levels of 11 g/dL at birth fall to about 8 g/dL between the 30th and 70th days and only begin to rise when the calves start to eat roughage. The daily intake of iron from milk is 2 to 4 mg in calves, and their daily requirement during the first 4 months of life is of the order of 50 mg, so that iron supplementation of the diet is advisable if the calves are fed entirely on milk. Even when hay and grain are fed to calves and lambs in addition to milk, there is a marked growth response to the administration of iron-dextran preparation at the rate of 5.5 mg/kg BW. The dietary iron requirement for fast-growing lambs is between 40 and 70 mg/kg BW, and growth rate is suboptimal on diets of less than 25 mg/kg BW.

Low serum iron concentration and low serum ferritin have been observed in hospitalized young foals. Microcytic anemia and hypoferrremia occur in Standardbred foals kept at pasture for 12 hours per day. These changes are not prevented by oral administration of four oral doses of 248 mg of iron, suggesting that higher levels of supplementation are needed. Conversely, hypoferrremia and anemia were reported in stalled foals but not in a pastured cohort. The stalled foals had clinical signs of anemia (lethargy) and low hematocrit, hemoglobin, and serum iron concentrations, which were restored to normal values by iron supplementation (0.5 g iron sulfate orally once daily, 3 g of iron sulfate top dressed on cut pasture fed to the foals and their dams, and unlimited access to a lick block containing iron). Although the colour of mares is rich in iron, milk has much lower concentrations, probably explaining the low serum iron of some nursed foals and demonstrating the need for access to iron supplements or, preferably, soil or pasture. Supplementation of foals with iron should be undertaken cautiously because of the documented hepatotoxicity of large doses of iron given orally to newborn foals. Toxic hepatopathy develops in newborn foals administered iron fumarate at 16 mg/kg BW within 24 hours of birth, similar to the situation in piglets.

Competition horses are frequently given iron supplementation to treat anemia and to improve performance, despite the fact that neither application has any scientific basis. In contrast, iron overload and toxicity have occurred in competition horses. Some studies have shown high total plasma iron in British 3-day event team horses before transport (77 µmol/L compared with normal levels of 24 µmol/L). Immediately after traveling for 3 days on the road, the plasma levels had declined to 29 µmol/L. The iron-binding antioxidant activity, an indicator of transferrin saturation, had also declined, suggesting greater saturation of available transferrin in the plasma or a decreased capacity to sequester iron. The saturation of mechanisms to sequester iron, such as may occur with excessive supplementation, may predispose the horses to iron-catalyzed oxidant injury. The total iron intake exceeded the normal recommendation of between 550 and 600 mg/d. Anemia (or a low packed cell volume) is not synonymous with iron deficiency but is frequently associated with disease processes. In addition, iron deficiency is unlikely to occur in healthy horses.

Calcium carbonate added to the diet of weaned and finishing pigs may cause a conditioned iron deficiency and a moderate anemia, but this effect is not apparent in mature pigs. Manganese may exert a similar antagonistic effect.

PATHOGENESIS

More than half the iron in the animal body is found as a constituent of hemoglobin. A relatively small amount is found in myoglobin and in certain enzymes that play a part in oxygen utilization.

Piglets at birth have hemoglobin levels of about 90 to 110 g/L. A physiologic fall to 40 to 50 g/L occurs in all pigs, with the lowest levels occurring at about the 8th to 10th day of life. Levels of iron in the liver at birth are unusually low in this species and cannot be increased appreciably by supplementary feeding of the sow during pregnancy. The IM injection of iron-dextran preparations to sows during late pregnancy does elevate the hemoglobin levels of the piglets during the first few weeks of life but not sufficiently to prevent anemia in them. Piglets with access to iron show a gradual return to normal hemoglobin levels starting at about the 10th day of life, but in piglets denied this access, the hemoglobin levels continue to fall.

One of the important factors in the high incidence of anemia in piglets is the rapidity with which they grow in early postnatal life. Piglets normally reach 4 to 5 times their birth weight at the end of 3 weeks, and 15 times their birth weight at the end of 8 weeks. The daily requirement of iron during the first few weeks of life is of the order of 15 mg. The average intake in the milk from the sow is about 1 mg/d, and the concentration in sow's milk cannot be elevated by feeding additional iron during pregnancy or lactation. Apart from the specific effect on hemoglobin levels, iron-deficient piglets consume less creep feed, and after the first 3 weeks of life they make considerably slower weight gains than supplemented piglets. Although specific pathogen-free pigs show a less marked response to the administration of iron than pigs reared in the normal manner, it is obvious that they need supplementary iron to prevent the development of anemia. Iron-deficient piglets appear to be more susceptible to diarrhea at about 2 weeks of age than are piglets that have received iron. A marked impairment of gastric secretion of acid and chloride and atrophic gastritis occurs in iron-deprived piglets. Villous atrophy of the small intestine and changes in the gastrointestinal flora also occur in iron-deficient piglets, which may contribute to the increased susceptibility to diarrhea.

In iron-deficient piglets, lymphocyte activity is impaired, resulting in a decrease in circulating B-lymphocyte numbers and decreased immunocompetence.

Severe iron deficiency in veal calves is characterized by impaired growth and reduced feed intake and utilization. The growth rate is reduced only when hemoglobin concentrations fall below 70 g/L. The reduced growth rate may be a result of reduction in the half-life of growth hormone.

CLINICAL FINDINGS

The highest incidence of iron-deficiency anemia in piglets occurs at about 3 weeks of age, but it can occur up to 10 weeks of age. Affected pigs may be well grown and in good condition, but the growth rate of anemic pigs is significantly lower than that of normal pigs, and feed intake is reduced. A mild diarrhea may occur, but the feces are usually normal in color. Dyspnea, lethargy, and a marked increase in amplitude of the apex beat of the heart can be felt after exercise. The skin and mucosae are pale and may appear yellow in white pigs. Edema of the head and forequarters, giving the animal a fat, puffed-up appearance, may be present. A lean, white, hairy look is probably more common. Death usually occurs suddenly, or affected animals may survive in a thin,
unthrifty condition. A high incidence of infectious diseases, especially enteric infection with E. coli, is associated with the anemia, and streptococcal pericarditis is a well-recognized complication. Under experimental conditions, similar signs occur in calves, and there is, in addition, an apparent atrophy of the lingual papillae. A high incidence of stillbirths is recorded in the litters of sows suffering from iron-deficiency anemia.

**CLINICAL PATHOLOGY**

The characteristic abnormality in iron-deficiency anemia is presence of hypochromic, microcytic red cells, although early in disease there can be macrocytic anemia as a result of chronic hemorrhage (Table 11-3). There is also reduced plasma or serum concentrations of ferritin and serum iron, increased total iron-binding capacity, and reduction in stainable iron in bone marrow. Anemia of iron deficiency must be differentiated from anemia resulting from chronic inflammatory disease (Table 11-3). 

In normal piglets there is a postnatal fall of hemoglobin levels to about 8 g/L and sometimes to as low as 4 to 5 g/L during the first 10 days of life. In iron-deficient pigs there is a secondary fall to 20 to 40 g/L during the third week. The hemoglobin level at which clinical signs appear in pigs is about 40 g/L. Erythrocyte counts also fall from a normal of 5 to 8 × 10^6 /L down to 3 to 4 × 10^6 /L and may be a better index of iron status than hemoglobin levels. Iron-deficiency anemia in piglets is a microcytic hypochromic anemia. In chronic blood-loss anemia in cattle infested with sucking lice, there is a nonregenerative anemia and a decrease in serum iron levels. Serum levels of iron considered to be normal in sheep and cattle are 100 to 200 μg/dL (17.9 to 35.8 μmol/L). In newborn calves, the levels are 170 μg/dL (30.4 μmol/L) at birth and 67 μg/dL (12.0 μmol/L) at 50 days of age. Serum ferritin concentration is an index for monitoring prenatal iron deficiency of calves. The borderline of iron-deficiency anemia of veal calves at 16 to 20 weeks of age has been defined as a hemoglobin concentration of 10 g/L and a saturation of total iron binding capacity of 10%. 

**NECROPSY FINDINGS**

The carcass is characterized by pallor, watery blood, and moderate anasarca. The heart is always dilated, sometimes extremely so. The cardiac dimensions in severely anemic neonatal pigs indicate that dilatation and hypertrophy occur consistently. The liver in all cases is enlarged and has a mottled tan-yellow appearance. Histologic examination of the bone marrow reveals maturation asynchrony of the erythroid line and a lack of hemosiderin stores. Other microscopic changes described include periacinar hepatic changes typical of hypoxia and decreased numbers of parietal cells in the gastric mucosa.

**Samples for Confirmation of Diagnosis**

- **Toxicology**—50 g liver (ASSAY [Fe])
  (Note that serum ferritin from surviving littermates is a better indicator of iron status.)
- **Histology**—liver, heart, bone marrow, stomach (LM)

**DIFFERENTIAL DIAGNOSIS**

Confirmation of the diagnosis will depend on hemoglobin determinations and curative and preventive trials with administered iron. The possibility that anemia in piglets may be caused by copper deficiency should not be overlooked, especially if the response to administered iron is poor. Isosmulation hemolytic anemia can be differentiated by the presence of jaundice and hemoglobinuria, and the disease occurs in much younger pigs. Erythroblastosis occurs in pigs of all ages, and the protozoan parasites can be detected in the erythrocytes.

**TREATMENT**

Principles of treatment are removal of the cause of iron loss (chronic bleeding, parasitism, inadequate diet) and provision of supplemental iron. The emphasis in treatment should be on removal of the inciting cause of iron deficiency.

Supplemental iron should be provided to correct the whole-body deficiency of iron and can be achieved by oral or parenteral administration. Oral administration is preferred because it is safer, is less expensive, and does not require the expertise needed for intravenous or intramuscular administration. Parenteral administration of iron preparations is associated with severe tissue reactions and, with intravenous administration, acute death.

**CONTROL**

Preventive measures must be directed at the neonatal piglets because treatment of the sows before or after farrowing is generally ineffective, although some results are obtained if the iron preparations are fed at least 2 weeks before farrowing. Ferric choline citrate appears to have some special merit in this field. Allowing the nursing piglets access to pasture or dirt yards or periodically placing sods in indoor pens can offer adequate protection. Where indoor housing on impervious floors is necessary, iron should be administered within 12 hours of birth because absorption has to occur through the perforate neonatal intestinal mucosa; later administration is not followed by absorption. Reduced iron (British Veterinary Codex) can be administered in large doses because it does not cause irritation of the alimentary mucosa. A single dose of 0.5 to 1 g once weekly is sufficient to prevent anemia. Alternatively, the painting of a solution of ferrous sulfate on the sow's udder has been recommended (450 g ferrous sulfate, 75 g copper sulfate, 450 g sugar, 2 L water—applied daily) but has the disadvantage of being sticky and of accumulating litter. Pigs raised on steel gratings can derive enough iron from them to avoid the need for other supplementation. Excessive oral dosing with soluble iron salts may cause enteritis, diarrhea, and some deaths in pigs. High intakes of ferric hydroxide cause diarrhea, loss of infestation and some bacterial diseases, especially erysipelas. If sods are put into pens, care must be taken to ensure that these diseases are not introduced.

**Dietary Supplementation**

**Sows**

Feeding sows a diet supplemented with 2000 mg iron/kg DM of diet will satisfactorily prevent iron-deficiency anemia in the piglets. The piglets will ingest about 20 g of sow fecs per day, which will contain sufficient iron and obviate the need for IM iron-dextran injections. The piglets grow and thrive as well as those receiving the iron-dextran injections.

**Veal Calves**

Milk replacers for veal calves may contain up to 40 mg/kg DM of iron for the first months, but commonly contain only 10 to 15 mg/kg DM for the finishing period. The best indicator of the onset of anemia in calves on vealer diets is loss of appetite, which is a more sensitive indicator than biochemical measurement.

**Heifer Calf Herd Replacements**

The National Research Council recommends that milk replacers fed to herd replacements or dairy beef contain 100 mg/kg of DM, with an upper limit of 1000 mg/kg DM. The pre-ruminant calf can tolerate between 2000 and 5000 ppm DM iron in milk replacer.

**Oral Dosing**

Daily dosing with 4 mL of 1.8% solution of ferrous sulfate is adequate. Iron pyrophosphate may also be used (300 mg/d for 7 days). To overcome the necessity for daily dosing, several other methods of administering iron have been recommended. A single oral treatment with iron-dextran or iron-galactan has been recommended, provided that an excellent creep feed is available, but the method seems unnecessarily expensive. With this oral treatment it is essential that the iron be given within 12 hours of birth because absorption has to occur through the perforate neonatal intestinal mucosa; later administration is not followed by absorption. Reduced iron (British Veterinary Codex) can be administered in large doses because it does not cause irritation of the alimentary mucosa. A single dose of 0.5 to 1 g once weekly is sufficient to prevent anemia. Alternatively, the painting of a solution of ferrous sulfate on the sow's udder has been recommended (450 g ferrous sulfate, 75 g copper sulfate, 450 g sugar, 2 L water—applied daily) but has the disadvantage of being sticky and of accumulating litter. Pigs raised on steel gratings can derive enough iron from them to avoid the need for other supplementation. Excessive oral dosing with soluble iron salts may cause enteritis, diarrhea, and some deaths in pigs. High intakes of ferric hydroxide cause diarrhea, loss of
weight, and low milk production in cattle. The presence of diarrhea in a herd prevents absorption of orally administered iron, and treatment by injection is recommended in this circumstance.

**Intramuscular Injection of Iron Preparations**

Suitable preparations must be used and are usually injected IM in piglets on one occasion only, between the day 3 and day 7 of life. Iron-dextran, fumarate, and glutamate are most commonly used. A dose of 200 mg of a rapidly absorbed and readily utilizable form of iron within the first few days of life will result in greater body weights at 4 weeks of age than in piglets given only 100 mg. Multiple injections give better hemoglobin levels but have not been shown to improve weight gain, and thus a second injection at 2 to 3 months gives better hemoglobin levels. In untreated lambs, an oral iron supplement given to these housed lambs improved red blood cell count and hemoglobin level significantly more than in piglets given only 100 mg. However, weight gains during the first 18 weeks of life were not affected.

**REFERENCES**

**COBALT DEFICIENCY**

Cobalt deficiency is a disease of ruminants ingesting a diet deficient in cobalt, which is required for the synthesis of vitamin B12 (cyanocobalamin) by rumen microflora. The disease is characterized clinically by anapetence and loss of body weight. Some effects on reproductive performance in sheep have been reported. Cobalt was first shown to be an essential nutrient for sheep and cattle following investigations in the 1930s of two naturally occurring diseases occurring on soils of Aeolian origin in Australia, coast disease of sheep and wasting disease of cattle. Soon after it was recognized that similar wasting disorders in several countries responded to cobalt supplementation, including cobalt pine in Scotland, salt sickness in Florida, Nakururitis in Kenya, and bush sickness in New Zealand.

**ETIOLOGY**

The disease is caused by a deficiency of cobalt in the diet, which results in a deficiency of vitamin B12. Vitamin B12 is central to many metabolic pathways, including the conversion of propionic acid to glucose (the only direct source of glucose for ruminants) and the metabolism of methionine, which is essential for wool growth and the transport of folate acid into liver cells.

**EPIDEMIOLOGY**

**Occurrence**

Acute poisoning and rapid death can occur in pigs given iron-dextran compounds parenterally if the piglets were born from sows that were deficient in vitamin E and selenium during gestation. This is discussed in the section on iron-dextran poisoning. In normal piglets, the iron-dextran compounds are safe and are usually not toxic even on repeated injection. These preparations are ideal for treatment because of the rapid response they elicit and the absence of permanent discoloration of tissues after their use if given during the first month of life. A combination of sodium selenite and iron-dextran has been given to piglets at 3 days of age and is superior to treatment with iron alone when the piglets are deficient in selenium.

Iron supplementation should also be administered to suckling piglets raised outdoors. Iron-deficiency anemia in housed lambs is preventable by the IM injection of 300 mg iron dextran at 24 hours of age. At 12 and 24 days after treatment, the hematological values in the treated group were significantly different from those of the unsupplemented group, and at weaning, the treated lambs were 1.0 kg heavier than untreated lambs. An oral iron supplement given to these housed lambs improved red cell and iron parameters but did not improve performance.

Comparable doses of parenteral iron-dextran compounds have been used for the treatment of iron-deficiency or iron-loss anemias in other species, but accurate doses have not been established, and the use of these preparations in cattle and horses is expensive. In addition, iron-dextran preparations given IM to horses may cause death within a few minutes after administration.

The most inexpensive method of supplying iron is to use ferrous sulfate orally at a dose of 2 to 4 g daily for 2 weeks to adult cattle and horses with iron-deficiency anemia. Iron injection of beef calves in the first week after birth will result in an increase in packed cell volume (PCV), hemoglobin (Hb), mean corpuscular volume (MCV), and mean corpuscular hemoglobin (MCH), which persists for 12 weeks. However, weight gains during the first 18 weeks of life were not affected.

**ETIOLOGY**

The disease is caused by a deficiency of cobalt in the diet, which results in a deficiency of vitamin B12. Vitamin B12 is central to many metabolic pathways, including the conversion of propionic acid to glucose (the only direct source of glucose for ruminants) and the metabolism of methionine, which is essential for wool growth and the transport of folate acid into liver cells.

**EPIDEMIOLOGY**

**Occurrence**

Cobalt deficiency occurs in Australia, New Zealand, the United Kingdom, North America, the Netherlands, and probably in many other parts of the world. Where the deficiency is extreme, large tracts of land are unsuitable for the raising of ruminants, and in certain areas, suboptimal growth and production may be limiting factors in the husbandry of sheep and cattle.

Historically, ill-thrift from cobalt deficiency was so marked that many calves and lambs died. In those that survived, growth rates were markedly depressed compared with cobalt-supplemented lambs. In most known deficient areas, signs of cobalt deficiency are now confined mainly in lambs because supplementation or cobalt fertilizer has been applied for many decades. However, cobalt-responsive ill-thrift in lambs still occurs where cobalt fertilizer applications or vitamin B12 injections to lambs are haphazard, with live weight gains following vitamin B12 injections of up to 180 g/d.

The soils on which cobalt deficiency occurs are usually well drained but can be of quite diverse geological origin, and the concentration of cobalt in the soil can vary widely. Where cobalt deficiency occurs, soil cobalt is usually less than 2 mg/kg DM, and the available (extractable) cobalt is less than 0.25 mg/kg DM. The availability of cobalt to plants is reduced by high concentrations of manganese in the soil and heavy liming.

Sheep are more susceptible to cobalt deficiency than cattle, and young animals are more susceptible than adults. The disease

---

**SYNOPSIS**

**Etiology** Dietary deficiency of cobalt resulting in a deficiency of vitamin B12.

**Epidemiology** Occurs worldwide, primarily in cattle and sheep, where soils are deficient in cobalt and no supplements are given. Associated with ovine white liver disease and phalalis staggers.

**Signs** Anapetence, gradual loss of body weight, pica, marked pallor of the mucous membranes, and laceramation. Decreased wool growth, milk production, and lambing percentage.

**Clinical pathology** Liver cobalt or vitamin B12 concentration, serum vitamin B12 (sheep). Elevated methylmalonic acid in plasma and urine; elevated formiminoglutamic acid in urine. Normocytic normochromic anemia.

**Necropsy findings** Emaciation, hemosiderosis of spleen.

**Diagnostic confirmation** Location of farm and soil type. Vitamin B12 and cobalt of liver. Response to supplementation.

**Differential diagnosis list**

Common causes of ill-thrift in ruminants:

- General nutritional deficiency (protein and energy)
- Intestinal helminthiasis
- Copper deficiency
- Johne’s disease

**Treatment** Oral dosing with cobalt or parenteral injections of vitamin B12.

**Control** Dietary supplementation with cobalt (cobalt pellets, top dressing of pastures or foliar sprays). Long-acting preparations of vitamin B12.
occurs most commonly in ruminants grazing pasture in severely deficient areas, but sporadic cases occur in marginal areas. In Australia this can occur after certain seasonal conditions, such as the intensive application of fertilizer and high spring rainfall that produces a flush of pasture growth, or in Europe after long periods of stable feeding. In the latter scenario, bulls, rams, and calves are most commonly affected.

A disease of moose called “moose sickness” occurs in eastern North America, mainly in the Tobetic and Cape Breton Highlands of Nova Scotia in Canada. Low concentrations of cobalt and vitamin B₁₂ are found in the liver and increased concentrations of methylocetic acid in the plasma. There are striking similarities between the North American moose sickness and a moose disease in Sweden caused by molybdenosis.

Cobalt deficiency is unlikely to occur in pigs and other omnivores or carnivors because vitamin B₁₂ is present in meat and other animal tissues. Horses appear to be unaffected.

Cobalt is also protective against the liver damage in sheep exposed to annual ryegrass and the neurologic signs induced in phalaris staggers.

**Risk Factors**

**Dietary and Environmental Factors**

Pastures containing less than 0.07 and 0.04 mg/kg DM result in clinical disease in sheep and cattle, respectively. The daily requirement for sheep at pasture is 0.08 mg/kg DM of cobalt, but growing lambs have a greater requirement (11 µg/d), and reduced growth is likely at pasture levels less than 0.10 mg/kg DM.

Variations in the cobalt content of pastures occur with seasonal variations in pasture growth, and an increased incidence of deficiency in spring may be related to domination of the pasture by rapidly growing grasses, which have lower cobalt content than legumes. There is also a great deal of variation between years. Forage grown on well-drained soils has greater cobalt content than that grown on poorly drained soils of the same cobalt status. Although plant growth is not visibly affected by low soil cobalt, the addition of excessive quantities may retard growth.

Primary cobalt deficiency occurs only on soils that are deficient in cobalt. Such soils do not appear to have any geological similarity, varying from windblown shell sands to soils derived from pumice, ironstone, and granite, and Japanese soils composed largely of volcanic ash are seriously deficient. The soils in New Brunswick, Canada, are naturally acidic, and the cobalt content of the soil is decreased by leaching associated with an annual rainfall of 120 cm. Surveys in this area show average values of 0.028 and 0.088 mg/kg DM for grasses and legumes, respectively, which justifies supplementation of ruminant diets with cobalt.

After the introduction of grazing livestock, large parts of New Zealand were found to be trace-element deficient (cobalt, selenium, and copper). Livestock grazing pastures grown on these soils may be deficient in one or more of these trace elements, and correcting these deficiencies is now a common and essential animal health management strategy. In New Zealand, soil types are categorized as severe, moderate, or marginal. Of the land considered suitable for farming, about 1 million hectares on the North Island and 918,000 hectares on the South Island are defined as cobalt deficient.

Outbreaks of cobalt deficiency have occurred in cattle grazing on pastures on the granite-derived northern tablelands of New South Wales in Australia and in sheep grazing pasture on soils derived from weathered rhyolite and ignimbrite, the former being inherently low in cobalt. Cobalt deficiency still occurs in areas where it has previously never been diagnosed, and so in seasons of lush spring and summer pasture growth it should be included as a differential diagnosis when investigating cases of unthriftness.

In the northern Netherlands, lambs grazing cobalt-deficient pastures and not supplemented with cobalt are 6.7 times more likely to die than supplemented lambs. This occurs despite affected farms often having acetic acid–extractable soil cobalt content of pastures greater than the reference value for cobalt deficiency (50.30 mg Co/kg dried soil).

Although soils containing less than 0.25 mg/kg cobalt are likely to produce pastures containing insufficient cobalt, the relationship between levels of cobalt in soil and pasture is not consistent. The factors governing this relationship have not been determined, although heavy liming and high concentrations of manganese reduce the availability of cobalt in the soil.

**Ovine White Liver Disease**

A specific hepatic dysfunction of sheep has been described in New Zealand, Australia, the United Kingdom, Norway, and in grazing lambs in the Netherlands. It is called white liver disease because of the grayish color of the liver. Clinically, it is manifested by photosensitization when the disease is acute and anemia and emaciation when the disease is chronic. It seems likely that the disease is a toxic hepatopathy (fatty liver degeneration) caused by the accumulation of methylocetic acid. This is converted into branched-chain fatty acids, causing liver failure, hepatic encephalopathy, and photosensitization. It is prevented by adequate dietary cobalt.

**Hepatic Lipidosis in Goats**

Hepatic lipidosis of goats in Oman is associated with low serum vitamin B₁₂ and low liver cobalt and can be experimentally reproduced by a low intake of cobalt. It is one of the most frequent causes of liver condemnation and a significant economic loss because goats are the predominant domesticated animal reared for meat in Oman.

**Experimental Reproduction of Cobalt Deficiency in Sheep**

Cobalt deficiency can be reproduced in sheep by feeding diets containing less than 70 µg/kg cobalt. A diet containing 4.5 µg/kg fed to lambs produced a condition similar to naturally occurring cobalt deficiency, with subnormal plasma and liver concentrations of vitamin B₁₂, reduced growth rate, serious ocular discharge, alopecia, emaciation, and fatty degeneration of the liver, which had reduced concentrations of vitamin B₁₂ (14.5 pmol/g) at necropsy. The liver lesions included accumulation of lipid droplets and lipofuscin particles in hepatocytes, association and necrosis of hepatocytes, and sparse infiltration by neutrophils, macrophages, and lymphocytes. Ultrastructural changes in hepatocytes included swelling, condensation and proliferation of mitochondria, hypertrophy of smooth endoplasmic reticulum, vesiculation and loss of arrays of rough endoplasmic reticulum, and accumulation of lipid droplets and lipofuscin granules in cytoplasm. Reduced activities of vitamin B₁₂-dependent enzymes, methionylmalonyl CoA mutase, and methionine synthesis, along with lipid peroxidation, are the likely mechanisms in the development of the liver lesions.

**PATHOGENESIS**

Cobalt is a unique essential trace element in ruminant nutrition because it is stored in the body in only limited amounts and not in all tissues. In the adult ruminants the only known function of cobalt is in the rumen, where participates in the production of vitamin B₁₂ (cyanocobalamin), and it has to be continuously ingested in the feed.

Ruminants have a much higher requirement for vitamin B₁₂ than other species. In sheep, this is around 11 µg/d, with up to 300 µg/d produced in the rumen but most being lost. Animals in the advanced stages of cobalt deficiency are cured by the oral administration of cobalt or by the parenteral administration of vitamin B₁₂. On cobalt-deficient diets, clinical signs are accompanied by a fall of as much as 90% in the vitamin B₁₂ content of the feces. Oral dosing with cobalt resolves the clinical signs, and vitamin B₁₂ levels in the feces return to normal. Parenteral administration of cobalt has no appreciable clinical effect, although some cobalt does enter the alimentary tract in the bile and leads to the formation of a small amount of cobalamin.

The essential defect in cobalt-deficient ruminants is an inability to metabolize proionic acid. A key biochemical pathway for
propionic acid from rumen fermentation involves adenosyl cobalamin, one of several cobalt-containing coenzymes of the vitamin $B_{12}$ complex that is required for the conversion of methylmalonyl coenzyme $A$ to succinyl coenzyme $A$, both intermediates in the utilization pathway of propionate. The propionate-succinate pathway is the first rate-limiting pathway in vitamin $B_{12}$ deficiency, and the lack of vitamin $B_{12}$ causes accumulation of methylmalonic acid, which can be measured in the serum. The clinical and pathologic signs of cobalt deprivation are preceded by characteristic biochemical changes in tissues and fluids of the body. As soon as depletion begins, the concentration of both cobalt and vitamin $B_{12}$ decreases in the rumen fluid. Serum vitamin $B_{12}$, an estimate of the amount of this vitamin in transit, shows an early decline reflecting reduced capacity of the amount of this vitamin in transit, and the lack of vitamin $B_{12}$ causes accumulation of methylmalonic acid, which can be measured in the serum. The clinical and pathologic consequences of cobalt deficiency are measured in the serum. The clinical and pathologic consequences of cobalt deficiency are measured in the serum.

Serum vitamin $B_{12}$, an estimate of the amount of this vitamin in transit, shows an early decline reflecting reduced capacity of the amount of this vitamin in transit, and the lack of vitamin $B_{12}$ causes accumulation of methylmalonic acid, which can be measured in the serum. The clinical and pathologic consequences of cobalt deficiency are measured in the serum.

The pathogenesis of ovine white liver disease is unclear, as it is not known if the disease is a simple cobalt deficiency or a hepatotoxic disease in cobalt/vitamin $B_{12}$-deficient lambs. A cobalt-deficient diet is essential for the development of the disease, which is characterized by hepatic dysfunction and elevated liver enzymes (alkaline phosphatase and aspartate aminotransferase). Affected lambs have elevated serum levels of copper compared with cobalt/vitamin $B_{12}$-supplemented lambs grazing the same pastures, and dosing affected lambs with copper-oxide needles can induce toxic levels of liver copper. It is suggested that the disease is a manifestation of $B_{12}$ deficiency exacerbated by factors triggering early hepatic fatty change, resulting in more severe liver damage and loss of intracellular homeostasis, rendering the hepatocytes more vulnerable to other elements such as copper. It is proposed that elevated concentrations of fructans in pasture could also contribute to the pathogenesis of the liver lesion by initiating hepatic lipodystrophy and hepatic insufficiency, and hence reduced growth and ovine white liver disease. The condition responds to treatment with parenteral vitamin $B_{12}$.

The pathologic changes in lambs grazing cobalt-deficient pastures are related to blood concentrations of vitamin $B_{12}$, methylmalonic acid, and homocysteine, and lesions are confined mainly to the liver and brain. Acute and chronic hepatitis are characteristic, and the liver lesions are associated with polymicrocavitation of the brain. Hepatic encephalopathy associated with cobalt deficiency and white liver disease has been described in lambs. Symmetric vacuolation and status spongiosus of the neuropil in the brain is seen, with hyperammonemia secondary to the hepatic lesion considered the cause of the brain lesions.

Caprine hepatic lipidosis has been induced experimentally using low intakes of low levels of dietary cobalt. Goats provided with a diet that contains the minimum daily requirement of cobalt as specified for sheep not only developed a syndrome characterized by reduced weight gains, dry scruffy hair coat, and a decline in erythrocyte indices, but also lesions consistent with hepatic lipidosis. Goats fed diets containing levels of cobalt less than 0.1 mg/kg DM could experience even greater clinical and pathologic consequences.

In ovine white liver disease, there are low concentrations of cobalt and vitamin $B_{12}$ in the liver and elevated methylmalonic acid in plasma. Serum cobalt concentrations of normal sheep range from 1 to 3 µg/dL (0.17 to 0.51 µmol/L), whereas in deficient animals these are reduced to 0.03 to 0.41 µmol/L.

Clinical signs of cobalt deficiency in sheep are associated with serum vitamin $B_{12}$ levels less than 0.20 mg/mL. This is the standard laboratory test for cobalt status in sheep, with levels of 0.2 to 0.25 µg/L indicative of deficiency, which rapidly increase to 0.5 to 1.0 µg/L following treatment. Depriving sheep of feed for 24 hours results in a marked increase in serum vitamin $B_{12}$. The serum vitamin $B_{12}$ levels of sheep at pasture are unreliable indicators of liver vitamin $B_{12}$.

In cattle, serum vitamin $B_{12}$ values greater than 0.2 µg/L are indicative of normal cobalt nutrition. However, there is considerable variability in this measure between laboratories because of binding within plasma. Consequently, liver vitamin $B_{12}$ is preferred, although the cost of obtaining a liver biopsy restricts the utility of this test. A range of 75 to 250 nmol/kg fresh weight indicates marginal cobalt nutrition in grazing cattle, but this may be too low for cattle on predominantly grain diets. Fatty infiltration of the liver will lead to underestimates of the liver concentration of vitamin $B_{12}$.

**CLINICAL PATHOLOGY**

**Biochemical Criteria to Determine Cobalt and Vitamin $B_{12}$ Status**

Changes in the concurrent serum concentrations of methylmalonic acid and vitamin $B_{12}$ of ewes and their lambs on cobalt-deficient pastures, and their response to cobalt supplementation, can be evaluated and monitored. Changes in these measures can be correlated with live-weight gains after the supplementation of lambs from suckling until after weaning.

A growth response to cobalt or vitamin $B_{12}$ supplementation is expected when cobalt levels in herbage fall below 0.08 to 0.1 mg/K DM.

**Serum and Liver Cobalt and Vitamin $B_{12}$ Concentrations**

Serum cobalt concentrations of normal sheep range from 1 to 3 µg/dL (0.17 to 0.51 µmol/L), whereas in deficient animals these are reduced to 0.03 to 0.41 µmol/L.

**Clinical signs of cobalt deficiency in sheep are associated with serum vitamin $B_{12}$ levels less than 0.20 mg/mL. This is the standard laboratory test for cobalt status in sheep, with levels of 0.2 to 0.25 µg/L indicative of deficiency, which rapidly increase to 0.5 to 1.0 µg/L following treatment. Depriving sheep of feed for 24 hours results in a marked increase in serum vitamin $B_{12}$. The serum vitamin $B_{12}$ levels of sheep at pasture are unreliable indicators of liver vitamin $B_{12}$. In cattle, serum vitamin $B_{12}$ values greater than 0.2 µg/L are indicative of normal cobalt nutrition. However, there is considerable variability in this measure between laboratories because of binding within plasma. Consequently, liver vitamin $B_{12}$ is preferred, although the cost of obtaining a liver biopsy restricts the utility of this test. A range of 75 to 250 nmol/kg fresh weight indicates marginal cobalt nutrition in grazing cattle, but this may be too low for cattle on predominantly grain diets. Fatty infiltration of the liver will lead to underestimates of the liver concentration of vitamin $B_{12}$.

**Concurrent Serum MMA and Vitamin $B_{12}$ Concentrations**

In ewes and nonsuckling lambs, the serum MMA concentration provides a more precise indication...
of responsiveness to vitamin B₁₂ or cobalt supplementation than serum vitamin B₁₂. Serum MMA concentrations greater than 13 µmol/L indicate responsiveness to supplementation, those from 7 to 13 µmol/L indicate a potential but marginal or inconsistent response, and no response is expected at concentrations less than 7 µmol/L. In a study of cobalt-deficient ewes, serum concentrations of vitamin B₁₂ decreased from 250 pmol/L during early lactation to a nadir of 100 pmol/L at peak lactation, at which time MMA concentration had increased to a range of 7 to 14 µmol/L. In this study, supplemented ewes were significantly heavier, and the vitamin B₁₂ concentration in ewe milk and the livers of their lambs was more than doubled. Supplementation of ewe with cobalt bullets appears to protect the growth performance of the lamb for 90 days and to influence the subsequent serum vitamin B₁₂ response in the lamb to vitamin B₁₂ supplementation.

On cobalt-deficient farms in New Zealand, serum vitamin B₁₂ and MMA have been compared as indices of cobalt/vitamin B₁₂ deficiency in lambs supplemented with either cobalt bullets or short- or long-acting preparations of vitamin B₁₂. Serum MMA concentrations greater than 9 to 14 µmol/L were a more reliable indicator of cobalt deficiency, but there is considerable variation between farms. An evaluation of serum MMA and vitamin B₁₂ concentrations used to assess cobalt deficiency in New Zealand found that the reference ranges for vitamin B₁₂ responsiveness may be conservatively high. This could result in an overdiagnosis of vitamin B₁₂ deficiency as a cause of ill-thriftiness of sheep, and so response trials to assess weight gain following supplementation may be a better alternative.

Liver Cobalt.
In lambs, normal liver cobalt ranges from 0.03 to 0.1 µg/g wet weight (WW). Concentrations less than 0.02 µg/g WW (0.07 µg DM) are associated with clinical deficiency, with 0.015 µg/g WW (0.05 µg DM) considered a critical level, and less than 0.025 µg/g WW in a sheep flock is considered marginal. In lambs with clinical signs of ovine white liver disease, mean hepatic cobalt concentrations range from 0.013 to 0.024 µg/g WW.

Serum Methylmalonic Acid.
Because of difficulties with the interpretation of serum vitamin B₁₂ results, other biochemical tests, especially MMA in plasma and urine, are now used. An elevated plasma concentration of MMA is a comparatively early indicator of functional vitamin B₁₂ deficiency, and thus this test can identify a cobalt deficiency earlier. The upper limits of MMA for grain- and pasture-fed animals are 10 and 5 µmol/L, respectively.

In cattle, serum MMA less than 2 µmol/L is considered normal, 2 to 4 µmol/L marginal, and greater than 4 µmol/L indicative of a deficiency. Urinary MMA in cobalt-deficient animals is abnormally high, and thus this is also an appropriate test for deficiency. Cobalt-replete lambs have plasma MMA levels less than 5 µmol/L, urinary MMA less than 120 µmol/L, and urinary MMA/creatinine values less than 0.022 µmol MMA/ mmol. An unequivocal result for methylmalonic acid is a concentration of greater than 30 µg/mL for 10 animals selected randomly from a flock. Samples must be acidified to avoid degradation of the methylmalonic acid if they are to be kept for more than 24 hours before testing.

Formiminoglutamic Acid.
Neither MMA nor formiminoglutamic acid is a normal constituent of urine, and so their presence in urine, without the need for a quantitative measurement, is an indication of cobalt deficiency. In lambs in the later stages of cobalt deficiency, when there is weight loss and ill-thrift, the concentration of urinary formiminoglutamic acid increases to 0.08 to 20 µmol/mL, then rapidly returns to zero following treatment. However, there is little or no increase in the urine of animals with subclinical cobalt deficiency, and thus this measure is not useful as a diagnostic test.

Hematology.
Affected animals have normocytic and normochromic anemia, but hemoglobin and erythrocyte values are often within the normal range because of hemococoncentration. There is a decrease in cellularity of the bone marrow that does not respond quickly to the administration of vitamin B₁₂ or cobalt. Affected animals are also hypoglycemic (<60 mg glucose/dL plasma) and have low serum alkaline phosphatase (<20 U/L). These measures rapidly return to normal after administration, but many other factors affect their concentration, and thus they are of little diagnostic value.

Necropsy Findings.
Emaciation is extreme, and in most cases of cobalt deficiency the spleen is dark as a result of the accumulation of hemosiderin. The livers of sheep affected with white liver disease are pale and fatty, with microscopic changes that include hepatocellular disassociation and intracytoplasmic accumulations of lipid and ceroid-lipofuscin within hepatocytes.

Biochemical assays reveal a very high concentration of iron in the liver and spleen and a low concentration of cobalt in the liver. In normal sheep, cobalt levels in the liver are usually above 0.20 mg/kg DM, but in affected sheep are usually less than 0.05 mg/kg DM. In cattle fed excessive amounts of cobalt and thought to be affected by cobalt poisoning, liver cobalt can be as high as 69 mg/kg DM.

The concentration of vitamin B₁₂ in the liver of cobalt-deficient lambs is 0.1 mg/kg compared with around 0.3 mg/kg in normal lambs. In cattle, concentrations greater than 0.3 mg/kg are necessary for optimum growth, normal levels range from 0.70 to 1.98 mg/kg, and clinical signs occur when liver vitamin B₁₂ is less than 0.1 mg/kg. After oral dosing, the concentration of cobalt in the liver rises but then returns to the pretreatment level in 10 to 30 days. Serum B₁₂ levels reflect cobalt status, and thus it is often useful to submit sera from surviving herdmates when attempting to confirm a diagnosis of cobalt deficiency.

Samples for Confirmation of Diagnosis.

- **Toxicology**—50 g liver (ASSAY [Co]), 2 mL serum (ASSAY [B₁₂])
- **Histology**—formalin-fixed liver (LM)

Differential Diagnosis.
Cobalt deficiency must be differentiated from other causes of ill-thrift or marasmus.

Ill-Thrift
The lack of total digestible nutrients is the most common cause of thin animals, but owners are usually aware of the shortage and do not present their animals for diagnosis. However, inexperienced stockowners may be unaware of the actual needs of animals, and so it is best to check the feed supply and whether the animals have any teeth or gum problems.

In young animals, nutritional deficiencies of copper, selenium, and vitamin D are other possible causes of ill-thrift.

In sheep, ovine Johne’s disease is a cause of ill-thrift in older animals. The differential diagnosis of anemia is discussed elsewhere, but haemochromatosis and erythrothromocytosis occur in younger sheep.

Internal Parasitism
Cobalt-deficient animals are more susceptible to parasitism, and thus the presence of a heavy worm burden (high fecal egg count or total worm count) should not rule out a diagnosis of primary cobalt deficiency. Parasitic disease and cobalt deficiency often occur together; thus, it may be necessary to initiate two control programs.

Dietary Supplementation Response
This is the most conclusive way of determining whether animal production is being affected by the deficiency of a trace mineral. The most common production measures are weight gain, milk production, wool production, and/or reproductive performance following the supplementation of animals with the element under consideration. However, if the response can be related to a tissue concentration of the element, or its metabolites, then tissue analyses may replace the need for field trials.
TREATMENT

Cobalt and Vitamin B₁₂

Affected animals respond to oral dosing with cobalt or the IM injection of vitamin B₁₂. Oral dosing with vitamin B₁₂ is effective, although the commonly used dose of 0.1 mg/kg will only increase serum B₁₂ for up to 6 weeks, and thus larger or repeat doses are often required. Oral cobalt sulfate is usually given to sheep at a rate of 1 mg of cobalt per day. This can be given as a weekly dose, but intervals of 2 weeks between dosing are too long for optimum growth. However, monthly dosing of lambs with oral doses of 300 mg cobalt does greatly reduce deaths and permit some growth, albeit at a suboptimal rate. The response to treatment is rapid, with a significant increase of serum vitamin B₁₂ within 24 hours. When large doses of cobalt are given to some sheep, other undosed sheep on the same pasture may ingest sufficient additional cobalt from the feces of their flockmates to meet their needs. No exact data are available on dose rates for cattle, but 10 times the prophylactic rate should be effective.

Vitamin B₁₂ can be given in 100- to 300-µg doses for lambs and sheep at weekly intervals, but is not likely to be used because of its high cost and the comparable effect and low cost of oral cobalt. Vitamin B₁₂ (hydroxocobalamin) may be a suitable therapeutic agent, with an injection of 1 mg providing protection for 14 weeks and up to 40 weeks for preruminant lambs and weaners, respectively. Lambs with ovine white liver disease respond quickly to treatment with hydroxocobalamin, with retreatment recommended 10 days later.

Cobalt Toxicity

Overdosing with cobalt compounds is unlikely, but toxic signs of loss of weight, rough hair coat, listlessness, anorexia, and muscular incoordination appear in calves at dose rates of about 40 to 45 mg of elemental cobalt per 50 kg BW/d. Sheep appear to be much more resistant to the toxic effects of cobalt than are cattle. Pigs can tolerate up to 200 mg of cobalt per 1 kg of diet, but at intakes of 400 and 600 mg/kg there is depression of growth, anorexia, stiff legs, incoordination, and muscle tremor. Supplementation of the diet with methionine, or with additional iron, manganese, and zinc, alleviates these toxic effects.

CONTROL

Supplementation of Diet With Cobalt

The recommended level of dietary cobalt for sheep and cattle is around 100 µg/kg DM, but for cattle the recommended amount of dietary cobalt to achieve maximum vitamin B₁₂ is 250 µg/kg DM. If this amount is not available, supplementation of the diet with cobalt is necessary, and calves reared on cobalt-deficient pastures need cobalt or vitamin B₁₂ supplementation before weaning.

Top Dressing of Pastures With Cobalt

In grazing animals, cobalt deficiency can be prevented by the top dressing of pasture with cobalt salts. The amount of top dressing needed will vary with the degree of deficiency, but recommendations include 400 to 600 g/ha cobalt sulfate annually or 1.2 to 1.5 kg/ha every 3 to 4 years. The response to pasture treatment is slow (weeks), and thus clinically affected animals should be treated with oral cobalt or vitamin B₁₂ injection for a quick, interim response.

In New Zealand, the requirement for cobalt of ruminants grazing on the pumice soils of the central plateau was established in the 1930s, and top dressing to increase the cobalt intake was practiced for many years. A survey in 1978 to 1979 found that cobalt inputs could be halved because adequate reserves of cobalt had accumulated in soil. However, an economic downturn resulted in less use of cobalt, with follow-up surveys identifying a decline in soil and pasture cobalt and an increased need for top dressing. Regular cobalt applications needed to build up reserves, with an initial requirement of around 350 g cobalt sulfate/ha for 7 to 10 years on the most deficient areas. Considerable variation occurs between farms, and thus it is necessary to monitor the soil, pasture, and animal cobalt status.

To achieve a critical level of cobalt in pastures for sheep (0.08 mg/kg DM in pasture), soil cobalt concentrations of 1.7 and 2.2 mg/kg DM are required for the yellow-brown pumice soils and yellow-brown loams, respectively.

Supplementation of the diet with 0.1 mg cobalt per day for sheep and 0.3 to 1.0 mg/d for cattle is required and can be accomplished by inclusion of the cobalt in salt or a mineral mixture. Cobalt can also be supplied to cattle in their drinking water supply.

Cobalt Pellet

The use of pellets containing 90% cobalt oxide is an effective way to maintain an adequate cobalt intake in a deficient area. These are a bolus (5 g for sheep, 20 g for cattle) that, when given orally, lodge in the reticulum and liberate cobalt in small but adequate amounts for 1 to 3 years. Pellets should not be given to lambs and calves less than 2 months old because they do not have a fully developed reticulum. Cobalt deficiency in suckling animals can be partially overcome if their dams are treated because of increased vitamin B₁₂ content in milk, although the daily intake of the lambs may still be well below their requirement. About 5% of the pellets do not lodge in the reticulum, and up to 20% are rejected within a year of administration; thus retreatment is advisable if no response occurs. Pellets can also become coated with calcareous material, particularly on limestone soils, when drinking water is highly mineralized, or with heavy pasture top dressing. This can be overcome by dosing with an abrasive metal pelot, or a second pellet, such as to correct a selenium deficiency. Pellets are more expensive than top dressing of pastures with cobalt, but they are preferred in extensive range grazing where top dressing is impracticable or animals are not handled frequently.

Cobalt in Anthelmintics

Trace elements such as selenium and cobalt (typically 20 to 100 mg cobalt per treatment) are often added to anthelmintics. However, the response to these supplements, especially cobalt, is usually transient, and more specific supplements, such as pellets or top dressing of pastures, are recommended.

Vitamin B₁₂ Injections

In lambs, the relationship between daily weight gains and serum and liver vitamin B₁₂ concentrations is well defined. Lambs with serum vitamin B₁₂ greater than 335 pmol/L and liver vitamin B₁₂ less than 280 nmol/kg fresh tissue are cobalt deficient and show a marked increase in growth rates when supplemented with cobalt or vitamin B₁₂.

The subcutaneous injection of a soluble vitamin B₁₂ in lambs can maintain adequate concentrations of vitamin B₁₂ for about 24 days. Thus in cobalt-deficient areas, lambs need a 2-mg dose of vitamin B₁₂ at least...
monthly to reduce the risk of vitamin B12 deficiency. A microencapsulated vitamin B12 in lactide/glycolide copolymers can maintain adequate concentrations of serum vitamin B12 in lambs for at least 210 days. For example, the growth of cobalt-deficient lambs, 4 to 6 weeks of age, was markedly improved by injections of 3.0, 4.5, or 6.0 mg of microencapsulated vitamin B12, and live weights were maintained for at least 260 days. An injection of 3 mg microencapsulated vitamin B12 given to lambs at tailing will prevent cobalt deficiency and increase and maintain live-weight gains in a flock for up to 8 months.

Compared with untreated controls, treating ewes with three injections of long-acting vitamin B12 (120 and 40 days prepartum, 40 days postpartum) increased serum and liver vitamin B12 concentrations by 70% during gestation and fetal liver vitamin B12 by 270%, and during lactation ewe serum and milk vitamin B12 concentrations were increased by at least 200% and 44%, respectively. However, liver vitamin B12 stores of the newborn lambs from the treated ewes were depleted within 58 days, and犊 lambs born of ewes with a high vitamin B12 status should have an adequate supply of vitamin B12 for at least the first 30 days of life.

In dairy calves, an injection of 0.12 to 0.24 mg/kg BW of a long-acting microencapsulated vitamin B12 increased and maintained vitamin B12 for at least 110 days.

**VITAMIN B12 DEFICIENCY (HYPOCYANOCOBALAMINOSIS)**

Vitamin B12 deficiency is unlikely to occur under natural conditions other than because of a primary dietary deficiency of cobalt, which is an important disease in many countries of the world and discussed under that topic. Concurrent disease can influence vitamin B12 absorption, such as in pigs with proliferative enteropathy, in which serum cobalamin concentrations are reduced and homocysteine concentrations are increased compared with those of healthy pigs. Although microbial synthesis of the vitamin occurs in the rumen in the presence of adequate cobalt and in the intestines of other herbivores such as the horse, it is probably a dietary essential in the pig and young calf. Animal protein is a good source. A deficiency syndrome has been produced in young calves on a synthetic ration, but signs of deficiency, evident as response to supplementation, are not present in grazing dairy calves in New Zealand. Signs of deficiency in calves include anorexia, cessation of growth, loss of condition, and muscular weakness. The daily requirement under these conditions is 20 to 40 µg of vitamin B12.

Detection of the efficacy of vitamin B12 administration to grazing sheep is best accomplished by measurement of concentrations of the vitamin itself or of methylmalonic acid, as opposed to measurement of homocysteine. Supplementation of grazing lambs in New Zealand with injectable vitamin B12 increased live-weight gain by 40%.

Sows vary in their ability to absorb the vitamin, and those with poor absorption ability or on deficient diets show poor reproductive performance. For pigs, 10 to 50 mg/ton of feed is considered to be adequate.

The vitamin is used empirically in racing dogs and horses to alleviate parasitic and dietary anemias in these animals at a dose rate of 2 µg/kg BW. Cyanocobalamin zinc tannate provides effective tissue levels of vitamin B12 for 2 to 4 weeks after one injection, and normal and abnormal blood levels have been established for all species. Administration of cobalt containing supplements, such as cyanocobalamin, increases blood and urine cobalt concentrations in horses and can have implications for control of doping in racing animals. It is also used as a feed additive for fattening pigs, usually in the form of fish or meat meal or as “animal protein factor.” It is essential as a supplement if the diet contains no animal protein, and maximum results from the feeding of antibiotics to pigs are obtained only if the intake of vitamin B12 is adequate. There is no beneficial effect of B2 supplementation to grazing dairy cows in New Zealand.

**VITAMIN K DEFICIENCY**

A primary deficiency of vitamin K is unlikely under natural conditions in domestic animals because of the high content of substances with vitamin K activity in most plants and the substantial synthesis of these substances by microbial activity in the alimentary canal. Neonates are relatively vitamin K deficient, and vitamin K–dependent bleeding is reported in foals.

Vitamin K, as a fat-soluble vitamin, is dependent on the presence of bile salts for absorption in the small intestine. Sporadic cases may occur when impairment of the flow of bile reduces the digestion and absorption of this fat-soluble vitamin.

Experimentally produced vitamin K deficiency in piglets is manifested by hypersensitivity, anemia, anorexia, weakness, and a marked increase in prothrombin time. The minimum daily requirement for newborn pigs is 5 µg/kg BW, and the minimum curative injection dose is four times larger.

A hemorrhagic disease of recently weaned pigs from 6 to 15 weeks of age is considered to be associated with vitamin K deficiency. Affected pigs fail to grow, become pale, develop large subcutaneous hematomas, and exhibit lameness and epistaxis. Excessive and fatal hemorrhage following routine castration may occur in pigs from 30 to 40 days of age, but not at 15 to 20 days of age. Subcutaneous massive hemorrhage is more common in pigs at 40 to 70 days of age. Prothrombin time (PT) and activated partial thromboplastin time (aPTT) are prolonged, along with decreased levels of vitamin K–dependent factors II, VII, IX, and X. At necropsy, hemorrhages are extensive in the muscles of the hindlimbs, forelimbs, and axillary and mandibular region. Vitamin K1 or vitamin K2 given at a dose of 3 mg/kg BW IM as a single dose, will restore the blood coagulation defects to normal. Vitamin K3 added to the feed at a rate of 25 mg/kg for 4 days was also shown to be effective. The cause of the vitamin K deficiency is considered to be related to the use of antibacterial drugs in the feed, but this has not been substantiated.

Vitamin K–dependent bleeding occurs rarely in foals and is evident as multiple hemorrhages or hemarthroses. Clotting profile reveals prolongation of those components of the clotting cascade that depend on vitamin K–related factors, including prothrombin time and activated partial thromboplastin time. Administration of vitamin K (2 mg/kg SC q 12 h for 2 days and then 0.5 mg/kg SC q 12 h for 17 days). Spontaneous bleeding ceased within 18 hours, and there was normalization of PT and aPTT. Vitamin K1 administered parenterally to horses causes kidney failure.

The most important therapeutic use of vitamin K in domestic animals is in sweet clover poisoning, in which toxic quantities of coumarin severely depress the prothrombin levels of the blood and interfere with its clotting mechanism. Industrial poisons used in rodent control that contain anticoagulants of the coumarin type (e.g., warfarin) cause fatal hypoprothrombinaemia; vitamin K is an effective antidote. For warfarin-induced anticoagulation in the horse, the administration of 300 to 500 mg of vitamin K3, SC every 4 to 6 hours until the PT returns to baseline values is recommended.
Defective gamma-glutamyl carboxylase activity causes bleeding in Rambouillet sheep. Administration of vitamin K does not restore clotting function because the enzyme is necessary for production of vitamin K-dependent clotting factors in the liver.

FOLIC ACID DEFICIENCY (HYPOFOLCOSIS)
Folic acid is necessary for nucleic acid metabolism, and its deficiency in humans leads to the development of pernicious anemia. A dietary source is necessary to all species, and an adequate intake is provided by pasture. Although naturally occurring deficiencies have not been diagnosed in domestic animals, folic acid has numerous and complex interrelationships with other nutrients, and the possibility of a deficiency playing a part in inferior animal performance should not be overlooked. Folic acid supplementation to dairy cows increased milk yield and milk protein concentration.

The vitamin has a particular interest for equine nutritionists. Permanently stabled horses and some horses in training may require additional folic acid, preferably on a daily basis by the oral route. Folic acid supplementation to dairy cows increased milk yield and milk protein concentration.

Control of this syndrome is by encouragement of grass growth in the pastures. Outbreaks can also be avoided if sheep are prevented from grazing lush, clover-dominant pastures in the autumn. Avoidance of stress, particularly malnutrition, is also important. The daily administration of molybdenum in the feed (7 mg/kg molybdenum) has been shown to greatly reduce the uptake of copper by lambs on diets of high copper content and has been used as a practical preventive measure. Molybdenized superphosphate (70 g/ha) and molybdenized licks or mineral mixtures (86 kg salt, 63 kg finely ground gypsum, 0.45 kg sodium molybdate) are suitable alternatives. When an outbreak occurs, the administration of ammonium molybdate (50 to 100 mg/head per day) together with sodium sulfate (0.3 to 1.0 g/head per day) will stop further deaths in sheep within 3 days. Solutions of the previously noted salts may be sprayed onto hay, and administration should be continued for several weeks.

Toxins Affecting the Hemolymphatic System
SECONDARY COPPER POISONING (“TOXEMIC JAUNDICE” COMPLEX)
Copper poisoning is a complex problem because of the many factors that influence the intake, metabolism, and excretion of the element. Consequently, secondary copper poisoning (“toxemic jaundice”) can occur even when intakes of copper are, in other dietary circumstances, nontoxic. The toxemic jaundice group includes the following syndromes:

• Phytophagous chronic copper poisoning is a condition in which relatively small amounts of copper are ingested, but excessive retention occurs because of the presence of specific plants that have no apparent association with liver damage.
• Hepatogenous chronic copper poisoning results from excessive retention of copper from the ingestion of specific plants that are associated with liver damage.

Phytophagous Chronic Copper Poisoning
Phytophagous chronic copper poisoning occurs in sheep grazing pastures containing normal amounts of copper. The copper intake is low, but liver copper levels are high, and a hemolytic crisis typical of chronic copper poisoning occurs. The predominant association is the domination of the pasture by subterranean clover (Trifolium subterraneum), which may contain lower-than-normal quantities of copper (15 to 20 mg/kg). British breeds of sheep and their Merino crosses are most susceptible.

Hepatogenous Chronic Copper Poisoning
Hepatogenous chronic copper poisoning occurs most commonly following ingestion of sufficient quantities of the plants Heliotropium europaeum, Echium plantagineum, and Senecio spp. over a period of 2 to 5 months to produce morphologic and biochemical changes in liver cells without major impairment of liver function. After ingestion of these plants the liver cells have an increased affinity for copper, and abnormally high amounts accumulate in the liver, resulting in an increased risk of a hemolytic crisis. Sheep grazed on H. europaeum and then on subterranean clover are particularly prone to this form of the disease. Control depends on preventing the ingestion of hepatotoxic plants and restricting copper retention by the methods described previously.

Poisoning by Heliotropium europaeum
Heliotropium europaeum contains hepatotoxic alkaloids, and continued ingestion of the plant is associated with liver damage. If elevated copper storage occurs, hepatogenous chronic copper poisoning may develop. Conversely, if the sheep's copper status remains normal, liver damage proceeds until the animal suffers from simple toxic hepatitis. The effects of the plant are cumulative; grazing for one season may be associated with little apparent harm, but further grazing in the subsequent year may be associated with heavy mortality. Control is aimed at eradication of the plant.

FURTHER READING

ANTICOAGULANT (DICOUMAROL, SWEET CLOVER POISONING) PLANT TOXICOSIS
SYNOPSIS
Etiology
Coumarol, mellitin, and ferulenol, which are normal constituents of some specified plants, are converted to dicoumarol in the process of infection by molds of the cut plant during the making or storage of hay or ensilage.

Epidemiology
Outbreaks occur when toxic plants or moldy hay made from specific plants, especially Melilotus spp., are ingested. Insignificant trauma is associated with massive hemorrhage.

Clinical pathology
Severe anemia, prolonged clotting times.

Lesions
Pallor and weakness, especially in newborn calves. Hemorrhage may be internal and not visible. Massive subcutaneous, subserosal hemorrhages and hematomas.

Diagnostic confirmation
High dicoumarol content of hay or ensilage.

Treatment
Primary: Vitamin K, parenterally.
Supportive: Blood transfusion.

Control
Avoid feeding moldy sweet clover hay or ensilage; dilute with other feed.

ETIOLOGY
Anticoagulant-containing plant toxicosis manifests as a bleeding diathesis. A common scenario is the presence of severe bleeding after surgery or injury or subcutaneous swelling of the head and neck in newborn animals. A short course (24 to 48 hours) and a high case-fatality rate are usual.
Coumarol (a coumarin glycoside) and mellitin, normal constituents in some plants, are converted to dicoumarol (dicoumarin or dihydroxycoumarin) by the fungi Aspergillus spp. and other unspecified molds, which grow in hay or ensilage made from the following plants:
- *Anthoxanthum odoratum*: sweet vernal grass
- *Lespedeza stipulacea*: lespedeza
- *Melilotus alba*: sweet or Bokhara clover

Grazing the crop is not dangerous, but making it into hay or ensilage without the development of mold is difficult because of the succulent nature of the plant.

Dicoumarol concentrations in sweet clover hay bales, hay stacks, or silage vary widely, being highest in small bales; round bales contain more than hay stacks, and the levels are low in silage. The levels of dicoumarol are highest in the outer parts of hay bales, presumably because they are exposed to moisture. Properly cured silage contains even less because of its anaerobic conditions; dicoumarol-producing fungi require oxygen.

### PATHOGENESIS

Dicoumarol competitively inhibits vitamin K 2,3-epoxide reductase. Reduced vitamin K is essential for final carboxylation and activation of clotting factors II (prothrombin), VII (proconvertin), IX (Christmas factor), and X (Stuart factor). Inadequate synthesis of these factors results in impaired fibrin stabilization of platelet plugs, and affected animals are subjected to internal and external hemorrhage. The degree of hypoprothrombinemia is directly related to the amount and duration of dicoumarol ingestion. Coagulation system activity is maintained until the natural decay of the clotting factors in place at the time that poisoning occurs (24 to 36 hours after the last intake of toxin).

### CLINICAL FINDINGS

Extensive hemorrhages into subcutaneous tissues, intermuscular planes, and under serous surfaces are associated with discomfort. The hemorrhages may be visible and palpable as hematomas, but they do not produce crepitus and are not painful. They may be associated with stiffness, lameness, disinclination to move, and even recumbency. One limb may be severely swollen. There are no signs of toxemia, the affected animal continues to eat well, and the temperature, respiration, and heart rate are normal until the terminal stages, but the mucosa are pale and often show petechiation or ecchymosis. Hematuria, epistaxis, and dysentery occur rarely. Accidental and surgical wounds are associated with severe bleeding, but frank hemorrhages from the mucosae seldom occur. Newborn calves may show extensive swelling of the head and neck and become weak from internal or external hemorrhages within a few hours of birth.

Large extravasations of blood into tissues may provide signs of disease because of the pressure exerted on internal organs. Large hemorrhages in the pelvic cavity and broad ligament of postpartum cows often delay uterine involution and shedding of fetal membranes.

When the loss of whole blood is severe, signs of hemorrhagic anemia appear. The animal is tachycardic and weak, the mucosae are pale, and the absolute intensity of the heart sounds is increased markedly. A short course of 24 to 48 hours and a high case-fatality rate is usual.

### CLINICAL PATHOLOGY

Severe anemia with markedly increased clotting times are characteristics of the intoxication. Laboratory values for packed cell volume (PCV), erythrocyte count, and hemoglobin are decreased; values for activated clotting time (ACT), activated partial thromboplastin time (aPTT), prothrombin time (PT), partial thromboplastin time (PTT), and PIVKA are all elevated. An increase in PT occurs before any clinical evidence of bleeding and is therefore a useful prognostic test in most species. PT time may be a more effective diagnostic test in horses.

Representative samples of suspected feed should be submitted for analysis of the dicoumarol content. Clinicopathological evidence of toxicity in sheep occurs on diets containing 10 mg/kg of dicoumarol. However, significant changes in clotting time do not occur on diets containing less than 20 to 30 mg/kg. Similar changes commence in lambs and calves when the dietary intake of dicoumarol rises to above 2 mg/kg BW.

Quantitative determinations of dicoumarol levels in blood and tissues are available and especially valuable in aborted fetuses and newborn calves in which there may have been inadequate opportunity for clinical examination. High levels of dicoumarol in the feed (20 to 30 ppm) and in the liver (1 ppm) are supportive evidence of toxicosis.

### NECROPSY FINDINGS

Subcutaneous hemorrhages and large hematoma occur in areas where normal activity produces mild contusion, such as the flanks, carpal and tarsal joints, and the side of the body where the animal exerts pressure while lying down. Hemorrhages of the serosal surface of the rumen and massive retroperitoneal hemorrhage around the kidneys are frequently observed. In contrast to hemorrhages typical of septicemia, extravasation is uncommon in the lungs, kidneys, and adrenals. The carcass is pale, and there is no intravascular hemolysis, jaundice, hemoglobinuria, or hemosiderosis. Histologic examination is unrewarding, other than as a means of eliminating other potential causes of diathesis, such as vascular diseases.
**SYNOPSIS**

**Etiology** Ingestion of anticoagulant-containing rodenticides.

**Epidemiology** All species worldwide are affected.

**Clinical pathology** Packed cell volume, erythrocyte count, and hemoglobin content are decreased; activated clotting time (ACT), activated partial thromboplastin time (aPTT), prothrombin time (PT), partial thromboplastin time (PTT), and PIVKA assays are prolonged.

**Lesions** Pallor of tissues and extensive, multiple hemor - rhages throughout the body.

**Diagnostic confirmation** Anticoagulants or their metabolites can be detected in blood or urine in live animals and in the liver of animals that have died.

**Treatment** Vitamin K₁ (phytonadione); blood transfusion in critical cases.

**Control** Prevent access to rodenticides.

**ETIOLOGY**

Warfarin, available since the 1940s, is a known first-generation anticoagulant. Related compounds are coumachlor, coumarfuryl, and coumatetalyl. These products have largely been displaced from the commercial market because of the development of resistance by rats and mice, although some resurgence in use has occurred. Single doses are less likely to be associated with poisoning, but repeated ingestion for some days may do so. Daily doses of warfarin of 0.2 to 0.5 mg/kg BW are fatal to pigs in 6 to 12 days. In cattle, 200 mg/kg daily for 5 days is associated with 50% mortality. At 0.25 mg/kg for 10 days, prothrombin times are depressed 20%; at 0.1 to 0.3 mg/kg, abortions occur.

Brodifacoum, bromidromione, difenacoum, difethialone, and flucoumafen, known as second-generation hydroxycoumarin anticoagulant rodenticides, and the indandione anticoagulants chloraphacinone, diphenacoum, and pindone, have largely replaced warfarin products in the commercial market. The development of relay toxicity in nontarget species has resulted in a decline in their popularity and in some countries a return to the use of first-generation products. All of these toxins are far more potent than warfarin, with brodifacoum estimated to be 100 times more potent. Poisoning most often occurs from a single dose because of their potency and prolonged elimination half-lives, but chronic, low-dose poisoning has occurred. Brodifacoum acts over a long period and is detectable in the liver up to 128 days after intake.

**EPIDEMIOLOGY**

These products are incorporated into baits, and use is widespread because they cause no poison shyness. Although most deaths occur because of misuse by farmers, contamination of feedstuffs at the milling plant is not unknown.

**Occurrence**

Calves and poultry are not usually affected, with most outbreaks being recorded in pigs, cats, and dogs. Horses and cattle are not commonly affected unless a single large ingestion occurs or chronic, daily exposure occurs. The LD₅₀ of brodifacoum in horses is estimated to be 0.1 to 0.2 mg/kg BW.

**Environmental Risk Factors**

Many animals are poisoned by old products inadvertently left in their environment, often in old buildings or in buckets on the back of trucks.

**PATHOGENESIS**

The oral absorption and bioavailability of these toxins is high. The mechanism of action is similar regardless of the species. The toxins exert their effect by interfering with the enzyme Vitamin K 2,3-epoxide reductase, thus inhibiting the synthesis of normal clotting factors II, VII, IX, and X. As vitamin K in the liver is depleted, hemorrhage occurs. Because it takes some time for depletion to occur, signs may be delayed for 2 to 4 days. Sudden massive hemorrhage into body cavities or the brain may cause immediate death, or death may occur slowly with accompanying lameness as a result of hemorrhage into subcutaneous tissues.

**CLINICAL FINDINGS**

The clinical signs are often nonspecific. The clinical syndrome includes pale mucosa, weakness, anorexia, dyspnea, tachycardia, hematuria, epistaxis, melena, hematoma formation, recumbency, and death. Coumatetalyl is associated with more specific signs in pigs, with lameness as a result of hemorrhage in and swelling of the legs. In many...
cases, sudden death occurs, or the animals are found dead.

**CLINICAL PATHOLOGY**

There are reduced values for packed cell volume, erythrocyte count, and hemoglobin content. Activated clotting time (ACT), activated partial thromboplastin time (APTT), prothrombin time (PT), partial thromboplastin time (PTT), and PIVKA assays are prolonged. In most animals, PT is utilized to assess clotting times; PTT may provide an earlier and more accurate picture in horses. Anticoagulants or their metabolites can be detected in blood or urine or in the liver of animals that have died of toxicosis.\(^1\,\^{2,3}\)

**NECROPSY FINDINGS**

Pallor of tissues and extensive, multiple hemorrhages are characteristic. Ruminants may have melena in the abomasum and entire intestinal tract.

**DIFFERENTIAL DIAGNOSIS**

**Differential diagnosis list:**
- African horse sickness
- Epizootic hemorrhagic disease of cattle and deer
- Equine infectious anemia
- Equine viral arteritis
- Hemangiooma/hemangiosarcoma
- Moldy sweet clover (Mellotius officinalis and Mellotius alba) toxicosis
- Purpura hemorrhagica
- Thrombocytopenia (idiopathic or known)

**TREATMENT**

**Primary Treatment**

Vitamin K\(_1\) (phytonadione) is the documented antidote; vitamin K\(_2\) should not be used, especially in horses, because it is associated with renal damage.\(^1\,\^{4}\) In ruminants, the recommended dose is 1 to 2 mg/kg BW IM or SQ.\(^1\) Oral phytodiosene is presumed to be degraded by the rumen and ineffective in those species. In horses, the recommended dose is 0.5 to 2.5 mg/kg BW IM.\(^1\,\^{5}\) The duration of treatment depends on the amount ingested but often is several weeks in duration. Serial PT and PTTs should be utilized to guide therapy.

**Further Treatment**

Animals with acute blood loss must be treated for shock and provided fresh frozen plasma or whole blood, which will restore clotting factors and provide immediate coagulation factors for clotting.

**TREATMENT AND PROPHYLAXIS**

| Horses: Vitamin K\(_1\) (phytonadione) (0.5 to 2.5 mg/kg BW IM) (R1) |
| Ruminants: Vitamin K\(_1\) (phytonadione) (1 to 2 mg/kg BW IM or SQ) (R1) |

**CONTROL**

Rodenticides should be kept sealed in containers and away from animal contact. Buckets and pails should not be left in the back of trucks or other areas where horses may find them. Old buildings should be inspected for the presence of rodenticides before allowing animal entry.

**FURTHER READING**

**REFERENCES**

**ETIOLOGY**

Most outbreaks of hydrocyanic acid (HCN) poisoning are associated with the ingestion of plants that contain cyanogenic glycosides (also referred to as cyanogenic glucosides). The glycosides themselves are nontoxic, but HCN may be liberated from them by β-glycosidase and lyase present in the plant tissue.\(^1\,\^{2}\) Ruminants are at risk because rumen microorganisms not only produce β-glycosidase but also rapidly hydrolyze cyanogenic glycosides. Horses and pigs are much less susceptible to the glycosides because the acidity of the stomach in monogastric animals inactivates β-glycosidase and is not great enough to be associated with acid hydrolysis of the glycosides.

Plants that contain enough cyanogenic glycosides to cause poisoning number about 120. The following list contains only the genera recognized as hazardous:
- *Acacia* (a few species only): wattle trees
- *Adenia*, for example, *A. digitata*
- *Amelanchier alnifolia*: Saskatoon serviceberry
- *Amygdalus communis*: almond
- *Aquelegia vulgaris*: columbine
- *Bahia oppositifolia*
- *Bona fousia sananlo* (see also “Nitrate–Nitrite Poisoning”)\(^1\)
- *Brachyachine* spp., for example, *B. convergens*: Gulf star grass, native couch\(^1\)
- *Breynia oblongifolia*: coffee bush
- *Bridelia* spp., for example, *B. leichhardtii*: scrub ironbark
- *Calotis scapigera*: tufted burr daisy
- *Carex vulpina*
- *Castalis spectabilis*: Transvaal bitou
- *Cercocarpus*, for example, *C. breviflorus*: mountain mahogany
- *Chenopodium* spp., for example, *C. carinatum*: green crumbweed (see also “Nitrate–Nitrite Poisoning”)
- *Clydia oblonga*: quince tree
- *Cynodon* spp., for example, *C. aethiopicus*: couch grass, Bermuda grass, African star grass
- *Digitaria* spp., for example, *D. sanguinalis*: summer grass
- *Dimorphotheca* spp., for example, *D. cuneata*: karoo bietou
- *Drosera* spp.: Sundew
- *Dryophila* spp., for example, *D. rhadinostachya*: red crumbweed (see also “Nitrate–Nitrite Poisoning”)\(^1\)
- *Eleusine* spp., for example, *E. indica*: crowfoot
- *Eremophila maculate*: native fuchsia\(^1\)
- *Eriobotrya japonica*: loquat
- *Eucalyptus* (a few spp. only), for example, *E. cladocalyx*: sugar gum tree\(^1\)
- *Euphorbia* spp., for example, *E. drummondii*—caustic creeper
- *Flagellaria indica*
- *Florestina tripteris*
- *Glycine maxima*: yellow popflower
- *Glyceria* spp., for example, *G. maxima*: reed sweet grass
- *Goodia* spp., for example, *G. latifolia*: clover-leaf poison
- *Heterorhodon*, for example, *H. oleifolium*: boonaree
- *Holcus lanatus*: Yorkshire fog grass
- *Jatropha* spp., for example, *J. multifida*: umbrella tree
- *Juncus* spp., for example, *J. effusus*: blue rush
- *Leptopus decaisnei*: andrachne
- *Linum* spp., for example, *L. usitassimum*: linseed or flax

**SYNOPSIS**

**Etiology** Ingestion of specific plant species containing cyanogenic glycosides.

**Epidemiology** Seasonal and other variations in glycoside content lead to periods of enhanced toxicity of pasture.

**Clinical pathology** None in particular.

**Lesions** Generally none with peracute and acute ingestion. Chronic poisoning results in a neonatal goiter or arthropathy, adult posterior ataxia, dysuria, frequent urination.

**Diagnostic confirmation** Assay of hydrocyanic acid in body tissues and fluids and in feed. Positive assay on rumen contents (difficult).

**Treatment** Primary treatment with sodium thiosulfate with or without sodium nitrite or other antidote.

**Control** Test feed for cyanide content.
**Plant Products**
Linseed in the form of cake or meal may also be highly toxic if eaten in large quantities.

**Storage**
Drying, hay-making, and physical factors, such as chilling and freezing, may appear to reduce the toxicity of cyanogenic material through destruction of β-glucosidase, but the plant material remains as potentially toxic as it was originally, requiring only the enzyme from ruminal microbes to become actively poisonous. Ensiled toxic forage loses much of its cyanide content and on exposure to air may give off large quantities of free HCN.

**Glycosides**
A number of specific glycosides have been isolated and include linamarin from linseed and flax, lotaustralin from Lotus asperula, dhurrin from sorghum, lotusin from Lotus arabicus, and amygdalin from bitter almonds. The glycosides are byproducts of the plant’s metabolism and probably form part of its defense system against herbivores such as insects and molluscs. Their concentration in the different plant species is variable depending on weather conditions and other factors that influence plant growth.

The minimum lethal dose (MLD) of HCN is about 2 mg/kg BW for cattle and sheep when taken in the form of a glycoside. The MLD of lotaustralin for sheep is approximately 4 mg/kg BW. Cyanide potential is often used to report results of laboratory tests as cyanide is not present before testing. Plant material containing more than 20 mg/kg BW of preformed HCN is potentially toxic. Plants must be unwilted at time of testing or false results may be obtained. Toxic doses quoted must be accepted with some reservation because the toxicity of a particular specimen varies with a number of factors, including the concentration of the hydrolyzing enzyme in the plant, the preceding diet of the animals, and particularly the speed with which the material is eaten.

**Animal Risk Factors**
Hungry animals are allowed access to dense plant growths.

**Traveling, recently introduced, or other animals are unaccustomed to local plants; animals accustomed to the plants and the poison can tolerate increasing doses with experience.

**Cattle or sheep may break out of dry, summer pastures into fields of young, lush, immature sorghum or Sudan grass and gorge on it.

**Plant Risk Factors**
Poisoning is most likely to occur when the cyanide content of the material is high and the plant is rapidly consumed. Plants with a cyanide potential of more than 200 mg HCN/kg plant dry matter are potentially toxic. Plants must be unwilted at time of testing or false results may be obtained. The cyanide content is highest in the following conditions:

- When plants grow rapidly after a previous period of retardation, for example, after autumn rains on drought pasture, after a crop is eaten back by livestock or grasshoppers, or after spraying with herbicides.
- When plants are wilted, frostbitten, or just young.
- In drought years.
- When plants are growing in soil with a high nitrogen content.
- When plants growing in soil with a low phosphorus content.

**Cyanogenic Risk Factors**
The rate of conversion of the glycoside to HCN in the rumen also affects the toxicity of the feed; factors affecting the conversion rate include the following:

- High pH values increase the rate and the risk of poisoning.
- The rate is less when the diet includes grain and long-stemmed hay rather than fresh pasture or cubed hay.
- The rate of conversion, and onset of signs, may be delayed if the ingested material is relatively indigestible, such as crabapples.

**Environmental Risk Factors**
Occasional cases of HCN poisoning occur when animals are exposed to any of the following:

- Chemicals used for fumigation.
- Calcium cyanamide containing fertilizers.
- Waste water and tailings from mines (gold ores).

**Farm Risk Factors**
Feeding of linseed meal or cake is associated with death when excess ingestion occurs in the following situations:

- Sheep fed large quantities of linseed meal at the end of a period of starvation.

---

**Toxic Variability**
The content of cyanogenic glycosides in these plants varies widely between seasons and between different parts of the plant, with young, growing leaves usually having the greatest concentration.

**Differences Between Plant Species**
Varieties of the same species often have different toxicities, for example, Amelanchier alnifolia var. cissifolia has three times the toxicity of A. alnifolia var. alnifolia. Of greatest importance are the cultivated and pasture plants. Sudan grass (Sorghum sudanense) and sorghum (S. bicolor) are used extensively in some countries for forage and may be associated with heavy mortalities in particular circumstances. Sugar cane contains a cyanogenic glycoside from which HCN can be released. Release occurs through the action of an enzyme in algarrobo pods (Prosopis glandulosa) when the two are fed together.
• Calves fed milk replacer containing linseed that has been soaked but not boiled

**PATHOGENESIS**

**Peracute or Acute Intoxication**

Peracute or acute intoxication is associated with tissue anoxia by its inhibition of the cytochrome $a_1$ moiety of complex IV (the terminal cytochrome $c$ oxidase) in the electron transport chain, thus preventing cellular aerobic respiration. Oxygen exchange is suspended, oxygen is retained in the blood, and hypoxia occurs. If the course is prolonged for more than a few minutes, venous blood may be bright as a result of the presence of oxyhemoglobin. The central nervous system is very sensitive to hypoxia, and the major manifestation of cyanide poisoning is cerebral anoxia followed by death.

**Chronic Poisoning**

Ingestion of amounts that do not produce clinical effects appears to be well tolerated. Hydrogen cyanide is volatile and exhaled or converted to thiocyanate by hepatic rhodanase and excreted in the urine. The tolerance appears to increase with experience.

Cyanides ingested in small amounts, however, are known to be goitrogenic through the effects of thiocyanate, for example, pregnant ewes grazing on star grass (*Cynodon niloufiensis*) develop goiter partly as a result of the low iodine intake and partly as a result of the cyanide intake. Their lambs may also be goitrous and have skeletal deformities. Alpine goats fed ground cassava leaves (*Manihot esculenta*; Crantz) developed leaves (*Sudan or hybrid Sudan grass*). In horses, the signs are most marked when mesencephalon spongiosis.5

A slight increase in the number of resorption vacuoles in the thyroid follicular colloid, a slight increase in the number of resorption vacuoles in the thyroid follicular colloid, slight periportal hepatocyte vacuolation, and abomasal subepithelial hemorrhages consistently occur. A smell of "bitter almonds" in the rumen is described as typical of HCN poisoning. It may occur with some plants but is inapparent with others. There are no characteristic histologic changes. Specimens submitted for laboratory examination should include rumen contents, liver, and muscle. Much HCN may be lost from specimens during transit unless the samples are shipped in a very tightly stoppered, airtight bottle. Muscle is least likely to lose its HCN and is the preferred tissue if the delay between death and necropsy has been long. To be satisfactory, liver samples must be taken within 4 hours of death and muscle tissue within 20 hours. A level of HCN of 0.63 µg/mL in muscle justifies a diagnosis of poisoning. Serum and rumen fluid of poisoned cattle have been assayed using gas chromatography mass spectrometry (GC-MS).

In chronic cases (arthrogryposis and cystitis–ataxia) there is focal axonal degeneration and demyelination in the spinal cord, with some cases of pyelonephritis in the cystitis–ataxia patients.

**Diagnostic Field Tests**

Most tests for the presence of cyanogenic glycosides are conducted in the laboratory, but suspected plants or ruminal contents can be tested in the field by the Henrici (picric acid) test. The material is placed in a test tube containing a little water and a few drops of chloroform and heated very gently in the presence of sodium picrate paper. A rapid change in the color of the reagent paper from yellow to red indicates the presence of free HCN. Once started, the color change occurs rapidly, although it may require 5 to 10 minutes of gentle warming before the change commences. The tube should be corked while being warmed and the paper hung from the top without touching the test material. Reagent papers are easily prepared by mixing 0.5 g picric acid and 5 g sodium carbonate in 100 mL water. Filter paper is dipped in the reagent and allowed to dry in a dark place. The reagent is stable for at least 6 months if kept in a cool place, but the papers deteriorate if kept for more than 1 week. Ruminal contents may also be tested by placing a drop of ruminal fluid on a test paper. A red discoloration is a positive reaction. The test is designed to detect free HCN and may not be positive even when cyanides are present if the gas is not liberated. Commercial test papers may give superior results.

**Samples for Confirmation of Diagnosis**

- **Toxicology**—50 g rumen content, liver, muscle in air-tight container (ASSAY [cyanide]).

**DIFFERENTIAL DIAGNOSIS**

The development of an acute anoxic syndrome in ruminants grazing on plants or being fed on feeds known to be cyanogenic usually suggests the occurrence of hydrogen cyanide (HCN) poisoning. Diagnostic confirmation is dependent on a positive assay for HCN in blood or cyanogenic glycosides in rumen contents.

**Differential diagnosis list**

- **Peracute or acute toxicosis**
  - 3-methyl indole toxicosis
  - Acute pulmonary edema and emphysema
  - Cyanobacteria (blue-green algae) toxicosis
  - Electrocuting (lightning strike)
  - Ipomeanol toxicosis
  - Nitrate/nitrite toxicosis

**Chronic (goiter, myelomalacia, and arthrogryposis)**

- Numerous and listed elsewhere
TREATMENT
The standard primary treatment is the IV injection of a mixture of sodium nitrite and sodium thiosulfate (5 g sodium nitrite and 15 g sodium thiosulfate in 200 mL water for cattle; 1 g sodium nitrite and 3 g sodium thiosulfate in 50 mL water for sheep), and field experience with it has been very good. Ruminants have been successfully treated with a 30% to 40% solution of IV sodium thiosulfate at 25 to 50 g/100 kg BW and no sodium nitrite. Horses can be given 10 to 20 mg/kg sodium nitrite IV in a 20% solution followed by 30 to 40 mg/kg BW sodium thiosulfate IV in a 20% solution. Results in cattle can be improved by using the following doses:

- Sodium thiosulfate in a much heavier dose (660 mg/kg BW in a 30% solution).13
- Sodium thiosulfate heavy dose combined with sodium nitrite (22 mg/kg BW).
- Sodium thiosulfate heavy dose with p-aminopropiophenone (1 to 1.5 mg/kg BW).
- Sodium thiosulfate heavy dose plus cobaltous chloride (10.6 mg/kg BW).

In all cases and in animals exposed but showing no signs, doses of 30 g of sodium thiosulfate are given orally to cattle and are repeated at hourly intervals.

Investigational Treatments
Hydroxocobalamin, the natural form of vitamin B12, is used successfully in many countries as an antidote in human beings, dogs, mice, guinea pigs, rabbits, and baboons. Recent work in swine demonstrated that hydroxocobalamin (150 mg/kg BW) was more effective than sodium thiosulfate (413 mg/kg BW) or a combination of hydroxocobalamin and sodium thiosulfate in treating experimentally induced cyanide poisoning.15

TREATMENT AND PROPHYLAXIS
Ruminants (See text for other options)
- All: sodium thiosulfate 660 mg/kg BW IV in a 30% solution (R1)
- Cows: 5 g sodium nitrite, 15 g sodium thiosulfate IV in 200 mL water (R2)
- Sheep: 1 g sodium nitrite, 3 g sodium thiosulfate in 50 mL water (R2)

Horses
- Sodium nitrite (10 to 20 mg/kg BW IV in a 20% solution) followed by sodium thiosulfate (20 to 40 mg/kg BW IV in a 20% solution) (R1)

CONTROL
Hungry cattle and sheep should not be allowed access to toxic plants, especially cultivated ones, when the plants are chronically drought-stressed, immature, wilted, frostbitten, or growing rapidly after a stage of retarded growth. For most Sorghum cultivars, stock should be allowed to graze them, or be fed green chop made from them, only after the plants exceed 75 cm in height. Hay should not be made from Sorghum, which is potentially toxic, because toxicity may persist. Sorghum silage is much safer than hay.

Sulfur deficiency in ruminants causing depressed feed intake and animal production may result from grazing Sorghum with high cyanide potential. This results from ruminal detoxification of cyanide with sulfur to form thiocyanate. Supplementation with salt licks containing 5% sulfur can counter this problem.

If there is doubt as to the toxicity of a field of these plants, a sample may be tested by the following assay:

NITRATE AND NITRITE TOXICOSIS
SYNOPSIS
Etiology Nitrate from plants, sodium or potassium nitrate fertilizer, contaminated drinking water; nitrite preformed in nitrate-rich, moldy plant material or as nitrate converted to nitrite in the rumen.

Epidemiology Worldwide herd outbreaks; rare equine cases.

Clinical pathology Methemoglobinemia.

Findings Sudden onset of severe dyspnea, brown mucosa and blood, death.

Diagnostic confirmation Positive assay for nitrate in feed, blood, or aqueous humor.

Treatment Intravenous 1% to 2% methylene blue (1 to 10 mg/kg BW).

Control Avoidance of nitrate-rich feeds, especially in transported and hungry animals.

ETIOLOGY
The toxic element as it occurs in growing plants is always nitrate, usually potassium nitrate, and may be ingested in sufficient quantities to be associated with gastroenteritis. Ruminal microbes reduce nitrate to nitrite,1,2 which when absorbed systemically is far more toxic and responsible for most of the clinical signs. Toxic doses are hard to compute because of variation in animal susceptibility, rate of production of nitrate from nitrate, and amount of nitrate present in specific plants. Plants grown during a drought...
period have higher nitrate concentrations than those in normal rainfall.\(^2,3\)

The roots and stems usually contain more nitrate than leaves,\(^1\) and a total plant content of 6000 to 10,000 ppm dry matter (DM) of nitrate is considered to be potentially toxic. Plants that accumulate more than 1.5% potassium nitrate in dry matter are potentially toxic. For animals at pasture probably 2% DM as nitrate is safe. Levels of potassium nitrate in plants may be as high as 20% of DM, and 3% is not uncommon in recognized forage plants such as sorghum; heavy mortality has occurred in animals that have foraged them. Dried plants retain their toxicity; ensiled plants decrease by about 30%.

Cattle
The minimum lethal dose of nitrite is 88 to 110 mg/kg BW or about 0.6 g of potassium nitrate per 1 kg BW. Daily doses of about 0.15 g potassium nitrate have been associated with abortion after 3 to 13 doses. Cattle can eat sufficient quantities of toxic plants to be associated with death in 1 hour.

Sheep
The lethal dose of nitrite is 40 to 50 mg/kg BW. Continued low-level dosing does not appear to affect sheep. Drinking water containing 1000 ppm of nitrate nitrogen is associated with appreciable methemoglobin formation but has no obvious clinical effect.

Swine
Pigs are most susceptible to preformed nitrates. The lethal dose of potassium or sodium nitrite is about 20 mg/kg BW. At dose levels of 12 to 19 mg/kg BW clinical signs occur, but the pigs recover.

Horses
The estimated oral lethal dose of nitrate in horses is 61 to 152 g/animal.\(^6\)

EPIDEMIOLOGY
Occurrence
Common sources of nitrate for farm animals include the following:

- Cereal crops used as pasture, for example, immature green oats, barley, wheat, and rye or hay; or green feeds, for example, Sudan grass, corn. Oat hay may contain 3% to 7% nitrate.
- Very heavy growths of rye grass (\textit{Lolium} spp.) in pastures\(^6\)
- Freshly pulled mangels—turnip tops may contain 8% nitrate, and sugar beet tops and rape have been associated with nitrite poisoning.
- Water from deep wells contaminated with fertilizer or from reservoirs created with explosives
- The following plants are recognized as important sources of hazardous nitrate concentrations:

  - \textit{Alternanthera denticulata}
  - \textit{Amaranthus} spp., for example, \textit{A. retroflexus:} redroot, pigweed\(^3\)
  - \textit{Prince of Wales feather} (see also “\textit{Amaranthus hybridus:} pigweed chico”)
  - \textit{Amaranthus dubius:} bledo liso; \textit{Amaranthus hybridus:} bledo chico\(^1\)
  - \textit{Aneilema acuminateum}
  - \textit{Arctotheca calendula:} capeweed
  - \textit{Atriplex muelleri:} annual saltbush
  - \textit{Avena sativa:} oats\(^2,3,4\)
  - \textit{Beta vulgaris:} sugar beets, feed beets, beetroots
  - \textit{Bidens frondosa:} beggar tick
  - \textit{Boufoussia sanahe}\(^1\)
  - \textit{Bromus catharticus:} prairie grass
  - \textit{Carduus spp.,} for example, \textit{C. tenuifloris:} winged, slender thistle
  - \textit{Chenopodium} spp., for example, \textit{C. ambrosioides:} mexican tea, goosefoot; \textit{Chenopodium album:} lamb’s quarters\(^1,3\)
  - \textit{Chromolaena odorata:} Siam weed
  - \textit{Cirsium arvense:} Canada thistle
  - \textit{Clayoxylo austre:}
  - \textit{Cleome serrulata:} Rocky Mountain bee plant
  - \textit{Dactyloctenium radulans:} button grass, but only when growing in high-nitrogen soil, such as in stockyards
  - \textit{Daucus carota:} wild carrot, Queen Anne’s lace
  - \textit{Dysphania spp.:} crumbweeds (see also “\textit{Cyanogenic Glycoside Poisoning}”)
  - \textit{Echinochloa} spp., for example, \textit{E. crus-galli:} barnyard grass, Japanese millet
  - \textit{Ehretia membranifolia}
  - \textit{Eleusine spp.,} for example, \textit{E. indica:} crowfoot (see also “\textit{Cyanogenic Glycoside Poisoning}”)
  - \textit{Franseria discolor:} white ragweed
  - \textit{Galenia pubescens}
  - \textit{Glaucium corniculatum}
  - \textit{Glycine max:}
  - \textit{Galenia pubescens:}
  - \textit{Gnaphalium purpureum:}
  - \textit{Helianthus annuus:} sunflower
  - \textit{Lolium} spp., for example, \textit{L. multiflorum:} annual saltbush
  - \textit{Malva parviflora:}
  - \textit{Medicago sativa:} alfalfa, lucerne
  - \textit{Millotia greevesii:} creeping milfoil
  - \textit{Montia perfoliata:} miner’s lettuce
  - \textit{Parsonia spp.,} for example, \textit{P. lilacina}
  - \textit{ Panicum capillare:}
  - \textit{Portulaca spp.,} for example, \textit{P. oleracea:}
  - \textit{Poisoning} (see also “\textit{Atriplex muelleri:} pigweed chico”)
  - \textit{Raphanus sativus:} radish
  - \textit{Salvia reflexa:} mintweed
  - \textit{Sigebeckia orientalis}
  - \textit{Sillyum marianum:} variegated thistle
  - \textit{Sinapis} spp., for example, \textit{S. alba:} white mustard
  - \textit{Sonchus} spp.: sow thistle
  - \textit{Sorghum spp.,} for example, \textit{S. bicolor:}
  - \textit{grain sorghum}
  - \textit{Spartothamnella juncea}
  - \textit{Stellaria media:} chickweed
  - \textit{Thelypodium lasiophyllum:} mustard
  - \textit{Tribulus terrestris:} caltrop
  - \textit{Triticum aestivum:}
  - \textit{Urochloa spp.,} for example, \textit{U. panicoides:} liversedge grass
  - \textit{Vigna unguiculata (catjang):} cowpea
  - \textit{Zaleya galericulata}
  - \textit{Zea mays:} maize, corn\(^1\)
  - \textit{Zygophyllum} spp., for example, \textit{Z. ammophillum:} twin leaf

Risk Factors
Animal Risk Factors
Species Differences
There is considerable variation between species in their susceptibility to nitrite poisoning, with pigs being most susceptible, followed by cattle, sheep, and horses, in that order.\(^1\) The susceptibility of cattle relative to sheep is attributable either to their ability to convert nitrate to nitrite in the rumen or to the known greater ability of sheep to convert nitrite to ammonia. Pigs are highly susceptible to nitrite poisoning but are generally affected only if they ingest it as preformed nitrite. They have a lower level of bacterial nitrite reductase in their saliva and lower levels of methemoglobin reductase.\(^5\) Nitrate or nitrite toxicity in horses is very rare.\(^3,6\)

Dietary Differences
Cattle reduce nitrate to nitrite in the rumen,\(^2,5,7\) and their capacity to do this is enhanced by continued feeding of nitrate.

Cases of nitrate poisoning that occur in sheep are associated with either the ingestion of preformed nitrite or ruminal conditions that favor reduction of nitrate. A diet rich in readily fermentable carbohydrate reduces nitrite production in the rumen of sheep. Nitrite poisoning also occurs in sheep fed an inadequate ration after dosing with nitrate at a level innocuous to sheep fed on a good ration. There is often a delay of a few days in the appearance of signs of poisoning after sheep go onto toxic forage. It seems likely that ruminal flora need to adapt to the changed nutrients. The degree of methemoglobinemia also varies with the quality of the diet.
Differences in Susceptibility
The most important factor influencing susceptibility appears to be the rate of ingestion of the nitrate-containing plant. Poorly fed animals, especially traveling or recently transported stock, are more susceptible to poisoning than those on good diets, probably because of the greater intake in hungry animals and possibly their need to adapt their ruminal flora to the conversion of nitrite to ammonia. Prior exposure to nitrate reduces susceptibility under experimental conditions; cattle on high-nitrate hay taken off the hay for a few days and then returned to it in self-feeders where they can gorge on it may be poisoned. Monensin facilitates the conversion of nitrate to nitrite in the rumen and may result in poisoning in cattle or sheep on high-nitrate-containing feeds.

Environmental Factors
Higher-than-normal levels of nitrate in plants are usually associated with the following:

- Application of excessive nitrogen-containing fertilizer, human sewage, or animal manure from intensive accommodation units, or with high levels of nitrogen-fixing bacteria
- Soil nitrate being taken up but not used by plants because weather conditions are unsuitable for photosynthesis, which would provide the energy to convert the nitrogen into protein—conditions that retard photosynthesis include cloudy or cold weather, nighttime, herbicide application, disease in the plants, wilting of the plants. Periods after a prolonged drought also retard photosynthesis. High levels of nitrate accumulate in the soil during the drought and are not leached out by rain. Plants absorb large amounts when the drought ends.
- Green chop fed indoors is more hazardous than grazing material, probably because the intake is more rapid.
- Cereals and root crops are likely to contain high concentrations when heavily fertilized with nitrogenous manures, especially crude sewage, and when growth is rapid during hot, humid weather.
- Ensiled material usually contains less nitrate than the fresh crop because normal silage fermentation destroys nitrate, but juices draining from silos containing high-nitrate materials may be toxic.
- Hay made from nitrate-rich material contains almost as much nitrate as when it was made, unless some of it is converted to nitrite by overheating and the activities of molds.
- Heavily fertilized grass made into grass cubes
- Nitrate combined with possible iodine deficiency is statistically associated with congenital deformities and hypothyroidism in foals in western Canada where mares were fed oats hay or green oat forage during pregnancy.
- Cereal hay, especially oat hay, when grown under drought conditions and cut when sappy, may develop a high concentration of nitrite when the stacked material develops some heat. Dry oat hay that is damp for some time before it is eaten, either in the stack or loose in the field in the hot sun, is also likely to contain a high concentration of nitrite.

Nitrate-nitrite poisoning by drinking polluted water can result from the following sources:

- Industrial contamination from rubber-processing plants
- Nitrogenous fertilizer contamination
- Manure and urine contamination
- Effluent from butchers' shops and meat processors where sodium nitrate is used in meat-pickling brine
- Effluent from premises where cheese is manufactured, where the whey may contain potassium nitrate
- Deep wells filled by seepage from highly fertile soils, which may contain levels as high as 1700 to 3000 ppm of nitrate
- Open surface storage tanks collecting rain runoff from roofs may contain toxic amounts of nitrite in the plant debris that collects at the bottom.
- Juices draining from silage-containing high-nitrate material may be toxic.
- Water of condensation in barns may trap ammonia and eventually contain 8000 to 10,000 ppm of nitrate.
- Composition lining board in animal barns may become highly impregnated with nitrite and is associated with poisoning if chewed.
- Water containing 2300 ppm of nitrate and less than 10 ppm of nitrite when mixed into a swill, stored in tanks, and then cooked has resulted in the production of a mixture containing 1200 to 1400 ppm of nitrite. Boiling does not reduce the nitrate content of water. Accidental poisoning with commercial nitrate compounds occurs sporadically when:
  - Sodium or potassium nitrate is used by mistake instead of sodium chloride or magnesium sulfate, or when ammonium nitrate solution is used instead of whey
  - Nitrates are utilized as explosives to blast out water holes used to store drinking water for cattle, which can be dangerous if the nitrate is left in the hole and the dam fills soon afterward

PATHOGENESIS
Nitrites have a direct caustic action on alimentary mucosa, and the ingestion of sufficiently large quantities is associated with gastroenteritis. Under normal circumstances, ingested nitrate is reduced in the rumen to nitrite and further converted to ammonia. When this system is overwhelmed by a large or sudden ingestion of nitrates, nitrites are rapidly absorbed into the blood. Nitrites are also absorbed but are less toxic. Ingestion of preformed nitrites often results in very rapid effects, but when conversion of nitrate to nitrite occurs in the rumen there is often a delay of some hours before clinical signs occur.

The nitrite anion oxidizes heme iron from the ferrous (Fe2+) to the ferric (Fe3+) state, resulting in methemoglobinemia and hypoxia. Nitrites are also vasodilators, which may contribute to the development of tissue hypoxia by causing peripheral circulatory failure, but this effect appears to be of little significance compared with that of methemoglobin formation. Clinical signs of toxicosis become evident when the methemoglobin level reaches 40% to 50%. Death may not show signs until the level reaches 60%. Death does not occur until a certain level of methemoglobinemia is attained. In cattle this is approximately 9 g methemoglobin per 100 mL blood; in pigs, death occurs when 76% to 88% of hemoglobin has been altered to methemoglobin. Death usually occurs within 12 to 24 hours of ingestion of the toxic material, although in acute poisoning the duration of illness may be even shorter, and clinical signs may not be observed.

CLINICAL FINDINGS
Clinical signs of acute nitrate and nitrite toxicosis include weakness, depression, respiratory distress, cyanotic mucous membranes, ataxia, tremors, and terminal convulsions. Abortions may occur in surviving cattle 3 to 7 days after acute toxicosis. Chronic exposure to lower levels of nitrates may result in anoxia, stillbirths and abortions, and progesterone abnormalities.

CLINICAL PATHOLOGY
There are no pathognomonic lesions in living animals. Chocolate-brown discoloration of the blood has been described but is not consistent. Contributory information is provided by blood levels of methemoglobin, but inaccuracy creeps in because of the rapid reversion of methemoglobin to hemoglobin. Methemoglobinemia may be detected by examination of the blood in a reversion spectrophotometer, but it is not diagnostic of nitrite poisoning, and results are not dependable unless the blood has been collected for less than 1 or 2 hours. Methemoglobin levels of 9 g/dL of blood are lethal in cattle; levels of 1.65 to 2.97 g/dL are recorded in association with obvious clinical signs compared with normal levels of 0.12 to –0.2 g/dL.

Ocular fluid is the body fluid of choice for diagnosis; blood (serum or plasma) is also acceptable. Samples should be collected
TREATMENT AND CONTROL

Methylene blue (1 to 10 mg/kg BW as a 1% solution IV; repeat q 6 to 8 hours prn) (R1)

CONTROL

Ruminants likely to be exposed to nitrates or nitrites should receive adequate carbohydrates in their diet, and animals should not be allowed access to dangerous plants. Haylage or silage suspected of dangerous levels of nitrate should be allowed to aerate overnight before feeding. Feeding corn-based supplements may help ruminants safely reduce nitrate and nitrites.

Toxic Levels

Acute nitrate poisoning is likely to occur when the concentration of nitrate fed on a dry matter basis exceeds 1%, and risk of abortion occurs at 0.5%. To be safe, the nitrate concentration in feed should not exceed 0.3% on a dry weight basis.

Ration Dilution

Hungry animals should be fed hay or dry pasture as a filler to reduce their rate of intake before access to potentially toxic feed. Feeding corn-based supplements may help ruminants safely reduce nitrate and nitrites.

Differential Diagnosis

Differential diagnosis list:
Acute bovine pulmonary edema and emphysema
Carbohydrate overload
Cyanide or hydrocyanic acid toxicity
Cyanobacteria (blue-green algae) toxicity
Hypomagnesemia (lactating cattle)
Urea (ammonia) toxicity

Treatments

Methylene blue is the specific antidote. In large amounts, it is associated with rapid reversion of methemoglobin to hemoglobin. The standard dose rate is traditionally 1 to 2 mg/kg BW, injected IV as a 1% or 2% solution, but a variety of doses up to 10 mg/kg BW have been used. Treatment may have to be repeated when large amounts of toxic material have been ingested. The half-life of methylene blue is about 2 hours, and if needed, treatment should be repeated at intervals of 6 to 8 hours. Tissues may become stained with methylene blue, and the urine may become dark green in color. The withdrawal time for slaughter is 180 days.

Necropsy Findings

The gastrointestinal mucosa is congested and hemorrhagic; the blood is dark red to coffee brown in color and clots poorly. Petechial hemorrhages may be present in the heart muscle and trachea, and there is general vascular congestion. There are no characteristic microscopic changes.

Specimens for laboratory examination should include blood and ocular fluid, blood for methemoglobin estimation, and samples of ingesta and/or suspected plants or water. Postmortem blood specimens for methemoglobin assay must be collected within 1 to 2 hours of death to be of any value.

Samples for Confirmation of Diagnosis

- Toxicology—1 cc aqueous humor (frozen); 1 cc urine (frozen); suspect forage material (dry); or other possible source of poison; 100 g ingesta (with chloroform or formalin added) (ASSAY [nitrate/nitrite]); 2 cc blood in 4 cc phosphate buffer (ASSAY [methemoglobin])

Synopsis

Etiology Allium spp. contain N-propyl disulfide and S-methyl sulfoxide and S-prop(en)yl cysteine sulfoxide (SMCO); Brassica spp. contain SMCO.

Epidemiology Outbreaks when mature plants are grazed. Heavy morbidity and case-fatality rates.

Clinical Pathology Methemoglobinemia, Heinz-body formation, hemolytic anemia, hemoglobinuria.

Lesions Live animals have an acute onset of pallor, hemoglobinuria, and jaundice (if the animal survives long enough). Necropsy findings include pallor, jaundice, dark-brown kidneys and urine; pieces of plant material in rumen.

Diagnosis confirmation High blood levels of dimethyl disulfide in SMCO poisoning. The test is not generally available.

Treatment No primary treatment; supportive treatment is blood transfusion.

Control Feed limited amounts and dilute with other feeds; limit access to plants.

Dysulfide Plant Toxicosis (Allium spp[Onions] and Brassica spp)

Etiology All plants in the Allium species can be toxic to domestic animals, but poisoning from the onion (Allium cepa) is the most widely reported in large animals, with sporadic reports involving the wild onion, Canada garlic (A. canadense). Others plants such as garlic (A. sativum), three-cornered garlic (A. triquetrum), leek (A. prorum), and chive (A. schoenoprasum) are reported as toxic to dogs and cats. Cattle are most often poisoned by being fed culled cultivated onions, whereas sheep and horses are more often poisoned by grazing in fields where wild onions grow or gaining access to areas where cultivated onions are grown. Onion toxicity is associated with methemoglobinemia, leading to Heinz-body formation and hemolytic anemia. Plants in the genus Allium contain the disulfides n-propyl disulfate, in addition to S-methyl sulfoxide and S-prop(en)yl cysteine sulfoxide (SMCO), amino acid derivatives. In the rumen, SMCO is hydrolyzed to thiosulfates and then metabolized to dipropyl disulfides and dipropenyl disulfides. Oxidative damage to the erythrocytes is caused by the disulfides.

Plants of all the Brassica species are associated with several syndromes, including hemolytic anemia resulting from SMCO poisoning as discussed here, blindness, pulmonary emphysema, polioencephalomalacia, and digestive disturbances, discussed in the section on glucosinolate poisoning. These syndromes may occur separately or in
combination. SCMO occurs in some genera of plants in the family Brassicaceae (e.g., *Brassica, Raphanus*). The plants known to contain SCMO are *Brassica campestris* (turnip rape, cole), *B. napobrassica* (swede, rutabaga), *B. napus* (rape = canola), *B. oleracea* (kale, kohlrabi, chou moellier, cabbage, cauliflower, broccoli, Brussels sprouts, calabrese), *Raphanus raphanistrum* (wild radish), and possibly *Thlaspi arvense* (fanweed) and *Berteroa incana* (hoary alisma). The green parts of the plants are the usual material involved in outbreaks.

The seeds and leaves of *Brassica* spp. also contain another glucosinolate, sinigrin, and its breakdown products, allyl cyanide and allyl isothiocyanate, which may depress food intake but appear to exert no hemolytic activity. The plants may also contain significant quantities of cyanogenic glycosides but rarely are associated with cyanide poisoning. Nitrate and nitrite poisoning have also been recorded on kale feeding.

Particular note should be taken of the occurrence of SMCO in cabbages, swedes, and stubble turnips. The level may be insufficiently high to be associated with anemia but may be associated with failure to gain weight satisfactorily or clinically evident ill-thrift.

**EPIDEMIOLOGY**

**Occurrence**

*Allium* spp. species specificity occurs and is likely related to structural differences of hemoglobin. Cattle are most susceptible to toxicity, followed by horses, sheep, and goats. Cattle may tolerate up to 25% culled onions or a DM basis, whereas sheep can be maintained on a diet of up to 50% DM. Goats may tolerate an onion diet of 30% to 40% DM. Adult cattle are more susceptible than calves; in contrast, adult sheep are less susceptible than young sheep. Cattle may tolerate up to 25% culled onions. Sheep and goats can tolerate larger amounts without evidence of toxicity than calves; in contrast, adult sheep are less susceptible than young sheep.

*Brassica* spp. rape and kale poisoning are well known where these plants are grown for feed, and in some areas they are no longer used because of the danger. The overall prevalence of poisoning is probably not great, but on individual farms the number affected is usually significant, and the mortality rate is high. The toxic dose of SMCO is 15 g/100 kg BW daily to produce severe, fatal anemia. Intakes of 10 g/100 kg BW are associated with a subacute, low-grade anemia. Although there may be no etiologic relationship, it is not uncommon for hemolytic disease to occur in the presence of hypophosphorosis and therefore at the same time as postparturient hemoglobinuria.

**Farm or Premise Risk Factors**

*Brassica* spp. plants are more toxic as they mature and when secondary growth begins; the flowers and seeds are particularly poisonous. The toxicity of the plants varies from year to year, and on rape grazing most outbreaks occur in wet years when early frosts occur and the leaves turn a purple color. The toxicity of kale also varies significantly between varieties of the plant, but the important factors in most outbreaks are the maturity of the crop and the amount eaten. The toxic element in kale is destroyed in heat-dried or ensiled material but is still present in frozen and dried material.

**PATHOGENESIS**

Dimethyl disulfide and the propyl disulfides are agents responsible for oxidative damage to the erythrocytes. Heme iron is oxidized to the ferric state, resulting in hemoglobinemia and decreased oxygen transport. Oxidative damage also results in Heinz-body formation from denatured hemoglobin in erythrocytes and, ultimately, hemolysis. The resulting hemolytic anemia affects all classes of ruminants, but its effects are most serious in heavily pregnant and recently parturient females. The reasons for the observed tendency for cycles of spontaneous improvement followed by recrudescence of the anemia are not explained. A previous suggestion that they were related to variations in the cellular content of reduced glutathione, which prevents the formation of Heinz bodies, has been discredited.

**CLINICAL FINDINGS**

In the anemia syndrome, the onset in severe cases may be so sudden that no signs are observed before the animal collapses and dies. If clinical illness is apparent, hemoglobinuria is observed first and is soon followed by weakness and depression. Pallor of the mucous membranes, moderate jaundice, tachycardia, and a slight increase in respiratory rate and depth are also observed. Diarrhea occurs commonly, and although body temperatures are usually normal to low, there may be fever up to 40.5°C (105°F). Death is common unless effective treatment is provided, and surviving animals require a long period of convalescence. A normal hematological status may not be regained for up to 6 weeks. In an affected herd it is common to find a number of animals that are not seriously ill but have subclinical anemia.

**CLINICAL PATHOLOGY**

The erythrocyte count, hemoglobin concentration, hematocrit, and leukocyte count are reduced, and Heinz bodies are present in up to 100% of erythrocytes. They are significantly increased in numbers before anemia appears. Methemoglobinemia and hemoglobinuria occur. The dimethyl disulfide content of the blood, which will be high at the time of occurrence of the poisoning, can be measured chromatographically. Necropsy findings

There is pallor, jaundice, hemoglobinuria, thin and watery blood, dark coloration of the kidney, accentuation of the lobular appearance of the liver and, in peracute cases, swelling of the spleen. Histologically there is moderate periarterial hepatocyte necrosis in the liver compatible with the effects of hypoxia.

**DIFFERENTIAL DIAGNOSIS**

The occurrence of the disease when cattle or sheep have consumed *Allium* spp. or grazing on plants of the family Brassicaceae suggests the presumptive diagnosis. Diagnostic confirmation is by measurement of dimethyl sulfide levels in the blood.

**Differential diagnosis list:**

- Bacillary hemoglobinuria
- Babesiosis
- Chronic copper toxicosis
- Leptospirosis in calves
- Postparturient hemoglobinuria

Red maple (*Acer rubrum*) toxicosis (horses)

**TREATMENT**

Primary treatment in the form of an antidote to SMCO toxicity is unavailable. Supportive treatment includes, in severe cases of anemia, an immediate blood transfusion. Hematocrit preparations and the provision of a highly nutritious diet are also used.

**CONTROL**

The disposal of superfluous onions is a major horticultural problem, best solved by feeding them to animals. This can be done without fear of causing anemia by feeding them to cows mixed into a balanced ration containing less than 25% of onions. Sheep and goats can tolerate larger amounts without evidence of clinical anemia.

Although the provision of ample hay either daily before the animals are pastured on the rape, as a stack in the rape field, or by allowing access to a field of rough grass, is recommended to reduce the consumption of rape. Rape showing purple discoloration should be regarded with suspicion and only limited grazing permitted until doubts as to its safety are satisfied. Cattle and sheep grazing on these plants should be kept under close observation so that affected animals can be treated in the early stages of the disease. An adequate phosphorus intake is particularly necessary. If feeding is stopped, the hemoglobin levels return to normal in about 3 weeks. Even if feeding is continued, there is a strong tendency for a spontaneous recovery and further similar cycles to occur. Some varieties of kale have lower concentrations of SMCO, and a genetic approach to preventing the disease might be worth examining.

**FURTHER READING**

Aslani MR, Mohri M, Movasaghi AR. Heinz body anemia associated with onion (*Allium cepa*)
Red maple (Acer rubrum) are native to eastern North America and cultivated in many parts of Europe. Toxicosis from red maple leaves is frequently reported in horses and more rarely in alpacas and zebras (Equus grevyi). The toxic dose is approximately 1500 mg leaves/kg BW, or approximately 1.5 to 2 pounds of dry or wilted leaves per 500-kg horse. Horses are most often poisoned in the fall when leaves are falling or when tree branches have fallen into their pastures after a storm.

The toxin causes an oxidative damage to the red blood cells, resulting in Heinz-body formation, hemolysis, and methemoglobinemia. Two clinical syndromes exist, characterized by hemolytic anemia, methemoglobinemia, or both. Currently, pyrogallic acid in red maple leaves may be recognized: two clinical syndromes exist, the red blood cells, resulting in Heinz-body formation, hemolysis (intra or extravascular), there is no antidote. Treatment options include IV crystalloids, mineral oil, whole-blood transfusion, hemoglobin-based oxygen carriers, ascorbic acid (30 to 50 mg/kg BW IV BID diluted in 5% to 10% dextran). Selenium deficiency, hypothermia, tachypnea, and laminitis (for cutaneous form). There is no known sequel.

SPORADIC BOVINE LEUKOSIS (ATYPICAL BOVINE LEUKOSIS)

SYNOPSIS

Etiology Unknown.
Epidemiology Occurs worldwide, with low prevalence.
Signs Three different forms of sporadic bovine leukemia (SBL) are differentiated based on age and organ primarily affected: juvenile, thymic, and the cutaneous form. Atypical forms have been reported. The juvenile form primarily affects calves up to 6 months of age with multiple enlarged lymph nodes. The thymic form affects animals up to 2 years of age with massive enlargement of the thymus. The cutaneous form affects animals between 1 and 3 years of age with dermal nodes and plaques.
Clinical pathology Histology on biopsy samples of enlarged lymph nodes, thymus, or skin lesions. Serologically negative for bovine leukemia virus (BLV).
Lesions Lymphoid tumors affecting different organs.
Diagnostic confirmation Histology and negative BLV serology.
Differential diagnosis list Enzootic bovine leukosis (EBL) Lymphadenitis as a result of tuberculosis and actinobacillosis Congestive heart failure as a result of traumatic pericarditis (for thymic form) Traumatic hernotoma of jugular vein (for thymic form) Ring worm (for early-stage cutaneous form)

ETIOLOGY

Sporadic bovine leukemia (SBL) is a lymphoproliferative disease of cattle of unknown etiology. Animals affected by SBL by definition must be negative for bovine leukemia virus (BLV) serology and PCR, which is why the etiology of SBL is considered to be different from enzootic bovine leukemia virus (EBL). Although the causative involvement of a pathogen other than BLV cannot be ruled out, SBL is currently considered to be noninfectious and noncontagious. In contrast to EBL, which is a B-cell proliferative lymphoma, lymphoid tumors in patients with SBL were found to be of either B- or T-cell lineage.

SBL primarily affects animals under 3 years of age, although atypical forms occurring in older cattle have been reported. Three different forms of SBL are currently recognized:
- **Calf or juvenile form:** Primarily occurs in calves less than 6 months old but may occasionally be seen in cattle up to 2 years of age; the condition is characterized by multiple lymph node enlargement.
- **Thymic form:** Is most common in animals between 6 months and 2 years old and is characterized by a marked enlargement of the cervical and/or the intrathoracic part of the thymus. Other organs and lymph nodes are frequently involved.
- **Cutaneous form:** Occurs in cattle 1 to 3 years old and is characterized by the development of nodes and plaques in the skin. Involvement of internal organs, particularly in advanced stages of the disease, is common.

In addition to these well-recognized forms of SBL, atypical cases affecting different organs or older animals have been reported in the literature. More recently the occurrence of a larger number of cases of SBL in adult cattle that were clinically and histologically indistinguishable from EBL and negative for BLV antibodies has been reported in the Netherlands.
these regions the juvenile form appears to be the prevalent form observed.

**PATHOGENESIS**
Malignant proliferation of a specific B- or T-cell lineage occurs for unknown reason, resulting in tumor formation in lymphatic tissue with a strong tendency to metastasize widely. The exact nature of the tumor is unclear. The tumors consist of aggregations of neoplastic lymphocytes.

**CLINICAL FINDINGS**

**Juvenile or Calf Lymphosarcoma**
Juvenile lymphosarcoma occurs in calves from 2 weeks to 6 months of age and is manifested by gradual loss of weight, the sudden enlargement of several or all lymph nodes, development of depression and weakness, and in some cases respiratory distress. Fever, tachycardia, and posterior paresis are less constant signs. Death occurs in 2 to 8 weeks after the onset of signs. Signs of pressure on internal organs, including bloat and congestive heart failure, may occur. Diffuse infiltration of major nerves of a limb may also occur. Unusually the disease may be fully developed in utero, so that the newborn calf is affected with tumors, or be delayed until 2 years of age. Lymphosarcoma of the pharyngeal region causing retropharyngeal swelling and dyspnea in a 7-month-old beef steer has been recorded. Some degree of aplastic anemia is frequently present; lymphocytosis may occur but is not characteristic. The presence of large numbers of immature lymphocytes in the blood smear is highly suggestive of the presence of the disease.

Bone and bone-marrow necrosis associated with the calf form has been recorded in calves 3 weeks to 8 months of age. Involvement of the tibiotarsal joint, ribs, and spinal canal may also occur, resulting in ataxia and paresis. Multiple bone infarcts and bone-marrow necrosis were present at necropsy. Lymphosarcoma of the mandible of a 2-year-old heifer has also been recorded.

**Thymic Lymphosarcoma**
Infiltration of the thymus is a common finding in animals 1 to 2 years of age and is characterized by massive enlargement of the cervical and/or intrathoracic part of the thymus. Concomitant involvement of the bone marrow and regional lymph nodes is common. Jugular vein engorgement and marked brisket edema extending to the sub-mandibular region are typical clinical findings. Moderate bloat resulting from inability to eructate because of compression of the esophagus may occur (Fig. 11-10). The thymic mass may or may not be palpable depending on what part of thymus is affected. This form is more common in beef than in dairy cattle. An atypical lymphosarcoma in a mature cow negative for BLV and similar to the thymic form has been reported. Metastatic thymic lymphosarcoma in a calf has been recorded, including a case with metastases causing spinal cord compression. A large number of cases of thymic lymphosarcoma occurred in calves in five regions in France over a period of 5 months. Most of the calves had been sired by the same bull, which suggests that the disease had an inherited basis.

**Cutaneous Lymphoma**
Cutaneous lymphoma is the most common in cattle less than 3 years of age. It is rare and manifested by cutaneous plaques (1 to 30 cm diameter) appearing on the neck, back, croup, and thighs (Fig. 11-11). The plaques become covered with a thick, gray-white scab, and the hair is shed; then the center becomes depressed, and the nodule commences to shrink. The surface of some plaques may become ulcerated and have a serosanguineous exudate. Some of the lesions have a cauliflower-like appearance, appear black, and are ulcerated and foul-smelling. After a period of weeks or months, hair
 grows again, and the nodules disappear, as
does the enlargement of the peripheral
lymph nodes. Spontaneous regression of
bovine cutaneous leukemia has been recorded.
Relapse may occur in 1 to 2 years with reap-
pearance of cutaneous lesions and signs of
involvement of internal organs, as in the
enzootic form of the disease. In one series of
10 heifers, all animals had lymphadenopathy.
Some had leukocytosis, and some had lymph-
phocytosis. The body condition may vary
from normal to thin and underdeveloped.
Some affected animals may have a fever.

Cutaneous T-cell lymphoma in two Frie-
sian cows in the Azores has been reported.
The lesions consisted of raised pink plaques,
with no pruritus or signs of associated pain,
which were extensively distributed over both
lateral and ventral body regions. Immunocy-
chemistry found the tumor cells positive
for CD3, confirming the T-cell origin of the
cells, which involved both skin and regional
lymph nodes.

**Clinical Pathology**

A tentative diagnosis can be made based on
the clinical presentation and anamnesis (age)
of the patient. A definitive postmortem diag-
nosis requires histologic examination of a
biopsy specimen as well as ruling out EBL by
conducting BLV serology or PCR. A needle
aspirate of an enlarged peripheral lymph
node may provide a rapid and inexpensive
diagnosis. Fine-needle aspirates of the
enlarged thymus when accessible or a biopsy
of an intracutaneous nodule present alterna-
tive diagnostic approaches. BLV serology or
virus isolation is required because lympho-
sarcoma in SBL cannot be differentiated
morphologically from EBL. An increased
lymphocyte count in blood with a large
number of atypical lymphocytes is suggestive
of a leukemic form of SBL.

Ultrasoundography of the mass in the
thoracic inlet of cattle with thymic

**Necropsy Findings**

Sporadic bovine lymphomas are generally
seen in younger cattle compared with cattle
with EBL. The thymic form is characterized
at necropsy by large cranial thoracic and
lower cervical masses in yearlings of the beef
breeds. Tumor masses may extend as far cra-
nially as the mandible and also to the heart
and lungs. Histologically, the masses are
composed of sheets of lymphocytes with a
diffuse architecture and minor stroma typical
of thymic lymphomas. Tumor cells are of the
high-grade, small uncleaved type. Immuno-
histochemical staining of formalin-fixed,
paraffin-embedded tissue sections of tumors
can be used to confirm that neoplastic lym-
phocytes are of thymic origin.

The juvenile type is seen in calves up to
6 months of age and may be present at birth.

The skin type occurs in cattle 1 to 3
years of age and is characterized by plaque-
like, round, raised skin lesions in different
parts of the body. The plaques are of varying
sizes, and some will be ulcerated or alopec-
ic. Although initially cutaneous, the lesions
usually spread to internal organs in advanced
cases. Such visceral lesions are grossly indis-
stinguishable from those of enzootic bovine
lymphoma. Microscopically, the skin lesions
are dermotropic and characteristically result
in dense infiltrations of tumor cells in the
papillary dermis and focal invasion of the
epidermis (Pautrier’s microabscess). The
cells are postulated to be of T-cell origin.1–3

**Differential Diagnosis**

Enzootic bovine leukemia (EBL)—can only be
ruled out by means of bovine leukemia
virus (BLV) serology or virus/provirus
polymerase chain reaction (PCR). Patients
with sporadic bovine leukemia (SBL) by
definition must be serologically and
virologically negative for BLV.

Tuberculosis—can be differentiated by the
Tuberculin test.

Right-sided heart failure (for thymic
lymphosarcoma)—with thymic
lymphosarcoma edema is more local at the
height of the thoracic inlet. In contrast to
right-sided heart failure, there is neither
distension of the udder vein nor liver
congestion.

Hematoma from trauma of jugular vein—may
be differentiated from thymic
lymphosarcoma by needle aspirate.

Ringworm (for early stages of cutaneous form
of SBL)

Dermatophilosis caused by Dermatophilus
congolensis (for early stages of cutaneous
form of SBL)

Skin tuberculosis (for cutaneous form of SBL)

**Treatment**

There is no treatment.

**Inherited Bleeding Disorders**

**Hemophilia**

Hemophilia A (deficiency of factor VIII, or classic hemophilia) occurs in Thoroughbred, Standardbred, Arab, and Quarter horses, causing persistent bleeding after injury or surgery, or spontaneously. This bleeding can be manifested by the sudden appearance of swellings over joints or the upper cervical region, causing dyspnea, or into joints or body cavities, causing acute hemorrhagic anemia, and blood can be aspirated from them. The platelet-dependent bleeding time is normal, but the fibrin-dependent bleeding time is markedly prolonged. The disease is genetically transmitted as a sex-linked recessive trait, appearing clinically only in males.

Hemophilia A occurs in male Japanese Brown cattle, in which it is evident as a bleeding tendency, sometimes resulting death of the animal. Cases had severely reduced factor VIII activity. Factor VIII activity is reduced in the dams of affected male cattle but does not result in excessive bleeding. The disease is caused by a mutation in the gene for factor VIII, which is X-linked. The nucleotide substitution is a T to A, resulting in an amino acid substitution of leucine to histidine (p.Leu2153His) in a highly conserved residue in the C1 domain of factor VIII.

von Willebrand’s disease has been identified in a Quarter horse that experienced bleeding episodes and a low blood level of vWF after a normal platelet count and negative coagulation screening tests. See “Inherited and congenital bleeding disorders” of this chapter.

**Bovine Factor XI Deficiency**

Factor XI (partial thromboplastin antecedent) is involved in coagulation, but animals affected by a deficiency of it can be clinically normal even though their whole-blood clotting time is very prolonged. The disease is best described in Holstein cattle and might be limited to this breed and to Japanese Black cattle. Others may have a severe bleeding tendency, but the frequency of hemorrhagic episodes with factor XI deficiency is very low. Heterozygotes may have serious ones, especially neonates, which may die at birth. Homozygotes may have a severe bleeding tendency in the presence of the conventional coagulation factors. The deficiency is of the order of less than 1% of normal levels of 63% to 150%. The activated partial thromboplastin time is markedly prolonged.

**Inherited Thrombopathia**

Thrombopathia (thrombocytopathy) is a rare autosomal-recessive genetic form of hemophilia caused by a missense mutation that produces platelets with abnormal fibrinogen receptor exposure and impaired dense granule release, resulting in bleeding tendencies primarily of mucosal surfaces. It causes uncontrolled bleeding in Simmental cattle. The disease in Simmental cattle is caused by a nucleotide change (c.701 T>C) that results in the substitution of a proline for a leucine within structurally conserved region 2 (SCR2) of the catalytic domain of calcium diacylglycerol guanine nucleotide exchange factor I (CalDAG-GEFI). This change is likely responsible for the thrombopathic phenotype observed in Simmental cattle.

Affected animals are homozygous. Collected blood undergoes good clot retraction, but platelet aggregation in response to adenosine diphosphate and collagen in a whole-blood aggregation system is badly impaired. Clinical findings include epistaxis, hematuria, the sudden development of subcutaneous swellings, hemorrhagic anemia as a result of intestinal bleeding, or bleeding after external lacerations or surgery.

**Glanzmann’s Thrombasthenia in Horses**

In Glanzmann’s thrombasthenia, a disorder of platelet function recognized in several breeds, including Peruvian Paso, Oldenbury, and Quarter horses, results in prolonged bleeding time. The abnormality is in platelet fibrinogen receptor and is likely caused by a 10-base-pair deletion causing a premature stop codon or a mutation in exon 2 of the gene encoding glycoprotein IIb.

**Afibrinogenemia (Related Diseases Are Hypofibrinogenemia and Dysfibrinogenemia)**

Afibrinogenemia is a rare cause of bleeding diathesis recorded in cattle, sheep, and goats, especially the newborn.

**Familial Polycythemia**

Familial polycythemia, an inherited defect, has been observed only in Jersey cattle and Japanese Black cattle. Hematologically there is marked elevation of erythrocyte count, hemoglobin concentration, and packed cell volume. The disease in Jersey cattle appears to be a primary polycythemia inherited as a simple autosomal-recessive trait.

**Reference**

The major histologic changes are hepato-cellular siderosis and periportal bridging, along with perivascular fibrosis. Heavy deposits of iron in the liver and deposits of hemosiderin are visible in liver tissue obtained by biopsy. Hepatic iron concentrations in clinically affected cattle range from 1500 to 10500 wet weight (reference range for cattle = <3 00g/g). Ultrastucturally, the heaviest intrahepatic deposition is in the hepatocyte. Iron in bone is associated with osteopenia.

INHERITED ANEMIAS

Inherited Dyserthropoiesis and Dyskeratosis (Bovine Congenital Anemia, Dyskeratosis, and Progressive Alopecia)

Inherited dyserthropoiesis and dyskeratosis occurs in 1- to 16-month-old calves in some Poll Hereford families in the United States, Canada, and Australia. 1 It is thought to be inherited as a simple autosomal-recessive character. Clinical signs commence at about 2 months of age and include skin lesions that appear on the face and neck, especially around the muzzle and along the edges of the ears, then extend in the midline down the back, then down the sides and onto the limbs; the long hairs on the tail tip are shed. The hyperkeratotic muzzle accumulates dust. The skin lesions comprise alopecia, with surviving hairs wiry, kinked, or tightly curled; accumulations of sebum; and hyperkeratosis and marked wrinkling. The alopecia and hyperkeratotic dermatitis extend, and the calves do not thrive, becoming small in stature, intolerant of exercise, susceptible to heat stress, and eventually pining away until they die or are euthanized. Histologically the skin is affected by dyskeratosis, hyperkeratosis, and orthokeratosis, and there are morphologic abnormalities of the nucleus in erythroid precursors; anemia results from ineffective erythropoiesis. There is a persistent, nonregenerative anemia as a result of a failure of maturation of erythrocytes; the blood contains many nucleated erythrocytes, and bone-marrow aspirates contain increased numbers of erythroid precursors. 2

Inherited Glucose-6-Phosphate Dehydrogenase Enzyme Deficiency

A single case inherited glucose-6-phosphate dehydrogenase enzyme deficiency, a persistent hemolytic disease, has been recorded in a yearling American Saddlebred colt. The disease in humans is well recognized as an inherited defect. A similar clinical disease is recorded in Murray Grey calves in Australia. Signs are observed first when affected calves are 3 to 8 weeks old. Both sexes are affected. Signs include poor growth, exercise intolerance, progressive weakness, severe jaundice, and death. There is a severe regenerative anemia, hemoglobin levels of 25 to 30 g/L, and an absolute nucleated erythrocyte count of 9 to 18 × 10 L. Necropsy lesions include jaundice; a grossly enlarged and, in some cases, misshapen and greenish liver; and brown urine. Histologic lesions are suggestive of a persistent intravascular hemolysis. A series of cases of hemolytic anemia of undetermined origin, recorded in a familial pattern in horses, was characterized by high blood levels of methemoglobin.

REFERENCE

PORPHYRIAS

Porphyria is not common in farm animals. 1 The congenital disease in cattle occurs in breeds including longhorns, Holstein, Limousin, and Blonde d’Aquitaine and manifests in calves as ill-thrift and pink-discolored teeth. 2 Affected calves often have photosensitization, but serum activity of liver-derived enzymes (such as GGT or GLDH) and serum concentrations of bilirubin are within the normal range. Postmortem findings include brown discoloration of bone, which fluoresces under ultraviolet light. Plasma porphyrin concentrations might not be increased over levels in healthy calves, whereas urine concentrations of porphyrin, expressed as a ratio to urine creatinine concentration, are increased, as are concentrations of porphyrin in feces. The cause in some cases is a genetic mutation affecting activity of the enzyme uroporphyrinogen III synthase, which mediates the stage of conversion of pyrrole groups to series 3 porphyrins. Excess series 1 porphyrins, physiologically inactive substances, are produced as a result, and there is flooding of the tissues with these coloring and photosensitizing substances. The high tissue levels of porphyrins sensitize the skin to light, and photosensitive dermatitis follows.

CLINICAL FINDINGS

In cattle, the passage of amber to port-wine-colored urine, a pink to brown discoloration of the teeth and bones, and severe photosensitization are characteristic. Additional signs include pallor of the mucosae and retardation of growth.

Affected pigs are usually normal, and photosensitivity does not occur, but the disease can be recognized by the red–brown discoloration of the bones and teeth, which is present even in the newborn.

CLINICAL PATHOLOGY

In porphyria the urine is amber to port wine in color when voided because of the high content of porphyrins. The urine of affected cattle may contain 500 to 1000 µg/dL of uroporphyrins and 356 to 1530 µg/dL of coproporphyrins. The urine of normal cattle contains 1.84 µg/dL of coproporphyrins and no significant quantity of uroporphyrins. The color of the urine darkens to brown on exposure to light. Spectroscopic examination is necessary to identify the pigment as porphyrin. Erythrocyte survival time is reduced considerably. Macrocytic, normochromic anemia occurs, and its severity appears to be related to the level of uroporphyrins in the erythrocytes, and there is evidence of a hemolytic anemia. Cattle with the highest
erythrocyte uroporphyrin levels are also the most sensitive to sunlight.

**NECROPSY FINDINGS**

In porphyric animals the teeth and bones are stained brown or reddish purple, with the pigment occurring chiefly in the dentine in teeth and often in concentric layers in the bones. Affected bones and teeth show a red fluorescence under illumination with ultraviolet light. The histologic findings are unique to this disease.

**DIFFERENTIAL DIAGNOSIS**

Confirmation of the diagnosis depends on identification of greatly increased levels of porphyrins in the blood and urine. Presumed affected cattle and pigs can be detected at birth by the discoloration of the teeth. Breeding trials are necessary to detect heterozygous, normal carrier animals.

**Differential diagnosis list:**

Other causes of photosensitive dermatitis

**TREATMENT**

Nonspecific treatment for photosensitization may be necessary. Affected cattle should be reared indoors.

**CONTROL**

Elimination of affected carrier animals from the breeding program is the only measure available. Periodic examination of the urine and feces for excessive quantities of coproporphyrin is carried out on bulls used for artificial insemination in breeds in which the disease occurs.

**INHERITED ERYTHROCYTIC PHOTOPORPHYRIA**

Inherited erythrocytic protoporphyria is an autosomal-recessive disease that occurs in Limousin, Holstein and Blonde d’Aquitaine cattle. It is similar to the same disease in humans and to porphyria but is milder. There is deficient activity of the enzyme ferrochelatase or uroporphyrinogen III synthase, resulting in excessive photosensitizing protoporphyrin accumulation, with high levels appearing in the erythrocytes and feces. The total amount of the enzyme is normal, but up to 96% of it is nonfunctional.

Protoporphyrin is clinically differentiated from porphyria by the absence of anemia and discoloration of the teeth and urine. The major clinical abnormality is photosensitive dermatitis affecting particularly the tips of the ears and the edges of the nostrils. There may be intense pruritus and exudative dermatitis involving the head and upper aspect of the thorax. The hematocrit values are within normal ranges, the teeth are normochromic, and there is no fluorescence of urine; however, whole blood fluoresces under ultraviolet light. Protoporphyrin binds to proteins that are not excreted by the kidney, and thus protoporphyrin will not be detected in the urine. In a Limousin calf, the disease was characterized by ataxia and intermittent seizures. At necropsy there is hepatic portal fibrosis, bile ductule hyperplasia, and swelling of parenchyma cells. Phagocytic cells in the dermis contain large heterogeneous lysosomes. Histologically, in some cases, the earliest lesions are moderate to severe acanthosis, hyperkeratosis, and parakeratosis with dermal angiofibroplasia. There may be intercellular edema and intraepithelial vesicles and pustules. Elimination of affected carrier animals from the breeding program is the only control measure available.

INHERITED DEFICIENCY OF LYMPHOCYTE MATURATION (LETHAL TRAIT A46, PARAKERATOSIS, ADEMA DISEASE)

Inherited deficiency of lymphocyte maturation is recorded in Black Pied Danish cattle but probably occurs in a number of European breeds of cattle, including Friesian-type cattle, and in beef Shorthorn calves in the United States. It is a defect of lymphocyte maturation and is inherited as an autosomal-recessive character.

Calves are normal at birth, and signs appear at 4 to 8 weeks of age; untreated animals die at about 4 months of age. There is exanthema and loss of hair, especially on the legs; parakeratosis in the form of scales or thick crusts around the mouth and eyes, under the jaw, and on the neck and legs; and a very poor growth rate. Lymphocyte numbers and function are reduced when the patient is in a zinc-deficient state, and antibody responses are suppressed.

At necropsy the characteristic skin lesion is acanthosis and hyperkeratosis, and there is atrophy of the thymus, spleen, lymph nodes, and gut-associated lymphoid tissue.

There is a significant response to oral treatment with zinc (0.5 g zinc oxide/day), and an apparently complete recovery can be achieved in a few weeks if treatment is continued. The disease reappears if treatment is stopped. The dose rate needs to be increased as body weight increases. It is thought that the disease is an inherited excessive requirement for zinc and that the thymic hypoplasia is a result of the dietary deficiency. Absorption studies with radioactive zinc have shown that there is impaired absorption of the element.

FELL PONY AND DALE PONY FOAL IMMUNODEFICIENCY SYNDROME

Fell pony immunodeficiency syndrome is a familial disease of Fell ponies characterized by immunodeficiency caused by B-cell lymphopenia, anemia, opportunistic infection, and death at 2 to 3 months of age. The same disease occurs in Dale pony foals.

ETIOLOGY

The disease is caused by a mutation on chromosome (ECA) 26 associated with two single-nucleotide polymorphisms (SNPs). The mutation is in the sodium/myo-inositol cotransporter gene (SLC5A3), which causes a P446L substitution in the protein. This gene plays a crucial role in the regulatory response to osmotic stress that is essential in many tissues, including lymphoid tissues, and during early embryonic development. The amino acid substitution alters the function of SLC5A3, leading to erythropoiesis failure and compromise of the immune system.

EPIDEMIOLOGY

The disease is restricted to Fell and Dale pony foals less than 3 months of age. Population screening identified the causative mutation in colored ponies and Fell and Dale ponies, but not in other pony breeds or in horses.

The disease is reported in this breed in the United Kingdom, the United States (which has a total population of Fell ponies of < 200), the Czech Republic, the Netherlands, and Germany. The frequency of the disease is not reported. The case-fatality rate is 100%.

PATHOGENESIS

There is immunodeficiency associated with low concentrations of immunoglobulins in serum and B lymphocytes in blood. T lymphocytes are present in normal concentration and respond appropriately to in vitro proliferation tests. Death is coincident with declines in concentrations of antibodies derived from colostrum. Immunodeficiency results in development of opportunistic infections, including glossitis, adenoviral pneumonia, and cryptosporidial diarrhea. Aplastic anemia develops and can contribute to death. Anemia is associated with aplasia of red cell series in bone marrow and is not a result of hemolysis or blood loss.

Failure of erythropoiesis and development of B-cell lymphopenia, and consequent hypogammaglobulinemia, occurs after birth; foals are not anemic and do not have depleted B cells at birth, and fetal red cell and B-cell hematopoiesis appears to be normal.

CLINICAL FINDINGS

Affected foals are lethargic at birth, are unable to keep up with the herd, and do not establish a strong bond with the dam. Foals develop ill-thrift, exercise intolerance, and diarrhea beginning at approximately 3 weeks of age. Clinical signs are attributable to anemia and opportunistic infections. At the time that foals develop other clinical abnormalities they are pyrexic and tachypneic. Most foals have bilateral mucopurulent nasal discharge and abnormal lung sounds consistent with pneumonia. The tongue is covered by a pseudomembranous, hyperkeratotic membrane suggestive of Candida spp. infection. Foals develop diarrhea and progressive illness, with death occurring by 3 to 4 months of age even in cases treated aggressively.

CLINICAL PATHOLOGY

The underlying hematology and serum biochemistry are influenced by the opportunistic infections that develop in all foals affected with Fell pony syndrome. Abnormalities consistently associated with the disease include anemia, B-cell lymphopenia, and variable to low concentrations of immunoglobulins in serum. It is important to note that these abnormalities are not present at birth and develop during the first weeks to months of life.

Necropsy findings

White blood cell concentration in affected foals is usually below or in the lower range of the reference range of normal, age-matched foals and is attributable to a B-cell lymphopenia. Concentrations of CD4+ and CD8+ cells in blood are normal in affected foals. The concentration of neutrophils is often elevated in affected foals.

Concentrations of immunoglobulins (IgGa, IgGb, IgG[T], and IgM) in serum are variable and depend on the amount of immunoglobulin ingested in colostrum and the age of the foal. Affected foals are unable to produce immunoglobulins and therefore have declining concentrations of immunoglobulins with age. Serum concentrations of IgM and IgA become undetectable before IgG does—a consequence of the shorter half-life of the former immunoglobulins in foals.

Measurement of low to undetectable concentrations of IgM at greater than 4 weeks of age provides a reasonable means of diagnosing the disease.

Differential Diagnosis

The differential diagnosis of immunodeficiency in foals is provided in Table 11-7.

Confirmation of Diagnosis

The disease is confirmed by presence of characteristic lesions at necropsy. Antemortem diagnosis is confounded by the presence of opportunistic infections but should be suspected in any Fell pony foal with anemia, ill-thrift, and declining serum concentrations of immunoglobulin. Affected foals have two copies of the mutated gene, whereas
unaffected carriers have one copy (are heterozygotes).4

TREATMENT
There is no effective treatment. Supportive treatment consisting of transfusions of blood or plasma and administration of antibiotics does not affect the eventual outcome of the disease.

CONTROL
The principles of control are as follows:4-6
- The genetic test can be used to unambiguously and quickly determine whether a foal has this immunodeficiency syndrome. Affected foals will have two copies of the mutation to the SLC5A3 gene.
- The genetic test can be used to detect carriers of the disease gene. These individuals are normal and healthy but have the potential to produce affected offspring and normal offspring. These horses will have one copy of the SLC5A3 mutation.
- The frequency of the disease gene will decrease over time without adversely affecting the extent of genetic variation in the population if carriers are not mated with carriers, allowing the eventual elimination of the disease.

Use of these control measures appears to have resulted in a reduction in the incidence of the disease in Fell and Dale pony foals.2

REFERENCES

INHERITED DEFICIENCY OF IMMUNOGLOBULIN SYNTHESIS
An inherited complete deficiency of IgG2 occurs in Red Danish cattle at a low level of incidence. Affected animals are unusually susceptible to severe infections, including gangrenous mastitis and pneumonia.

INHERITED COMBINED IMMUNODEFICIENCY IN FOALS OF ARABIAN BREEDING

Epidemiology
Familial pattern of occurrence with autosomal-recessive inheritance. Approximately 8% of Arabian horses are heterozygous for the mutation (carriers). Random mating results in approximately 1 in 600 foals being affected, but not all matings are random, and the incidence of the disease is less than this number.

Clinical findings
Foals normal at birth but succumb to systemic infection soon after birth and die before 3 months of age. Death from acute sepsis or recurrent or chronic continuous infection, usually of respiratory tract. Poor response to normally effective antibiotic therapy.

Clinical pathology
Lymphopenia, hypogammaglobulinemia. Polymerase chain reaction (PCR) test detects animals heterozygous (carriers, parents of affected foals) or homozygous (affected foals) for the mutated gene.

Necropsy findings
Thymic, lymph node, and splenic hypoplasia and a marked reduction in the numbers of splenic and lymph node lymphocytes.

Diagnostic confirmation. PCR detection of mutated gene (homozygous in affected foals). Lymphopenia and agammaglobulinemia in a foal of Arabian breeding.

Treatment
None.

Control
Genetic testing and eventual elimination of the mutated gene by not breeding carrier animals. The disease can be prevented by not breeding a carrier animal to another carrier. Testing results in a decline in frequency of the abnormal gene in the population of horses.

ETIOLOGY
The fundamental defect in inherited combined immunodeficiency (CID) is a 5-base-pair deletion in the specific gene that codes for DNA-dependent protein kinase. The gene is located on chromosome ECA9. This mutation causes a lack of activity of the catalytic subunit of DNA-dependent protein kinase. The deficiency of protein kinase activity, which is absolute in affected foals, results in the inability to join DNA strands that have been broken as part of the normal process of creation of V (variable) regions of T-cell and B-cell antigen receptors on lymphocytes. Without these receptors the lymphocytes are unable to respond to antigens, and thus the foal is not capable of mounting adaptive, either cellular or humoral (antibody), immune responses.

EPIDEMIOLOGY
The immunodeficiency is inherited as an autosomal-recessive defect. The disease occurs in purebred and part-Arabian horses. It has also occurred in an Appaloosa foal that had an Arab stallion in the fifth generation of its mother's pedigree. In one survey of Arabian foals in the United States, the prevalence rate of affected foals was 2.3% of 257 foals of Arabian breeding, and 25.7% of the parents of affected foals were estimated to be carriers of the genetic defect. However, this likely represents an overestimation of the incidence of the disease and prevalence of the mutation in the population of Arabian horses because of selective testing. The frequency of carriers of the mutation for severe combined immunodeficiency is approximately 8%, with an estimated 0.2% (1 in 600) of foals of random matings between Arabian horses affected with the disease, based on a survey of 250 horses. Approximately 17% of Arabian horses were heterozygous for the mutation, and 0.3% of foals were homozygous, among the more than 6000 horses tested by a commercial laboratory. The frequency of occurrence of the allele (heterozygous) in Arabian horses in South Africa declined from 6.4% of those tested in 2004/2005, the first year that the test was offered, to 3.4% in 2009/2010, indicating the effectiveness of a program of education of owners and availability of testing for carriers. The importance of the effect of even a small number of heterozygous stallions on frequency of the disease, or of the abnormal allele, is indicated by data from Morocco that identified the source of the mutant gene as three affected stallions.7

Affected foals usually appear normal at birth but are highly susceptible to infections from 2 to 65 days after birth and usually die of one or more infections by 3 months of age. The sires and dams of affected foals are clinically normal and have normal lymphocyte counts and serum immunoglobulin concentrations.

Severe combined immunodeficiency occurred in a Caspian filly. Clinicopathologic testing confirmed the nature of the disease and immunodeficiency, but genomic testing to identify the underlying genetic cause was not performed.8

A similar naturally occurring disease is reported in pigs.4

PATHOGENESIS
Affected foals are born with a combined immunodeficiency associated with a deficiency in both B lymphocytes (which produce immunoglobulins) and T lymphocytes (which provide cellular immunity). There is a marked lymphopenia and failure of immunoglobulin (Ig) synthesis and absence of delayed hypersensitivity of skin responses. Foals that receive immunoglobulins from the dam's colostrum derive passive immunity and can survive for as long as 4 months. Foals that do not receive colostrum die much earlier. The cause of death is infectious disease.

Affected foals are susceptible to infections of all kinds, but mostly of the respiratory tract. Adenoviral pneumonia is considered to be the most common secondary complication, probably because adenovirus infection
is so widespread in the horse population. Affected foals may also die of hepatitis, enteritis, or infection of other organs without pulmonary involvement. Although adenoviral pneumonia is the most common complication, infections with bacteria and *Pneumocystis carinii* also occur. *Cryptosporidium* spp. have also been recorded in a number of foals with diarrhea, which is also a common complication.

**CLINICAL FINDINGS**

Affected foals usually become ill from 10 to 35 days of age. Commonly there is a history suggesting a mild disease of the respiratory tract, especially the appearance of a bilateral nasal discharge, which often becomes sufficiently thick to interfere with sucking. The foal is unthrifty, is lethargic, and tires easily but still nurses and eats solid feed. A deep dry cough and a serous to mucopurulent ocular and nasal discharge are common when pneumonia is present. There is moderate fever (39.5°C; 103°F) and an increase in the heart and respiratory rates. The depth of respirations is increased and a double expiratory effort is common. On auscultation, loud bronchial tones and moist and dry crackles are common over the anterior ventral aspects of both lungs. Chronic diarrhea is present in some foals, and alopecia and dermatitis, commonly associated with an infection by *Dermatophilus congolensis*, also occur. An important clinical feature is that affected foals do not respond favorably to treatment with antimicrobial agents. The course of the illness will vary from a few days to a few weeks and probably depends on the degree of immunodeficiency and the nature of the infection. Most affected foals become progressively worse over a period of 2 to 4 weeks, and death by 3 months of age is the usual outcome.

**CLINICAL PATHOLOGY**

Lymphopenia is a constant finding, with counts often less than 1000/mL, and there is a concurrent hypogammaglobulinemia in foals that have not received colostrum. There is no IgM in precolostral serum of the foal. Following ingestion of colostrum, all subclasses of immunoglobulin will be present, but in affected foals the level of IgM will steadily decrease weekly until at about 36 days when IgM is detectable. The lack of IgM is because of lack of synthesis and the shorter half-life of this isotype of immunoglobulin in foals—serum IgG concentrations decline more slowly. Until the development of the PCR test for detection of homozygous foals and confirmation of the disease, the measurement of serum Ig concentrations was considered essential for a definitive diagnosis. Additional tests include enumeration of B-lymphocyte and T-lymphocyte responses to phytohaemagglutinin and other tests of lymphocytic immunologic function, but these tests are no longer required for diagnostic confirmation of the disease.

**NECROPSY FINDINGS**

The lymph nodes are small, and splenic follicles are not visible. A viral interstitial pneumonia and a secondary bacterial bronchopneumonia are common. The thymus gland is usually hypoplastic. Histologically the lymph nodes and spleen are depleted of lymphocytes, and germinal centers are absent. In some foals there are foci of necrosis of the intestinal epithelium but with minimal infiltration of inflammatory cells. Inclusion bodies of adenovirus may be present in the cells of several different body systems. Additional histologic findings include a severe adenoviral pancreatitis and adenitis of the salivary glands.

**DIFFERENTIAL DIAGNOSIS**

Diagnostic confirmation in an apparently chronic case of pneumonia in a young foal depends on the identification of the characteristic lymphopenia. The differential diagnosis list includes the following:

- Septicemia and pneumonia of foals, caused by *Rhodococcus equi*
- Agammaglobulinemia or hypogammaglobulinemia resulting from failure of transfer of maternal immunoglobulins from colostrum—in many foal populations as many as 20% of foals are immunodeficient for this reason
- Other immunodeficiencies (Table 11–7)—foals with these deficits are very susceptible to a variety of infectious diseases and are usually chronically ill, most often with respiratory infections. However, because they have partial protection, they survive, and their life span is much longer than that of foals with CID, usually over 1 year and often 18 months. Hematologically the foal is normal unless an infection is in process, but electrophoretic examination usually reveals a marked deficiency of beta globulins. Further tests are needed to identify the exact deficiency. A radioimmunodiffusion assay is used to quantitate serum immunoglobulins—lgA and IgM levels are usually at negligible levels, but IgG levels are discernible, although diminished. An intradermal test by injection of phytohaemagglutinin determines T-lymphocyte status; a normal response is migration of mononuclear cells.
- An isoimmune neonatal leukopenia can cause immune deficiency in foals; antibodies to the sire’s lymphocytes are detectable in the mare’s serum.
- Neonatal septicemias

**TREATMENT**

There is no satisfactory treatment for CID in foals. Hyperimmune serum, whole-blood transfusions, and broad-spectrum antibiotics are all used, but without more than a temporary response. Affected foals may be kept alive by twice-weekly injections of hyperimmune serum and a constant antibiotic cover. Immunotherapy using a transplant of bone marrow and a fetal thymus transplant has been attempted without success. Corticosteroids are contraindicated.

**CONTROL**

Horses heterozygous for the mutation can be detected using a commercial PCR assay. These horses have normal serum immunoglobulin concentrations and lymphocyte counts. Detection of heterozygous animals, which is required by some national breed organizations, is useful for several reasons. First, it should, ideally, permit elimination of the disease from the population by breeding of only homozygous normal animals. However, this approach has not met with success because of the financial and emotional value of some heterozygous animals. Second, identification of the status of an animal permits controlled breeding such that the risk of producing homozygous affected foals is eliminated. This is achieved by mating only pairs of homozygous normal animals, in which case none of the offspring will carry the mutated gene, or by mating a heterozygous animal with a homozygous normal animal. In this instance 1 in 4 of the progeny will carry the mutated gene, but none of the progeny will be homozygous for the mutated gene and therefore afflicted with the disease. This second approach, if applied consistently, should almost eliminate the disease. The effectiveness of a program of education of owners and availability of testing for carriers is demonstrated by the observation that frequency of occurrence of the allele (heterozygous) in Arabian horses in South Africa declined from 6.4% of those tested in 2004/2005, the first year that the test was offered, to 3.4% in 2009/2010.1

**Diseases of Unknown Etiology**

**POSTPARTUMRIENT HEMOGLOBINURIA IN CATTLE**

**SYNOPSIS**

**Etiology** Uncertain. Dietary phosphorous deficiency, feeding cruciferous plants or sugar beet byproducts, high dietary molybdenum content, and copper deficiency have been incriminated.

**Epidemiology** Sporadic disease predominantly observed in older
high-producing dairy cows, 2 to 4 weeks after calving.

**Signs** Hemoglobinuria, inappetence, depression, reduced milk production, pallor of mucous membranes, tachycardia, dyspnea, icterus in later stages. Death may occur. Recovery takes several weeks.

**Clinical pathology** Low packed cell volume (PCV), hemoglobinemia, hemoglobinuric, regenerative anemia; frequently associated with hypophosphatemia.

**Necropsy findings** Icterus, hepatomegaly, red urine in bladder.

**Diagnostic confirmation** Low PCV, hemoglobinuria.

**Treatment** Whole-blood transfusion. Phosphate salts intravenously and orally.

**Control** Ensure adequate intake of dietary phosphorus and copper.

**ETIOLOGY**

The etiology of postparturient hemoglobinuria (PPH), a condition that is characterized by peracute and severe intravascular hemolysis occurring in older early lactating dairy cows, is still unclear. Phosphorus deficiency has been incriminated as a primary cause because hypophosphatemia is observed in many, but certainly not all, affected animals. Phosphorus deficiency in early lactation can be the result of high losses of phosphorus through the mammary gland, inadequate dietary phosphorus supply, or excessive dietary molybdenum content that hampers intestinal phosphate absorption.1,2 Doubts about the role of phosphorus in the etiology of PPH have been raised because of the rare occurrence of PPH, whereas marked hypophosphatemia is common even in healthy periparturient dairy cows.2,3,4 Although most studies experimentally inducing phosphorus depletion in cattle failed to reproduce clinical signs consistent with PPH, experimental induction of PPH is documented in only one single case after feeding a phosphorus deficient ration for over 30 months. Therapeutic parenteral and oral supplementation of phosphate salts yielded variable results.

The feeding of cruciferous plants and plants containing potential hemolysins such as saponins (e.g., alfalfa or sugar beet byproducts) has been associated with the disease, but many cases occur unassociated with such diets, and thus their role as a cause remains uncertain. It has been proposed that ingested hemolytic agents, some of them identified, for example, in rape, some of them not, cause erythrocyte lysis in some circumstances.

In New Zealand, one form of the disease may be related to copper- and selenium-deficient diets.

**EPIDEMIOLOGY**

The occurrence of PPH is rare, and generally only individual or few animals of a herd are affected. The case-fatality rate may be as high as 50%. Only adult cows develop the typical hemolytic syndrome, usually in the period 2 to 4 weeks after calving. High-producing dairy cows in their third to sixth lactations are most commonly affected. The disease does not commonly occur in beef cattle. Phosphorus-deficient soils, drought conditions, or rations based on sugar beet byproducts or clover are considered predisposing causes. In areas of severe phosphorus deficiency, the disease may occur at pasture, but in Europe and North America, it is more common during prolonged periods of housing.

In New Zealand, two distinct forms have been observed. In one situation, young cattle at about 2 years of age are affected with subclinical anemia of the Heinz-body type, and hypophosphatemia is not a feature. In the other, the North American type of the disease is also seen, in which older, mature, high-producing cows are affected, and hypophosphatemia is common in the affected animals and in healthy herdmates. In New Zealand, copper deficiency is considered an important etiologic factor because copper supplementation reduces the incidence of the disease in herds in marginally copper-deficient areas. The particular circumstances in which the erythrocytes of a cow become more sensitive than normal to these hemolysins include hypophosphatemia and hypocupremia, and in New Zealand possibly also selenium deficiency. However, no abnormality in copper status is present in most cases of PPH in other countries. Low levels of copper in the blood and liver of cows with the Heinz-body anemia and in the pasture grazed are also observed. The low copper status appears to be related to the application of molybdenum and lime.

The ingestion of cold water or exposure to extremely cold weather may precipitate an episode of hemoglobinuria. A similar condition accompanied by hypophosphatemia has been observed in late pregnancy in Egyptian buffalo and in the postparturient period in Indian buffalo.

**PATHOGENESIS**

There is an association with hypophosphatemia and a low dietary intake of phosphorus, and it is presumed that the drain of phosphorus at the onset of lactation causes further depletion of phosphorus reserves. The dependence of mammalian red blood cells on glucose metabolism for the main source of energy for viable function and structure makes them highly vulnerable to factors inhibitory to the glycolytic pathways. Hypophosphatemia results in a decrease in red blood cell glycolysis and adenosine triphosphate (ATP) synthesis. A marked decline of the intracellular ATP concentration in red blood cells results in altered function and structure, a loss of the normal deformability of these cells, and an increase in osmotic fragility and hemolysis. The changes in the red blood cells are irreversible, and the life span of the cells is probably diminished because they are unable to regain their previous structure and function. Copper and selenium may be important because they are commonly deficient in feedstuffs. Both copper and selenium may also provide some protection against the effects of orally acquired hemolytic agents in cruciferous plants. The clinical findings are those of acute hemolytic anemia; in fatal cases, death results from anemic anoxia.

**CLINICAL FINDINGS**

Hemoglobinuria, inappetence, and weakness develop suddenly, and there is a severe depression of the milk yield, although in some less acute cases, the cow continues to eat and milk normally for 24 hours after discoloration of the urine is evident. Dehydration develops quickly, the mucous membranes are pale, and the cardiac impulse and jugular pulse are much augmented. A moderate temperature rise (40°C; 103.5°F) often occurs. The feaces are usually dry and firm. Dyspnea may be obvious, and tachycardia is common. Jaundice may be apparent in the late stages. The course of the acute disease extends from 3 to 5 days; the cow becomes weak and staggery, then finally recumbent. Death may occur within a few days. In nonfatal cases, convalescence requires about 3 weeks, and recovering animals often show pica. Ketosis commonly occurs concomitantly as a result of anorexia during the early postparturient period.

**CLINICAL PATHOLOGY**

The urine is dark-reddish-brown to black in color and usually moderately turbid. No red cells are present in the urine. Blood plasma is hemolytic, and the packed cell volume,
erythrocyte counts, and hemoglobin levels are also greatly reduced. Heinz bodies may be present in erythrocytes in the New Zealand disease. Marked hypophosphatemia is a common result of the serum chemical analysis. A low copper status of the blood and liver of affected cows and the pasture grazed has been reported in some cases. In advanced stages serum hyperbilirubinemia and icterus resulting from hemoglobin breakdown are commonly seen.

NECROPSY FINDINGS
The blood is thin, and icterus is widespread throughout the body. The liver is swollen, and fatty infiltration and degeneration are evident. Discolored urine is present in the bladder.

TREATMENT
In severe cases of hemolytic anemia, whole-blood transfusion is indicated. A delay of 12 hours often seems to lead to an irreversible state. A minimum of 5 to 6 L of blood to an adult cow is required. This will usually suffice for up to 48 hours, by which time an additional transfusion may be necessary if the cow remains weak and the mucous membranes pale. Following successful blood transfusions, fluid therapy is recommended as both supportive therapy and to minimize the danger of hemoglobinuric nephrosis. The administration of phosphate to acutely ill animals has been proposed, but treatment outcomes are variable. Parenteral phosphate supplementation in the form of 30 g of monosodium dihydrogen phosphate (NaH₂PO₄) dissolved in 300 mL deionized water that is administered intravenously is often recommended. Because the treatment effect of intravenous phosphate salt solutions is very short lived, the combination of this treatment with oral phosphate supplementation of cattle in a copper-deficient area.

NaH₂PO₄ (30 g dissolved in 300 deionized water IV for an adult cow) (R2)
Butafosfan (IM or IV) (R3)
Toldimfos (IM or IV) (R3)
NaH₂PO₄ (250 to 300 g PO for an adult cow q 12-24 hours for 5 days) (R2)

CONTROL
An adequate intake of phosphorus according to the requirements for maintenance and milk production should be ensured, particularly in early lactation. A decrease in the incidence of the disease is reported after copper supplementation of cattle in a copper-deficient area.

MULTISYSTEMIC, EOSINOPHILIC, EPITHELIOTROPIC DISEASE

Multisystemic, eosinophilic, epitheliotropic disease of horses is characterized by eosinophilic infiltrates in a variety of tissues and organs, including the skin, lungs, liver, pancreas, biliary tree, and gastrointestinal tract. Eosinophilic enterocolitis occurs either as part of the multisystemic, eosinophilic, epitheliotropic disease complex or as a lone entity. The lone entity (focal, idiopathic eosinophilic enteritis) is discussed separately (Chapter 7).

Multisystemic, eosinophilic, epitheliotropic disease occurs in adult horses of any age and without apparent breed or sex predisposition, although some reports suggest a predominance of younger horses that are Standardbreds or Quarter horses. The etiology is unknown, but some cases are associated with lymphosarcoma or increased numbers of CD3-positive cells in the lesions, suggesting that the disease in these horses is a result of clonal expansion of a T-lymphocyte population that secretes interleukin-5. The disease is idiopathic in most horses.

Clinical signs are variable and include weight loss in all cases and diarrhea and/or dermatitis in approximately two-thirds of cases. The disease is usually slowly progressive, with most affected horses having signs of the disease for more than 2 months. Affected horses do not usually have a fever. The dermatitis occurs mainly on the face, limbs, and ventral abdomen and is exudative, with alopecia, hyperkeratosis, and lichenification. Lesions of the coronary band and mouth are common. Urticaria occurs in some horses. Possible variations of this disease include eosinophilic pneumonia (distinct from equine multinodular pulmonary fibrosis) and eosinophilic meningoen cephalitis, although these diseases do not have infiltration of eosinophils into a wide range of tissues. The disease can cause pulmonary and hepatic diffuse granulomas, the former resulting in veno-occlusive remodeling and epistaxis.

Hypereosinophilia is not a consistent feature of the disease, and blood leukocyte concentrations are usually within the reference range. Most affected horses have low serum protein and albumin concentrations. There are often elevations in serum activity of gammaglutamyl transpeptidase (GGT) and alkaline phosphatase, consistent with lesions in the biliary tree. This can be useful in differentiating horses with this disease from horses with granulomatous enteritis.

Differential diagnoses include parasitism, both gastrointestinal (cyathostomiasis) and pulmonary (D. arnfieldi), other causes of protein-losing enteropathy, eosinophilic leukemia, and pemphigous foliaceus. Diagnosis is based on demonstration of diffuse eosinophilic and lymphoplasmacytic infiltration of the skin, liver, lungs, biliary tract, and/or gastrointestinal tract. Rectal biopsy can reveal the presence of eosinophilic granulomas, but these must be differentiated from the more common eosinophilic infiltrate secondary to parasitism, and the test is likely not sufficiently specific.

Treatment is usually ineffective, and the prognosis for recovery is very poor. Affected horses should be administered an anthelmintic in case the disease is a result of nematodasis. Administration of corticosteroids (dexamethasone, prednisolone) is the usual treatment but is only transiently effective in most cases. Hydroxyurea, which is used to treat a similar syndrome in people, was only transiently effective in one horse. There are no recognized control measures.

Principles of Respiratory Insufficiency

The principal function of the respiratory system is gas exchange in which oxygen is transferred from the environment to the blood and carbon dioxide is moved in the opposite direction. Other important functions include a role in thermoregulation in most species; in acid-base regulation in concert with the kidney; in functioning as an endocrine organ (e.g., angiotensin-converting enzyme); in the metabolism of metabolically active substances, including eicosanoids and nitric oxide; and in the immune response to inhaled immunogens and pathogens. Capillaries in the lungs of the farm animal species and horses also possess intravascular macrophages, which are important as a reticuloendothelial organ in the processing of antigens—an action achieved by similar cells in the liver of dogs, cats, and humans. Interference with these functions can occur in a number of ways and can have a variety of manifestations that are apparent during disease. The most readily apparent failure of the respiratory system is failure of gas exchange with resultant hypoxemia and hypercapnia. However, failure of other functions of the respiratory system can also result in clinically apparent disease.

Failure of gas exchange, and the resultant hypoxia and hypercapnia, is responsible for most of the clinical signs of respiratory disease and for respiratory failure, the terminal event of fatal cases. Death as a result of respiratory failure is attributable to hypoxia. An understanding of hypoxia, hypercapnia, and respiratory failure is essential to the study of clinical respiratory disease.

DEFINITIONS

A number of terms are used to describe the function of the respiratory tract, or abnormalities that arise because of a variety of diseases. Many of these terms are described in more detail in the text that follows, but a brief definition of each is provided here:

- Hypoxia is a broad term meaning diminished availability of oxygen to tissues.
- Hypoxemia is deficient oxygenation of blood, usually assessed by measurement of blood oxygen tension, or by measurement of blood hemoglobin saturation and hemoglobin concentration, and subsequent calculation of blood oxygen content.
- Hypercapnia is an abnormally high carbon dioxide tension in blood.
- $P_{O_2}$ is the oxygen tension (partial pressure) in arterial blood.
- $P_{O_2}$ is the oxygen partial pressure in alveolar gas.
- $P_{CO_2}$ is the carbon dioxide tension (partial pressure) in arterial blood.
- $P_{CO_2}$ is the carbon dioxide partial pressure in alveolar air.
- $C_{O_2}$ is the arterial oxygen content (milliliters of $O_2$ per 100 mL of blood).
- $P_{O_2}$ is the oxygen tension (partial pressure) in venous blood.
- $P_{CO_2}$ is the carbon dioxide tension in venous blood.
- $C_{O_2}$ is the venous oxygen content (milliliters of $O_2$ per 100 mL of blood).
- Respiratory failure is the inability of an animal to maintain arterial blood oxygenation and carbon dioxide tension within the normal range.

- Dyspnea refers to signs of respiratory distress in animals (in humans it describes the sensation of air hunger, which is a symptom and not a sign).
- Polypnea is an excessively high rate of breathing.
- Tachypnea is an excessively high rate of breathing, with the implication that the breathing is shallow.
- Hyperpnea is an increased minute ventilation.

HYPOXIA

Failure of the tissues to receive an adequate supply of oxygen occurs in a number of ways, and the differences are clinically relevant because they are associated with failure of different organ systems and different diseases, and they have fundamentally different pathophysiologic mechanisms.

Hypoxic (or Hypoxemic) Hypoxia

Hypoxic (or hypoxemic) hypoxia occurs when there is inadequate oxygenation of blood (hypoxemia) and is usually associated with disease of the respiratory tract or other causes of hypoventilation. Situations in which there is inadequate oxygenation of blood in the lungs include hypoventilation, ventilation-perfusion mismatches, diffusion impairment, low inspired oxygen tension, and extrapulmonary right-to-left shunting.

Hypoventilation occurs in animals with depressed consciousness, such as occurs with general anesthesia and heavy sedation, or in newborns, in which the central respiratory drive is suppressed. Airway obstruction
caused by the presence of foreign bodies in the airway, luminal obstruction by masses such as retropharyngeal abscesses in horses with strangles, laryngeal spasm, or broncho-constriction can cause inadequate alveolar ventilation and hypoxemia. Diseases that prevent adequate inflation of lungs cause alveolar hypoventilation and the consequent hypoxemia. These diseases include pneumonia, pleural effusion, or respiratory muscle weakness, such as can occur with botulism, tick paralysis, tetanus, strychnine poisoning, or severe white muscle disease.

Ventilation-perfusion (V/Q) mismatches occur when the distribution of blood flow in the lungs does not match the distribution of alveolar ventilation, with the result that areas of lung that are well ventilated are not adequately perfused and those areas that are well perfused by blood are not well ventilated. Ventilation-perfusion mismatches are the most important cause of hypoxemia in many lung diseases, including pneumonia.

Diffusion impairment occurs when there is decreased transfer of oxygen from alveolar air that has a normal $P_{O_2}$ to red blood cells in alveolar capillaries because of increased distance of diffusion through the alveolar membranes, such as might occur with pulmonary edema; decreased surface area available for diffusion, such as occurs with positional atelectasis or pulmonary embolism; or decreased transit time of red cells through the alveolar capillaries, such as occurs in horses during heavy exercise.

Low inspired oxygen tension occurs naturally only in animals at high altitude. It can also occur during anesthesia if there are defects in the ventilator causing low oxygen tension in the gases delivered to the animal.

Extrapulmonary right-to-left shunting occurs most commonly as a vascular defect (see Ch. 10).

The actual cause of hypoxemia in an individual animal or disease is often multifactorial and not simply a result of one of the mechanisms described previously. For instance, cows placed in dorsal recumbency during general anesthesia become hypoxic because of compression of the thorax by the abdominal viscera, thereby causing hypoventilation and compression atelectasis with diffusion impairment, ventilation-perfusion mismatching, and reduced cardiac output because of reduced venous return.

Anemic Hypoxia
Anemic hypoxia occurs when there is a deficiency of hemoglobin per unit volume of blood (anemia). The percentage saturation of the available hemoglobin and the oxygen tension of arterial blood are normal but as a result of the low hemoglobin concentration the oxygen-carrying capacity of the blood is reduced. Anemia resulting from any cause has these characteristics. The decrease in oxygen-carrying capacity caused by a 50% reduction in hemoglobin concentration from normal values (from 20 down to 10 g/dL) is much greater than the decrease that results from a 50% reduction in arterial oxygen tension from normal (e.g., a reduction from 100 to 50 mm Hg).

Alteration of hemoglobin to pigments, such as methemoglobin or carboxyhemoglobin, that are not capable of carrying oxygen has the same effect on oxygen content as anemia. Thus in poisoning caused by nitrite, in which hemoglobin is converted to methemoglobin, and in that caused by carbon monoxide, when the hemoglobin is converted to carboxyhemoglobin, there is hypoxia as a result of inadequate oxygenation of blood.

Circulatory Hypoxia
Circulatory hypoxia occurs as a result of inadequate delivery of oxygen to tissue because of inadequate perfusion of tissues by blood. The blood is usually adequately oxygenated but blood flow rate to tissues is not, and therefore the rate at which it delivers oxygen to tissue is less than the amount of oxygen required to support the metabolic function of that tissue. In other words, the rate of delivery of oxygen to tissue does not match the metabolic requirements of that tissue. A common cause of this is low cardiac output, such as occurs with congestive heart failure or hypovolemic shock. It also occurs with local interruption to arterial flow, such as the thrombotic emboli of thromboembolic colic of horses or compression of vessels, such as in right displacement and torsion of the abomasum.

Histotoxic Anoxia
Histotoxic anoxia occurs when oxygen delivery to tissue is adequate because both oxygen content of arterial blood and blood flow are appropriate, but the tissue is unable to utilize oxygen. Cyanide poisoning is the only common cause of this form of anoxia.

Consequences of Hypoxia
Consequences of inadequate delivery of oxygen include changes in almost all body systems. The central nervous system and heart are most susceptible to the immediate and acute effects of hypoxia, whereas clinical signs related to hypoxic damage to the gastrointestinal tract and kidneys are somewhat delayed. Central nervous system hypoxia is evident as mild changes in mentation, such as depression, progressing through decreased alertness to coma and death. Cardiac changes include a reduction in the force and efficiency of contraction as a result of impaired myocardial contractility, and an increased susceptibility to arrhythmia. The kidney, gut, and liver are all metabolically active tissues and therefore susceptible to hypoxia. Renal function is reduced during hypoxia, with the renal medulla being most sensitive to decreases in oxygen delivery.

Signs of gastrointestinal dysfunction during hypoxia include ileus, abdominal pain, and abdominal distension as a result of accumulation of gas and liquid in the gastrointestinal tract. Liver dysfunction can be evident as decreases in blood glucose concentration and increases in serum activity of liver-derived enzymes (alkaline phosphatase, gamma-glutamyl transpeptidase, sorbitol (inositol) dehydrogenase), and metabolites (bile acids, bilirubin).

Some metabolically active tissues, when deprived of oxygen, use anaerobic metabolism to sustain energy supply for short periods of time (depending on the tissue, but the brain cannot survive without oxygen for more than 2-3 minutes). Use of anaerobic glycolysis for energy causes metabolic acidosis. Animals in respiratory failure therefore often have a mixed acid-base disturbance characterized by metabolic and respiratory acidosis.

Compensatory Mechanisms
Compensation of respiratory insufficiency occurs as both short-term and long-term events. Short-term compensatory mechanisms for low arterial oxygen tension or oxygen delivery to tissues occur within seconds to minutes and include respiratory, cardiovascular, and behavioral responses. Stimulation of respiratory centers in the medulla oblongata by low arterial oxygen tension ($P_{O_2}$) and high arterial carbon dioxide tension ($P_{CO_2}$) causes an increase in respiratory minute volume mediated by an increase in tidal volume and respiratory frequency. Both low oxygen tension and high carbon dioxide tension in arterial blood, together or separately, are potent stimulators of these events. Inadequate tissue oxygenation also stimulates an increase in cardiac output, mainly as a result of increased heart rate and to a lesser extent by an increase in stroke volume. Splenic contraction, in those species such as the horse in which the spleen is an important reservoir of red blood cells, increases both blood volume and hemoglobin concentration, thereby increasing the oxygen-carrying capacity of blood. Hypoxemia also causes animals to attempt to decrease their oxygen requirement by decreasing physical activity, including moving and eating.

Longer-term compensatory mechanisms include an increase in erythropoietin secretion by the kidney with subsequent increases in bone marrow production of red blood cells and an increase in hemoglobin concentration in blood. This polycythemia increases the oxygen-carrying capacity of blood. Severe polycythemia, such as occurs with congenital cardiac anomalies causing chronic right-to-left shunting, increases the viscosity of blood and impairs tissue perfusion, increases the workload of the heart and the risk of thromboembolism. Longer-term
compensatory mechanisms also include changes in ventilatory pattern, such as in horses with heaves, and behavior.

**CARBON DIOXIDE RETENTION (HYPERCAPNIA)**

Respiratory insufficiency results in decreased elimination of carbon dioxide and its accumulation in blood and tissues. Animals breathing room air that are hypercapnic are always hypoxicemic. Increasing the oxygen tension of inspired air can alleviate the hypoxicemia but, by reducing hypoxic stimulation of the respiratory center, can cause further increments in arterial PaCO₂.

Acute hypercapnia causes a respiratory acidosis that reduces both blood and cerebrospinal fluid pH. The clinical signs of acute hypercapnia are initial anxiety followed by central nervous system depression and eventual coma and death. These clinical abnormalities are attributable to declines in the pH of cerebrospinal fluid (CSF), a consequence of the ease with which carbon dioxide crosses the blood–brain barrier. Decreases in CSF pH are greater for respiratory acidosis than for a similar degree of metabolic acidosis. Severe hypercapnia also causes peripheral vasodilation, which can contribute to arterial hypotension, and cardiac arrhythmia. The acid-base effects of chronic hypercapnia are compensated by renal mechanisms that return the arterial and CSF pH to almost normal and therefore do not cause more than mild clinical disease in most instances. So long as oxygen delivery to tissue is maintained, animals can tolerate quite high arterial carbon dioxide tensions for a number of days or longer; this is referred to as “permissive hypercapnia” and is sometimes an alternative to artificial or mechanical ventilation of animals with respiratory insufficiency.

**RESPIRATORY FAILURE**

Respiratory movements are involuntary and are stimulated and modified by the respiratory centers in the medulla. The centers appear, at least in some species, to have spontaneous activity that is modified by afferent impulses to higher centers, including the cerebral cortex and the heat-regulating center in the hypothalamus, from the stretch receptors in the lungs via the pulmonary vagus nerves, and from the chemoreceptors in the carotid bodies. The activity of the center is also regulated directly by the pH and oxygen and carbon dioxide tensions of the cranial arterial blood supply. Stimulation of almost all afferent nerves may also cause reflex change in respiration, with stimulation of pain fibers being particularly effective.

Respiratory failure is the terminal stage of respiratory insufficiency in which the activity of the respiratory centers diminishes to the point where movements of respiratory muscles cease. Respiratory failure can be paralytic, dyspneic or asphyxial, or tachypneic, depending on the primary disease.

The respiratory failure that occurs in animals with pneumonia, pulmonary edema, and upper respiratory tract obstruction is caused by combinations of hypoventilation, ventilation-perfusion mismatch, and diffusion impairment, which leads to hypercapnia and hypoxemia. Hypercapnia and hypoxia stimulate the respiratory center, and there is a potent respiratory drive evident as markedly increased respiratory rate and effort. As the disease progresses these changes become more marked until death occurs as a result of central nervous system or cardiac failure. Animals that die of the central nervous system effects of respiratory failure typically have dyspnea followed by periods of gasping and apnea just before death.

**Paralytic** respiratory failure is caused by depression of the respiratory centers or paralysis of the muscles of respiration. Depression of the respiratory center occurs with poisoning by respiratory center depressants, such as general anesthetics, or damage to the respiratory center, such as might occur with brainstem injury. Paralysis of respiratory muscles occurs in disease such as botulism, tetanus, strychnine poisoning, white-muscle disease, severe hypocalcemia, and tick paralysis. The signs of paralytic respiratory failure are a gradual or abrupt cessation of respiratory movements without preceding signs of increased respiratory effort or dyspnea. The animal is often unconscious, or unable to move, during the later stages of the disease.

The differentiation of these types of failure is of some importance in determining the type of treatment necessary. In the paralytic form of respiratory failure, the optimal treatment is mechanical ventilation, alone or with removal of the inciting cause. Administration of respiratory stimulants is seldom effective as sole therapy. The more complex pathogenesis of respiratory failure in most diseases requires a therapeutic approach that removes each of the underlying defects. In most cases this is achieved by treating the inciting disease, for example, administering antimicrobials to an animal with pneumonia or furosemide to an animal with pulmonary edema, in addition to supportive care, including, potentially, nasal or pharyngeal insufflation with oxygen or mechanical ventilation.

**ABNORMALITIES IN RATE, DEPTH, AND EASE OF BREATHING**

**Polypnea** is a rate of breathing that is faster than observed in clinically normal animals of the same species, breed, age, sex, and reproductive status in a similar environment.

**Tachypnea** also describes an increased rate of breathing, although with the implication that breathing is shallow (i.e., of a reduced tidal volume).

**Hyperpnea** is an abnormal increase in the rate and depth of breathing (an abnormally high minute volume), but the breathing is not labored and is not associated with signs from which one could infer represent distress on the part of the animal (i.e., the animal is not dyspneic). This assessment requires measurement of minute ventilation or arterial blood gas tensions.

**Dyspnea** is a term borrowed from human medicine, in which it refers to the sensation of shortness of breath or air hunger. It is used in veterinary medicine to describe labored or difficult breathing in animals that also display some signs of distress, such as anxious expression, unusual posture or stance, or unusual behavior.

Dyspnea is a physiologic occurrence after strenuous exercise and is abnormal only when it occurs at rest or with little exercise. It is usually caused by hypoxia with or without hypercapnia, arising most commonly from diseases of the respiratory tract. In pulmonary dyspnea one other factor may be of contributory importance; there may be an abnormally sensitive Hering–Breuer reflex. This is most likely to occur when there is inflammation or congestion of the lungs or pleura. Rapid, shallow breathing results.

**Expiratory dyspnea** is prolonged and forceful expiration, usually associated with
diffuse or advanced obstructive lower airway disease. The dyspnea of pulmonary emphysema is characteristically expiratory in form and is caused by anoxic anoxia and the need for forced expiration to achieve successful expulsion of the tidal air. It is commonly accompanied by an audible expiratory grunt in ruminants but less so in pigs and almost never in horses.

**Inspiratory dyspnea** is prolonged and forceful inspiration as a result of obstruction of the extrathoracic airways, such as with laryngeal obstruction or collapse of the cervical trachea. It may also be associated with abnormalities that restrict thoracic expansion, such as restrictive lung diseases and space-occupying lesions of the thorax. It is accompanied by a stridor or loud harsh sound on inspiration when the cause is obstruction of the extrathoracic airways, such as is typical of laryngeal or tracheal disease.

**Open-mouth breathing** is labored breathing with the mouth held open, commonly with the tongue protruded in ruminants and most commonly associated with advanced pulmonary disease or obstruction of the nasal cavities.

### DISEASES CAUSING DYSPNEA AT REST OR LACK OF EXERCISE TOLERANCE

Dyspnea, along with hypoxemia and hypercapnia, are the clinical and laboratory findings most likely to attract attention to the possible presence of disease in the respiratory system. It is most important, when attempting to differentiate diseases that cause dyspnea, to include diseases of systems other than the respiratory system that can result in dyspnea. Dyspnea at rest is usually, but not always, caused by respiratory tract disease, whereas exercise intolerance can be caused by disease in the respiratory, cardiovascular, musculoskeletal, and other body systems.

### Respiratory Tract Disease

Respiratory tract diseases interfere with normal gas transfer, through the mechanisms discussed previously. Characteristics of respiratory disease that lead to dyspnea or lack of exercise tolerance include the following:

- **Flooding of alveoli with inflammatory cells** and/or protein-rich fluid—pneumonia and pulmonary edema
- **Atelectasis** (collapsed alveoli and small airways)—pleural effusion, hemothorax, hydrothorax, pneumothorax, chylothorax, pyothorax, prolonged recumbency of large animals, and diaphragmatic hernia
- **Airway obstruction**—nasal obstruction, pharyngeal/laryngeal obstruction, tracheal/bronchial obstruction, bronchoconstriction, and bronchiolar obstruction.

### Cardiovascular Disease

Cardiovascular disease causes inadequate perfusion of tissues including the lungs. There is reduced oxygen delivery to tissues, even in the presence of normal arterial oxygenation.

- **Cardiac disease**. Cardiac dyspnea results from heart failure and is multifactorial. In animals with dyspnea attributable to cardiac disease, there are other readily evident signs of heart failure.
- **Peripheral circulatory failure**—usually as a result of hypovolemic shock, although shock associated with toxemia, including endotoxemia, can cause dyspnea. There are always other prominent signs of disease.

### Diseases of the Blood

Diseases of the blood cause inadequate delivery of oxygen to tissues because of anemia or presence of hemoglobin that is unable to carry oxygen.

- **Anemia**—an abnormally low concentration of hemoglobin
- **Altered hemoglobin**—methemoglobinemia (e.g., in nitrite poisoning of cattle, red maple toxicosis of horses), Carboxyhemoglobinemia

### Nervous System Diseases

Diseases of the nervous system affect respiratory function by one of several mechanisms:

- **Paralysis of respiratory muscles** occurs in tick paralysis or botulism. Tetanic spasm of respiratory muscles, such as in tetanus or strychnine toxicosis, also impairs or prevents alveolar ventilation. Both flaccid and tetanic paralysis cause hypercapnia and hypoxemia and, in extreme situations, death by suffocation.
- **Paralysis of the respiratory center** as in poisoning by nicotine sulfate, or overall central nervous system depression, causes hypoventilation because of impaired ventilatory drive.
- **Stimulation of the respiratory center**, so-called neurogenic dyspnea, occurs as a result of stimulation of the center by a small irritative lesion, such as in animals with encephalitis, or administration of drugs, such as lobeline, that increase sensitivity of the respiratory center to hypoxemia or hypercapnia.

### Musculoskeletal Diseases

- **Muscle diseases**—diseases of the respiratory muscles can impair ventilation. These include white-muscle disease in lambs, calves, and foals, and some congenital diseases (such as glycerol branching enzyme deficiency in foals).

## General Systemic States

Tachypnea can occur in a number of systemic states in which there is no lesion of the respiratory tract or nervous system. These include:

- **Pain**—such as in horses with colic
- **Hyperthermia**—as can occur with intense or strenuous exercise
- **Acidosis**—as a metabolic disturbance associated with any of a number of diseases but notably gastrointestinal disease that causes excessive loss of cationic electrolytes in feces

### Environmental Causes

- Low inspired oxygen tension, such as in animals at high altitude
- Exposure to toxic gases.

### Miscellaneous Poisons

A number of poisons cause dyspnea as a prominent sign, but in most cases the pathogenesis has not been identified. These poisons include the following:

- Farm chemicals, including metaldehyde and dinitrophenols (probable mechanism is stimulation of respiratory center)
- Organophosphates and carbamates (probable mechanism is alteration of pulmonary epithelium), urea (probably effective as ammonia poisoning)
- Nicotine depressing the respiratory center
- Poisonous plants, including fast-death factor of algae and the weeds Albizia, Helium, Eupatorium, Ipomea, Taxus spp., and Laburnum and ironwood (Erythrophleum spp.), all appear to act at least in part by central stimulation.

### ABNORMAL POSTURE

Animals with respiratory disease, and especially those in respiratory distress, often adopt an unusual posture and are rarely recumbent except in the terminal stages of the disease. Animals in severe respiratory distress will stand with the head and neck
Diseasedes transmitted through the lung and chest wall. This sound is then generated by turbulent airflow. Sound is generated at the interface of two media of markedly different densities—such as air and tissue—and less sound is transmitted. Thus in the normal lung there is marked attenuation (softening) of breath sounds because of the extensive air–tissue interfaces. This is evident by comparing the intensity of breath sounds heard over the trachea to those heard over the chest wall. However, lung sounds are more readily transmitted when areas of the lung do not contain air, such as occurs with atelectasis, pulmonary edema or infiltration of lung by inflammatory exudates. Sounds generated in the large airways are more readily transmitted through this consolidated tissue and are evident at the chest wall as louder bronchial breath sounds. The presence of bronchial breath sounds that are audible on the chest surface is dependent on the presence of a patent bronchus with airflow to generate the lung sounds and of tissue that readily transmits the sounds generated in the bronchus. Lung sounds will not be heard if they are not generated (as a result of lack of airflow in bronchi) or are muffled by extensive accumulations of fluid or fat between the lung and the chest wall. Lung sounds are reduced in animals with airflow of low velocity in large airways, such as occurs in animals with low tidal volumes, or in which there is obliteration of the bronchial lumen by fluid or tissue. Low tidal volumes occur in animals at rest or in those in which there is rapid but shallow (low tidal volume) breathing. Obliteration of the bronchial lumen occurs in many diseases, including pneumonia.

**NORMAL AND ABNORMAL BREATH SOUNDS**

Auscultation of the lungs and air passages is the most critical of the physical examinations made of the respiratory system. The examination should be performed in as quiet an environment as possible, although it is often difficult to achieve a silent listening environment in large animal practice. The animal should be adequately restrained so that the examiner can concentrate on the lung sounds, and should not be sedated or anesthetized because of the depression in lung sounds that can occur in these instances. To be effective and diagnostically reliable, auscultation must be systematic. Both the upper and lower parts of the respiratory tract must be examined in every case. It is preferable to begin the examination by auscultating the larynx, the trachea, and the area of the tracheal bifurcation to assess the rate of airflow and the volume of air sound to be heard over the lungs.

**GENERATION OF BREATH SOUNDS**

The animal must be breathing to generate lung sounds. The lung sounds are generated by movement of air in the large and midsized airways, including the trachea and bronchi. The greater the velocity of air in the airways, the louder the noise, explaining the loud sounds that are generated in the trachea. Air movement in the bronchioles, terminal airways, and alveoli is silent because of the large combined cross-sectional area of these airways and consequent low velocity of airflow and laminar character of the airflow. Sound is generated by turbulent airflow and the degree of turbulence is affected by the velocity of airflow and the diameter of the airway. This sound is then transmitted through the lung and chest wall to the surface of the thorax, where it can be detected by use of a stethoscope.

Quiet breath sounds can be a result of low tidal volume with resultant low velocity of airflow or impaired transmission of sounds to the surface of the chest. Sound is transmitted most readily through dense liquids such as water. Most tissue, except fat, is approximately 70% water and transmits sounds readily. Sound is reflected at the interface of two media of markedly different densities—such as air and tissue—and less sound is transmitted. Thus in the normal lung there is marked attenuation (softening) of breath sounds because of the extensive air–tissue interfaces. This is evident by comparing the intensity of breath sounds heard over the trachea to those heard over the chest wall. However, lung sounds are more readily transmitted when areas of the lung do not contain air, such as occurs with atelectasis, pulmonary edema or infiltration of lung by inflammatory exudates. Sounds generated in the large airways are more readily transmitted through this consolidated tissue and are evident at the chest wall as louder bronchial breath sounds. The presence of bronchial breath sounds that are audible on the chest surface is dependent on the presence of a patent bronchus with airflow to generate the lung sounds and of tissue that readily transmits the sounds generated in the bronchus. Lung sounds will not be heard if they are not generated (as a result of lack of airflow in bronchi) or are muffled by extensive accumulations of fluid or fat between the lung and the chest wall. Lung sounds are reduced in animals with airflow of low velocity in large airways, such as occurs in animals with low tidal volumes, or in which there is obliteration of the bronchial lumen by fluid or tissue. Low tidal volumes occur in animals at rest or in those in which there is rapid but shallow (low tidal volume) breathing. Obliteration of the bronchial lumen occurs in many diseases, including pneumonia.

**REBREATHING (“BAGGING”) EXAMINATION**

Detection of abnormal lungs sounds is optimized by increasing the animal’s tidal volume, and thereby the velocity of airflow in large airways. An expeditious means of temporarily increasing the animal’s tidal volume is to occlude the nostrils for a brief period (30–60 seconds). When the animal is again allowed to breathe, it will take several large, deep breaths, during which lung sounds can be auscultated. However, the increase in tidal volume is transient and does not permit time for detailed auscultation of the chest. A preferred technique is to place an airtight bag over the animal’s muzzle such that all the air that it inhales is contained within the bag. The volume of air in the bag should exceed the anticipated stimulated tidal volume of the animal. As a rule of thumb, the volume of the bag should be sufficient to allow the animal a tidal volume of 10 to 15 mL of air per kilogram of body weight (BW). A 500-kg horse or cow therefore needs a bag that contains 10 L of air. Hyperventilation is stimulated by an increase in carbon dioxide content of inspired air with subsequent hypercapnia and stimulation of the respiratory center. A more refined technique has the animal inhaling gas that is 5% carbon dioxide and 95% oxygen, thereby preventing hypoxemia as a result of the examination. Rebreathing examinations (or “bagging”) are not indicated if abnormal lung sounds are detected on initial examination because the results of the rebreathing examination will not add any additional information. Animals in respiratory distress should not be subjected to a rebreathing examination because it might worsen the hypoxemia or hypercapnia already present and is inhumane. Rebreathing examinations are indicated when respiratory disease is suspected but initial auscultation of the thorax does not reveal abnormal lung sounds.

**INTERPRETATION OF BREATH SOUNDS**

Terminology used to describe normal and abnormal lung sounds is now well established and should be used consistently so that it is a useful diagnostic aid. Associations between abnormal respiratory sounds and diseases and abnormalities of respiratory function are well established. Correct identification of lung sounds, and consistency in terms used to describe them, therefore permits greater diagnostic accuracy and provides the ability to accurately and precisely describe diseases. The identification and clinical significance of respiratory sounds are summarized in Table 12-1. The clinician must carefully auscultate both the upper respiratory tract (larynx, trachea) and the entire aspects of both lung fields and interpret the sounds that are audible or not audible. The variables that must be interpreted include the following:

- **The nature of the sounds** (increased or decreased breath sounds, crackles or wheezes)
- **The timing of the sounds in the respiratory cycle**
- **Their anatomic location**

The questions that should be asked are as follows:

- Are breath sounds audible?
- Are the breath sounds of normal intensity?
- Are the breath sounds normal or abnormal?
- If abnormal sounds are present, what are they (crackles, wheezes, stridor, stertor, etc.; see Table 12-1)?
- Are breath sounds audible over all lung fields?

Interpretation of these variables should indicate the nature of the lesion. Examples are summarized in Table 12-1. Lung sounds can
be divided into normal breath sounds and abnormal breath sounds.

**Breath sounds** are produced by air movement through the tracheobronchial tree. The terms **bronchial sounds** and **vesicular sounds** are not anatomically accurate or based on physiologic principles and should not be used. The term **breath sounds** should be used.

These are the sounds that are audible clearly over the trachea and that are attenuated over the lungs. Breath sounds are of normal, increased, or decreased intensity. Abnormally loud or soft breath sounds can be attributed to either changes in sound production in the airways by changes in flow rate or altered transmission of sound through various normal or abnormal tissues or fluids in the thorax, as discussed previously.

### Normal Breath Sounds

Normal breath sounds vary in quality depending on where the stethoscope is placed over the respiratory tract. They are loudest over the trachea and base of the lung.

### Table 12-1 Identification and clinical significance of breath sounds

<table>
<thead>
<tr>
<th>Sounds</th>
<th>Acoustic characteristics</th>
<th>Significance and examples</th>
</tr>
</thead>
<tbody>
<tr>
<td>Normal breath sounds</td>
<td>Soft blowing sounds, longer and louder on inspiration than on expiration, audible over the trachea and lungs.</td>
<td>Normal respiratory tract</td>
</tr>
<tr>
<td>Increased audibility of breath sounds</td>
<td>Mild to moderate increase in loudness of breath sounds audible on inspiration and expiration over the trachea and lungs.</td>
<td>Any factor that increases respiratory rate or depth of respirations, including fever, excitement, exercise, high environmental temperatures, lung disease. Harsh loud breath sounds are audible over the lungs with any disease resulting in collapse or filling of alveoli and leaving bronchial lumina open; pulmonary consolidation and atelectasis.</td>
</tr>
<tr>
<td>Decreased audibility of breath sounds</td>
<td>Decreased audibility of breath sounds on inspiration and/or expiration over the lungs.</td>
<td>Obese animal, pleural effusion, space-occupying mass of lung or pleural cavity, pneumothorax, diaphragmatic hernia, occlusive (lung) airway disease as in bronchial lumen filled with exudate.</td>
</tr>
<tr>
<td>Crackles</td>
<td>Short duration, interrupted, nonmusical breath sounds. Coarse crackles are loud and most commonly heard over large airways in animals with pulmonary disease and may be heard during inspiration and expiration. Fine crackles are of short duration, less intense, and higher pitched.</td>
<td>Coarse crackles are caused by air bubbling through, and causing vibrations in, secretions in large airways. Fine crackles are caused by sudden explosive popping open of a series of airways closed during expiration. May be detected in early or late inspiration. Suggest the presence of secretions and exudate in airways and edematous bronchial mucosa as in exudative bronchopneumonia, tracheobronchitis, aspiration pneumonia, and obstructive pulmonary disease. Loud crackles may be audible in animals with interstitial pulmonary emphysema.</td>
</tr>
<tr>
<td>Wheezes</td>
<td>Continuous musical-type squeaking and whistling sounds audible over the lungs.</td>
<td>Narrowing of large airways; expiratory polyphonic wheezing common in equine reactive airway disease bronchopneumonia, any species; inspiratory monophasic wheezing occurs when upper extrathoracic airways are constricted, such as in laryngeal disease.</td>
</tr>
<tr>
<td>Pleuritic friction sounds</td>
<td>&quot;Sandpaper-like&quot; sound; grating; sound close to the surface; on inspiration and expiration; tend to be jerky and not influenced by coughing.</td>
<td>Pleuritis; diminish or disappear with pleural effusion.</td>
</tr>
<tr>
<td>Stridor</td>
<td>A harsh, high-pitched sound on inspiration audible with or without stethoscope over the larynx and trachea.</td>
<td>Obstruction of upper airways, especially the larynx (as a result of edema, laryngitis, paralysis of vocal cord); prime example is calf diphtheria and retropharyngeal abscessation in strangles in horses or tracheal collapse in horses.</td>
</tr>
<tr>
<td>Stertor</td>
<td>Snoring sound (low-pitched, coarse, and raspy) audible without a stethoscope on inspiration and expiration over the pharyngeal and laryngeal areas.</td>
<td>Partial obstruction of the upper respiratory tract, commonly attributable to abnormalities of soft palate and nasopharynx.</td>
</tr>
<tr>
<td>Expiratory grunting</td>
<td>Loud grunting on expiration, which is usually forced against a closed glottis with sudden release, audible on auscultation of the thorax, over the trachea, and often audible without the aid of a stethoscope.</td>
<td>Severe diffuse pulmonary emphysema; pleuropneumonia and pericarditis; extensive consolidation; in acute pleurisy and peritonitis; a groan indicating pain may occur.</td>
</tr>
<tr>
<td>Transmitted upper respiratory tract breath sounds</td>
<td>Abnormal tracheal breath sounds (crackles and wheezes) audible by auscultation over the extrathoracic trachea during inspiration.</td>
<td>Indicates presence of abnormalities of the upper respiratory tract (larynx, nasopharynx, nasal cavities, and upper trachea), resulting in accumulation of respiratory secretions causing constriction of airways. Laryngitis is an excellent example.</td>
</tr>
<tr>
<td>Extraneous sounds heard on auscultation of respiratory tract</td>
<td>Loud superficial crackling sounds induced by movement of stethoscope over the skin.</td>
<td>Subcutaneous emphysema from pulmonary emphysema in cattle; trauma to any part of respiratory tract that results in penetration of airway, allowing accumulation of air subcutaneously; gas-forming bacteria in subcutaneous tissues.</td>
</tr>
<tr>
<td>Crepitations in subcutaneous tissues</td>
<td>Gurgling, grating, rumbling, squishing sounds audible over the lungs.</td>
<td>Gastrointestinal sounds transmitted from the abdomen: ruminal sounds in cattle; stomach and intestinal sounds in horse. Does not indicate diaphragmatic hernia unless other evidence such as an absence of breath sounds is present.</td>
</tr>
</tbody>
</table>
and quietest over the diaphragmatic lobes of the lung. Normal breath sounds are louder on inspiration than on expiration because inspiration is active with more rapid airflow, whereas expiration is passive in normal animals and associated with lower rates of airflow. Breath sounds may be barely audible in obese animals or in the noisy surroundings common in field conditions.

**Increased loudness** of breath sounds is heard in normal animals with increased respiratory rate and depth of respiration. This can occur for physiologic reasons such as exercise, excitement or a high environmental temperature. They can also occur in abnormal states such as fever, acidosis, or pulmonary congestion in early pneumonia or myocardial disease.

**Decreased loudness** or an almost complete absence of breath sounds occurs in pleural effusion or pneumothorax because of almost complete reflection of the breath sounds at the pleural surface as a result of the mismatching of the acoustic properties of the pleural tissues and fluids. **Space-occupying masses** between the lung and the thoracic wall also cause a relative absence of breath sounds over the site as do areas of lung that are not ventilated, such as a pulmonary abscess. Thoracic auscultation is of limited value in detecting localized areas of consolidation in the lungs of calves or foals, with ultrasonographic examination having much greater sensitivity. The sensitivity of auscultation to detect lung consolidation, detected by ultrasonographic examination, in calves is only 6%. Computer-aided lung auscultation has a reasonable sensitivity for detection of bovine respiratory disease in feedlot cattle (93%), compared with clinical examination by a veterinarian.

**Increased loudness of breath sounds** occurs in some instances and can have diagnostic importance. The normal breath sounds heard over the trachea may sound abnormally loud over the lungs because of changes in the transmission properties of the respiratory system. This is because when sound waves pass through structures of different physical properties, the amount of sound transmitted depends on the matching of acoustic properties of the different structures. Consolidation results in less reflection of sound at the thoracic wall and consequently more transmission to the stethoscope. Thus in consolidation, the breath sounds are much louder than normal. These are harsh breath sounds that approximate those heard over the trachea. They are audible on inspiration and expiration but become louder on expiration in abnormal states such as consolidation or atelectasis. Any disease in which the bronchial lumen remains open and the surrounding lung tissue has been replaced by cells, exudate, or tissues (consolidation) that transmit sound without reflection will result in increased bronchial sounds.

**Abnormal Breath Sounds**

Abnormal breath sounds include **crackles** and **wheeze**s. Crackles are discontinuous sounds and wheezes are continuous sounds. **Crackles** are abnormal lung sounds described as clicking, popping or bubbling sounds. They are caused by airways that remain closed for a portion of inspiration and then suddenly open. The crackling is caused by the sudden equalization of pressure between the proximal and distal part of the airway. Crackles may thus be caused by the presence of exudate and secretions in the airways, and edematous bronchial mucosa. Crackling lung sounds are also audible in cattle with interstitial pulmonary emphysema. Cracking sounds may move their point of maximum intensity following coughing, presumably as a result of movement of exudate.

**Wheeze**s are continuous whistling, squeaking sounds caused by vibrations of airways or air passing through a narrowed airway. They can be characterized as monophonic (single tone) or polyphonic (multiple tones) and by the timing of their occurrence in the respiratory cycle. **Inspiratory wheezing** suggests obstruction of the upper airways, usually extrathoracic. **Expiratory wheezing** usually indicates intrathoracic airway obstruction, such as bronchoconstriction, with or without distal airways that are narrowed because of tenacious exudate.

**Pleuritic friction sounds** are a combination of continuous and discontinuous sounds produced by the rubbing together of inflamed parietal and visceral pleura. The sound is loud, coarse, and usually not influenced by coughing. Pleuritic friction sounds are not common, and their absence does not preclude the presence of pleuritis, particularly in the horse. Pleuritic friction rubs may also occur in cattle with severe diffuse pulmonary emphysema as the relatively dry parietal and visceral surfaces rub together during the respiratory cycle.

**Absence of lung sounds** occurs when the breath sounds are reflected at the interface between the lung and thoracic wall by the presence of a medium such as a space-occupying mass, fluid, or air. The common causes of the “silent lung” include pleural effusion; space-occupying masses of the thorax; large pulmonary abscess; complete destruction of a lobe of lung including the terminal airways, such as can occur with bronchial lumen occlusion by a foreign body or tumor; and diaphragmatic hernia.

**Extraneous sounds** are miscellaneous unexpected sounds that are occasionally audible over the thorax and include peristaltic sounds, skin and hair sounds caused by the stethoscope, crepitating sounds as a result of subcutaneous emphysema, and muscular contractions. Subcutaneous emphysema occurs in diseases in which there is leakage of air from the lungs or airways into the subcutaneous space. This occurs with bullous lung disease in cattle, rib fractures and pneumothorax, and after percutaneous tracheal aspiration in animals that cough. Coughing in these animals causes air to be forced out of the trachea through the hole through which the tracheal aspirate was obtained. This occurs in the period of coughing when intratracheal pressures are markedly increased just before the opening of the glottis.

**RESPIRATORY NOISES**

Respiration may be accompanied by audible noises that indicate certain normal or abnormal occurrences in the respiratory tract such as sneezing, snorting, stridor, stertor or snoring, wheezing, roaring, inspiratory grunting, and snuffling, bubbling, and rattling sounds.

**Sneezing** is a sudden, involuntary, noisy expiration through the nasal cavities caused reflexively by irritation of the nasal mucosa. Sneezing occurs in rhinitis and obstruction of the nasal cavities and digital manipulation and examination of the nasal mucosa.

**Snorting** is a forceful expiration of air through the nostrils as in a sneeze, but a snort is a voluntary act used by horses and cattle as a device to intimidate potential predators.

**Stridor** is an inspiratory stenotic sound originating from a reduction in the caliber of the larynx, as occurs in laryngeal edema and abscess.

**Sneror or snoring** is a deep guttural sound on inspiration originating from vibrations of pharyngeal mucosa. Snoring is often intermittent, depending on the animal’s posture. For example, a fat young bull will often snore when he is dozing half asleep, with his head hung down, but the snore will disappear when he is alert and his head is held up in a more normal position. Stertor can occur during expiration in horses with dorsal displacement of the soft palate.

**Wheeze**ing is a high-pitched sound made by air flowing through a narrow lumen, such as a stenotic or inflamed nasal cavity.

**Roaring** may occur during exercise and is caused by air passing through a larynx with a reduced lumen (e.g., laryngeal hemiplegia in horses).

**Expiratory grunting** is a clearly audible grunting noise synchronous with expiration. It is most common in cattle with diffuse pulmonary disease. A painful grunt may occur in painful diseases of the thorax such as fibrinous pleuritis and is unassociated with inspiration or expiration.

**Snuffling, bubbling, or rattling sounds** may be audible over the trachea or base of the lungs when there is an accumulation of secretion, or exudate, in the nasal cavities, larynx, or trachea. These are most clearly audible on inspiration.
Coughing

A cough is an explosive expiration of air from the lungs. It is initiated by reflex stimulation of the cough center in the medulla oblongata by irritation of sensory receptors in one of various organs, especially the respiratory tract. The stimulus may originate in the pharynx, larynx, trachea, or bronchi. Coughing may also be initiated by irritation of the esophagus, as in choking. The act of coughing consists of several stages:

- Deep inspiration followed by closure of the arytenoid cartilages (glottis)
- Compression of the air in the lungs and large increase in pressure in the thorax and airways by a forced expiratory effort against a closed glottis
- A sudden relaxation of the arytenoid adductor muscles, resulting in opening of the larynx and abrupt, vigorous, and forced expiration. Coughing in horses is associated with transient dorsal displacement of the soft palate so that material in the airways caudal to the larynx is expelled through the mouth.
- The sudden opening of the glottis allows an explosive expiration, during which the linear velocity attains a speed of several hundred kilometers per hour. The intrathoracic airways collapse after opening of the glottis during the forced expiration, whereas the extrathoracic airways are momentarily dilated.

The purpose of coughing is to remove the excess mucus, inflammatory products or foreign material from the respiratory tract distal to the larynx. An example of where impaired ability to cough reduces the capacity to clear tracheal respiratory secretions is in horses after surgical correction for recurrent laryngeal neuropathy. In this instance one side of the glottis is fixed open, thereby preventing the horse from achieving high flow rates normal associated with the explosive stage of coughing. This markedly reduces expectoration of material in the trachea.

Coughing indicates the existence of primary or secondary respiratory disease. Coughing can be assessed according to several characteristics. Coughing is infrequent in the early stages of respiratory tract disease but can become frequent as the degree of inflammation in the larynx, trachea and bronchi becomes more severe. Assessment of the severity of coughing, at least in horses, requires prolonged observation (preferably for an hour). Coughing is a fairly specific but not very sensitive indicator of pulmonary inflammation. If coughing is detected, it is quite likely that the animal has inflammation of the airways, whereas failure to detect coughing does not reliably rule out the presence of clinically significant airway inflammation. The severity of coughing in horses is closely linked to the severity of inflammation and accumulation of mucus in the airways. Racehorses that cough are 10 times more likely to have more than 20% neutrophils in a tracheal aspirate and more than 100 times more likely to have more than 80% neutrophils. The frequency of coughing correlates well with maximal changes in pleural pressure, extent of mucus accumulation, and proportion of neutrophils in bronchoalveolar lavage fluid of horses with heaves (recurrent airway obstruction). Coughing is therefore a specific indicator of the presence of respiratory inflammation.

The frequency of coughing is an indicator of the severity of lung disease in horses and presumably in other species. Horses that cough more than four times per hour have increased likelihood of mucus accumulation and higher pleural pressure changes during breathing than do horses that cough fewer than four times per hour. Use of cough sound analysis enables detection of outbreaks of respiratory disease in pigs and housed calves. Automated sound analysis systems can differentiate sounds of coughing from other sounds in the barn or piggery.

A cough cannot be induced in normal adult cattle and horses by manual manipulation of the larynx or trachea. If a cough can be induced in an adult horse by manual manipulation of the larynx or trachea, then this indicates airway inflammation and is a reason for further examination of the respiratory tract.

The most common causes of coughing in farm animals are diseases of the larynx, trachea, bronchi and lungs, which are presented under the headings of diseases of those parts of the respiratory tract later in this chapter.

Cyanosis

Cyanosis is a bluish discoloration of the skin, conjunctivae, and visible mucousa caused by an increase in the absolute amount of reduced hemoglobin in the blood. It can occur only when the hemoglobin concentration of the blood is normal or nearly so, and when there is incomplete oxygenation of the hemoglobin. Cyanosis is apparent when the concentration of deoxygenated hemoglobin in blood is greater than 5 g/dL. Peripheral cyanosis does not occur in anemic animals. The bluish discoloration should disappear when pressure is exerted on the skin or mucosa. In most cases, the oral mucous membranes are examined for evidence of cyanosis, although the skin of the pinna and the urogenital mucous membranes will suffice. Examination of vaginal mucosa is preferred in horses that have severe congestion of the oral and nasal mucosa as a result of disease affecting the head, such as cellulitis or bilateral jugular thrombophlebitis. Artificial lighting and skin pigmentation affect the ability to detect cyanosis.

Methemoglobinemia is accompanied by discoloration of the skin and mucousa but the color is more brown than blue and cannot be accurately described as cyanosis.

Cyanosis is classified as central or peripheral. Central cyanosis is present when arterial oxygen saturation is below normal with concentration of deoxygenated hemoglobin exceeding 4 to 5 g/dL. Peripheral cyanosis occurs when there is localized desaturation of blood despite arterial oxygen saturation being normal. This usually occurs because there is diminished blood flow to tissue, with a resulting increase in oxygen extraction by the ischemic tissues and low end-capillary and venous hemoglobin saturation.

Central cyanosis is caused by diseases include the following:

- Congenital cardiac diseases that cause right-to-left shunting
- Pulmonary diseases that cause hypoxemia—cyanosis is not usually marked in pulmonary disease unless the degree of ventilation-perfusion mismatch is severe.
- Upper airway obstruction causing hypoxemia—cyanosis is common and is a sign of life-threatening disease in severe cases of laryngeal obstruction, as occurs in severe laryngitis in calves with necrotic laryngitis or horses with bilateral laryngeal paralysis (lead poisoning, after tracheal intubation during anesthesia, idiopathic).
- Abnormalities in hemoglobin function.

Peripheral causes of cyanosis include the following:

- Arterial obstruction, such as is seen in horses with aortoiliac thrombosis (“saddle thrombus”) or thrombosis of distal limbs (such as can occur with severe sepsis)
- Venous obstruction
- Severe vasoconstriction

Central cyanosis is characterized by decreased arterial oxygen saturation as a result of right-to-left shunting of blood or impaired pulmonary function. Central cyanosis resulting from congenital heart disease or pulmonary disease characteristically worsens during exercise. Central cyanosis usually becomes apparent at a mean capillary concentration of 4 to 5 g/dL reduced hemoglobin (or 0.5 g/dL methemoglobin). Because it is the absolute quantity of reduced hemoglobin in the blood that is responsible for cyanosis, the higher the total hemoglobin content, the greater the tendency toward cyanosis. Thus cyanosis is detectable in patients with marked polycythemia at higher levels of arterial oxygen saturation than in patients with normal hematocrit values, and cyanosis may be absent in patients with anemia despite marked arterial desaturation. Patients
with congenital heart disease often have a history of cyanosis that is intensified during exertion because of the lower saturation of blood returning to the right side of the heart and the augmented right-to-left shunt. The inspiration of pure oxygen (100% \( F\text{O}_2 \)) will not resolve central cyanosis when a right-to-left shunt is present, but it can resolve when primary lung disease or polycythemia is causing the cyanosis.

Peripheral cyanosis is caused by obstruction of blood flow to an area. This can occur as a result of arterial or venous obstruction, although it is usually more severe when arterial blood flow is obstructed. Obstruction of arterial blood flow also causes the limb to be cold and muscle and nerve function in the ischemic area to be impaired. Cyanosis can also occur as a result of cutaneous vasoconstriction attributable to low cardiac output or exposure to cold air or water. It usually indicates stasis of blood flow in the periphery. If peripheral cyanosis is localized to an extremity, arterial or venous obstruction should be suspected. Peripheral cyanosis resulting from vasoconstriction is usually relieved by warming the affected area.

Heart failure can cause cyanosis that is restricted to the extremities, probably because of reduced blood flow to extremities during this disease and the consequent markedly lower end-capillary oxygen content. Blood in the venous end of the capillaries, and in the venous bed draining these tissues, is therefore deoxygenated and cyanosis is observed. Although this type of cyanosis has a peripheral distribution, its underlying cause is central.

**NASAL DISCHARGE**

Excessive or abnormal nasal discharge is usually an indication of respiratory tract disease. Nasal discharges are common in all the farm animal species. Cattle can remove some or all of the nasal discharge by licking with their tongue, whereas horses do not remove any.

**Origin**

The nasal discharge is usually obvious but the determination of its origin and significance can be difficult and elusive. The history should determine the duration of the nasal discharge and if it has been unilateral or bilateral.

Nasal discharges may originate from lesions in the nasal cavities, congenital defects of the hard palate such as cleft palate in the newborn, paranasal sinuses, gullet pouch in the horse, pharynx, larynx, trachea, and lungs. Diseases of the esophagus and stomach that cause dysphagia and regurgitation or vomiting can also cause a nasal discharge stained with feed material.

The origin of a nasal discharge is sometimes determined by close inspection of the external nares and the visible aspects of the nasal cavities using a pointed source of light. Some important infectious diseases of the respiratory tract characterized by lesions of the nasal mucosa can be identified by examination of the external nares for the origin of a nasal discharge. If the source of the discharge is not apparent on this examination, then more detailed investigation is warranted.

**Examination**

The characteristics of the discharge are noted carefully by inspection. It may be copious, serous, mucoid, purulent, caseous, streaked with blood, and foul smelling (ozena), or it may contain feed particles.

- A copious bilateral serous nasal discharge is characteristic of early inflammation of the nasal cavities such as in viral rhinitis.
- A bilateral mucoid discharge suggests inflammation of a few days’ duration.
- A bilateral purulent discharge can indicate inflammation in the upper or lower respiratory tract.
- A copious bilateral caseous discharge suggests an allergic or bacterial rhinitis.
- Foul-smelling nasal discharges are usually associated with necrosis of tissues anywhere in the nasal cavities, the gullet pouch in the horse, or severe necrotic and gangrenous pneumonia.
- A bilateral foul-smelling discharge containing feed particles suggests dysphagia, regurgitation, or vomiting.
- In most cases, a chronic unilateral nasal discharge suggests a lesion of one nasal cavity.
- A bilateral nasal discharge suggests a lesion posterior to the nasal system.

**Examination of the paranasal sinuses for evidence of pain and facial deformity will assist in the diagnosis of sinusitis.** Percussion is useful in identifying paranasal sinuses that are filled with fluid or tissue because sinuses affected in this way do not produce a resonant sound when the skin overlying the sinuses is tapped. The pharynx and larynx of cattle can be examined through the oral cavity, whereas a flexible endoscope is necessary for close examination of the upper and lower respiratory tract of horses or cattle of almost any age to determine the origin of a nasal discharge. The examination should include both nares, the region of the opening of the nasomaxillary sinus (this opening cannot be seen), the nasopharynx (in horses) or the pharynx (in other species), the gullet pouches in horses, the larynx, and the trachea, preferably to the level of the carina, although this might not be possible in large animals or when short endoscopes are used.

**Radiography** of the structures of the head and pharynx is also useful to locate lesions of the nasal cavities and paranasal sinuses that might be the origin of a nasal discharge.

**Nasal Discharge and Location of Lesion**

There is not necessarily a correlation between the characteristics of a nasal discharge and the nature of any pulmonary lesions. In exudative pneumonias in cattle, mucopus is produced and is moved up the trachea and into the pharynx by the mucociliary mechanism or by coughing. Some of it is then swallowed, and some may be deposited in the nasal cavities and moved forward to the external nares by ciliary action. In the horse, with its long soft palate, most purulent material from the lungs will be deposited in the nasal cavities and appear as a nasal discharge.

**Sampling of Nasal Discharge**

When infectious disease is suspected, nasal swabs can be collected and submitted for microbiological examination. Nasal swabs are useful only when a specific etiologic agent is suspected and demonstration of its presence will confirm the cause of the disease. Examples of this include *Streptococcus equi*, influenza (equine or porcine), infectious bovine rhinotracheitis, and *Mycoplasma bovis*. Submission of nasal swabs for culture yields mixed flora and the results are impossible to interpret, with the exception noted previously. Organisms cultured from nasal or nasopharyngeal swabs are not representative of those cultured from lungs in individual animals but might be somewhat useful in herd outbreaks of disease. Culture of transtracheal aspirates or, in cattle but not horses, bronchoalveolar lavage fluid is representative of organisms causing pulmonary disease. Cytologic examination of the nasal discharge can reveal exfoliated cells in the case of nasal tumors or eosinophils when allergic rhinitis is present.

**EPISTAXIS AND HEMOPTYSIS**

- **Epistaxis** (blood from the nostril) is in most instances a result of disease of the mucosa of the upper respiratory tract but it may originate anywhere in the upper or lower respiratory tract. Epistaxis occurring during or within several hours of intense exercise by horses is caused by exercise-induced pulmonary hemorrhage.
- **Hemoptysis** is the coughing up of blood. The blood usually originates from hemorrhage in the lower respiratory tract. The presence of hemoptysis is difficult to detect in animals. Hemoptysis occurs in horses, which is perhaps unexpected given the anatomic separation of the nasopharynx and oropharynx.

Pulmonary hemorrhage, particularly in the horse, may be manifested as epistaxis.
Pulmonary hemorrhage in cattle is commonly manifested as hemothysis and epistaxis. These are described in more detail later in this chapter.

A small amount of serosanguineous fluid in the nostrils, as occurs in equine infectious anemia and infectious equine pneumonia, does not represent epistaxis, which must also be differentiated from the passage of blood-stained froth caused by acute pulmonary edema. In this instance the bubbles in the froth are very small in size, and passage of the froth is accompanied by severe dyspnea, coughing, and auscultatory evidence of pulmonary edema.

**THORACIC PAIN**

Spontaneous pain, evidenced by grunting with each respiratory cycle, usually indicates pleural pain, such as from a fractured rib, torn intercostal muscle, or traumatic injury, including hematomata of the pleura, or pleurisy. A similar grunt may be obtained by deep palpation or gentle thumping over the affected area of the thoracic wall with a closed fist or a percussion hammer. Pain as a result of a chronic deep-seated lesion cannot be detected in this way. The use of a pole under the sternum, as described under “Traumatic Reticuloperitonitis,” provides a useful alternative.

---

**Special Examination of the Respiratory System**

In addition to the routine clinical examination of the respiratory tract, there are a number of diagnostic techniques that can be used to aid in making a specific diagnosis, providing a reliable prognosis and formulating the most rational treatment. These techniques are being used more commonly by species specialists, particularly on valuable animals. Most equine practices have flexible endoscopes for the examination of the upper respiratory tract of horses. Medical imaging using thoracic radiography and ultrasonography of animals with suspected lung disease is now common, and the laboratory evaluation of respiratory tract secretions and exudates are commonplace. Almost all of these techniques increase the costs of making a diagnosis, and it is therefore important to consider whether the additional diagnostic testing will improve the final outcome of the case. Techniques for advanced evaluation of the respiratory system include the following:

- Auscultation and percussion of the thorax
- Endoscopy of the upper airways, guttural pouch (in Equidae), trachea, bronchi, and larger bronchioles
- Invasive endoscopic examination of the sinuses using rigid endoscopes
- Pleuroscopy using either rigid or flexible endoscopes
- Radiographic examination of the skull, pharynx, larynx, guttural pouch (in Equidae), trachea, and thorax
- Computed tomographic and magnetic resonance imaging
- Scintigraphic examination of respiratory function
- Ultrasonographic examination of the soft tissue of the pharynx and larynx, and thorax
- Collection and evaluation of the following respiratory tract secretions:
  - Nasal
  - Paranasal sinus
  - Guttural pouch
  - Pharyngeal
  - Tracheobronchial (tracheal aspirates, bronchoalveolar lavage)
  - Pleural (thoracoacentesis)
- Pulmonary function testing, including measurement of tidal and minute volumes, pleural pressure, forced expiratory volume, flow-volume loops, forced oscillometry, and CO₂ breathing
- Arterial blood gas analysis
- Venous blood gas analysis
- Blood lactate concentration
- Pulse oximetry
- Collection and analysis of exhaled breath condensate
- Lung biopsy
- Respiratory sound spectrum analysis
- Exercise testing.

**AUSCULTATION AND PERCUSSION**

The techniques of auscultation and percussion used in examination of the thorax are discussed in Chapter 1, and references on percussion of the thorax are available in earlier editions of this text. Percussion of the thorax is a useful means of determining lung margins and therefore of detecting the presence of overinflation, as occurs with heaves in horses, or areas of consolidation. Consolidation is evident as a loss of resonance, and detection of this abnormality can reveal the presence of excessive pleural fluid or pulmonary consolidation. There is excellent agreement in the assessment of lung margins determined by percussion and by ultrasonographic examination. Percussion is therefore a valuable diagnostic tool, especially when ultrasonographic examination is not available.

**ENDOSCOPIC EXAMINATION OF THE AIRWAYS (RHINOLARYNGOSCOPY, TRACHEOBRONCHOSCOPY)**

Horses

Flexible endoscopes allow examination of the upper respiratory tract of horses, including the nasal cavities, nasopharynx, auditory tube diverticula (guttural pouches), palatal arch, epiglottis, larynx, trachea, and major bronchi. For examination to the level of the rostral trachea an endoscope of 1 m in length is suitable. However, an endoscope of 1.5 m in length is useful for examining to the level of the thoracic inlet. The endoscope is usually less than 1.5 cm in diameter. Endoscopic examinations are tolerated by most horses with the minimum of restraint (application of a nose or ear twitch). Sedation should be avoided if a purpose of the examination is to determine the functional integrity of the pharynx and larynx. Sedation depresses laryngeal function and impairs assessment of the symmetry and abductor function of the arytenoid cartilages. Sedated horses are more likely to displace the soft palate and to fail to return it to its normal position.

**Rhinolaryngoscopy**

Examination of horses should include a careful examination of the ventral and middle meatuses, turbinates, region of the nasomaxillary sinus opening (this cannot be visualized directly but discharge from it can be detected), ethmoidal turbinates, nasopharynx, soft palate, guttural pouches, dorsal pharyngeal recess, epiglottis, and larynx. The endoscope should be used to examine both left and right nasal cavities and ethmoid turbinates. Both guttural pouches should be examined. Passage of the endoscope into the guttural pouch is best achieved by passing the endoscope through the ipsilateral nasal cavity. The guttural pouch is then entered by first introducing a thin, stiff tube, such as an endoscopic biopsy instrument, through the biopsy port of the endoscope into the guttural pouch. The endoscope is then rotated so that the entrance to the guttural pouch is opened, and the endoscope is carefully advanced into the pouch. An alternative technique involves insertion of a stiff catheter, such as a Chambers mare uterine catheter, into the guttural pouch such that the entrance is dilated to enable passage of the endoscope.

Many disorders of the equine pharynx and larynx manifest only during strenuous exercise because of the high pressures generated in the airways by the large minute ventilation of exercising horses. Pressures in the pharynx and larynx that are of similar magnitude to those occurring during intense exercise can be induced in resting horses by 60 seconds of nasal occlusion. The respiratory efforts of horses during nasal occlusion can therefore be used to simulate those during exercise, thereby permitting detection of disorders of the pharynx (displacement of the soft palate) and larynx (mild laryngeal hemiplegia) that would not otherwise be apparent in a resting horse. Rhinolaryngoscopic examination can also be performed on horses running on a treadmill (see following “Exercise Testing” section) or, by use of dynamic endoscopy, in horses running over ground.

**Bronchoscopic examination** requires an endoscope that is at least 2 m in length and...
anesthesia. The procedure is technically challenging and is usually performed by surgeons experienced in the use of arthroscopic equipment inserted through portals created by trephining holes in the sinus. The side to be examined is determined by physical, radiographic, and rhinoscopic examination of the animal. Endoscopic examination is indicated in animals in which diagnosis of the disease requires collection of tissue from the sinus. Therapeutic interventions that can be performed during endoscopic examination of the paranasal sinuses include lavage, removal of accretions of inflammatory material, drainage of cysts, and creation or enlargement of drainage holes.

PLEUROSCOPY

Pleuroscopy using a rigid or flexible endoscope enables direct visual inspection of the pleural cavity for the diagnosis of pleural disease. The procedure is well tolerated in healthy horses and cattle.8,9 The technique is particularly valuable in diagnosis of diseases of the thorax that extend to the pleural surface and do not exfoliate large quantities of cells, thereby making diagnosis by examination of fluid obtained by pleurocentesis unlikely. The procedure is useful in collection of tissue samples, such as from suspected thoracic neoplasia,10-12 or in therapeutic procedures including relief of pleural adhesions and resection of lung sections, and in collection of large biopsies samples from the lung.

The procedure is performed in standing, sedated horses restrained in stocks. Strict aseptic technique is used. The portal for insertion of the endoscope is at the level of the 8th to 12th intercostal space, with optimal examination of intrathoracic structures obtained via the 10th or 12th intercostal space. Either a rigid endoscope (10-mm diameter, 57-cm length) or flexible endoscope (10-mm diameter, 1-m length) can be used. The endoscope is inserted through a small incision in the intercostal space made under local anesthesia. The ipsilateral lung is partially collapsed by induced pneumothorax to permit visualization of intrathoracic structures. The mediastinum is intact in most horses. Inadequate collapse of the lung increases the likelihood of it being damaged during the procedure. The lung is reinflated by removal of air in the pleural space at the end of the procedure. Potential complications of the procedure include pneumothorax, hemothorax, damage to intrathoracic structures, and infection.

RADIOGRAPHY

Radiography of the head, neck, and thorax is valuable in the diagnosis of diseases of the respiratory tract of animals. Examination is hindered by the large size of adult horses and cattle, the need for specialized high-capacity equipment for obtaining radiographs, and the need for adequate restraint. Radiographic examination of adult animals in the field using portable radiographic units is very limited. However, large practices with fixed radiographic units capable of generating sufficient voltage and amperage can obtain diagnostic radiographs of the thorax of adult horses and cattle. Exposure values for radiographs of the thorax of adult horses and cattle are in the range of 110 kV and 40 mAs for caudodorsal regions to 150 kV and 70 mAs for craniocentral regions.14 Diagnostic films of smaller animals, including adult sheep and goats and foals and calves, can be obtained using portable units capable of generating 80 to 100 kVp and 15 to 20 mA.

Examination of the thorax of large animals is restricted to lateral radiographs because the large amount of tissue prevents adequate exposure for ventrodorsal views. Multiple films (usually four overlapping views) are required for complete examination of the thorax, and the exposure needed for optimal-quality films varies among anatomic sites.14 Localization of focal lesions can be achieved by examining sets of radiographs that include images collected with the horse or cow standing first with one side to the plate and then with the other side toward the plate. The lesion will appear larger in views obtained with the lesion closer to the source of x-rays. The radiographic anatomy of the horse has been described.14

Interpretation of thoracic radiographs of horses has classically used an approach using terms such as bronchial, alveolar, interstitial, and vascular patterns. An alternative approach that is recently suggested, and which we recommend, is depicted in Figure 12-1. The process involves identification of areas of opacity, their extent and characteristics of the borders of the opacity (poorly defined vs. discrete), and the number and location of opacities. A differential diagnosis can then be established for each pattern of abnormalities (Box 12-1).11

Radiographs of calves and foals can be recorded with them standing or recumbent. Images obtained with the foal or calf in lateral recumbency with the forelimbs pulled forward permit optimal examination of the cranial thorax. However, calves or foals that are recumbent for prolonged periods of time (e.g., > 30 min) can develop atelectasis of the down lung that can mimic pneumonia radiographically. Ventrodorsal views assist with localizing lesions in foals and calves. Radiographic evidence of lung disease is common in ill neonatal foals (74% having such lesions in one study), and is not related to clinical evidence of respiratory disease or dyspnea. The characteristics of lung lesions detected in neonatal foals are associated with likelihood of survival. Guidelines for recognition of pulmonary patterns in foals have been proposed (Table 12-2), and these guidelines are likely to be useful aids for interpretation and
description of pulmonary patterns in neonates of other species.

Indications for thoracic radiography in horses (and likely in other large animal species) include the following:1

- Mild respiratory disease that is unresponsive to treatment
- Severe respiratory distress
- Thoracic trauma
- Signs of respiratory disease and weight loss or recurrent colic
- Suspicion of infectious or aspiration pneumonia
- Suspected thoracic or mediastinal mass

than 50% of affected foals detected by radiographic examination.12

Many pulmonary diseases do not have lesions that are readily detected on radiographic examination. Failure to detect abnormalities on radiographic examination of the thorax does not eliminate pulmonary disease. Furthermore, radiographically detectable signs of lung disease can persist after the animal has clinical and clinicopathologic signs of recovery or improvement.

**Bronchography** utilizing contrast agents is of value in determining the patency of the trachea and bronchi, but general anesthesia is required to overcome the coughing stimulated by the passage of the tracheal catheter. Using a fluoroscope to determine the location of the catheter tip, the contrast agent can be deposited in each dependent lobe in turn. This technique is used infrequently.

Radiographic examination of the trachea can reveal the presence of abnormalities in shape, such as occur with tracheal collapse, or the presence of foreign bodies or exudate.

Radiographic examination of the head can identify diseases of the paranasal sinuses, ethmoids and pharynx. Radiographic examination is useful in defining diseases of the guttural pouches and in detecting retropharyngeal abscesses or abnormalities, such as the presence of foreign bodies.

**MAGNETIC RESONANCE IMAGING**

The utility of magnetic resonance imaging (MRI) in large-animal medicine is constrained by the size of the imaging bore on MRI units which limits the size of the animal, or anatomic region, that can be imaged. MRI is useful in diagnosis of diseases of the head of horses and other large animals,16 and the anatomy as visualized on MRI of the head of horses and pigs has been reported.17 The lack of units suitable for examination of large animals precludes routine use of this imaging modality.

**COMPUTED TOMOGRAPHY**

Examination of the lung through **computed tomographic** (CT) is very sensitive and specific for lung disease in companion animals and is technically feasible in calves,14 foals,15,20 and small ruminants.15 The technique is useful in the diagnosis of mediastinal disease in foals and correlates well with postmortem estimates of the volume of consolidated lung in experimentally induced pneumonia in calves.22 CT is likely to be useful in evaluation of extent, severity and progression of lung disease in calves.

The CT anatomy of the head of horses and foals has been described including detailed anatomy of the guttural pouches and paranasal sinuses.23 CT imaging of the nasal cavities and paranasal sinuses of horses is useful in the detection of diseases of these

Structures and of the teeth, pharynx, larynx, and guttural pouches.25,26 For example, CT of the head of horses with suspected ethmoidal hematoma provides information that influences the treatment of approximately two-thirds of cases, including identification of bilateral disease and the extent of involvement of the parasal sinuses (and in particular the sphenopalatine sinus). CT is recommended for patients in which the lesion cannot be viewed endoscopically, when sinus involvement or multifocal disease are suspected, or when the lesion has been unresponsive to treatment.27

The technique is technically feasible in ruminants and pigs, including detection of otitis media, pulmonary and pharyngeal abscesses, and congenital pulmonary anomalies in calves.28,29 CT is useful in pigs for quantification of the extent of atrophic rhinitis and evaluation of pneumonia, in addition to assessment of body composition.30

SCINTIGRAPHY (NUCLEAR IMAGING)

The basis of pulmonary scintigraphy is detection at the body surface of radiation emitted from the lungs after injection or inhalation of radioactive substances. The technique has been described in both horses and calves. The technique has limited diagnostic usefulness in large animals because of the need for availability of appropriate isotopes and detection equipment.31 Furthermore, the large size of adult cattle and horses limits the sensitivity of the technique. The technique has been used to determine the distribution of pharmaceuticals administered by aerosolization and the presence of ventilation-perfusion mismatches. Alveolar clearance can be detected using scintigraphic examination. Currently pulmonary scintigraphy is largely a research tool.

ULTRASONOGRAPHY

Ultrasonographic examination of the thorax of farm animals and horses is a very useful diagnostic tool. Ultrasonographic examination of the thorax provides diagnostic information that is not obtained by radiographic examination and is more sensitive than radiography in detecting pulmonary abscesses in foals and is more useful than auscultation in detecting consolidation in lungs of preweaned calves.12,13,14 The widespread availability of portable ultrasound units and the ability to image parts of the thorax using ultrasound probes intended for examination of the reproductive tract of mares and cows makes this a potentially valuable diagnostic aid for both field and hospital-based practitioners. Furthermore, the absence of radiation exposure and the “real-time” nature of images obtained by ultrasonography aid in frequent assessment and monitoring of abnormalities and performance of diagnostic or therapeutic procedures such as thoracocentesis or aspiration of masses.

There are limitations to imaging imposed by aerated lung and the bones of the ribcage. Examination of the thorax is limited by the presence of ribs and aerated lungs because the sound waves used to create ultrasound images are reflected from these surfaces. Ultrasonography cannot reveal lesions of the lungs that are not confluent with the visceral pleura. Imaging windows are restricted to the intercostal spaces, but this impediment can be overcome by scanning through adjacent intercostal spaces and angling of the ultrasound beam.

Ultrasonographic examination of the thorax should be performed in a consistent manner that ensures thorough examination of the thorax. Preferences for the pattern of examination differ somewhat among examiners, but one common and successful technique is to scan each intercostal space from dorsal to ventral starting at the 17th intercostal space in horses and the 12th intercostal space in cattle. The ultrasound probe is slowly moved from dorsal to ventral while the examiner studies the images. When one scanning of one intercostal space is completed, the probe is moved to the most dorsal aspect of the next intercostal space, and the examination is repeated. Each side of the chest is
examined in this manner. This consistent and thorough examination ensures that no important or localized abnormalities are missed. The examination is performed in adult horses and cattle with the animal standing. The rostral thorax is scanned by pulling the ipsilateral forelimb forward. This is more readily achieved in horses than in cattle. Thorough examination of the rostral thorax might require placing the animal in lateral recumbency. Calves and foals can be examined either standing or in lateral recumbency.

Ultrasound examination of the thorax is particularly useful for detecting diseases of the pleura, pleural space, or lung surface. This is in addition to the well-documented utility of ultrasonographic examination of the heart and great vessels (see Ch. 11). The normal ultrasonographic anatomy of the thorax of cattle, horses, and calves has been determined. The following is a partial list of disorders or abnormalities detectable by percutaneous ultrasonographic examination of the thorax of farm animals or horses (excluding cardiac abnormalities):

- Excess pleural fluid
- Characteristics of pleural fluid (floculent, bubbles, fibrin)
- Extent of pleural fluid accumulation
- Localized areas of pleural fluid accumulation
- Nonaerated lung (atelectatic, consolidated)
- Pulmonary abscesses (must be confluent with visceral pleura)
- Intrathoracic masses (thymic lymphoma, cranial thoracic mass, gastric squamous-cell carcinoma)
- Pleural roughening (‘comet-tail’ lesions)
- Pneumothorax
- Pulmonary hemoptysis
- Exercise-induced pulmonary hemorrhage
- Hemothorax
- Diaphragmatic hernia
- Fractured ribs (especially in neonates).

Ultrasonographic examination is more sensitive and specific than radiographic examination in detecting the presence of pleural fluid and is particularly useful in the diagnosis and management of pleuritis in horses and cattle and pneumonia in calves. The extent of pulmonary lesions detected at necropsy correlates closely with the results of ultrasonographic examination of calves with pasteurellosis. Ultrasonographic examination is useful in diagnosis of thoracic diseases of cattle. Ultrasonography can identify pulmonary lesions in horses with infectious viral pneumonia. Ultrasonography is useful in identifying the presence of pleural fluid and guiding thoracocentesis to sample and drain this fluid.

Ultrasonographic examination of the larynx and associated structures is useful in identifying recurrent laryngeal neuropathy in horses, arytenoid chondritis, and dynamic laryngeal collapse. Sensitivity and specificity for ultrasonographic examination of the larynx for detection of recurrent laryngeal neuropathy was 71% to 79% and 86% to 91%, respectively, compared with dynamic endoscopy.

**LABORATORY EVALUATION OF RESPIRATORY SECRETIONS**

**SAMPLING RESPIRATORY SECRETIONS**

When an inflammatory disease process of the respiratory tract is suspected, the collection of samples of secretions and exudate for microbiological and cytologic examination can be considered. The objective is to obtain a sample uncontaminated with environmental flora, which are common in the upper respiratory tract, and to isolate the pathogen(s) or demonstrate inflammatory cells which may be associated with the lesion. This can be done by the following methods:

- Swabbing the nasal cavities or the pharynx
- Collection of fluid from the paranasal sinus
- Collection of fluid from the guttural pouch of Equidae
- Transtracheal aspirate
- Tracheal lavage
- Bronchoalveolar lavage
- Thoracocentesis

**NASAL SWAB**

A swab of the nasal cavities is a reliable method for the evaluation of the secretions associated with disease of the upper respiratory tract such as infectious bovine rhinotracheitis. However, when attempting to assess the health status of the lungs the nasal swab can be unsatisfactory because microbiological examination usually yields a large population of mixed flora, consisting of pathogens and nonpathogens, which is difficult to interpret. Examination of nasal swabs is only useful when seeking to detect specific pathogens (Strep. equi, influenza) and when the diagnostic tests are directed toward detecting these agents.

**NASOPHARYNGEAL SWABS**

For more reliable results and to lessen the contamination that occurs with nasal cavity samples, swabs of the laryngeal–pharyngeal area can be collected. A swab in a long covered sheath, of the type used for collecting cervical swabs from mares, is easily passed through the nasal cavities to the pharyngeal area. Important differences exist between the microbial isolates from nasopharyngeal swabs and those from lung tissues, which makes nasal swabs unreliable for diagnosis. For example, at the individual animal level, nasopharyngeal swabs and bronchoalveolar lavage show only moderate agreement; at the group or herd level, the isolation rates of various organisms are similar.

For isolation of viruses associated with disease of the upper respiratory tract, nasal swabs are satisfactory provided a copious amount of nasal discharge is collected, and the swabs are kept moist during transport to the laboratory. Nasal swabs sometimes contain an insufficient amount of secretion, and certain viral pathogens can become inactivated in transit.

**NASAL LAVAGE**

When larger quantities of nasal discharge are required for research purposes, nasal washings are usually collected, with the simplest technique being irrigation of the nasal cavities and collection into an open dish. From these samples, it is possible to isolate bacteria and viruses and identify immunoglobulins. The development of immunofluorescent and enzyme-linked immunosorbent assay (ELISA) tests for agents of infectious disease has provided reliable systems for the diagnosis of a variety of virus diseases in the early stages of infection. A technique and apparatus are available that obtain much better samples than the conventional cotton-wool swab provides. A vacuum pump aspirates epithelial cells and secretion from the nasal passage and pharynx. Cell smears are then prepared for microscopic examination and the mucus, and cells are used for conventional microbiological isolation.

**PARANASAL SINUS FLUID**

Fluid can be collected from the frontal and paranasal sinuses of most of the domestic large animals. Indications for collection of fluid include the presence or suspected presence of disease of the paranasal sinuses. Medications can be administered and infected sinuses lavaged using this approach. Absolute contraindications are few but include failure to be able to adequately restrain the animal.

Demonstration of fluid in the paranasal sinuses is aided by radiographic examination of the skull. Fluid is collected by percutaneous centesis of the frontal or maxillary sinus and submitted for cytologic and bacteriologic examination (Gram stain, culture). The procedure begins with restraint of the animal, which can include the induction of moderate sedation by administration of alpha-2 agonists and narcotics, or in cattle restraint in a head gate with the head secured with a halter. Next, the area over the sinus site is prepared aseptically and the skin and subcutaneous tissues are anesthetized with local anesthetic. A stab incision (< 1cm) is made in the skin and subcutaneous tissues. A hole is then drilled into the sinus using a Jacobs chuck with a Steinmann pin (2- to 4-mm diameter). Only a short (5-mm) length of the Steinmann pin should be exposed by the chuck. The hole is drilled by applying steady pressure and making alternating clockwise and counterclockwise...
movements with the chuck. Entry into the sinus cavity is evident as a sudden release of tension and easy passage of the Steinmann pin. The pin is then withdrawn, and sterile polyethylene tubing is inserted into the sinus cavity. Fluid can be aspirated at this time or, if none is forthcoming, 10 to 20 mL of sterile 0.9% saline or similar fluid can be instilled to the sinus cavity. Some of this fluid may run out the nostril if the animal’s muzzle is lower than the sinus.

Complications include injury to adjacent structures, including the infraorbital nerve (trigeminal nerve), nasolacrimal duct or parotid salivary duct near its entrance to the oral cavity at the level of the upper cheek teeth. Hemorrhage is usually minor and self-limiting. Subcutaneous emphysema resolves within days. Cellulitis is a risk, especially for animals with septic processes in the paranasal sinuses. Prophylactic administration of antibiotics should be considered in these cases.

**GUTTURAL POUCH FLUID**

Indications for collection of fluid from the guttural pouches of equids include bacteriologic or polymerase chain reaction (PCR) examination to determine whether the horse is infected by *S. equi* (the etiologic agent of strangles) or to investigate the suspected presence of other inflammatory or neoplastic disease. The preferred method of collection is during endoscopic examination of the guttural pouch. During this examination, fluid can be collected through a polyethylene tube inserted through the biopsy port of the endoscope. Fluid collected in this manner is potentially contaminated by organisms in the upper respiratory tract, and results of bacteriologic examination should be interpreted with caution. Usually, bacteriologic examination is for the presence of *S. equi* and demonstration of its presence is all that is required for a diagnosis of infection. Fluid can also be obtained from the guttural pouch by blind passage of a firm catheter, such as a Chambers mare catheter or 10 French dog urinary catheter, into the guttural pouch. This procedure requires some skill, and there is always the uncertainty that one might not have actually manipulated the catheter into the guttural pouch. A third technique involves percutaneous puncture of the guttural pouch just posterior to the ramus of the mandible and ventral to the ear. This technique has the potential to yield fluid that is uncontaminated by organisms from the upper respiratory tract, but it carries with it a high risk of injury to the important vascular and neural structures in and around the guttural pouch (internal and external carotid arteries, pharyngeal branch of the vagus nerve, hypoglossal nerve, and others). Percutaneous sampling of guttural pouch fluid should not be undertaken without careful consideration of the risks and benefits of the procedure.

**TRACHEOBRONCHIAL SECRETIONS**

The collection and evaluation of tracheobronchial secretions is a useful method for assessing lower airway disease and is widely used in the determination of the etiology of infectious pneumonia (viral, mycoplasmal, fungal, and parasitic) or the severity of disease (bronchoalveolar lavage fluid cytology in horses with heaves, exercise-induced pulmonary hemorrhage in athletic horses). It is also used as a tool in evaluating the respiratory health of intensively housed animals, such as in piggeries. Cytologic examination of recovered fluid can provide valuable information about the severity, extent, and etiology of disease of the lower airway. There are two methods of sampling tracheobronchial secretions—aspiration of tracheal fluid or lavage of bronchioles and distal airways. Each sampling method yields fluid of differing characteristics and source, and interpretation of the results of examination of these fluids depends on their source and the method of collection.

**Comparison of Tracheal Aspirates and Bronchoalveolar Lavage Fluid**

Examination of tracheal aspirates and bronchoalveolar lavage fluid yields different, but often complementary, information about the lower respiratory tract. The differences between tracheal aspirates and bronchoalveolar lavage fluid arise because cell populations, and types of cell, differ markedly among segments of airsaws. There is no correlation between cytologic features of tracheal aspirates and bronchoalveolar lavage fluid of horses, and this is probably the case in other species. Tracheal aspirates are representative of cell and bacterial populations of the large conducting airways (trachea and mainstem bronchi), which can originate in both the large and small conducting airways and the alveoli. Secretions of more distal airways can be modified during rostrad movement, such that fluid in a tracheal aspirate is not representative of processes deeper within the lung. Furthermore, disease localized to one region of the lung can alter tracheal fluid. Examination of tracheal aspirates is useful for detecting inflammation of the large airways and for isolation of microorganisms causing disease in these structures. There is no good evidence that findings on examination of tracheal aspirates correlate with abnormalities in pulmonary function, although they can correlate with exercise performance (racing). Tracheal aspirates do not accurately reflect lesions in the lungs of horses, but presence of excess mucus, detected on endoscopic examination, is associated with impaired performance, whereas presence of excess neutrophils is not.

Bronchoalveolar lavage is useful for sampling secretions in the more distal airways. It provides a sample of secretions that have not been contaminated by upper respiratory tract organisms or secretions before collection, and the sample is therefore assumed to be more representative of small airway and, to a lesser extent, pulmonary parenchymal and alveolar secretions or exudates. Bronchoalveolar lavage is useful in the detection of widespread lung disease but not necessarily in the detection of localized disease. Tracheal aspirates, because they in theory represent a composite sample of secretions from all regions of the lung, are likely to be more sensitive in detecting focal disease, such as a pulmonary abscess. Bronchoalveolar lavage fluid composition correlates well with pulmonary function in horses.

There is little agreement in cytologic examination of tracheal aspirates and bronchoalveolar lavage fluid of sick and healthy horses, and this difference probably exists in other species. Typically, the proportion of cells that are neutrophils is much higher in tracheal aspirates than in bronchoalveolar lavage fluid of both horses with heaves and normal horses. Mast cells are detected more frequently, and eosinophils less frequently, in bronchoalveolar lavage fluid than in tracheal fluid of normal horses.

**Tracheal Aspirates**

**Indications** for collection of tracheal aspirates include the need for microbiological and cytologic assessment of tracheal fluids. The primary indication is collection of samples for microbiological diagnosis of infectious respiratory disease. Other indications include detection and characterization of inflammation of the conducting airways. **Contraindications** include severe respiratory distress, although this is not an absolute contraindication, inability to adequately restrain the animal, and severe, spontaneous coughing. Percutaneous tracheal aspirate collection performed in animals with severe coughing can result in development of severe subcutaneous emphysema as a result of the high intratracheal pressures associated with the early phase of coughing. Most animals in which percutaneous tracheal aspirates are collected subsequently have radiographic evidence of pneumomediastinum.

Tracheal aspirates can be collected either by percutaneous puncture of the trachea or through an endoscope passed through the upper airways. The advantage of percutaneous collection of tracheal aspirates is that there is minimal risk of contamination of the sample by upper respiratory tract or oropharyngeal secretions. Microbiologic examination of the samples is therefore likely to accurately reflect microbes present in tracheal fluid. Collection of tracheal aspirates through an endoscope markedly increases the risk of contamination of the sample with oropharyngeal fluids, and it compromises the diagnostic utility of culture of the sample. This disadvantage is partially alleviated by the use of guarded catheters inserted through the endoscope. The disadvantage of percutaneous collection of tracheal fluid is that it is invasive, and there is a risk of localized
cellulitis and emphysema at the site of puncture. Endoscopic collection is relatively noninvasive and readily accomplished.

**Pericutaneous Transtracheal Aspiration**

Pericutaneous transtracheal aspiration is a practical method that has been used extensively in the horse and is adaptable to cattle, sheep and goats. For the horse, a 60-cm no. 240 to 280 polyethylene tube is passed through a 9- to 14-gauge needle inserted into the trachea between two rings. Commercially prepared kits for performing tracheal aspirations in horses are available that include all catheters and needles required. An alternative to polyethylene tubing is to use an 8 to 10 French male dog urinary catheter inserted through an appropriately sized cannula. The site for insertion of the needle or cannula is at the junction of the proximal and middle one-third of the ventral neck. The horse is usually sedated before insertion of the needle or cannula. The skin site is prepared aseptically, and a short stab incision is made after the area has been anesthetized. The cannula is removed to avoid cutting the tube, and the tube is pushed in as far as the thoracic inlet. Fluid typically pools in the trachea at the thoracic inlet in horses with lung disease (the tracheal lake or pool), and it is this fluid that is aspirated. Thirty to 50 mL of sterile saline (not bacteriostatic saline) is rapidly infused. The catheter or tubing should be rotated until tension is felt on aspiration by a syringe. Fluid is aspirated and submitted for cytologic, microbiological, or other examination.

Complications such as subcutaneous emphysema, pneumomediatinum, and cellulitis can occur, which necessitates care and asepsis during the procedure. Sudden movement of the cannula during insertion of the tube may cause part of the tube to be cut off and to fall into the bronchi, but without exception this is immediately coughed up through the nose or mouth.

**Endoscopic Sampling of Tracheal Secretions**

The flexible fiberoptic endoscope can be used to obtain tracheal lavage samples and at the same time visualize the state of the airways. The process is as for rhinolaryngoscopic examination with the addition of passage of a catheter through the biopsy port of the endoscope. Tracheal fluid is then visualized and aspirated through the catheter. The clinical advantages of the endoscopic collection include noninvasiveness, visual inspection of the airways, guidance of the catheter, and speed. The use of an endoscope with a guarded tracheal swab minimizes contamination by oropharyngeal secretions but does not eliminate it.

**Assessment of Results**

Microbiological examination can yield any one or more of a variety of bacteria, depending on the species examined, the animal's age, and its clinical condition. Tracheal aspirates of normal animals rarely yield any bacterial growth on culture. Growth of unusual organisms or known oropharyngeal commensal bacteria from samples obtained by endoscopic examination should not be given undue clinical significance as they probably result from contamination of the tracheal aspirate during collection. *Pseudomonas* spp. and anaerobes isolated from tracheal aspirates collected by endoscopy are almost always contaminants and of no clinical significance. The extent of contamination of tracheal aspirate samples by oropharyngeal bacteria can be estimated from the number of squamous epithelial cells in the sample. There is an apparent approximate linear relationship between the number of squamous cells per milliliter of fluid and the number of colony-forming bacterial units in tracheal aspirates. Samples containing over approximately 10 squamous epithelial cells per milliliter of tracheal aspirate had markedly greater bacterial contamination. Examination of Gram-stained smears of tracheal fluid is specific but not very sensitive for detection of bacteria, compared with culture. In other words, if examination of a Gram-stained smear of tracheal fluid reveals bacteria, then the sample is likely to yield bacteria on culture, whereas failure to detect bacteria predicts poorly the likelihood of growth of bacteria on culture of the sample. This indicates that examination of Gram-stained samples of tracheal fluid does not reliably predict bacterial isolation, and if an infectious etiology is suspected, the fluid should be cultured. Results of the microbiological examination of the tracheal fluid should be consistent with the animal's clinical condition and expected isolates.

Cytologic examination of tracheal fluid is an important diagnostic tool. Various stains are available to aid identification of cell types and numbers in tracheal aspirates. Neutrophils, macrophages, lymphocytes, and epithelial cells are readily identified on the basis of their classical morphology and staining using fast Romanowsky stain (Diff-Quik), but this stain is not suitable for identifying mast cells in equine tracheal fluid and probably that of other species. Leishman's stain is useful to identify mast cells. Clinically normal horses typically have fewer than 20% to 30% of cells as neutrophils with the majority of remaining cells being macrophages, lymphocytes and epithelial cells. Animals with inflammation of the airways typically have increased cell counts and proportion of neutrophils and large amounts of mucus. Horses with inflammatory airway disease such as heaves typically have more than 20% of the cells as neutrophils (see following "Heaves" section), and those with infectious pneumonia often have 50% to 90% of cells as neutrophils. Exercise markedly increases the proportion of neutrophils in tracheal fluid collected within 1 hour of the horse completing intense exercise. The presence of eosinophils is considered abnormal and is consistent with parasite migration (*Parascaris equorum* in foals, *Dictyocaulus viviparus* in calves). The presence of hemosiderin-laden macrophages is evidence of prior pulmonary hemorrhage.

**Bronchoalveolar Lavage**

Bronchoalveolar lavage provides a sample of secretions and cells of the distal airways and alveoli, referred to as bronchoalveolar lavage fluid. It is a widely used procedure in horses and, to a lesser extent, cattle and calves, sheep, camelds, and pigs. The procedure can be performed on foals, either sedated or anesthetized with improved fluid recovery in the latter. Analyses performed on bronchoalveolar lavage fluid include measurement of cell number and concentrations of various acute-phase proteins, analysis of type of immune proteins and surfactant, culture (usually in pigs and cattle), and use of PCR to detect specific pathogens (e.g., the causative agent of ovine pulmonary adenocarcinoma). It is a relatively noninvasive procedure that allows cytologic and biochemical evaluations of the lower airways and alveoli, which are useful diagnostic aids when evaluating animals with lung disease. Although fiberoptic bronchoscopy and tracheal aspirates permit assessment of the major bronchi and upper airways, bronchoalveolar lavage offers an extension of the diagnostic potential by sampling the terminal airways and alveolar spaces.

The primary indication for collection of bronchoalveolar lavage fluid is acute or chronic lung disease. This includes both infectious and noninfectious diseases, although interpretation of samples collected by passage of the collection tube through the nostrils or mouth is complicated by the inevitable contamination of the sample by oropharyngeal commensal bacteria. Despite this shortcoming, the technique has been used to detect pneumonia associated with *Mycoplasma* sp. in cattle. Contraindications are few, with respiratory distress being an obvious one. Complications of bronchoalveolar lavage are also few, and include a mild neutrophilia in lavaged sections of lungs and changes in phagocytic function of pulmonary macrophages, and microbial content, for several days after the procedure. Transient bronchial collapse can occur during the procedure in horses and is an indication of airway inflammation.

A shortcoming of bronchoalveolar lavage is that it lavages only a small region of the lung, with the risk that focal lung disease is not detected. There is clear evidence that important differences can exist in bronchoalveolar lavage fluid from left and right lungs and that the ideal technique involves collection of fluid from both lungs. This is best exemplified in pneumonia in horses, in...
which bronchoalveolar lavage fluid from pneumonic horses can contain large numbers and a high proportion of neutrophils or can be normal, depending on the lung or area of lung lavaged. Therefore the bronchoalveolar lavage procedure is a very specific but not very sensitive test for pneumonia in horses. Abnormal lavage fluid is helpful diagnostically, whereas normal results do not exclude the presence of foci of pulmonary disease. The lavage samples may be normal in horses affected with pneumonia or pleuropneumonia, and because of these false-negative results, this is not the best diagnostic technique to evaluate a horse with pneumonia. In contrast, the tracheobronchial aspirates are more sensitive and most horses with pneumonia have cytologic abnormalities.

Endoscopic Bronchoalveolar Lavage
Endoscopic bronchoalveolar lavage has the advantage of permitting visual examination of the airways during the procedure and selection of the region of the lung to be lavaged. This technique does require access to sophisticated endoscopic equipment. The technique described here for horses can be modified for use in other species.

Horses for bronchoalveolar lavage should be appropriately restrained. Sedation is usually essential and is achieved by administration of alpha-2-agonists. Coadministration of narcotics is recommended by some authorities to reduce the frequency and severity of coughing. Butorphanol tartrate 10 mg for a 400-kg horse is recommended, although this drug is not as effective as intra-tracheal lidocaine at reducing the frequency or severity of coughing when combined with detomidine for collection of bronchoalveolar lavage fluid. Effective suppression of coughing during collection of bronchoalveolar lavage fluid can be achieved by instillation of lidocaine (60 mL of a 0.7% solution—made by diluting 20 mL of 2% lidocaine solution by addition of 40 mL of isotonic saline). The lidocaine solution is administered as the endoscope enters the rostral trachea. A twitch can be applied to the nares. The endoscope must be at least 2 m in length and the external diameter should be 10 to 15 mm. Endoscopes of 10-mm diameter will pass to about the fifth-generation bronchi, whereas endoscopes of larger diameter will not pass quite as far into the lung. The endoscope is passed until it wedges, and then 300 mL of warmed (to reduced bronchospasm) isotonic saline is introduced in 5×60 mL aliquots. Air is infused after the last aliquot to ensure that all fluid is instilled. After the horse has taken between one and three breaths, the fluid is withdrawn and the aliquots are mixed. There is no difference in the cytologic composition of the first and subsequent aliquots.

Blind Bronchoalveolar Lavage
Commercial bronchoalveolar lavage tubes are available for use in horses, and are suitable for use in adult cattle and calves. The tubes are made of silicone and are therefore considerably more pliable than stomach tubes (which are not suitable for this procedure). The tubes are 2 m in length and have an external diameter of about 8 mm. The horse is restrained and sedated as for endoscopic bronchoalveolar lavage, and the tube is passed through one nostril into the trachea. The tube is then advanced until it wedges, evident as no further insertion of the tube with mild pressure. Continued vigorous attempts to pass the tube can result in the tube flexing in the pharynx and a loop of the tube entering the mouth. After the tube wedges, the cuff on the tube is inflated to prevent leakage of fluid around it, 300 mL of warm isotonic saline is instilled, the tube is flushed with air, and fluid is aspirated. The fluid should be foamy and, if cell counts are high, slightly cloudy.

Bronchoalveolar lavage can be performed in conscious sheep by insertion of 1.7-mm external diameter polyethylene tubing through a cannula inserted percutaneously in the trachea. The tubing is inserted until resistance is detected (about 40-45 cm in an adult sheep) and the lung is lavaged with 30 mL of sterile isotonic saline.

Laboratory Assessment of Tracheobronchial Secretions
A problem with comparison of cell counts of bronchoalveolar lavage fluid reported by different authors is the use of inconsistent quantities of fluid to perform the lavage. The use of different volumes alters the extent of dilution of the fluid. There is a need for uniformity in technique. An approach to this problem has been to measure substances in the bronchoalveolar lavage fluid that can provide an indication of the extent of dilution of the sample. Both endogenous (urea, albumin) and exogenous (inulin, methylene blue) markers have been used. Dilution factors using urea concentration in plasma and in bronchoalveolar lavage fluid appear to be useful. The assumption is that urea concentrations in bronchial and alveolar secretions will be identical to that in plasma. The formula for correcting for dilution that occurs during collection of bronchoalveolar lavage fluid is:

\[
\text{Dilution factor} = \frac{\text{Urea concentration in bronchoalveolar lavage fluid}}{\text{Urea concentration in plasma}}
\]

where urea concentration in bronchoalveolar lavage fluid and in plasma is expressed in the same units. The volume of the pulmonary epithelial lining fluid can then be calculated:

\[
\text{Pulmonary epithelial lining fluid volume} = \text{Dilution factor} \times \text{Volume of bronchoalveolar lavage fluid}
\]

Samples for cytology are submitted for preparation involving centrifugation of the sample to concentrate cells for preparation of slides for staining and microscopic examination. At least for samples from horses, examination of smears made directly from the sample, without centrifugation, is diagnostically useful. As for tracheal fluid, the proportion of mast cells in equine bronchoalveolar lavage fluid is underestimated if cells are stained with fast Romanowsky stain (Diff-Quik). Ideally, five fields are examined for each slide, rather than simply counting 400 cells, to ensure that the cell proportions are accurately reported, particularly for mast cells.

Diagnostic Value
The aspirates from normal animals contain ciliated columnar epithelial cells, mononuclear cells, and a few neutrophils with some mucus. Bronchoalveolar lavage fluid samples can be collected at 24-hour intervals without affecting the composition of the fluid, whereas collection as soon as 2 hours can result in a neutrophilic response. The concentration of the cells depends on the volume of fluid infused and the disease status of the animal. Representative values for various species are listed in Table 12-3. The general pattern is that animals with inflammatory airway disease, either infectious or noninfectious, have a higher proportion of neutrophils than do disease-free animals. However, ranges of normal values vary considerably depending on the species, the age of the animal, and its management (primarily housing conditions). Care should be taken not to overinterpret findings on examination of tracheal aspirates or bronchoalveolar lavage fluid. Although there is good correlation between microbiological results and cell counts in bronchoalveolar lavage fluid of calves with pneumonia and Thoroughbred racehorses with inflammatory airway disease, this association might not hold for all diseases or species.

There is the potential for a seasonal effect on bronchoalveolar lavage fluid composition, with mastocytosis occurring more commonly in the antipodean spring and neutrophilia and eosinophilia more common in the summer. Aged horses have a higher percentage of lymphocytes and lower proportion of macrophages than do younger horses. The clinical importance of this finding is unclear.

Thoracocentesis (Pleurocentesis)
Paracentesis of the pleural cavity is of value when the presence of pleural fluid is suspected and, in the absence of ultrasonographic examination, needs to be confirmed, and when sampling of pleural fluid for cytologic and bacteriologic examination is indicated. The primary indication for sampling pleural fluid is the presence of excess pleural fluid. Sampling of pleural fluid is usually accompanied by therapeutic drainage, in which case the cannula used for sampling is

Values are mean ± SD or median and range (*); NR, not reported. See Radostits et al. Veterinary Medicine 10th edition. 2006. Page 488. Table 10-3 for references.

Larger than if only collection of pleural fluid is desired. Contraindications are minimal, especially if the procedure can be performed under ultrasonographic guidance. The principal contraindication is the inability to restrain an unruly animal because this increases the risk of laceration of the lung or a coronary vessel, or cardiac puncture. Complications include hemorrhage from lacerated intercostal or pleural vessels, pneumothorax secondary to laceration of the lung or introduction of air through the cannula, cardiac puncture and sudden death, irritation of the myocardium and ventricular arrhythmia (premature ventricular contractions), or coronary artery laceration and subsequent cardiac tamponade and death. There is a risk of cellulitis at the site of centesis, especially if indwelling cannulas are maintained for more than a day.

The procedure is performed with the animal standing. Sedation or systemic analgesia is usually not needed, unless it is medically indicated or the animal is not easily restrained. The equipment for sampling of pleural fluid from adult horses or cattle is a blunt 10- to 15-cm cannula of approximately

...
3 mm in diameter (such as a bovine test cannula) or a 7.5-cm spinal needle. The blunt-tipped cannula is preferred because use of it reduces the risk of laceration of vital structures. A three-way stopcock or similar device should be attached to the hub of the needle or cannula and closed to prevent aspiration of air when the pleural cavity is entered. The site for centesis is best identified by ultrasonographic examination of the thorax or, if that is not available, by percussion and auscultation of the chest to identify the fluid level. A commonly used site is the seventh intercostal space on the left side and the sixth intercostal space on the right side. The skin should be clipped of hair and aseptically prepared. The region can be anesthetized with approximately 10 mL of 2% lidocaine, mepiricaine, or a similar product.

The cannula or needle should be introduced over the rib and then directed cranial to the rib (the intercostal vessels and nerves course along the caudal edge of the rib). If a cannula is used, then a slight “popping” sensation is felt as the cannula perforates the parietal pleura. A syringe is attached to the cannula or needle and fluid is aspirated from the pleural space. Collected fluid should be examined visually. Normal pleural fluid, which is present in small quantities in normal animals, is clear and slightly yellow. Abnormal fluid can be bloody, thick, and yellow, suggestive of purulent material, or flocculent. The material should be smelled—a foul odor is usually present when the pleural fluid is infected by anaerobic bacteria and is a sign of a poor prognosis. Cytologic examination should be performed, including white cell count and measurement of total protein concentration. Ancillary measurements on pleural fluid include pH, Pco₂, Po₂, bicarbonate, glucose, and lactate. Sterile pleural fluid has a pH, Po₂, and Pco₂ and lactate, glucose, and bicarbonate concentrations similar to those of venous blood. Infected pleural fluid is acidic, is hypercarbic, and has an increased concentration of lactate and decreased concentrations of bicarbonate and glucose compared with venous blood. Pleural fluid should be cultured for aerobic and anaerobic bacteria and mycoplasmas. Antimicrobial susceptibility should be determined for isolated organisms. Fungal cultures are rarely indicated.

Ultrasound-guided needle puncture of a suspected lung abscess to determine the species of bacteria present is sometimes practiced, but there is the risk that infection will be spread to the pleura by this technique. This technique is not recommended as a routine procedure because microbiological examination of tracheal aspirates will probably yield the offending bacteria.

### PULMONARY FUNCTION TESTS

Pulmonary function tests provide quantitative assessment of pulmonary ventilatory function through measurement of expired and inspired gas volumes, intrathoracic pressures, and derivations of these variables—sometimes referred to as pulmonary mechanics. The techniques are widely used in research into pulmonary diseases, especially heaves in horses, and have been adapted for use in ruminants. A relatively simple assessment of pulmonary function is measurement of pleural pressure changes during respiration. This can be achieved by either insertion of a blunt cannula through the intercostal space or passage of a balloon catheter into the thoracic esophagus. The pressure changes during respiration are then recorded and the maximal pressure change between inspiration and expiration is calculated. The pressure change is closely correlated with airway resistance to airflow and is an excellent indicator of the severity of bronchoconstrictive diseases.

More complex measurements are made by application of an airtight face mask containing a flow meter to the animal. Combined with measures of airway pressure, airflow during tidal breathing yields measures of tidal volume, minute volume, respiratory rate, pulmonary resistance, and pulmonary dynamic compliance. Measurements made with the animal at rest are relatively insensitive to small changes in pulmonary function, and the sensitivity of these tests to detect heaves is low. The sensitivity of changes in maximal pleural pressure and resistance of the lower airways are 44% and 22%, respectively. The sensitivity of the test can be increased by measuring these variables during exercise. Measurements of respiratory mechanics in horses with heaves is reproducible over both short (hours) and long (months) periods of time, indicating the usefulness of these techniques for monitoring of disease progression and response to therapy.

Measurement of flow–volume loops has been performed for both stationary and exercising horses. A number of variables are derived from these measures and used as indicators of pulmonary function. However, the large variability in these measures in stationary horses (16%-32%) severely limits the utility of this test to detect mild or subclinical respiratory disease. Similarly, flow–volume loops in exercising horses with obstructive lung disease of moderate severity do not differ markedly from those of the same horses when they do not have lung disease. Flow–volume loops have limited use in evaluation of lung function in animals.

Other tests of pulmonary function include the nitrogen dilution test and the single-breath diagram for CO₂. The nitrogen dilution test concentrations of nitrogen in exhaled air are measured while the animal breathes 100% oxygen. A number of variables are calculated from the decay curve of nitrogen concentration in exhaled air, including the functional residual capacity. There are clinically significant differences between animals with normal respiratory function and those with pulmonary disease. However, this test is not readily adapted for routine clinical use. Pulmonary function obtained include estimates of dead space ratio, physiologic dead space volume and alveolar efficiency. The clinical utility of this test and its ability to detect mild or subclinical disease in animals have not been demonstrated.

Impulse oscillometry offers the potential of being a potentially clinically useful test of respiratory function in horses, pigs, and cattle. The technique involves fitting an airtight facemask containing a pneumotachograph for measurement of respiratory volumes and tubing to a horse. The tubing is attached to a loudspeaker, which is used to generate square-wave signals containing harmonics between 0 and 10 Hz. Information from the system is analyzed using a computer program and indices of pulmonary resistance and reactance are determined. The forced oscillation technique in feedlot cattle with naturally occurring shipping fever indicates the presence of a large increase in pulmonary resistance and a decrease in dynamic compliance with obstructive lung disease located mainly at the level of large airways but also in small airways.

The test is more sensitive than conventional techniques in detecting partial upper airway obstruction, heaves, and inflammatory airway disease in horses, and in pigs with lung disease. Impulse oscillometry can also be used to monitor response to therapy. The sensitivity of these tests can be increased by provocative tests in which animals are administered agents, such as histamine or methacholine, that cause bronchoconstriction in animals with reactive airways.

Measurement of forced expiratory flow–volume curves and forced vital capacity in horses is a sensitive indicator of bronchoconstriction. The test involves the heavily sedated horse having a nasotracheal tube inserted. The nasotracheal tube is then attached to a large vacuum reservoir and a valve is opened abruptly. The maximum rate of forced
expiratory airflow is measured and various variables indicative of pulmonary function are calculated, including forced expiratory volume in 1 second (FEV1). The clinical utility of this test of pulmonary function is limited by the extensive instrumentation of the animal and the need for sophisticated electronics.

**ARTERIAL BLOOD GAS ANALYSIS**

Measurement of $P_{O_2}$, $P_{CO_2}$, and arterial oxygen content ($C_{O_2}$) provides valuable information about pulmonary function and oxygen delivery to tissues. The arterial oxygen tension and arterial oxygen content are not equivalent. The arterial oxygen tension ($P_{O_2}$) is a measure of the partial pressure of oxygen in arterial blood determined by the amount of oxygen dissolved in the blood (not the amount bound to hemoglobin) and the temperature of the blood—it is not a direct measure of arterial oxygen content. Arterial oxygen content is the amount of oxygen per unit of blood and includes both dissolved oxygen and that bound to hemoglobin. The oxygen tension can be viewed as the driving force for diffusion of oxygen from capillaries into mitochondria (in which the oxygen tension is about 2 mm Hg), whereas the oxygen content is the amount of oxygen delivered to tissue. Both are important measures of pulmonary function and oxygen delivery to tissue.

Measurement of oxygen tension in blood is achieved by analysis of an appropriately collected sample of arterial blood using a blood gas analyzer (oxygen electrode). Instruments designed for medical or veterinary clinical use measure pH, $P_{O_2}$, and $P_{CO_2}$ at a temperature of 37°C (98.6°F). Depending on the software included with the instrument, various derived values are also reported, including bicarbonate concentration, base excess, and oxygen saturation. It is important to understand that oxygen saturation reported by blood gas instruments is a calculated value and might not be correct. Oxygen saturation is measured by a cooximeter, which is different from a blood gas machine, and the amount of oxygen carried by hemoglobin is then calculated from this value, with the assumption that each gram of hemoglobin, when fully saturated, carries approximately 1.34 to 1.39 mL of oxygen. The total oxygen content of blood is calculated by adding the amount carried by hemoglobin to the amount of oxygen dissolved in the aqueous phase of the blood. The formula is:

$$O_2\text{ content} = (S_{O_2} \times 1.34 \times [Hb]) + (0.003 \times P_{O_2})$$

where $O_2$ content is in mL/100 mL, $S_{O_2}$ is the arterial oxygen saturation (%), 1.34 is the amount of oxygen carried by fully saturated hemoglobin (mL/g), Hbwsa is the concentration of hemoglobin in blood (g/100 mL), 0.003 is the amount of oxygen dissolved in the aqueous phase of 100 mL of blood for each 1-mm Hg increase in $P_{O_2}$, and $P_{O_2}$ is the oxygen tension in arterial blood. The appropriate substitutions can be made to calculate the oxygen content of venous blood.

The oxygen content of arterial blood is the critical factor (with cardiac output) in determining oxygen delivery to tissues. However, measurement of arterial oxygen content is not as readily accomplished as measurement of arterial oxygen tension. Therefore in animals with normal hemoglobin concentration and function the arterial oxygen tension is used as a surrogate measure of arterial oxygen content. In doing so, it must be recognized that the extent of hemoglobin saturation with oxygen is dependent on both the affinity of hemoglobin for oxygen and the oxygen tension of the blood. The oxygen tension/percentage saturation relationship is sigmoidal, with 50% saturation occurring at about 30 mm Hg in most species (there are minor variations) and 80% saturation at a $P_{O_2}$ of 45 to 55 mm Hg. The sigmoidal shape of the oxygen–hemoglobin saturation curve has important clinical consequences. Small decrements in $P_{O_2}$ from normal values (usually 95-105 mm Hg in animals breathing ambient air at sea level) have a minimal effect on oxygen content of blood. Many modern blood gas analyzers have software that calculates oxygen content of blood, but it must be recognized that these calculations often use an assumed, not measured, hemoglobin concentration (usually 15 g/dL) and values for the human $S_{O_2}$–$P_{O_2}$ relationship. These assumed values may not be correct for animals, and one should always check the assumptions used to calculate oxygen content of blood before accepting and acting on those values. Direct measurement of blood oxygen content is restricted to research laboratories—indirect estimates gained from oxygen saturation and hemoglobin concentration are usually sufficiently accurate for clinical use.

The oxygen tension in blood is proportional to the amount of oxygen dissolved in the aqueous phase of the blood and the temperature of the blood. For a given amount of oxygen dissolved in blood, the tension varies according to the temperature of the animal. Almost all blood gas analyzers measure the $P_{O_2}$ at 37°C (98.6°F). If the animal’s body temperature is markedly different from that, then the reported $P_{O_2}$ can be erroneous. For instance, the $P_{O_2}$ of a horse with a body temperature of 40°C (104.0°F) measured using an analyzer with a temperature of 37°C (98.6°F) would be 80 mm Hg (the $P_{CO_2}$ would be 35 mm Hg). If the $P_{O_2}$ was adjusted for the difference between the horse’s body temperature and that of the analyzer, then the reported $P_{O_2}$ would be 100 mm Hg (and the $P_{CO_2}$ would be 44 mm Hg). Failure to make the appropriate temperature corrections can result in errors of 6% to 7% per °C (3% to 4% per °F). When interpreting blood gas values, attention should be paid to the temperature of the animal and consideration given to adjusting gas tension values according to the animal’s body temperature. This is probably only clinically important when there are extreme deviations from normal temperature and oxygen tension. Most blood gas analyzers include software that makes the appropriate corrections.

The arterial oxygen tension is determined in the alveolus by the alveolar oxygen tension and the alveolar–arterial difference. The alveolar oxygen tension ($P_{O_2}$) can be calculated from the following equation:

$$P_{O_2} = F_{O_2}(P_a - P_HO_2) - (P_{CO_2}/RQ)$$

where $F_{O_2}$ is the inspired oxygen fraction (21% for ambient air), $P_a$ is the barometric pressure (760 mm Hg at sea level), $P_HO_2$ is the partial pressure of water vapor in the alveolar air (47 mm Hg at 37°C, 98.6°F), and $RQ$ is the respiratory quotient (usually assumed to be 0.8 for resting animals). The alveolar–arterial $P_{O_2}$ difference ($A – P_{O_2}$) is calculated as:

$$A – a P_{O_2} = P_{O_2} – P_{O_2}$$

The $A–a P_{O_2}$ difference has clinical significance in that it is an indicator of pulmonary function that is somewhat independent of inspired oxygen fraction and is therefore useful in animals being supplemented with oxygen (there is a small increase in the $A–a$ difference with marked increases in $F_{O_2}$). Increases in $A–a P_{O_2}$ difference are indicative of ventilation-perfusion mismatches, with the $A–a P_{O_2}$ difference increasing with worsening ventilation-perfusion abnormalities.

**Normal Values**

Values obtained from clinically normal animals breathing room air at sea level vary slightly between species, with most animals having an arterial $P_{O_2}$ of 95 to 105 mm Hg and a $P_{CO_2}$ of 35 to 45 mm Hg. Oxygen saturation in clinically normal animals breathing air at sea level is above 98% and oxygen content of arterial blood is 16 to 24 mL/dL of blood (this depends on the hemoglobin concentration in blood). The difference in oxygen content of arterial and mixed venous blood is usually 4 to 8 mL/dL of blood. Values can be influenced substantially by changes in physiologic state (exercise, hyperpnea), positioning, pulmonary disease, and altitude (Table 12-4). Positioning of the animal can be important, especially in neonatal foals, in which the compliant chest wall can impair ventilation in laterally recumbent foals—foals have lower arterial oxygen tension when in lateral recumbency than when in sternal recumbency.

**Collection of Arterial Blood Gas Samples**

Arterial samples can be collected from any of the appropriate peripheral arteries, which

Vary depending on species. An arterial sample is representative of aortic blood in almost all instances. Samples can be collected from the carotid, transverse facial, metacarpal, and metatarsal arteries in horses and foals, and from the carotid, radial, and coccygeal arteries in cattle and calves. Minimally invasive arterial access is difficult in pigs.

Samples should be collected in glass, in which the dead space has been filled with heparin solution, and stored at 0°C until analyzed. Typically, a 3-mL plastic syringe containing approximately 0.1 mL of sodium heparin and attached to a 22- to 25-gauge needle is used. All air should be expelled from the syringe before collection of the sample, and care should be taken not to introduce air into the syringe until blood gas tensions are measured. Air in the syringe will increase the measured oxygen tension of blood from normal animals. The sample should be measured as soon after collection as possible (within minutes). If immediate analysis is not available, the sample should be stored in iced water until analysis to prevent consumption of oxygen, production of carbon dioxide and a decrease in pH.

Storage of arterial samples in plastic syringes in iced water can increase the oxygen tension of blood from normal animals. The sample should be measured as soon after collection as possible (within minutes). If immediate analysis is not available, the sample should be stored in iced water until analysis to prevent consumption of oxygen, production of carbon dioxide and a decrease in pH.

Measurement of venous oxygen tension, saturation, or content can be useful in assessment of the adequacy of oxygen delivery to tissue. The oxygen tension, saturation and content of venous blood depends on the extent of oxygenation of arterial blood, the blood flow to the tissues, the metabolic rate of the tissues drained by the veins from which blood is sampled, and the transit time of blood through capillaries. The multiplicity of these factors means that determining the precise reasons for abnormalities in venous blood gas tensions is not possible. However, some generalizations can be made about venous oxygen tension, saturation and content.

In normal, resting animals, oxygen delivery to tissues exceeds oxygen needs (demand) of the tissue, with the result that venous blood draining these tissues is only partially desaturated. Hence, venous blood from the pulmonary artery (mixed venous blood) has oxygen tension, saturation, and content of approximately 35 to 45 mm Hg, 80% to 90%, and 12 to 18 mL/100 mL, respectively (the latter depending on hemoglobin concentration in addition to hemoglobin saturation). However, in situations in which oxygen delivery to tissue is decreased to levels that only just meet or do not meet the oxygen needs of tissue, there is extraction of a greater proportion of oxygen in blood, and venous oxygen tension, saturation, and content decline, and the arterial–venous difference in oxygen content increases. Reasons for oxygen delivery to tissue not meeting the oxygen needs of that tissue are decreased perfusion of tissue, such as can occur with shock or circulatory failure, anemia, or decreased $P_{A}O_2$. Additionally, tissues with a high metabolic rate, such as exercising muscle, have high oxygen demands that can outstrip delivery.

Ideally, whole-body assessment of oxygen delivery by measurement of venous blood gas tensions is best achieved by examination of mixed venous blood. Mixed venous blood represents an admixture of blood draining all tissues and is collected from the pulmonary artery (although samples collected from the right ventricle or atrium are also appropriate in most instances). Although this blood is optimal for assessment of oxygen delivery to tissue, collection of mixed venous samples is not routine because of the need for catheterization of the pulmonary artery. Samples from peripheral veins are therefore used, but care should be taken when interpreting these values as venous blood gas tensions can vary considerably among veins. For animals with normal circulatory status, blood gas tensions in jugular vein blood are likely to be reasonable estimates of mixed venous gas tensions. However, if circulatory function is not normal, then samples from peripheral veins may not be indicative of values in mixed venous blood.

Samples for venous blood gas analysis should be collected into syringes in which the dead space is filled with sodium or lithium heparin solution. The volume of heparin should not be more than 2% of the amount of blood. Samples should be processed promptly. If samples cannot be processed within an hour, they should be stored in iced water. Samples stored in iced water for 24 hours have values that are minimally different from those before storage, whereas samples stored at 25°C (77°F) change markedly in 2 to 3 hours.

**PULSE OXIMETRY**

Pulse oximeters are devices for measurement of blood oxygen saturation that attach to skin or mucous membranes and sense the absorption spectrum of light by hemoglobin (the same principle is used in bench top cooximeters) in the underlying tissues. The devices are widely used for noninvasive monitoring of oxygenation in humans and have been adopted for use in animals. However, important challenges to their use exist in animals, not least of which is the presence of hair and densely pigmented skin in most farm animals. The devices have important deficiencies when used in foals and adult horses, but those applied to the ear, lip, or tongue of
foals have good sensitivity and specificity for detecting arterial $S_0_2$ of less than 90 mm Hg (12 kPa). The devices consistently underestimate arterial $S_0_2$ at low saturations. Care should be taken when using these devices to monitor arterial hemoglobin saturation in animals.

**BLOOD LACTATE CONCENTRATION**

Measurement of blood lactate concentration is useful in assessing the adequacy of oxygen delivery to tissues and is now provided by point-of-care units, some of which have been validated for use in horses and calves. Hypoxia causes a shift to anaerobic metabolism and the production of lactate. Lactate production is related to the severity and duration of hypoxia, with more severe hypoxia resulting in greater accumulation of lactate in tissues and its subsequent diffusion or transport into blood. Hypoxia also reduces the rate of removal of lactate from blood. The combination of increased production and decreased removal causes lactate to accumulate in blood. Measurement of blood lactate concentrations (which are usually lower than plasma lactate concentrations) is gaining increasing clinical usefulness as point-of-care analyzers become more readily available and testing more affordable.

**Samples** for measurement of blood lactate can be collected into syringes containing heparin solution (as used for measurement of blood gas tensions) if the sample is to be analyzed within 30 minutes. Samples should be stored in iced water until analysis. Prolonged storage at room temperature results in increases in blood lactate concentration. If sample collection is anticipated to be delayed, then samples should be collected into evacuated tubes containing sodium fluoride and potassium ethylenediamine tetraacetic acid (EDTA)—the sodium fluoride inhibits glycolysis. However, plasma lactate concentrations collected in these tubes are approximately 10% lower than in samples collected into tubes containing heparin, probably because of the osmotic effect of sodium fluoride/potassium EDTA on red cells. Samples for clinical analysis should be collected into syringes containing a heparin solution and analyzed within 30 minutes of collection. Measurement of blood or plasma lactate concentrations can be made using point-of-care analyzers, although these can yield results that differ markedly from traditional analyzers, especially in animals with extreme values for hematocrit (severe anemia or polycythemia). Ideally, blood and plasma lactate concentrations should be measured only on analyzers that have been validated for the species and clinical situation being studied.

Blood lactate and plasma lactate concentrations are not equal, with blood lactate concentration being lower because of the dilutional effect of red blood cells, which have a lower lactate concentration than plasma. However, most clinical assessments are based on blood lactate concentrations.

Mixed venous or arterial blood lactate concentrations in most farm animal species are less than 2 mmol/L in normal, healthy animals. Tissue hypoxia, in addition to other conditions such as toxemia and septic shock, can increase blood lactate concentration. Blood lactate concentrations between 2 and 4 mmol/L should be interpreted with caution, whereas values above 4 mmol/L are indicative of clinically important disruption of oxygen transport and cellular metabolism. Repeated measurements over time can be useful for assessing progression of disease or efficacy of treatment. For instance, plasma lactate concentrations above 4 mmol/L in cattle with pneumonia are predictive of death within 24 hours.

**COLLECTION AND ANALYSIS OF EXHALED BREATH CONDENSATE**

Collection and analysis of exhaled breath condensate have use primarily in research studies at the current time and are not likely to be sensitive or specific markers of specific disease states, although they might provide a means of assessing disease severity or pathogenesis. Breath condensate is collected and analyzed for markers of pulmonary or systemic disease, including pH and markers of oxidative stress. The pH of breath condensate is affected by the design of the collection device and condensation surface temperature, precluding comparison of data between studies using different methodologies. Examples of use of analysis of breath condensate include that induction of pneumonia in calves by infection with Pasteurella multocida increases the concentration of leukotriene B$_4$ in breath condensate, horses with heaves have higher concentrations of hydrogen peroxide than normal horses, probably a result of the airway neutrophilia in affected animals, and altered oxidative stress state in foals with Rhodococcus equi pneumonia.

**LUNG BIOPSY**

Percutaneous biopsy of the lung is useful in confirming diagnosis of lung disease by providing tissue for histologic and microbiologic examination in cattle, sheep, and horses. The technique is most useful by providing a histologic diagnosis of diffuse lung diseases or, when used with ultrasonographic guidance or performed by thoracoscopy, for focal disease. Biopsy provided a diagnosis in ~80% of 65 horses with clinical evidence of diffuse lung disease.

Biopsy is usually percutaneous but can also be performed during thoracoscopy. Indications for the procedure include the presence of diseases of the lungs in which a diagnosis cannot be arrived at through other forms of examination, including tracheal aspiration or bronchial-vascular lavage. It can also be used for assessing the severity of histologic changes and response to therapy. The procedure is best suited for widespread diseases of the lung, but it can be used for diseases that produce focal lesions if the biopsy is performed with ultrasonographic guidance. Contraindications include abnormalities in clotting function, pneumothorax, and severe respiratory distress. The danger in performing lung biopsy in animals in severe respiratory distress is that complications of biopsy, such as pneumothorax, hemotorax, or hemorrhage into airways, could further impair lung function and cause the death of the animal.

Complications include pneumothorax, hemothorax or hemorrhage into airways with subsequent hemoptysis or epistaxis, pulmonary hematoma, and dissemination of infection from infected lung to the pleural space. The risk of complications increases as the number of attempts at biopsy increase. Pneumothorax, which is usually not clinically apparent, occurs in some horses in which the procedure is performed. Coughing and epistaxis occur in about 20% and 10% of horses, respectively. Life-threatening hemorrhage occurs uncommonly (~2% of cases). Bleeding into the airways, detected by tracheobronchoscopic examination, occurred in 16 of 50 horses after use of the manually discharged biopsy needle and in 5 of 50 horses after use of the automatically discharged needle. Two of 60 cows collapsed immediately after the procedure, but subsequently stood and recovered. The remaining cows had no clinical abnormalities detected after biopsy, although necropsy examination 24 hours later revealed small lesions in the pulmonary parenchyma at the site of biopsy. One of 10 healthy sheep had coughing and bloody nasal discharge after lung biopsy.

The procedure is performed in adult horses and cattle using a 14-gauge biopsy needle, either manually operated or one that discharges automatically. Such instruments yield tissue in over 95% of attempts in cattle. The area for examination is best determined by radiographic or ultrasonographic examination of the thorax. A common site for biopsy is at the junction of the dorsal and middle thirds of the thorax at the 9th intercostal space with the 13th intercostal space in horses. The procedure is best performed with the animal standing. The skin over the area should be clipped of hair and aseptically prepared and local anesthesia induced by injection of 2% lidocaine or a similar compound into the intercostal space. A 0.5-cm incision is made through the skin, and the biopsy instrument is advanced through the caudal intercostal space (intercostal vessels and nerves course along the
Diseases

VetBooks.ir

caudal aspect of the ribs) and into the lung perpendicular to the skin surface. The instrument is advanced approximately 2 cm into the lung, and tissue is collected at the end of inspiration. The procedure is repeated as necessary for collection of samples for histologic and microbiological examination. The skin incision is closed with a single suture if necessary. The animal is then monitored closely for 12 to 24 hours for signs of coughing, epistaxis, hemoptysis, fever, or respiratory distress. Hemorrhage into the airways is usually evident, often within minutes of completing the procedure, by the animal coughing. Hemorrhage into the airways is often evident as hemoptysis, even in horses. Respiratory distress can be caused by pneumothorax, hemothorax, or hemorrhage into airways. Treatment includes percutaneous aspiration of pleural air, administration of oxygen by mask or catheterization, and mechanical ventilation.

An alternative technique in cattle involves collection of lung tissue through the right cranioventral intercostal 2 space using a manual or automated 12- or 14-gauge biopsy needle. Lung was successfully harvested from 56% of feedlot steers with chronic bovine respiratory disease and had the same pathologic diagnosis as that obtained by necropsy examination in 75% of animals. One animal of 34 had fatal complications.

RESPIRATORY SOUND SPECTRUM ANALYSIS

Analysis of respiratory sounds has utility in the diagnosis of disorders of the upper respiratory tract of horses. Respiratory sounds can be detected by a small microphone near the horse’s nostril with the recording made by a tape recorder or similar device worn on the saddle or girth strap. Studies can be performed with horses running on either a treadmill or outside over ground. Dorsal displacement of the soft palate produces broad-frequency expiratory noises with rapid periodicity (rattling), whereas dynamic unilateral collapse of the arytenoid causes an increase in inspiratory broad band high-frequency noise. The technique correctly identifies more than 90% of horses with dynamic collapse of the left arytenoid cartilage (“roarers”).

EXERCISE TESTING

Exercise testing for assessment of respiratory tract function is essentially limited to horses, in which it is the gold standard for diagnosis of dynamic upper respiratory disease in horses. Tests available for use on horses running on a treadmill include endoscopic examination of the upper airway, respiratory noise analysis, blood gas analysis, and measurement of respiratory mechanics. The most important of these in a clinical setting is videendoscopy during exercise to detect dysfunction of the upper airway of horses. With the exception of recurrent laryngeal neuropathy, there is only poor correlation between results of endoscopic examination performed in standing horses compared with results of dynamic endoscopic examination during exercise. Endoscopy of standing horses has very limited capacity to detect disorders that occur only during exercise, and some disorders of the upper respiratory tract, such as progressive weakness of the laryngeal abductor muscles, axial deviation of the aryepiglottic fold, and epiglottic retroversion, can only be diagnosed by endoscopic examination performed during strenuous exercise. Another finding is the presence of multiple upper airway abnormalities in a high proportion of horses examined during exercise.

Although testing has historically been conducted on a high-speed treadmill, a recent advance has been the development of endoscopes and recording systems that allow horses to be examined while exercising in the field (overground or dynamic endoscopy). Such overground endoscopy systems comprise an endoscope, water pump, endoscope control unit (for manipulating the tip of the endoscope), and a recording/transmitting unit carried on the horse or the rider (Fig. 12-2) weighing up to 2.5 kg. The source of light are light emitting diodes in the end of the endoscope. Preferred is a recording unit that simultaneously transmits the image in real time, usually using Bluetooth or similar technology, to an observer situated a short distance (up to 220 m depending on the unit) from the horse. The development of overground endoscopy has enabled more widespread use of examination of the upper airway of horses during exercise and the refinement of understanding of dynamic obstructive disorders of the upper airway.

Overground endoscopy has the great advantage that it enables examination of the horse while it is performing wearing its usual tack, ridden by its usual rider, and performing its customary exercise. Overground endoscopy performed on Standardbred racehorses does not appear to impair race time in qualifying races, and allows detection of important abnormalities associated with poor performance. A disadvantage is that the intensity of exercise might not be as easily controlled by the veterinarian, or that exercise intensity that mimics that of actual competition in racehorses is not achieved, although exercise protocols to ensure the consistency of exercise are available.

Principles of Treatment and Control of Respiratory Tract Disease

TREATMENT OF RESPIRATORY DISEASE

Treatment of diseases of the lower respiratory tract depends on the cause of the disease. However, the common principles are as follows:
Transport abnormalities cause hypoxemia with normal ventilation-perfusion but it is impractical for long-term treatment. (foals have better respiratory function and increased rates of flow up to 200 mL/min. The ability to elevate arterial oxygen increases with age from birth to 7 days of age because of the existence of right-to-left shunts in the newborn foal. Maximal changes in arterial oxygen tension occur within 2 minutes of the start of supplementation. In normal foals a flow rate of 4 L/min increases arterial oxygen tension, but responses in sick foals are often attenuated at a rate of positional effects on gas exchange (recumbency) and other causes of hypoventilation.

Nasal insufflation improves arterial oxygen tensions and acid-base status in healthy foals and in mildly to moderately affected foals but might not be sufficient for oxygenation of foals with severe impairment of gas exchange. The efficacy of nasal insufflation of oxygen through intranasal catheters in foals depends on the rate of oxygen administration and whether catheters are inserted in one or both nostrils. When arterial oxygen tensions ($P_{O_2}$) and inspired oxygen fraction ($F_{O_2}$) are measured in arterial blood collected from the metatarsal artery and thoracic trachea, respectively, of healthy, standing, 5- to 7-day-old foals, insufflation results in significant increases in $F_{O_2}$ and arterial oxygen tension (Table 12-5). Unilateral administration of oxygen at flow rates of 50 mL O$_2$ per kg body weight per minute resulted in an increase in $F_{O_2}$ from 18% to 23% and in arterial oxygen tension from 93 to 136 mm Hg. Bilateral administration and increased rates of flow up to 200 mL/kg/min resulted in further increases. 38 It is important to note that this study was done in healthy, standing foals and that the effect of oxygen insufflation on $P_{O_2}$ could be attenuated by recumbency and lung disease. However, $F_{O_2}$ is unlikely to be affected by these variables and this information will allow calculation of the $P_{O_2}$: $F_{O_2}$ ratio in foals as a way of detecting lung injury. Intranasal catheters are also difficult to maintain in active sucking foals and require the use of higher oxygen flow rates to achieve beneficial effects. Flow rates in foals with lung injury should be adjusted based on repeated measurement of arterial oxygen tension with the aim of maintaining $P_{O_2}$ at ≥ 100 mm Hg and $S_{O_2}$ at greater than 90%.

A transtracheal oxygen delivery system has been used in foals with pneumonia and rapidly progressive dyspnea and hypoxemia despite intranasal oxygen therapy. A catheter is inserted into the midcervical trachea and directly distally in the tracheal lumen for approximately 25 cm. The catheter is attached to about 6 m of oxygen tubing and suspended above the foal, allowing it to move around the stall and suck the mare for up to 6 days without dislodging the catheter. This system was more effective than nasal insufflation in increasing arterial oxygen tension, probably because the catheter tip is in the distal trachea and bypasses a significant length of dead space that would not be oxygenated were the oxygen delivered into the nasopharynx.

In foals with neonatal respiratory distress, signs of respiratory failure may be evident at birth or several hours after birth. Tachypnea, shallow and paradoxical respiration, an expiratory grunt with accentuated abdominal effort, and cyanosis are all common. Management of foals with respiratory distress includes oxygen therapy, but when the distress is severe, oxygen insufflation alone is insufficient to improve the $P_{O_2}$, which is usually 45 to 60 mm Hg (6.0-8.0 kPa). The atelectasis and alveolar hypoventilation worsen, resulting in progressive hypoxemia and respiratory acidosis, which requires ventilatory assistance by the use of continuous positive airway pressure.

In cattle and adult horses, the nasal tube must be inserted to the nasopharynx because passage short of this causes excessive waste of oxygen. The length of tube inserted should equal the distance from the nostril to a point one-third of the way from the lateral canthus of the eye to the base of the ear. Insertion of a nebulizer in the system permits the simultaneous administration of antibiotics and moisture to prevent drying of the pharyngeal mucosa. The volume of oxygen used should be about 10 to 20 mL of oxygen per min per kg of body weight. Repeated measurement of arterial oxygen tension, if available, is useful for determining the flow rate. Arterial oxygen tension responds to changes in the rate of administration of oxygen within several minutes.

Oxygen toxicity is a risk in animals breathing pure oxygen for periods exceeding 1 to 2 days, but this rarely occurs in veterinary medicine because supplementation with oxygen does not result in the animal breathing pure oxygen (except for animals under general anesthesia). Oxygen toxicity
can be prevented by limiting the $F_{O_2}$ to less than 60%.86

**RESPIRATORY STIMULANTS**

Use of respiratory stimulants, including doxapram, picrotoxin, leptazol (Metrazol), lobeline, theophylline, nikethamide (Coralene), caffeine, and amphetamine sulfate, has been advocated in animals with hypoxemia resulting from respiratory disease. In many of these animals, and especially in adults, there is already maximal stimulation of the respiratory center, and administration of drugs such as caffeine or doxapram is at best useless and at worst harmful, in that exacerbation of any oxygen deficit.

The situation appears to be different in neonates, in which the depression of respiration is a result of diminished central control, as is the case in foals with neonatal encephalopathy and in premature calves. Doxapram (constant rate infusion of 0.02-0.05 mg/kg/h IV) is more effective than caffeine (loading dose of 7.5-12 mg/kg followed by maintenance dose of 2.5-5 mg/kg PO q24 h) in reducing arterial carbon dioxide tension in neonatal foals with respiratory acidosis ($P_{CO_2} > 55$ mm Hg and pH < 7.35) secondary to neonatal encephalopathy. There was no difference in survival rates although the number of animals (eight in each group) was likely too low to detect important effects on survival.86 Similarly, in healthy newborn calves doxapram (40 mg IV) increased respiratory rate, peak inspiratory and expiratory flow rates, minute volume and $P_{O_2}$, and reduced $P_{CO_2}$ within minutes of administration, although the effect lasted less than 90 minutes.87Administration of doxapram (40 mg IV), atropine or caffeine to neonatal calves with naturally occurring asphyxia resulted in improvement in arterial blood gas values with all treatments with the greatest effect, and lowest death rate, among doxapram-treated calves.88Doxapram appears to be useful in stimulating respiration in foals with pharmacologic depression of the respiratory center by general anesthetics.90

**MECHANICAL Ventilation**

**Short-term** mechanical ventilation can be achieved in neonates and small adults by use of a nasotracheal tube and a hand-operated bellows, which is usually in the form of a resiliant bag equipped with a one-way valve. The animal’s trachea is intubated and the bag is connected and squeezed to supply a tidal volume of approximately 5 to 10 mL/kg BW at a rate of approximately 20 breaths per minute. Commercial bags (Ambubag) are available in a variety of sizes suitable for neonates and small ruminants. There is a simple device for respiratory resuscitation of newborn calves and lambs consisting of a mouthpiece, a nonreturn valve, a flange and an oral tube. Ventilation of larger animals requires use of compressed gases and appropriate valving systems, including a Hudson demand valve. In an emergency situation, artificial ventilation of neonates and small ruminants can be achieved by mouth-to-nose ventilation by the veterinarian. This should be done only with an awareness of the risks of disease transmission (e.g., a weak newborn calf could be infected by *Brucella* sp. or *Leptospira* sp.).

Prolonged mechanical ventilation is an activity requiring special equipment and expertise. It is indicated for the treatment of diseases of neonates, and perhaps adults, that cause hypoxemia and hypercarbia. There is usually a significant component of hyperventilation in these diseases and this is a prime indication for use of mechanical ventilation. An excellent example is the use of mechanical ventilation to treat foals with botulism. In experienced hands, this technique is effective. Because of the highly technical and demanding requirements for mechanical ventilation, the interested reader is referred to more detailed sources for descriptions of the methodology.

**ANTI-INFLAMMATORY THERAPY**

Many infectious and noninfectious diseases of the lower respiratory tract have inflammation as a major component of the tissue response to the initial insult. Primarily inflammatory diseases include heave and inflammatory airway disease of horses. Inflammation is an important component of pneumonia and some of the allergic or toxic lung diseases. Suppression of the inflammatory response is indicated when the inflammatory response is exacerbating clinical signs of the disease through obliteration of alveoli (inflammatory atelectasis), blockage of airways by inflammatory exudates and infiltration of bronchial walls, and bronchoconstriction as a consequence of inflammation increasing airway reactivity.

Administration of antiinflammatory drugs is indicated as the definitive therapy in nonfected inflammatory airway diseases (with control achieved by environmental controls; see following discussion). Care must be taken that suppression of the inflammatory response does not impair innate and adaptive immune responses to infectious agents.

Antiinflammatory drugs used in the treatment of diseases of the respiratory tract include glucocorticoids and nonsteroidal antiinflammatory drugs (NSAIDs), with other agents such as leukotriene antagonists, interferon, and cromolyn sodium used in particular situations.

Nonsteroidal antiinflammatory drugs are useful in the treatment of infectious respiratory disease of cattle and horses, and likely other species. The drugs act by inhibiting the infecting organism and tissue necrosis. Meloxicam (0.5 mg/kg subcutaneously, once), when administered with tetracycline, improves weight gain and reduces the size of lesions in lungs of cattle with bovine respiratory disease complex over those of animals treated with tetracycline alone. NSAIDs also improve the clinical signs of cattle with respiratory disease. Use of these drugs is routine in horses with pneumonia or pleuritis.

Glucocorticoids are administered for control of inflammation in a variety of inflammatory lung diseases but notably heaves of horses and interstitial pneumonia of foals. Treatment can be administered orally, by intravenous or intramuscular injection, or by inhalation. Oral, intramuscular, or intravenous administration results in systemic effects of the agents. Inhalation of glucocorticoids provides therapy directed to the site of the disease and minimizes, but does not always prevent the systemic effects of the drugs. Drugs for inhalation are usually human preparations of fluticasone, beclometasone, and flunisolide that are available as metered-dose inhalers. The compounds are administered through a mask adapted so that a large proportion of the drug is inhaled. Antiinflammatory responses in the airways are pronounced and result in marked improvement in respiratory function in horses with heaves (see Heaves, Recurrent airway obstruction).

**IMMUNOMODULATORS**

Interferon is used for the treatment of inflammatory airway disease in racehorses and feedlot cattle with respiratory disease. A dose of 50 to 150 IU of interferon-alpha administered orally once daily for 5 days reduced signs of airway inflammation in young Standardbred racehorses. Immune stimulation by injection of a suspension of Propionibacterium acnes has been investigated for treatment of chronic inflammatory airway disease in horses. The compound enhances expression of interferon-gamma and NK-lysin in peripheral blood mononuclear cells, increases the proportion of CD4 cells in peripheral blood and increases phagocytic activity of cells in peripheral blood. Similar changes were detected in bronchoalveolar lavage fluid. The effect on respiratory disease has yet to be definitively determined.

**ANTIMICROBIAL THERAPY**

Bacterial infections of the respiratory tract of all species are treated with antimicrobial agents given parenterally or, less commonly, orally. Individual treatment is usually necessary, and the duration of treatment will depend on the causative agent and the severity when treatment was begun. In outbreaks of infectious respiratory disease, the use of mass medication of the feed and water supplies may be advisable for the treatment of subacute cases and for convalescent therapy. The response to mass medication will depend on the total amount of the drug ingested by the animal and this is a reflection of the appetite or thirst of the animal, the palatability of the drug, and its concentration in the feed or water. The choice of drug used will depend on its cost, previous experience on similar cases, and the results of drug sensitivity tests if available. The individual treatment of all in-contact animals in an affected group may be useful in controlling an outbreak of respiratory disease such as shipping fever in feedlot cattle.

Selecting antimicrobials is based on the principles detailed in Chapter 6. Briefly, antimicrobials for treatment of bacterial respiratory disease should be active against the causative agent, should be able to achieve therapeutic concentrations in diseased lung, and should be convenient to administer. The antimicrobials should be affordable and, if used in animals intended as human food, must be approved for use in such animals. Antimicrobials for treatment of lung disease are preferably those that achieve therapeutic concentrations in diseased lung tissue after administration of conventional doses. This has been convincingly demonstrated for the macrolide (azithromycin, erythromycin, clarithromycin), triamidine (tulathromycin), and fluoroquinolone (danofoxacin, enrofloxacin) antimicrobials, and florfenicol in a variety of species. The beta-lactam antimicrobials (penicillin, ceftiofur) are effective in treatment of pneumonia in horses, pigs, and ruminants despite having chemical properties that do not favor their accumulation in lung tissue.

Routes of administration include oral (either individually or in medicated feed or water), parenteral (subcutaneous, intramuscular, intravenous), or by inhalation. Intratracheal administration of antimicrobials to animals with respiratory disease is not an effective means of achieving therapeutic drug concentrations in diseased tissue. Aerosolization and inhalation of antimicrobials has the theoretic advantage of targeting therapy to the lungs and minimizing systemic exposure to the drug. However, although administration by inhalation achieves good concentrations of drug in bronchial lining fluid, it does not penetrate ventilated regions of the lungs, in which case parenteral or oral administration of antimicrobials is indicated. Gentamicin, marbofloxacin, ceftiofur, and defquinone all achieve high concentrations in pulmonary epithelial lining fluid when administered to horses. Aerosol administration of gentamicin to normal horses results in gentamicin concentrations in bronchial lavage fluid 12 times that achieved after intravenous administration. Aerosolized ceftiofur sodium (1 mg/kg) is superior to intramuscular administration in treatment of calves with Pasteurella (Mannheimia) haemolytica.

**BRONCHODILATOR DRUGS**

Bronchoconstriction is an important component of the increased airway resistance present in many animals with disease of the lower respiratory tract. Administration of bronchodilators can relieve respiratory distress and improve arterial blood oxygenation. Bronchodilatory drugs are beta-2-agonists (clenbuterol, albuterol/salbutamol, terbutaline), parasympatholytic drugs (ipratropium, atropine), and methylxanthines (aminophylline, theophylline).

The indication for the use of bronchodilators is relief of bronchoconstriction. Bronchoconstriction is an important component of the pathophysiology of many diseases of the lungs and airways. Bronchodilators are used extensively in horses with heaves and inflammatory airway disease and less so in animals with infectious diseases. Contraindications are few, but caution should be exercised when using these drugs in animals that are severely hypoxic because the beta-2-agonists can transiently worsen gas exchange by increasing perfusion of nonventilated sections of the lung, and in pregnant animals, in which the tocolytic effect of the beta-2-agonists can delay parturition. The use of beta-2-adrenergic agonist bronchodilator drugs in food animals is not permitted in most countries because of the risk of contamination of foodstuffs intended for consumption by people. This is particularly the case with clenbuterol, a drug approved in many countries for use in horses that is administered to cattle illicitly as a growth promoter. People can be poisoned by clenbuterol in tissues of treated cattle.

The beta-2-adrenergic agonists are potent and effective bronchodilators that can be administered orally, intravenously, or by inhalation. These drugs also enhance mucociliary clearance of material from the lungs. Most administration is oral or by inhalation. Use of these drugs is restricted to horses, and the drugs are discussed in the section on heaves.
Parasympatholytic (anticholinergic) drugs relieve vagally mediated bronchoconstriction. Again, their use is restricted to horses. These drugs can cause tachycardia and gastrointestinal dysfunction, including ileus.

The methylxanthines are used in horses and have been investigated for use in cattle with respiratory disease. Their use in horses is mainly of historical interest because the availability of the more efficacious beta-2-adrenergic agonists and parasympatholytic drugs has superseded the use of methylxanthines. The use of theophylline in feedlot cattle with respiratory disease in field conditions is associated with accumulation of toxic concentrations in blood and an excessive mortality rate.

MUCOLYTICS, MUCOKINETIC, AND ANTITUSSIVE DRUGS

Many groups of drugs are used in the therapy of respiratory diseases with the objective of improving mucocytosis or effective mucociliary clearance. Mucokinetic agents have been divided into six groups according to their mode of action:

- Diluents, surface acting agents, and mucolytics are supposed to reduce the viscosity of the respiratory secretions.
- Bronchomucotropic agents, formerly called expectorants, are supposed to increase the production of a less viscous mucus.
- Other agents, such as beta-adrenergic agonists and methylxanthine derivatives, promote more effective clearance of mucus and act as ciliary augmentors or bronchodilators.

The aim of mucokinetic agents is to decrease the viscosity of the respiratory secretions, but in some animals with respiratory disease the excessive secretions are of low viscosity and the use of a mucolytic agent in such cases would further decrease mucocytosis. There is little or no evidence that administration of mucolytic or mucokinetic agents, with the possible exception of clenbuterol and dembrexine, relieves signs of respiratory disease or hastens recovery.

Inflammation of the lower respiratory tract results in production of mucus and immigration of inflammatory cells. This accumulation of material is cleared by rostral movement into the pharynx, where it is discharged through the nostrils or swallowed. Clearance is by the mucociliary apparatus or coughing. Mucolytics are agents that alter the constituents of mucoid or purulent respiratory secretions and make them less viscous. Bromhexine is a popular mucolytic with horse owners. It is said to reduce the viscosity of airway mucus and increase mucus production, although its clinical efficacy has not been determined. It may be of some value in cattle to increase mucociliary clearance.

Dembrexine alters the carbohydrate side chains of mucin and improves its flow properties and is reported to decrease coughing and hasten recovery in horses with respiratory disease.

Hyperhydration, the administration of large quantities of fluids intravenously, has been suggested as being useful in the treatment of horses with accumulation of excessive amounts of mucus or mucopus in the lower airways. However, experimental trials have demonstrated that this approach is not effective in horses with heaves.

Bronchomucotropic agents (expectorants) are administered with the intention of augmenting the volume of respiratory secretions by stimulating the mucus-producing cells and glands. Formerly called expectorants, they are supposed to increase the production of a less viscous mucus. These compounds include the iodides and ammonium and glycerol guaiacolate, which are commonly found in cough mixtures. These are commonly used in farm animals, especially horses, although their efficacy is unknown.

Coughing is a common sign in animals with respiratory disease, and it is an important pulmonary defense mechanism, allowing the expulsion of mucus and foreign bodies. Antitussive (cough suppressant) drugs are infrequently used in large-animal medicine. These drugs should only be used when definitive therapy has been implemented for the underlying disease. Control of the underlying disease will in almost all instances resolve the coughing. It is not appropriate to use antitussive agents (butorphanol, codeine, diphenhydramine) to suppress a cough when the underlying cause is unknown or untreated.

SURFACTANT

Surfactant is critical to normal alveolar function, and a lack of this complex phospholipid results in progressive alveolar collapse. Composition of surfactant from lungs of neonatal foals differs from that of adult horses, with that from foals having a lower protein concentration and higher surface tension. Lack of surfactant is an important cause of respiratory disease in newborn animals, with those born prematurely being at increased risk. Attempts have been made to prevent acute respiratory disease in premature newborn foals, such as those delivered by cesarean section because of maternal disease, but the results have been disappointing.

SURGERY

Many conditions of the upper respiratory tract of horses are amenable to surgical correction. Tracheostomy is often used in the emergency or urgent relief of acute upper airway obstruction and in the removal of large amounts of tracheal debris, such as occurs in animals with smoke inhalation. Drainage of excessive or infected pleural fluid can be therapeutic in animals with pleuritis.

GENERAL NURSING CARE

Animals with respiratory disease should have minimal or no enforced activity, and environmental stressors should be minimized. One of the most important aspects of the treatment of respiratory tract disease in farm animals is the provision of a comfortable, well-ventilated environment during and after the disease episode. Affected animals should be placed in a draft-free area that is adequately ventilated and supplied with an abundance of bedding for comfort and warmth, particularly during convalescence. Feed and water should be readily available and dusty feeds avoided.

CONTROL OF RESPIRATORY DISEASE

Infectious diseases of the respiratory tract of farm animals are caused by a combination of infectious agents and predisposing causes such as inclement weather, the stress of weaning or transportation, and poorly ventilated housing, each of which can weaken the defense mechanisms of the animal. Prevention and control of these diseases include the following tactics:

- Minimizing exposure to inciting agents (infectious or physical)
- Maximizing innate resistance by ensuring that the animals are in excellent general health through attention to nutrition, housing, and animal welfare
- Maximizing adaptive resistance by the administration of effective vaccines such that maximal resistance is produced to coincide with the time of greatest risk of the disease

IMPORTANCE OF DIAGNOSIS

For some complex respiratory diseases of food animals, it is becoming increasingly more difficult to obtain a definitive etiologic diagnosis because some of the common diseases appear to be caused by multiple infections rather than a single one. Most of the infective agents that cause respiratory disease are ubiquitous in the environment and are present as normal residents in the nasal cavities of normal animals. This often creates difficulty with the interpretation of the microbiological findings in outbreaks of respiratory disease because the infectious agents can commonly be isolated from both sick and well animals. Thus there may be no well-defined cause-and-effect relationship, and the predisposing causes begin to assume major importance in any control program.

MANAGEMENT TECHNIQUES

Most of the common respiratory diseases occur at certain times under certain
conditions, and successful control will depend on the use of management tech-
niques before the disease is likely to occur. For example, in beef cattle, pneumonic pas-
teurriosis can be kept to a minimum with the use of certain management procedures that
minimize stress at weaning. The inci-
dence of pneumonia can be minimized in
young bulls destined for a performance
testing station if they are weaned well in
advance of movement to the test center. In
North America, bovine respiratory disease is
most common in feedlots where young cattle
from several different backgrounds have
been mingled after having been transported
long distances. Outbreaks of equine respira-
tory disease occur in young horses that are
assembled at the racetrack for training or at
horse shows.

HOUSING FACILITIES
The quality of air in housing facilities is a critical determinant of the respiratory
health of most species, including humans who work in these facilities. Poor air
quality, such as high particulate concentra-
tions, persistently high humidity, bacterial and fungal growth, and excessive concen-
trations of ammonia, predispose to infec-
tious and noninfectious diseases in animals
housed in the barns. The incidence of pulmonary inflamma-
tion, excessive mucus in airways and cough-
ing (heaves) in horses is much higher in
those that are housed in barns that are dusty
and not ventilated compared with horses
kept outdoors. Bad stabiling manage-
ment as a major cause of coughing in horses
was described almost 200 years ago, but there
is still a major emphasis on the clinical man-
agement of chronic coughing in housed
horses using a wide spectrum of antibiotics,
expectorants, and other drugs. Attention to
barn design such that concentration of small
particulates in the air is minimized will
improve the respiratory health of horses
housed in the barn. In pigs, enzootic pneumonia is
widespread, but the effects of the pneumonia can be
maintained at an insignificant level with
adequate housing, ventilation, and nutrition.
Too much emphasis has been placed on the
attempted eradication of Mycoplasma spp.,
which is extremely difficult, and insufficient
emphasis on building design and ventilation
methods.

VACCINES
Vaccines are available for the immunization of farm animals against some of the common
infectious diseases of the respiratory tract. Their advantages and disadvantages are
discussed under each specific disease. The general principles underlying use of vac-
cines for control of respiratory disease are as follows:

• The disease must be caused by a
disease that is infectious.
• There must be an effective vaccine
suitable for use in the species and
age group of animals at most risk of
the disease. Ideally, this will be
published from appropriately
designed trials testing the vaccine in
a group of animals identical to those
in which the vaccine will be used in
practice.
• The vaccine must be administered
to animals in such a manner (route,
timing, frequency) to optimize the
immunization (adaptive immunity).
• The timing of the vaccination
program should be such that
maximal resistance to the anticipated
diseases is achieved at the time of
greatest risk of the disease.
• Vaccination should be part of an
ongoing program of disease control
and should not be regarded as a
panacea with which to rectify other
shortcomings in management of the
animals.

ENVIRONMENTAL CONTROL
In effect, the principles of control and preven-
tion of airborne respiratory disease are
based largely on keeping the levels of patho-
gens in the air at a low level. This can be
accomplished by a combination of the fol-
lowing practices:
• The use of filtered-air positive-
pressure ventilation systems
• The removal of affected animals from
the group
• Increasing the ventilation rate of the
building unit
• Subdivision of the unit into small
units, each with its own ventilation
system
• A continual disinfection system
so that during cold weather the
ventilation can be maintained and
animals will not huddle together to
keep warm and thereby increase the
exposure rate of infection
• The use of vaccines for specific
diseases of the respiratory tract
• Effective dust control

Diseases of the Upper Respiratory Tract

RHINITIS

Rhinitis (inflammation of the nasal mucosa) is characterized clinically by sneezing, wheezing, and stertor during inspiration and a nasal discharge that can be serous, mucoid, or purulent in consistency depending on the cause.

ETIOLOGY

Rhinitis usually occurs in conjunction with inflammation of other parts of the respiratory tract. It is present as a minor lesion in most bacterial and viral pneumonias, but the diseases listed are those in which it occurs as an obvious and important part of the syndrome.

Cattle

- Catarrhal rhinitis in infectious bovine rhinotracheitis; adenoviruses 1, 2, and 3; and respiratory syncytial virus infections
- Ulcerative/erosive rhinitis in bovine malignant catarrh, mucosal disease, rinderpest
- Actinobacillus lignieresii can cause outbreaks of respiratory disease in adult cattle characterized by stertorous breathing, nasal discharge, and excessive salivation. Lesions included thickening and ulceration of the nasal planum, turbinates, and paranasal sinuses. Treatment with oxytetracycline was associated with resolution of the disease.
- Nasal schistosomiasis
- Nasal mycosis
- Infection by Pseudallescheria boydii species complex
- Nasal actinomycosis
- Rhinosporidiosis caused by fungi and atopic rhinitis
- Familial allergic rhinitis and allergic nasal granuloma
- Bovine nasal eosinophilic granuloma attributable to Nocardi a sp.

Horses

- Glanders, strangles, and epizootic lymphangitis
- Infections with the viruses of equine viral rhinopneumonitis (herpesvirus-1), equine herpesvirus-3, equine viral arteritis, influenza H3N8 equine rhinovirus, parainfluenza virus, reovirus, adenovirus
- Chronic rhinitis claimed to be caused by dust in dusty stables, and acute rhinitis occurring after inhalation of smoke and fumes
- Nasal granulomas as a result of chronic infections with Pseudallescheria boydii and Aspergillus, Conidiobolus, and Mucoraceous fungi
- Equine grass sickness (dysautonomia) in the chronic form causes rhinitis sicca

Sheep and Goats

- Meliodosis, bluetongue; rarely, contagious corytha and sheep pox
- Oestrus ovis and Elaeophora schneideri infestations
- Allergic rhinitis
- Purulent rhinitis and otitis associated with P. aeruginosa in sheep showered with contaminated wash
- Infection by Conidiobolus spp. and Pythium spp.
- Nasal polyps in sheep

Pigs

- Atrophic rhinitis, inclusion-body rhinitis, swine influenza, some outbreaks of Aujeszky's disease

PATHOGENESIS

Rhinitis is of minor importance as a disease process except in severe cases when it causes obstruction of the passage of air through the nasal cavities. Its major importance is as an indication of the presence of some specific diseases. The type of lesion produced is important. The erosive and ulcerative lesions of rinderpest, bovine malignant catarrh, and mucosal disease; the ulcerative lesions of glanders, melioidosis, and epizootic lymphangitis; and the granular rhinitis of the anterior nares in allergic rhinitis all have diagnostic significance.

In atrophic rhinitis of pigs, the destruction of the turbinate bones and distortion of the face appear to be a form of devitalization and atrophy of bone caused by a primary inflammatory rhinitis. Secondary bacterial invasion of facial tissue of swine appears to be the basis of necrotic rhinitis.

CLINICAL FINDINGS

The primary clinical finding in rhinitis is a nasal discharge, which is usually serous initially but soon becomes mucoid and, in bacterial infections, purulent. Erythema, erosion, or ulceration may be visible on inspection. The inflammation may be unilateral or bilateral. Sneezing is characteristic in the early acute stages, and this is followed in the later stages by snorting and the expulsion of large amounts of mucopurulent discharge. A chronic unilateral purulent nasal discharge lasting several weeks or months in horses suggests nasal granulomas associated with mycotic infections.

“Summer Snuffles”

“Summer snuffles” of cattle presents a characteristic syndrome involving several animals in a herd. Cases occur in the spring and autumn when the pasture is in flower and warm, moist environmental conditions prevail. The disease may be most common in Channel Island breeds. There is a sudden onset of dyspnea with a profuse nasal discharge of thick, orange to yellow material that varies from a mucopurulent to caseous consistency. Sneezing, irritation, and obstruction are severe. The irritation may cause the animal to shake its head, rub its nose along the ground, or poke its muzzle repeatedly into hedges and bushes. Sticks and twigs may be pushed up into the nostrils as a result and cause laceration and bleeding. Stertorous, difficult respiration accompanied by mouth breathing may be evident when both nostrils are obstructed. In the most severe cases, a distinct pseudomembrane is formed that is later snorted out as a complete nasal cast. In the chronic stages, multiple proliferative nonerosive nodules 2 to 8 mm in diameter and 4 mm high with marked mucosal edema are visible in the anterior nares.

Familial Allergic Rhinitis

In familial allergic rhinitis in cattle, the clinical signs begin in the spring and last until late fall. Affected animals exhibit episodes of violent sneezing and extreme pruritus manifested by rubbing their nostrils on the ground, trees, and other inanimate objects and frequently scratching the nares with their hindfeet. Dyspnea and loud snoring sounds are common, and affected animals frequently clean their nostrils with their tongues. The external nares contain a thick mucoid discharge, and the nasal mucosa is...
edematous and hyperemic. The clinical abnormalities resolve during the winter months. All affected animals are positive to intradermal skin testing for a wide variety of allergens.

**Mycotic Rhinitis**
Mycotic rhinitis in the horse is characterized by noisy respirations, circumferential narrowing of both nasal passages, and thickening of the nasal septum. The nasal conchae and turbinates may be roughened and edematous, and the ventral meati decreased in size bilaterally. The nasal discharge may be unilateral or bilateral. Endoscopically, granulomas may be found in almost any location in the nasal cavities and extending to the soft palate and into the maxillary sinus. The disease is discussed in detail in this chapter.

**Endoscopic Examination**
Endoscopic examination is useful for the visual inspection of lesions affecting the nasal mucosa of horses and cattle that are not visible externally. Radiographic or computed tomographic imaging can be used to detect atrophic rhinitis, although use of these techniques on a wide scale is clearly not practical.

**CLINICAL PATHOLOGY**
Examination of nasal swabs of scrapings for bacteria, inclusion bodies, or fungi may aid in diagnosis. Discharges in allergic rhinitis usually contain many more eosinophils than normal. Nasal mucosal biopsy specimens are useful for microbiological and histopathologic examination.

**NECROPSY FINDINGS**
Rhinitis is not a fatal condition, although animals may die of specific diseases in which rhinitis is a prominent lesion.

### Differential Diagnosis
Rhinitis is readily recognizable clinically. Differentiation of the specific diseases listed previously under "Etiology," is discussed under their respective headings.

**Allergic rhinitis in cattle** must be differentiated from maduromycosis, rhinosporidiosis, and infection with the pasture mite (Tyrophagus palmarum). The differential diagnosis may be difficult if allergic rhinitis occurs secondary to some of these infections.

**Rhinitis in the horse** must be differentiated from inflammation of the facial sinuses or gullet pouches in which the nasal discharge is usually purulent and persistent and often unilateral, and there is an absence of signs of nasal irritation. A malodorous nasal discharge, frontal bone distortion, draining tracts at the poll, and neurologic abnormalities are common in cattle with chronic frontal sinusitis as a complication of dehorning.

### Treatment
Specific treatment aimed at control of individual causative agents is described under each disease. Thick tenacious exudate that is causing nasal obstruction may be removed gently and the nasal cavities irrigated with saline. A nasal decongestant sprayed up into the nostrils may provide some relief. Newborn piglets with inclusion-body rhinitis may be affected with severe inspiratory dyspnea and mouth breathing that interferes with sucking. The removal of the exudate from each nostril followed by irrigation with a mixture of saline and antimicrobials will provide relief and minimize the development of a secondary bacterial rhinitis. Animals affected with allergic rhinitis should be taken off the pasture for about a week and treated with antihistamine preparations.

### References

### Nasal Discharge
Nasal obstruction occurs commonly in cattle and sheep. The disease is usually chronic and occurs as a result of the following:

- In sheep, infestation with *Oestrus ovis*
- In cattle, most often enzootic nasal granuloma, acute obstruction or the allergic condition "summer sniffles." Cystic enlargement of the ventral nasal conchae in cattle can cause unilateral or bilateral nasal obstruction.

Minor occurrences include the following:

- Large mucus-filled polyps developing in the posterior nares of cattle and sheep and causing unilateral or bilateral obstruction
- Granulomatous lesions caused by a fungus, *Rhinosporidium sp.*, and by the blood fluke, *Schistosoma nasalis*
- A chronic pyogranuloma as a result of *Coccidioides immitis* infection has occurred in the horse.
- Foreign bodies may enter the cavities when cattle rub their muzzles in bushes in an attempt to relieve the irritation of acute allergic rhinitis.
- Nasal amyloidosis occurs rarely in mature horses and is characterized clinically by stertorous breathing and raised, firm, nonpainful, nodular swellings on the rostral nasal septum and floor of the nasal cavity. Affected horses do not have any other illness, and surgical removal of the lesions is recommended.

### Neoplasms
Neoplasms of the olfactory mucosa are not common but do occur, particularly in sheep, goats, and cattle, where the incidence in individual flocks and herds may be sufficiently high to suggest an infectious cause. The lesions are usually situated just in front of the ethmoid bone, are usually unilateral but may be bilateral, and have the appearance of adenocarcinomas of moderate malignancy. In cattle, the disease is commonest in 6- to 9-year-olds and may be sufficiently extensive to cause bulging of the facial bones. The tumors are adenocarcinomas arising from the ethmoidal mucosa, and they metastasize in lungs and lymph nodes. Clinical signs include nasal discharge, often bloody; mouth breathing; and assumption of a stretched-neck posture. There is evidence to suggest that a virus may be associated. A similar syndrome is observed in cattle with other nasal tumors such as osteoma.

Neoplasia that obstructs the nasal cavity occurs in horses with squamous-cell carcinoma or adenocarcinoma of the sinus or nasal cavity or ethmoids,11 angiosarcoma, and a variety of other rare tumors. Epidermal inclusions cysts of the nasal diverticulum of horses can cause obstruction of the nasal cavity, but are not neoplasms. Cysts of the paranasal sinuses can cause marked facial deformity and obstruction to air passages.

### Enzootic Nasal Adenocarcinoma
Enzootic nasal adenocarcinoma is a contagious disease that occurs in sheep and goats, in which it is associated with a virus—enzoctic nasal tumor virus.1 The putative etiologic agent is a beta-retrovirus, with different strains occurring in sheep and goats. The disease can be reproduced by inoculation of 14-day-old lambs with the virus.2 The clinical findings include a persistent serous, mucous, or mucopurulent nasal discharge and stridor.3 Affected sheep and goats progressively develop anorexia, dyspnea, and mouth breathing, and most die within 90 days after the onset of signs. The tumors originate unilaterally or occasionally bilaterally in the olfactory mucosa of the ethmoid turbinates.2 They are locally invasive but not metastatic. Histologically, the tumors are classified as adenomas or, more frequently, adenocarcinomas. Budding and extracellular retrovirus-like particles have been observed ultrastructurally in enzootic nasal tumors of goats. A reverse-transcription polymerase chain reaction (RT-PCR) can detect the virus in healthy and affected sheep, although its clinical utility in allowing control of the infection has not been determined.3
Progressive Ethmoidal Hematomas in Equids

Ethmoidal hematomas are non-neoplastic tumors that are encapsulated, usually expanding, insidious, potentially distorting and obstructing lesions of the nasal cavities that occur in horses. The etiology is unknown but a viral etiology (papilloma virus) should be considered. Chronic unilateral nasal discharge is common, and lesions are usually advanced at the time of diagnosis. There is stertorous breathing and upper airway obstruction in later stages of the disease. The nasal discharge is serous or mucoid and intermittently sanguineous, sanguinopurulent, and usually unrelated to exercise. The tumor arises in the ethmoids and can invade paranasal sinuses, and especially the sphenopalatine sinus, and is bilateral in approximately 50% of horses.

Diagnosis is made by endoscopy and radiography (Figs. 12-3 and 12-4). Computed tomographic examination yields information additional that obtained by radiographic examination (Fig. 12-5) and is useful in determining treatment modality and approach and prognosis. Magnetic resonance imaging (MRI) yields similar information to that obtained by computed tomography (CT) examination.

Surgical removal is possible and successful in some cases. Surgical removal is challenging and often associated with clinically important hemorrhage and the need for intraoperative or postoperative blood transfusion. Surgical removal of the tumor can be achieved in some horses during a standing procedure, but the long-term success has yet to be determined.

Multiple intralesional injection of formalin (1-100 mL of 10% neutral buffered formalin injected at 10-day intervals) through an endoscope can cure the tumor, but there is the risk of serious adverse effects if the ethmoidal hematoma penetrates the cribiform plate. The procedure involves the injection of a sufficient volume of 10% neutral buffered formalin to distend the lesion. The formalin is injected via an endoscope once every 10 days until the lesion resolves by sloughing. Between 1 and 20 injections will be required. The combination of intralesional injection of formalin and laser ablation resulted in severe neurologic complications in one horse with ethmoidal adenocarcinoma treated in this way. Similar adverse effects can occur with use of these treatments in horses with ethmoidal hematomas.

However, the prognosis for long-term resolution of the tumor is poor because of high rates of recurrence.

CLINICAL FINDINGS

In cattle, sheep, and pigs there is severe inspiratory dyspnea when both cavities are blocked. The animals may show great distress and anxiety and breathe in gasps through the mouth. Obstruction is usually not complete and a loud, wheezing sound occurs with each inspiration. A nasal discharge is usually present but varies from a small amount of blood-stained serous discharge when there is a foreign body present to large quantities of purulent exudate in allergic rhinitis. Shaking of the head and snorting are also common signs. If the obstruction is unilateral, the distress is not so marked, and the difference in breath streams between the two nostrils can be detected by holding the hands in front of the nose. The magnitude of the air currents from each nostril on expiration can be assessed with the aid of a piece of cotton thread (watching the degree of deflection).
stomach tube through each nasal cavity may reveal evidence of a space-occupying lesion. Endoscopic examination is frequently diagnostic.

TREATMENT

Treatment must be directed at the primary cause of the obstruction. Removal of foreign bodies can usually be effected with the aid of long forceps, although strong traction is often necessary when the obstructions have been in position for a few days.

REFERENCES

EPISTAXIS AND HEMOPTYSIS

Epistaxis is bleeding from the nostrils regardless of the origin of the hemorrhage, and hemoptysis is the coughing up of blood, with the hemorrhage usually originating in the lungs. Both epistaxis and hemoptysis are important clinical signs in cattle and horses. The bleeding can be in the form of a small volume of blood-stained serous discharge coming from one or both nares, or it can be a large volume of whole blood coming from both nostrils and sometimes the mouth. Pulmonary hemorrhage as a cause of epistaxis or hemoptysis is dealt with under that heading (“Pulmonary Hemorrhage” section in this chapter). The first and most important decision is to determine the anatomic location of the lesion causing bleeding.

ETIOLOGY

Epistaxis occurs commonly in the horse and may be caused by lesions in the nasal cavity, nasopharynx, auditory tube diverticulum (guttural pouch), or lungs (see Table 12-12 in the section on exercise-induced pulmonary hemorrhage in horses). Epistaxis in horses can also be a result of trauma, progressive ethmoidal hematoma, foreign bodies lodged in the respiratory tract, hemorrhagic diatheses, sinusitis, nasal amyloidosis, polypos, and bleeding from the nasolacrimal duct. Exercise-induced pulmonary hemorrhage is described under that heading later in this chapter.

Hemorrhagic lesions of the nasal cavity, nasopharynx, and guttural pouch in the horse usually cause unilateral epistaxis of varying degree depending on the severity of the lesions. Pulmonary lesions in the horse resulting in hemorrhage into the lumen of the bronchi also result in epistaxis. Blood originating from the lungs of the horse is discharged most commonly from the nostrils and not the mouth because of the anatomy of the horse’s soft palate.

Bleeding from lesions of the upper respiratory tract of horses usually occurs spontaneously while the horse is at rest. One of the commonest causes of unilateral epistaxis in the horse is guttural pouch mycosis with erosion of the internal carotid artery.2

Other less common causes of nasal bleeding include hemorrhagic polypos of the mucosa of the nasal cavity or paranasal sinuses, and ethmoidal hematoma (see “Progressive ethmoidal hematoma” in the section on Nasal discharge in this chapter.). Another cause, most uncommonly, is a parasitic arteritis of the internal carotid artery as it courses around the guttural pouch. Pseudoaneurysm of the palatine artery causes unilateral epistaxis.

Mild epistaxis is a common finding in horses and cattle with severe thrombocytopenia.4

Erosions of the nasal mucosa in glanders, granulomatous disease such as cryptococcal sinusitis,5 neoplastic diseases, and trauma as a result of passage of a nasal tube or endoscope, or from physical trauma externally, are other obvious causes. Trauma to the head and skull fractures can result in epistaxis.6 Rupture of the longus capitus muscle and fracture of the basisphenoid bone in horses that rear and fall backward and strike the head and skull fractures can result in epistaxis.7 Rupture of the maxillary sinus depends on the cause. Hemorrhage from the sinus usually originates from a posterior ethmoidal sinus and is associated with guttural pouch mycosis.8 Space-occupying lesions of the nasal mucosa or erosion of a blood vessel by neoplasia, notably hemangiosarcoma, of the upper or lower respiratory tract can cause epistaxis. Osteoma of the nasal bones causes nasal obstruction and epistaxis in cattle.8,9

Envenomation of horses by rattlesnakes in the western United States causes a clinical syndrome that includes swelling of the head, dyspnea, and epistaxis.10 Poisoning by bracken fern or moldy sweet clover is a common cause of spontaneous epistaxis in cattle.11 The epistaxis can be bilateral, and hemorrhages of other visible and subcutaneous mucous membranes are common. An enzootic ethmoidal tumor has been described in cattle in Brazil and was at one time a disease of some importance in Sweden. The lesion occupies the nasal cavities, causes epistaxis, and can invade paranasal sinuses.

In hemoptysis in horses, the blood flows along the horizontal trachea and pools in the larynx until the swallowing reflex is stimulated and swallowing occurs; or coughing is stimulated and blood is expelled through the mouth and nostrils. The origin of the hemorrhage is usually in the lungs, and in cattle the usual cause is a pulmonary arterial aneurysm and thromboembolism from a posterior vena caval thrombosis (see “Caudal Vena Cava Syndrome”). Recurrent attacks of hemoptysis with anemia and abnormal lung sounds usually culminate in an acute intrapulmonary hemorrhage and rapid death.

The origin of the hemorrhage in epistaxis and hemoptysis may be obvious, as in traumatic injury to the turbinates during passage of a stomach tube intranasally or if a systemic disease with bleeding defects is present. In many other cases, however, the origin of the hemorrhage is not obvious, and special examination procedures may be required. Careful auscultation of the lungs for evidence of abnormal lung sounds associated with pulmonary diseases is necessary.

CLINICAL EXAMINATION

The nasal cavities should be examined visually with the aid of a strong, pointed source of light through the external nares. Only the first part of the nasal cavities can be examined directly but an assessment of the integrity of the nasal mucosa can usually be made. In epistaxis resulting from systemic disease or clotting defects, the blood on the nasal mucosa will usually not be clotted. When there has been recent traumatic injury to the nasal mucosa or erosion of a blood vessel by a space-occupying lesion such as tumor or nasal polyp, the blood will usually be found in clots in the external nares.

The nasal cavities should then be examined for any evidence of obstruction as set out in the previous section. When the blood originates from a pharyngeal lesion there are frequent swallowing movements and a short explosive cough, which may be accompanied by the expulsion of blood from the mouth. Hematologic examinations are indicated to assist in the diagnosis of systemic disease or clotting defects. Radiologic examinations of the head are indicated when space-occupying lesions are suspected.

Use of the flexible fiberoptic endoscope will permit a thorough examination of the nasal cavities, nasopharynx, guttural pouch and larynx, trachea, and major bronchi.

TREATMENT
