Specific treatment of epistaxis and hemoptysis depends on the cause. Hemorrhage from traumatic injuries to the nasal mucosa does not usually require any specific treatment. Space-occupying lesions of the nasal mucosa might warrant surgical therapy. Epistaxis associated with guttural pouch mycosis usually requires surgical intervention. There is no successful treatment for the hemoptysis attributable to pulmonary aneurysm and posterior vena caval thrombosis in cattle. General supportive therapy is as for any spontaneous hemorrhage and includes rest, blood transfusions, and hematinics.

PHARYNGITIS
Pharyngitis in all species is associated with infectious diseases of the upper airway. It is most studied in horses, probably because of the frequency of examination of the upper airway in this species. Pharyngitis in horses has many similarities to tonsillitis in children.

The disorder in horses involves follicular lymphoid hyperplasia of the pharynx affecting both the pharyngeal tonsil and the extensive and diffuse lymphoid tissue in the walls and dorsal aspect of the pharynx. These tissues form the mucosal associated lymphoid tissues and are an important component of the normal immunologic response of horses. The condition occurs in a high proportion of Thoroughbred racehorses and is probably as common in other breeds of horse. The condition is first detectable in 2- to 3-month-old foals and reaches its highest prevalence and greatest severity in yearlings and 2-year-old foals and reaches its highest prevalence and greatest severity in yearlings and 2-year-old horses in race training. It is evident on endoscopic examination as diffuse, multiple, small, white nodules in the roof and walls of the pharynx. The nodules can be confluent, and there is often excessive mucus present in severely affected horses. The clinical significance of the condition is debated. Affected racehorses do not have impaired race performance. Affected horses recover spontaneously as they age or after treatment with topical antiinflammatory drugs. The condition is probably a normal aging process and necessary for development of a competent immune system in young horses.

Infestation of the nasopharynx of horses by larvae of the bot fly Gasterophilus pecorum causes obstruction of the upper airway and a parasitic pharyngitis. Diagnosis is by visualization of the parasite during endoscopic examination.

LARYNGITIS, TRACHEITIS, BRONCHITIS
Inflammation of the air passages usually involves all levels, and no attempt is made here to differentiate between inflammations of various parts of the tract. They are all characterized by one or more of cough, noisy inspiration, and some degree of inspiratory embarrassment.

ETOLOGY
All infections of the upper respiratory tract cause inflammation, either acute or as chronic diseases. In most diseases the laryngitis, tracheitis, and bronchitis form only a part of the syndrome, and the causes listed here are those diseases in which upper respiratory infection is a prominent feature.

Cattle
- Infectious bovine rhinotracheitis (bovine herpesvirus-1), calf diphtheria (necrotic laryngitis), Histophilus somnus
- Tracheal stenosis in feedlot cattle, “honker cattle,” etiology unknown
- Necrotic laryngitis in calves
- Syngamus laryngeus infests the larynx of cattle in the tropics
- Trauma, including balling gun-induced injury

Sheep
- Chronic infection with Actinomyces pyogenes

Horses
- Equine herpesvirus 1, 2 or 5 (EVR), equine viral arteritis (EVA), equine viral influenza (EVI), strangles (S. equi)
- Idiopathic ulceration of the mucosa covering the arytenoid cartilages
- Lymphoid hyperplasia of the pharynx of horses—the disease is more common in younger horses and might be associated with reduced athletic capacity or increased propensity to palatal instability

- Bronchitis and tracheitis of horses, most evident in athletic horses, and characterized by accumulation of mucus in the trachea and increased proportion of neutrophils in tracheal or bronchoalveolar lavage fluid—the condition is associated with impaired athletic performance.

Pigs
- Swine influenza
- Necrotic tracheitis (akin to “honker syndrome” in cattle) of uncertain etiology

PATHOGENESIS
Irritation of the mucosa causes frequent coughing, and swelling causes partial obstruction of the air passages, resulting inspiratory dyspnea. Necrotic laryngitis in calves is associated with marked changes in pulmonary function, modifies tracheal dynamics, and disturbs the growth process by increasing the energetic cost of breathing; this can result in impaired feed intake and predisposition to secondary pulmonary infection and subsequent respiratory failure from progressive exhaustion.

CLINICAL FINDINGS
Coughing and inspiratory dyspnea with laryngeal roaring or stridor are the common clinical signs. In the early stages of acute infections, the cough is usually dry and nonproductive and is easily induced by grasping the trachea or larynx, or by exposure to cold air or dusty atmospheres. In acute laryngitis, the soft tissues around the larynx are usually enlarged and painful on palpation. In chronic infections, the cough may be less frequent and distressing and is usually dry and harsh. If the lesions cause much exudation or ulceration of the mucosa, as in bacterial tracheobronchitis secondary to infections bovine rhinotracheitis in cattle, the cough is moist, and thick mucus, flecks of blood, and fibrin may be coughed up. The cough is very painful, and the animal makes attempts to suppress it. Fever and toxemia are common, and affected animals cannot eat or drink normally.

Examination of the larynx is usually possible through the oral cavity using a cylindrical speculum of appropriate size and a bright, pointed source of light. This is done relatively easily in cattle, sheep, and pigs but is difficult in the horse. Lesions of the mucosae of the arytenoid cartilages and the covering of the arytenoids are sometimes visible. The use of a fiberoptic endoscope allows a detailed examination of the upper respiratory tract. The use of a fiberoptic endoscope allows a detailed examination of the upper respiratory tract. Inflammation or lesions of the larynx may be severe enough to cause marked inspiratory dyspnea and death from asphyxia. In calves and young cattle with diphtheria, the lesion may be large enough (or have a pedicle and act like a valve) to cause severe inspiratory dyspnea, cyanosis, anxiety, and rapid death. The excitement associated with loading for transportation to a clinic or of a clinical examination, particularly the oral examination of the larynx, can exaggerate...
the dyspnea and necessitate an emergency tracheotomy. Most cases of bacterial laryngitis will heal without obvious residual sign after several days of antimicrobial therapy. Some cases in cattle become chronic in spite of therapy as a result of the inflammation extending down into the arytenoid cartilages resulting in a chronic chondritis caused by a sequestrum similar to osteomyelitis. Abscess formation is another common cause of chronicity. Secondary bacterial infection of primary viral diseases, or extension of bacterial infections to the lungs, commonly results in pneumonia.

Tracheal stenosis in cattle is characterized by extensive edema and hemorrhage of the dorsal wall of the trachea, resulting in coughing (honking), dyspnea, and respiratory stertor. Complete occlusion of the trachea may occur. Affected animals may be found dead without any premonitory signs.

**CLINICAL PATHOLOGY**

Laboratory examinations may be of value in determining the presence of specific diseases.

**Necropsy Findings**

Upper respiratory infections are not usually fatal, but lesions vary from acute catarrhal inflammation to chronic granulomatous lesions depending on the duration and severity of the infection. When secondary bacterial invasion occurs, a diphtheritic pseudomembrane may be present and be accompanied by an accumulation of exudate and necrotic material at the tracheal bifurcation and in the dependent bronchi.

**DIFFERENTIAL DIAGNOSIS**

Inflammation of the larynx usually results in coughing and inspiratory dyspnea with a stertor and loud abnormal laryngeal sounds on auscultation over the trachea and over the base of the lungs on inspiration. Lesions of the larynx are usually visible by laryngoscopic examination; those of the trachea and major bronchi are not so obvious unless special endoscopic procedures are used. Every reasonable effort should be used to inspect the larynx and trachea. Obstruction of the nasal cavities and other parts of the upper respiratory tract may also be difficult to distinguish unless other signs are present.

**Treatment**

Most of the common viral infections of larynx, trachea, and major bronchi will resolve spontaneously if the affected animals are rested, not worked, and not exposed to inclement weather and dusty feeds. Secondary bacterial complications must be recognized and treated with the appropriate antimicrobial.

The bacterial infections can result in severe inflammation with necrosis and granulomatous lesions and must be treated with antimicrobials. Calves with calf diphtheria should be treated with a broad-spectrum antimicrobial daily for 3 to 5 days. Several days are usually required for the animal to return to normal. A broad-spectrum antimicrobial daily or more often for up to 3 weeks or more may be necessary for treatment of the chondritis.

NSAIDs such as flunixin meglumide may be used in an attempt to reduce the laryngeal edema associated with some severe cases of bacterial laryngitis in cattle.

Animals with severe lesions and marked inspiratory dyspnea may require a tracheotomy and insertion of a tracheotomy tube for several days until the lesion heals. The tube must be removed, cleaned out, and replaced at least once daily because of the accumulation of dried mucus plugs, which interferes with respiration. The techniques of tracheotomy and permanent tracheostomy in the horse have been described. Surgical excision of chronic granulomatous lesions and abscesses of the larynx may be indicated following failure of long-term antimicrobial therapy, but postoperative complications of laryngeal and pharyngeal paralysis may occur. Laryngotomy as a treatment for chronic laryngeal obstruction in cattle with long-term survival of 58% has been described.

**Tracheolaryngostomy**

of calves with chronic laryngeal obstruction as a result of necrobacillosis has been used with success.
extent of collapse and high rate of complications associated with surgical repair, there is not an ideal method for alleviating the condition. A “honking” respiratory noise is common in affected calves when coughing spontaneously or when the trachea is palpated. Tracheal collapse in calves is associated with injuries associated with dystocia and clinical signs usually occur within a few weeks after birth. In some cases the trachea is compressed at the level of the thoracic inlet in association with callus formation of healing fractured ribs attributed to dystocia. In some cases in cattle, there is no history of dystocia or preexisting disease or previous manipulation of the trachea, and the overall lumen size may be reduced to less than 25% of normal. Auscultation of the thorax may reveal loud referred upper airway sounds. A similar syndrome is described in pigs with development of acute tracheal edema, hemorrhage, and tracheitis. Clinical signs are of sudden onset of respiratory distress, open-mouth breathing, loud inspiratory stridor, and death soon after clinical signs became apparent. The lesion is edema, hemorrhage, and mixed cellular infiltration in the tunica adventitia, with lung lesions of mild to severe fibrinonecrotic or hemorrhagic pleuropneumonia. No infectious etiology has been identified.

Tracheal obstruction and collapse can result from tracheitis associated with pneumonia in the horse, tracheal neoplasia, tracheal stricture, presence of foreign bodies in the trachea, and compression by masses external to the trachea. It is suggested that increased respiratory effort associated with pneumonia causes collapse of the soft tissue structures of the trachea, rather than collapse of the tracheal rings. Tracheal rupture as a result of blunt trauma in the horse may result in severe subcutaneous emphysema and pneumomediastinum. Conservative therapy is usually successful. Tracheal compression secondary to enlargement of the cranial mediastinal lymph nodes can also cause inspiratory dyspnea, and conservative treatment with antimicrobials is successful.

Diseases of the Lung Parenchyma

**PULMONARY CONGESTION AND EDEMA**

Pulmonary congestion is caused by an increase in the amount of blood in the lungs as a result of engorgement of the pulmonary vascular bed. It is sometimes accompanied by pulmonary edema, and the temporal relationship between the two can be difficult to determine. The various stages of the vascular disturbance are characterized by respiratory compromise, the degree depending on the extent of interference with pulmonary gas exchange as a result of diffusion impairment across the alveolus, ventilation/perfusion mismatch in the lungs, and decreases in pulmonary blood flow.

**ETIOLOGY**

Pulmonary congestion and edema is a common terminal event in many diseases but is frequently overshadowed by other disturbances. Congestion that is clinically apparent can be primary when the basic lesion is in the lungs or secondary when it is in some other organ, most commonly the heart.

Pulmonary edema occurs because of imbalances in the Starling forces across the pulmonary capillary. From a clinical perspective, the common proximate causes of pulmonary edema are injury to the endothelium of the pulmonary capillary with subsequent leakage of protein-rich fluid into the interstitial spaces, elevated blood pressure in the alveolar capillaries, or, less commonly, low plasma oncotic pressure.

Damage to pulmonary vascular endothelium can occur in infectious diseases (e.g., African horse sickness) or intoxications (endotoxemia). Physical injury, including inhalation of excessively hot air or smoke, can damage the alveolar epithelium with secondary damage to capillary endothelium. Elevated pulmonary capillary pressure occurs in left-sided heart failure (ruptured chordae tendineae of the mitral valve or congenital cardiac anomalies) and during strenuous exercise by horses. Air embolism causes acute heart failure and pulmonary edema in horses. Low plasma oncotic pressure occurs in diseases causing hypoproteinemia but is rarely a cause for pulmonary edema by itself, although it contributes to the pulmonary edema in hypoproteinemic animals administered large volumes of fluids intravenously.

**Primary Pulmonary Congestion**
- Early stages of most cases of pneumonia
- Inhalation of smoke and fumes
- Anaphylactic reactions
- Recumbency, especially in large animals
- Yew (*Taxus* sp.) intoxication
- Racehorses with acute severe exercise-induced pulmonary hemorrhage

**Secondary Pulmonary Congestion**
- Congestive heart failure (cardiogenic pulmonary edema), including ruptured chordae tendineae of the mitral valve, ionophore toxicosis, and left-sided heart failure

**Pulmonary Edema**

Pulmonary edema as a sequela to pulmonary capillary hypertension or pulmonary...
microvascular damage occurs in the following situations:
- Acute anaphylaxis
- Acute pneumonia—Pasteurella haemolytica produces several virulence factors that induce direct or leukocyte-mediated pulmonary endothelial cell injury. Pulmonary edema is one of a number of abnormalities in cattle infected by Theileria annulata.6
- Gram-negative sepsis in ruminants and pigs
- Congestive heart failure and acute heart failure (e.g., the myocardial form of enzootic muscular dystrophy in inherited myocardiopathy of Hereford calves); ruptured mitral valve or chordae tendoana
- Inhalation of smoke or manure gas
- Transient upper airway obstruction in the horse (negative-pressure pulmonary edema)7
- After general anesthesia in horses8
- Yew (Taxus sp.) intoxication
- Exercise-induced pulmonary edema in racehorses
- Fumonisin intoxication in pigs9
- Specific diseases, including: mulberry heart disease of swine; East Coast fever in cattle; the pulmonary form of African horse sickness; Hendra virus infection of horses; poisoning with organophosphates, alpha-naphthyl thiourea (ANTU), ionophore antibiotics (monensin, salinomycin), or 1080 (sodium fluoroacetate);10 plant poisonings by oleander, Hymenoscyphus spp., and Phenosciadium spp.
- Doxycycline intoxication of calves
- Clostridium perfringens type D epsilon toxin in calves and sheep
- The Barker syndrome in young pigs
- Semen embolism

**PATHOGENESIS**

In pulmonary congestion, ventilation is reduced, and oxygenation of the blood is impaired. Oxygenation is reduced by the decreased rate of blood flow through the pulmonary vascular bed. Hypoxemic anoxia develops and is the cause of most of the clinical signs that appear.

Hypoxemia occurs in pulmonary edema because of ventilation-perfusion abnormalities, diffusion abnormalities (although this is usually a minor contributor to the hypoxemia), and hypoventilation caused by the physical obstruction of airflow by fluid and foam in the airways. The edema is caused by damage to the capillary walls by toxins or anoxia or by transudation of fluid as a result of increased hydrostatic pressure in the capillaries. Filling of the alveoli, and in severe cases the bronchi, effectively prevents gaseous exchange.

**Smoke inhalation** in horses results in decreased oxygen content of inspired air and exposure of the respiratory tract tissues to various noxious gases. Following smoke inhalation, diffuse tracheobronchial mucosal sloughing occurs, which, if progressive, causes separation of the epithelium and development of pseudomembranous casts, which may cause partial or complete airway obstruction. Pulmonary edema is also extensive.

**CLINICAL FINDINGS**

All degrees of severity of pulmonary congestion and edema occur commonly in farm animals, and only the most severe form is described here. The depth of respiration is increased to the point of extreme dyspnea with the head extended, the nostrils flared, and mouth breathing. Breathing movements are greatly exaggerated and can be best described as heaving; there is marked abdominal and thoracic movement during inspiration and expiration. A typical stance is usually adopted, with the front legs spread wide apart, the elbows abducted, and the head hung low. The respiratory rate is usually increased, especially if there is hyperthermia, which occurs in acute anaphylaxis and after violent exercise and in the early stages of pneumonia. The heart rate is usually elevated (up to 100/min), and the nasal mucosa is bright red or cyanotic in terminal cases. Radiography reveals diffuse pulmonary opacity in animals with pulmonary edema.

In acute pulmonary congestion, there are harsh breath sounds, but no crackles are present on auscultation.

When pulmonary edema develops, loud breath sounds and crackles are audible over the ventral aspects of the lungs. In longstanding cases, there may be emphysema with crackles and wheezes of the dorsal parts of the lungs, especially if the lesion is caused by anaphylaxis.

Coughing is usually present, but the cough is soft and moist and is not painful. A slight to moderate severe nasal discharge occurs in the early stage of congestion, but in severe pulmonary edema this increases to a voluminous, frothy nasal discharge, which is often pink-colored as a result of blood.

The primary importance of pulmonary congestion is as an indicator of early pathologic changes in the lung or heart. Spontaneous recovery occurs quickly unless there is damage to alveolar epithelium or myocardial asthma develops. Severe pulmonary edema has much greater significance and usually indicates a stage of irreversibility. Death in cases of pulmonary edema is accompanied by respiratory failure.

Smoke inhalation in horses is characterized by the following:1
- Polyneea and dyspnea
- Diffuse wheezes throughout the lungs
- Coughing

**CLINICAL PATHOLOGY**

Laboratory examinations are of value only in differentiating the causes of the congestion or edema. Bacteriologic examination of nasal swabs and a complete hematologic examination, looking particularly for the presence of eosinophilia, are the standard examinations that are carried out.

**NECROPSY FINDINGS**

In acute pulmonary congestion the lungs are dark red in color. Excessive quantities of venous blood exude from the cut surface. Similar but less marked changes occur in milder forms of congestion but are only seen in those animals that die of intercurrent disease. Histologically, the pulmonary capillaries are markedly engorged and some transudation and hemorrhage into alveoli is evident.

Macroscopic findings in pulmonary edema include swelling and loss of elasticity of the lungs, which pit on pressure. They are usually paler than normal. Excessive quantities of serous fluid exude from the cut surface of the lung. Histologically, there are accumulations of fluid in the alveoli and parenchyma.

**DIFFERENTIAL DIAGNOSIS**

The diagnosis of pulmonary congestion and edema is always difficult unless there is a history of a precipitating cause, such as an infectious disease, strenuous exercise, ingestion of toxicants, or inhalation of smoke or fumes. Pneumonia usually presents itself as an alternative diagnosis and a decision cannot be based entirely on the presence or absence of pyrexia. The best indication is usually the presence of toxemia, but this is not entirely dependable. Bacterial pneumonia is usually accompanied by some toxemia, but cases of viral pneumonia are often free of it. Response to antibacterial treatment is one of the best indications, the only variable being the tendency for congestion and edema of allergic origin to recover spontaneously. In many instances there will be doubt, and it is then advisable to treat the animal for both conditions.

**TREATMENT**

The principles of treatment of pulmonary congestion and edema are one or more of the following: reduction of pulmonary capillary pressure (by reduction either of pulmonary venous or pulmonary arterial pressure), alleviation of pulmonary microvascular damage,
and correction of low plasma oncotic pressure. The treatment of pulmonary congestion and edema must first be directed at correction of the primary cause as listed under etiology. Affected animals should be confined at rest in a clean, dry environment and exercise avoided.

**Pulmonary capillary pressure** can be reduced in animals with left-sided heart failure by reduction of cardiac preload, improvement in cardiac pump function, or a combination of these factors. These topics are dealt with in detail in Chapter 12. Briefly, preload can be reduced by administration of furosemide and pump function improved by administration of drugs that improve myocardial function (digoxin) or decrease afterload (arterial vasodilators). The usual first step is the administration of furosemide (1-2 mg/kg intravenously). 9

**Alleviation of pulmonary microvascular damage** is more difficult. Administration of antiinflammatory drugs, including NSAIDs or glucocorticoids, is indicated in animals in which microvascular damage is suspected. These drugs are used to treat, among other diseases, smoke inhalation of horses.

**Plasma oncotic pressure** can be increased by intravenous infusion of plasma (10–40 mL/kg) or synthetic colloids such as hetastarch. Administration of crystalloid solutions should be judicious and the amount of fluid administered must be monitored carefully to ensure that only sufficient fluids to meet the needs of the animal are given.

**Oxygen** should be administered to hypoxic animals in conjunction with other specific treatments.

**Special Diseases**

When edema is attributable to organophosphate poisoning, prompt administration of atropine may reduce fluid transudation. In these cases, the animal is in considerable danger, and repeated injections may be necessary. Details of the recommended treatment regimen are given in the section on treatment of poisoning by organophosphorus compounds.

**Epinephrine** is recommended in pulmonary edema resulting from anaphylaxis. It will have an immediate pharmacologic effect, which may be followed by the use of a corticosteroid to maintain vascular integrity and to decrease permeability of pulmonary vessels. Antihistamines are commonly used in conjunction with epinephrine for the treatment of acute pulmonary edema resulting from anaphylaxis. However, recent studies of experimental anaphylaxis in cattle and horses have shown that the antihistamines may be of limited value because histamine and serotonin are of relatively limited significance as mediating substances. On the other hand, the kinins, prostaglandins, and slow-release substances may be more important.

Studies in cattle have found that antihistamines and 5-hydroxytryptamine (5-HT) antagonists failed to protect cattle in experimental hypersensitivity. Sodium meclofenamate has been more successful in antagonizing experimental anaphylaxis in cattle and horses. Acetylsalicylic acid was more effective than antihistamines or antiserotonin agents in providing symptomatic relief in experimental acute interstitial pneumonia of calves.

It is difficult, however, to extrapolate the results of these studies in which the drugs were usually given before or at the same time as the experimental disease was produced. There is a need for development of more effective antianaphylactic drugs for the treatment of acute anaphylaxis in farm animals, which invariably results in pulmonary edema and emphysema. Thus epinephrine is the drug of choice for the emergency treatment of pulmonary edema resulting from anaphylaxis.

**REFERENCES**

**PULMONARY HYPERTENSION**

Pulmonary hypertension is an increase in pulmonary arterial pressure above values in healthy animals. It is usually a result of structural or functional changes in the pulmonary vasculature and can result in heart failure. Primary pulmonary hypertension occurs in cattle with high-altitude disease (Brisket disease, see Chapter 10). 1,2 Chronic pulmonary hypertension results in right-sided congestive heart failure caused by right ventricular hypertrophy or cor pulmonale. 3

**Causes**

Hypoxemia is a potent stimulus of pulmonary arterial pressure through increased pulmonary vascular resistance induced by pulmonary vasoconstriction. Pulmonary artery pressure can also increase in response to increased in cardiac output that are not matched by pulmonary vasodilation—the most extreme example of this being the large increase in pulmonary arterial pressure of strenuously exercising horses. Alveolar hypoxia causes constriction of the precapillary pulmonary vessels, resulting in pulmonary hypertension. Conditions that can induce hypoxia include the following:

- Exposure to high altitude
- Respiratory impairment secondary to thoracic wall abnormalities
- Airway obstruction
- Pneumonia, including granulomatous pneumonia
- Pulmonary edema
- Emphysema
- Pulmonary vascular disease
- Heaves (recurrent airway obstruction of horses) 3,4

At high altitudes, the low inspired oxygen tension causes hypoxic pulmonary vasoconstriction and hypertension that are common causes of cor pulmonale (brisket disease) in cattle. Susceptible cattle can be identified by measurement of pulmonary artery pressure before clinical disease develops. This test is used to select bulls for use in high-altitude pastures. Cattle grazing pastures that contain lowweed have an increased incidence of brisket disease but the pathogenesis is unknown. Although uncommon, right-sided congestive heart failure and pulmonary hypertension can occur in cows at low altitudes with primary lung disease.

Pulmonary hypertension is a component of heaves in horses and results in abnormalities in myocardial function, which can progress to overt heart failure. 5,6 Progression to heart failure is uncommon, but should be considered in horses with severe or prolonged heaves. Similarly, heart function should be considered in horses with long-standing pneumonia. 7,8

Pulmonary hypertension occurs in neonates and is a consequence of persistent fetal circulation. This is particularly a problem of cloned calves (see “Diseases of Cloned Off-spring,” Chapter 19).

An outbreak of pulmonary hypertension in a group of dairy calves 5 to 6 months of age has been described. Some affected calves died suddenly. Clinical findings included lethargy, anorexia, pale mucous membranes, tachypnea, tachycardia, weakness, engorged jugular veins, and loss of body condition. Right-sided cardiac catheterization revealed pulmonary hypertension. Necropsy findings revealed evidence of right-sided congestive heart failure and periarteritis and fibrosis of the pulmonary and bronchial arteries. Lesions were characterized by variable stages of vasculitis; the airways were free of pathologic changes. Ingestion of monocrotaline, a pyrrolizidine alkaloid, can cause similar pulmonary vascular lesions in rats, but no evidence of such ingestion was found in affected calves.

Pulmonary hypertension occurs secondary to left-sided heart disease in horses, although the hypertension has been mistakenly identified as the primary lesion.

**REFERENCES**

Atelectasis is collapse of the alveoli as a result of failure of the alveoli to inflate or because of compression of the alveoli. Atelectasis is therefore classified as obstruction (resorption), compression, or contraction. Obstruction atelectasis occurs secondary to obstruction of the airways, with subsequent resorption of alveolar gases and collapse of the alveoli. This disease is usually caused by obstruction of small bronchioles by fluid and exudate. It is common in animals with pneumonia or aspiration of a foreign body. Compression atelectasis occurs when intrathoracic (intrapleural) pressure exceeds alveolar pressure, thereby deflating alveoli. This occurs when there is excessive pleural fluid or the animal has a pneumothorax. It also occurs in the dependent lung or portions of lung in recumbent animals and is evident on computed tomographic or radiographic examination of the lungs of foals (Fig. 12-7). Compression atelectasis is the explanation for the large shunt fraction and hypoxemia that occurs in anesthetized horses, causing marked reduction in ventilation of the dependent lung. Compression atelectasis and secondary bronchopneumonia can occur in horses kept in isolation tanks for up to several weeks for treatment of skeletal injuries. Contraction atelectasis occurs when there is compression of parts of the lung by fibrotic changes in the pleura. Patchy atelectasis occurs in the absence of surfactant, such as can occur in newborns. Failure of the lung to inflate, or development of atelectasis of the lungs of the newborn, usually those born prematurely, occurs because of lack of pulmonary surfactant. The disorder can progress to hyaline membrane disease. Affected newborn animals are severely dyspneic, hypoxemic, cyanotic, and weak, and they commonly die in a few hours.

The clinical signs of atelectasis are not apparent until there is extensive involvement of the lungs. Animals develop respiratory distress, tachypnea, tachycardia, and cyanosis. Blood gas analysis reveals hypoxemia, with or without hypercapnia. Thoracic radiographic pneumonia may result in consolidation and proliferation of alveoli. Ultrasonographic examination of the thorax demonstrates consolidated lung.

Atelectasis is reversible if the primary obstruction or compression is relieved.

PULMONARY EMPHYSEMA

Pulmonary emphysema is distension of the lung caused by overdistension of alveoli with rupture of alveolar walls with or without escape of air into the interstitial spaces. Overinflation describes the situation in which there is enlargement of airspaces without tissue destruction. Pulmonary emphysema is always secondary to some primary lesion that effectively traps an excessive amount of air in the alveoli. It is a common clinicopathologic finding in many diseases of the lungs of all species and is characterized clinically by dyspnea, hypoxemia, poor exercise tolerance, and forced expiration.

ETIOLOGY

Pulmonary emphysema is an important lesion only in cattle, although occasional cases occur in pigs. Approximately 3.4% of cattle examined after slaughter in Tanzania had lesions of emphysema sufficiently severe to warrant condemnation of the carcass. The bovine lung is highly susceptible to the development of emphysema from many different causes, not all of them respiratory in origin. In those of respiratory origin, it is common to find pulmonary emphysema when the primary lesion in the lung causes trapping of air in alveoli or terminal bronchioles. Endotoxemia, for example, can result in diffuse alveolar damage resulting in pulmonary edema and emphysema. Some causes of emphysema are as follows.

- Acute interstitial pneumonia
- Parasitic pneumonia with pulmonary edema in acute anaphylaxis
- Perforation of the lung by foreign body as in traumatic reticuloenteritis

Fig. 12-7 Ventrodorsal radiograph of the chest of a 7-day-old foal immediately after ~30 minutes of enforced lateral recumbency. Note the consolidation of the previously dependent lung. Repeat radiographic examination 24 hours later, and without a period of recumbency, did not reveal lesions in the lungs.

Fig. 12-8 Epistaxis and hemoptysis in a cow with pulmonary hemorrhage and vena caval thrombosis. (Reproduced with permission from Braun 2008.)
Retention of carbon dioxide stimulates an increase in the depth of respiration, but maximum respiratory effort necessitated by exercise cannot be achieved. Anoxia develops and metabolism of all body tissues is reduced. The characteristic effect of emphysema is to produce an increase in expiratory effort necessitated by the failure of normal elastic recoil.

Interference with the pulmonary circulation results from collapse of much of the alveolar wall area and a consequent diminution of the capillary bed. The decreased negative pressure in the chest and the abnormally wide respiratory excursion also cause a general restriction of the rate of blood flow into the thorax. The combined effect of these factors may be sufficient to cause failure of the right ventricle, especially if there is a primary defect of the myocardium. Acidosis may also result because of the retention of carbon dioxide.

There are no characteristic hematologic findings, but if there is a significant secondary bronchopneumonia, a leukocytosis and left shift may be evident. In the appropriate location, an examination of feces for lungworm larvae may be desirable. In cases suspected of having an allergic origin, swabs of nasal secretion may reveal a high proportion of eosinophils, and a hematologic examination may show eosinophilia.

**Necropsy Findings**

The lungs are distended and pale in color and may bear imprints of the ribs. In interstitial emphysema, the interalveolar septae are distended with air, which may spread to beneath the pleura, to the mediastinum, and under the parietal pleura. There may be evidence of congestive heart failure. On histopathologic examination, a bronchiolitis is present in most cases. This may be diffuse and apparently primary or originate by spread from a nearby pneumonia.

**Treatment**

The treatment of pulmonary emphysema will depend on the species affected, the cause of the emphysema, and the stage of the disease.

There is no known specific treatment for the pulmonary emphysema associated with acute interstitial pneumonia in cattle, which is discussed under that heading. The emphysema secondary to the infectious pneumonias will usually resolve spontaneously if the primary lesion of the lung is treated effectively. In valuable animals, the administration of oxygen may be warranted if the hypoxia is severe and life-threatening. Antihistamines, atropine, and corticosteroids may be desirable.
have been used for the treatment of pulmonary emphysema secondary to interstitial pneumonia in cattle, but their efficacy has been difficult to evaluate.

DIFFERENTIAL DIAGNOSIS

Acute emphysema in cattle is often accompanied by pulmonary edema with the presence of consolidation and crackles in the ventral parts of the lungs. It may be similar to acute pulmonary congestion and edema caused by anaphylaxis, but forced expiration is not a characteristic of these latter conditions.

Acute pneumonia in cattle or horses is characterized by fever and localization of abnormal respiratory sounds, which are not as marked nor as widely distributed as those of emphysema.

Chronic pneumonia is characterized by dyspnea, chronic toxemia, crackles and wheezes, and poor response to therapy.

Pneumothorax is accompanied by forced inspiration and an absence of normal breath sounds.

REFERENCES

PNEUMONIA

Pneumonia is inflammation of the pulmonary parenchyma, usually accompanied by inflammation of the bronchiolae and often by pleuritis. It is manifested clinically by an increase in the respiratory rate, changes in the depth and character of respiration, coughing, abnormal breath sounds on auscultation, and, in most bacterial pneumonias, evidence of toxemia.

ETIOLOGY

Pneumonia may be associated with viruses, mycoplasmas, bacteria, or a combination of all three; fungi; metazoan parasites; and physical and chemical agents. Most of the pneumonias in animals are bronchogenic (inhalation) in origin, but some originate by the hematogenous route, such as pneumonia of foals and calves with septicemia. Mycoplasmal pneumonias can be devastating in cattle, goats, and pigs (Table 12-6). The pneumonias that occur in farm animals are grouped here according to species.

Cattle
- Pneumonic pasteurellosis (shipping fever)—M. haemolytica, P. multocida with or without parainfluenza-3 virus
- Histophilus somnus in feedlot cattle is not necessarily associated with the septicemic form of the disease. The role of the organism as a primary pathogen in acute bovine respiratory disease is uncertain.
- Bibersteinia trehalosi appears to be a component of the bovine respiratory disease complex, as it is in sheep.12
- Enzootic pneumonia of calves—bovine respiratory syncytial virus; bovine herpesvirus-1 (the IBR virus); parainfluenza-3; adenovirus-1, -2, and -3; rhinovirus; reovirus; and Chlamydia spp., Mycoplasma spp., Pasteurella spp., Mannheimia spp., Trueperella (formerly Actinobacillus or Arcanobacterium or Corynebacterium) pyogenes, Streptococcus spp., Bedsonia sp., and Actinobacillus actinoides
- Corona virus infection in adult feedlot cattle13
- Pneumonia, mastitis, and arthritis in cattle associated with Mycoplasma bovis and in calves with Mycoplasma californicum or M. bovis
- Viral interstitial pneumonia in recently weaned beef calves associated with bovine respiratory syncytial virus; it may also occur in yearling and adult cattle.
- Contagious bovine pleuropneumonia—Mycoplasma mycoides
- Acute and chronic interstitial pneumonia associated with D,L-tryptophan, moldy hay, and other pneumotoxic agents
- Atypical interstitial pneumonia associated with ryegrass staggers in calves
- Massive infestation with pig ascarid larvae
- Lungworm pneumonia—Dictyocaulus viviparous
- Klebsiella pneumoniae infection in calves and nursing cows with mastitis associated with this organism
- Sporadically in tuberculosis associated with M. bovis
- Fusobacterium necrophorus as a complication of calf diphtheria, and sporadically in feedlot cattle
- There is a preliminary report of circovirus in adult cattle with pneumonia.

Pigs
- Enzootic pneumonia—Mycoplasma sp. with Pasteurella sp. secondarily
- Pneumonic pasteurellosis—P. multocida
- Pleuropneumonia—Actinobacillus pleuropneumoniae
- Interstitial pneumonia—septicemic salmonellosis
- Bordetella bronchiseptica, Salmonella choleraesuis
- Influenza virus
- Porcine reproductive and respiratory syndrome virus
- Haemophilus parasuis
- Actinobacillus pyogenes
- Paramyxovirus causing respiratory and central nervous system disease in pigs
- Uncommonly, lungworm pneumonia
- Anthrax by inhalation, causing pulmonary anthrax

Horses
- Pleuropneumonia in mature horses as a result of aerobic and anaerobic bacteria—the aerobic bacteria most commonly isolated are alpha-hemolytic Streptococcus spp., Pasteurella spp., Escherichia coli, and Enterobacter spp. The anaerobic bacteria most frequently isolated are Bacteroides spp., Prevotella spp., Fusobacterium spp., and Clostridium spp.
- Newborn foals—Streptococcus spp., E. coli, Actinobacillus equuli, and other agents causing septicemia in this age group
- In immunodeficient foals, and rarely adult horses,1 a pneumonia associated with adenovirus or Pneumocystis jiroveci (formerly P. carinii)
- Immunosuppression following corticosteroid therapy for other diseases
- Older foals—R. equi, equine herpesvirus-1 or 4 (EVR)
- Bronchointerstitial pneumonia in foals 1 to 8 months of age—etiology uncertain
- Eosinophilic pneumonia secondary to parasite migration (Parascaris equorum) or Dictyocaulus arnfieldi infection, or as part of the multisystemic eosinophilic syndrome in adult horses
- Interstitial proliferative pneumonia in foals from 6 days to 6 months of age, and the adult form in horses 2 years of age and older
- Nippostrongylus semincola in adult horses
- Bordetella bronchiseptica in adult horses
- Glanders and epizootic lymphangitis (Histomonas meleagris) usually include pulmonary lesions.
- Paecilomyces spp. in foals
- Pleuropneumonia associated with pulmonary hydatidosis in a horse
- As a sequela to strangles
- Interstitial pneumonia associated with equine infectious anemia virus infection
- Rarely, as a sequel to equine viral arteritis or equine viral rhinopneumonitis in adult animals
- Equine influenza virus causes pneumonia in foals and adult horses
- Equine nodular pulmonary fibrosis (putatively caused by EHV-5 infection)
- Equine rhinitis A virus infection (putative cause)
- Mycotic pneumonia associated with Ennomonsa crescens (adiaspiromycosis) in adult horses
- Pulmonary aspergillosis in adult horses with predisposing conditions (such as colitis) and in donkey foals
- Strenuous exercise in very cold conditions can cause damage to the airways of horses (and probably other species).

Sheep
- Pneumonic pasteurellosis (Mannheimia spp.) as acute primary pneumonia in feedlot lambs, or secondary to parainfluenza-3 or Chlamydia sp. infection
- Newborn lambs—uncommonly Streptococcus zooepidemicus, Salmonella abortusovis
- Severe pneumonia as a result of Mycoplasma sp. in lambs—kaged in Iceland and Switzerland
- Clinically inapparent pneumonias without secondary infection—adenovirus, respiratory syncytial virus, reovirus, Mycoplasma spp. (including M. ovis pneumoniae, M. dispar)
- M. bovis in sheep
- Corynebacterium pseudotuberculosis—sporadic cases only
- Melioidosis (Pseudomonas pseudomallei)
- Lungworm (Dictyocaulus filaria)
- Ovine herpesvirus-2
- Progressive interstitial pneumonia (maedi) and pulmonary adenomatosis (jaagsiekte)
- Carbolic dip toxicoisis

Goats
- Pleuropneumonia associated with Mycoplasma strain F 38 or Mycoplasma capri, a devastating disease
- Chronic interstitial pneumonia with cor pulmonale as a common sequela associated with a number of Mycoplasma spp., but M. mycoides var. mycoides appears to be the most commonly recorded.
- Parainfluenza type 3
- Contagious ecthyma virus
- Retrovirus infection

All Species
- Toxoplasmosis—rare, sporadic cases
- Systemic mycoses
- Aspiration pneumonia is dealt with as a separate entity.
- Sporadic secondary pneumonia associated with Streptococcus spp., Corynebacterium sp., Dermatophilus sp.
- Interstitial pneumonia, pulmonary consolidation and fibrosis by toxins in plants—Eupatorium glandulosum in horses, Zieria arborescens (stinkwood) in cattle, Astragalus spp. in all species

EPIDEMIOLOGY
In addition to the infectious agents that cause the pneumonia, there are risk factors that contribute to the susceptibility of the animal. Three risk factors interact in the pathogenesis of specific pneumonias:
- Animal
- Environmental and management
- Pathogen

These are of paramount importance in any consideration of pneumonia, and the details of the epidemiology of each specific pneumonia are presented with each specific disease in this book. As examples, some of the commonly recognized risk factors include the following:
- The weaning of beef calves in northern climates
- The long transportation of beef cattle to feedlots
- The collection and mixing of animals at auction marts where they might be deprived of feed and water for prolonged periods
- The transportation of Thoroughbred horses farther than 500 miles and viral respiratory tract disease or exposure to horses with respiratory tract disease
- Housing dairy calves in poorly ventilated, overcrowded barns
- Marked changes in weather
Susceptibility to pneumonia is determined by the animal’s resistance to infection by agents that cause or predispose to pneumonia. Factors that impair innate resistance or adaptive resistance (immunity) increase the animal’s susceptibility to pneumonia. For instance, shipping not only increases the risk of exposure of animals to pathogens to which they have not been exposed but also can compromise innate resistance through damage to the respiratory tract by airborne irritants, dehydration, food deprivation, and the effects of stress.

**PATHOGENESIS**

**Pulmonary Defense Mechanisms**

Under normal conditions the major airways and the lung parenchyma prevent the entry of and neutralize or remove injurious agents, so that the lung contains very few, if any, organisms beyond the large airways. Many infections of the respiratory tract originate from aerosolized particles carrying infectious agents that arise external to or within the respiratory tract. To induce an infection by the aerosol route, an etiologic agent must be aerosolized, survive in the aerosol, be deposited at a vulnerable site in the respiratory tract of a susceptible host, and then multiply. Thus the pathogenesis of these respiratory infections is related to the deposition of particles and infectious agents within the respiratory tract.

Under normal conditions a complex of biochemical, physiologic, and immunologic defense mechanisms protect the respiratory tract from inhaled particles that could be injurious or infectious. The major defense mechanisms of the respiratory tract include (Fig. 12-10) the following:29

- Aerodynamic filtration by the nasal cavities
- Sneezing
- Local nasal antibody
- The laryngeal reflex
- The cough reflex
- Mucociliary transport mechanisms
- Alveolar macrophages
- Systemic and local antibody systems

Compromise of one or more of these defense mechanisms can result in infection, or proliferation, of infectious agents, leading to development of pneumonia. Factors that can compromise respiratory defense systems include stress, administration of glucocorticoids, viral infections, exposure to cold air by animals unaccustomed to it, or poor air quality.29

**Respiratory Mucociliary Clearance**

The mucociliary escalator has important functions in the lung’s physical defenses against the constant challenge of inhaled pathogens. By various physical mechanisms, mucus traps and subsequently transports inhaled particles to the pharynx, where they are normally swallowed. Mucus also protects the airways by absorbing inhaled chemicals and gases, by humidifying the inspired air and by keeping the underlying mucosa hydrated. Mucus contains antibodies, especially IgA, which together with lactoferrin and lysozyme provide immunologic defense.

Airway secretions consist of two layers. An underlying liquid layer, known as the periciliary fluid, in which the cilia beat, originates largely from transepithelial osmosis. An overlying gel or mucus layer is composed of intertwined mucin strands. Airway mucus is secreted in small globules, which expand several hundredfold within seconds and are later drawn into strans and transported nasally by ciliary activity.

The secretion of respiratory mucus is a protective mechanism by which inhaled particles touching the airway mucosa stimulate local mucus production, which then traps and transports the particle from the lung. Airway mucus is produced mainly by submucosal glands and goblet cells, also known as mucus-producing cells. Airway secretions also contain alveolar fluid, surfactant and alveolar cells, including macrophages, which are drawn into the mucociliary ladder by surface tension.

Airway mucus is a complex substance consisting of 95% water and a 5% combination of glycoproteins, proteoglycans, lipids, carbohydrates, and minerals. Mucin is the main nonaqueous component. Effective mucociliary clearance or mucokinosis can occur over a range of mucus viscosity, but very-low-viscosity mucus is poorly transported and tends to gravitate toward the airways, whereas excessively viscous mucus, which is also poorly transported, may lodge in the airways and become inspissated.

In respiratory disease, mucociliary clearance is impaired through disruption of effective ciliary activity or changes in the quantity or quality of the mucus or periciliary fluid, or all three factors. In viral pulmonary disease, ciliary activity can be disrupted because of temporary deciliation or lesions of the respiratory mucosa. The defective mucociliary clearance may also last for several weeks. In chronic obstructive pulmonary disease in the horse, metaplasia of ciliated epithelium to a nonciliated epithelium may occur in the smaller airways.

**Changes in the quality of mucus** are common in respiratory tract disease, especially increases in viscosity with pulmonary disease. The destruction of leukocytes and respiratory epithelial cells and the release of DNA increases the viscosity. Large increases in the glycoprotein content of mucus also occur, which affects the mucokinetic properties. Purulent respiratory secretions have reduced elasticity and together with the increased viscosity affect the mucociliary clearance. Acute inflammation also results in the production of serum proteins from the airway exudate, which alters the viscoelasticity of mucus and further reduces mucokinosis.

Yellow or green respiratory secretions are attributable to the enzyme myeloperoxidase, released from leukocytes in the static secretion, or to high numbers of eosinophils.
The quantity of mucus increases in most cases of respiratory disease as a result of stimulation of goblet cells and submucosal glands by inflammatory mediators. The abnormal production can also exacerbate the original pulmonary dysfunction. Tracheal mucociliary clearance can be assessed endoscopically, in vivo, by dropping dye or small markers on the tracheal mucosa and measuring their rate of transit visually or using radioactive particles detected by scintigraphy.

**Large Particles in Upper Respiratory Tract**
Large aerosolized particles that are inhaled are removed by the nasal cavities and only small ones are able to get into the lung. In the upper respiratory tract, essentially 100% of particles more than 10 µm in diameter and 80% of particles of the 5-µm size are removed by gravitational settling on mucosal surfaces. Particles deposited between the posterior two-thirds of the nasal cavity and the nasopharynx and from the larynx to the terminal bronchioles land on airways lined by mucus-covered, ciliated epithelium and are removed by means of the mucociliary transport mechanism. The nasopharyngeal and tracheobronchial portions of the ciliated airways transport mucus toward the pharynx, where it can be eliminated by swallowing. The cilia beat most effectively in mucus at a certain elasticity, viscosity, and chemical composition. Anything that interferes with the secretion and maintenance of normal mucus will interfere with the clearance of particles from the upper respiratory tract. The damaging effect of viruses on mucociliary clearance has been documented in laboratory animals and in humans.

*Mycoplasma pneumoniae* infection slows tracheobronchial clearance for as long as 1 year, suggesting a possible explanation for the predisposition to bacterial pneumonia commonly observed after these infections. Viral diseases of the upper respiratory tract of farm animals are common and a similar interference in the mucociliary transport mechanism may explain the occurrence of secondary bacterial pneumonia.

**Cough Reflex**
The cough reflex provides an important mechanism by which excess secretions and inflammatory exudates from the lungs and major airways can be removed and disposed of by expectoration or swallowing. In animals with relatively normal lungs, coughing represents a very effective means of expelling inhaled foreign bodies, or excessive or abnormal respiratory secretions, down to the level of the fourth- or fifth-generation bronchi. If the airways become deciliated, the cough reflex is the main and only mucociliary clearance mechanism remaining. The cough reflex is valuable for transporting the increased secretions present in equine pulmonary disease, and antitussive agents should therefore not be used in horses.

In the presence of severe tracheitis and pneumonia, coughing may result in retrograde movement of infected material to the terminal respiratory bronchioles and actually promote spread of the infection to distal parts of the lung. Any process that causes airway obstruction can predispose the lung to secondary bacterial infections. Experimental obstruction of the bronchi supplying a lobe of lung in sheep allows the development of secondary bacterial pneumonia. It has been postulated that damage to small airways following viral infections may allow the accumulation of exudate and cellular debris, which may facilitate secondary bacterial infections.

**Small Particles Into Lower Respiratory Tract**
Particles of 1 to 2 µm in size settle in the lungs through the action of gravity in the alveolar spaces, and particles below 0 to 2 µm settle through diffusion of air. The alveolar macrophage plays a major role in clearing inhaled particles from the lung. Under normal conditions, bacteria that gain entry into the alveoli are cleared quickly and effectively in a matter of hours. Experimental parainfluenza-3 (PI-3) virus infection has the greatest adverse effect on the pulmonary clearance of *M. haemolytica* administered by intranasal aerosol on the seventh day following viral infection. The effect on pulmonary clearance is much less when the bacteria are given on the 3rd or 11th day following the initial viral infection.

The presence of preexisting antibody to *M. haemolytica* eliminates the effect of the viral infection on pulmonary clearance. Thus there is some evidence that in domestic animals, lung clearance mechanism may be affected by a concurrent viral infection. This may have major implications in the control of some of the common infectious respiratory diseases of farm animals.

**Species Susceptibility**
The anatomic and physiologic features of the respiratory system of cattle may predispose them to the development of pulmonary lesions much more than other farm animal species. Cattle have a small physiologic gaseous exchange capacity and greater resultant basal ventilatory activity. The small gaseous exchange capacity may predispose cattle to low bronchial or alveolar oxygen levels during exposure to high altitudes and during periods of active physical or metabolic activity. During these times, low oxygen tension or hypoxia may slow mucociliary and alveolar macrophage activity and decrease pulmonary clearance rates. The basal ventilatory activity is comparatively greater than other mammals, which results in the inspired air becoming progressively more contaminated with infectious, allergenic, or noxious substances.

The bovine lung also has a higher degree of compartmentalization than other species. This may predispose to airflow hypoxia peripheral to airways that become occluded. This results in reduced phagocytic activity and the retention or multiplication of infectious agents. In addition, because of the low numbers of alveolar macrophages in the bovine lung, the pulmonary clearance mechanism may not be as effective as in other species. There is also a low level or atypical bioactivity of lysozyme in bovine respiratory mucus, which may make cattle more susceptible to infection of the respiratory tract than other species.

**Development of Pneumonia**
The process by which pneumonia develops varies with the causative agent and its virulence and with the portal by which it is introduced into the lung.

**Bacteria are introduced** largely by way of the respiratory passages and cause a primary bronchiolitis that spreads to involve surrounding pulmonary parenchyma. The reaction of the lung tissue may be in the form of an acute fibrinous process as in pasteurellosis and contagious bovine pleuropneumonia, a necrotizing lesion as in infection with *F. necrophorum*, or as a more chronic caseous or granulomatous lesion in mycobacterial or mycotic infections. Spread of the lesion through the lung occurs by extension but also by passage of infective material along bronchioles and lymphatics. Spread along the air passages is facilitated by the normal movements of the bronchiolar epithelium and by coughing. Bronchiectasis and pulmonary abscesses are complications and common causes of failure to respond to therapy. Hematogenous infection by bacteria results in a varying number of septic foci, which may enlarge to form lung abscesses. Pneumonia occurs when these abscesses rupture into air passages and spread as a secondary bronchopneumonia.

**Viral infections** are also introduced chiefly by inhalation and cause a primary bronchiolitis, but there is an absence of the acute inflammatory reaction that occurs in bacterial pneumonia. Spread to the alveoli causes enlargement and proliferation of the alveolar epithelial cells and the development of alveolar edema. Consolidation of the affected tissue results but again there is an absence of acute inflammation and tissue necrosis so that toxemia is not a characteristic development. Histologically, the reaction is manifested by enlargement and proliferation of the alveolar epithelium, alveolar edema, thickening of the interstitial tissue, and lymphocytic aggregations around the alveoli, blood vessels, and bronchioles. This interstitial type of reaction is characteristic of viral pneumonias.

The **pathophysiology** of all pneumonias, regardless of the way in which lesions develop, is based on interference with
gaseous exchange between the alveolar air and the blood. Anoxia and hypercapnia develop, which results in polypnea, dyspnea, or tachypnea. Consolidation results in louder than normal breath sounds, especially over the anteroventral aspects of the lungs, unless a pleural effusion is present to muffle the sounds. In bacterial pneumonias, there is the added effect of toxins produced by the bacteria and necrotic tissue; the accumulation of inflammatory exudate in the bronchi is manifested by abnormal lung sounds such as crackles and wheezes on auscultation. Interstitial pneumonia results in consolidation of pulmonary parenchyma without involvement of the bronchi, and on auscultation loud breath sounds predominate in the early stages.

**Extension of the pneumonia** to the visceral surface of the pleura results in pleuritis, pleuroneumonia, pleural effusion, and thoracic pain. Fibrinous pleuritis is a common complication of pneumonic pasteurellosis in cattle. Pleuritis and pleural effusion secondary to pneumonia and pulmonary abscesses are commonly recognized in adult horses with the pleuroneumonia complex associated with aerobic and anaerobic bacteria. Anaerobic bacterial pleuroneumonia in the horse is accompanied by a putrid odor of the breath, the sputum, or the pleural fluid. It is suggested that most anaerobic bacterial pulmonary infections in the horse are the result of aspiration of oropharyngeal contents, and they are most commonly located in the right lung because of the proximity of the right mainstem bronchus. Some horses with pleuroneumonia may develop acute hemorhagic pulmonary infarction and necrotizing pneumonia.

Restriction of gaseous exchange occurs because of the obliteration of alveolar spaces and obstruction of air passages. In the stage before blood flow through the affected part ceases, the reduction in oxygenation of the blood is made more severe by failure of part of the circulating blood to come into contact with oxygen. Cyanosis is most likely to develop at this stage and to be less pronounced when hepazation is complete and blood flow through the part ceases. An additional factor in the production of anoxia is the shallow breathing that occurs. Pleuritic pain causes reduction in the respiratory excursion of the chest wall, but when no pleurisy is present the explanation of the shallow breathing probably lies in the increased sensitivity of the Hering–Breuer reflex. Retention of carbon dioxide with resulting acidosis is most likely to occur in the early stages of pneumonia because of this shallow breathing.

**CLINICAL FINDINGS**

- **Polypnea** may be quite marked with only minor pneumonic lesions; the rapidity of the respiration is an inaccurate guide to the degree of pulmonary involvement.
- **Coughing** is another important sign, with the type of cough varying with the nature of the lesion.

Bacterial bronchopneumonia is usually accompanied by a moist and painful cough. In viral interstitial pneumonia, the coughing is frequent, dry, and hacking, often in paroxysms. Auscultation of the thorax before and after coughing may reveal coarse crackling sounds suggestive of exudate in the airways. Cyanosis is not a common sign and occurs only when large areas of the lung are affected. A nasal discharge may or may not be present, depending on the amount of exudate present in the bronchioles and whether or not there is accompanying inflammation of the upper respiratory tract. The odor of the breath may be informative: it may have an odor of decay when there is a large accumulation of inspissated pus present in the air passages; or it may be putrid, especially in horses affected with anaerobic bacterial pleuroneumonia.

In **acute bacterial bronchopneumonia**, toxemia, anorexia, depression, tachycardia, and a reluctance to lie down are common. In the advanced stages, severe dyspnea with an expiratory grunt are common.

In **viral interstitial pneumonia**, affected animals are usually not toxemic, but they may have a fever and be inappetent or anorexic. However, some cases of viral interstitial pneumonia can be diffuse and severe and cause severe respiratory distress, failure to respond to therapy, and death within a few days. A severe bronchointerstitial pneumonia of foals aged 1 to 2 months of age has been described. The disease was characterized clinically by sudden onset of fever and increasing severe dyspnea with respiratory distress and no response to treatment. In **acute interstitial pneumonia of cattle**, exemplified by the acute disease seen in mature cattle moved on to a lush pasture within the previous 10 days, some animals may be found dead. Other affected animals are severely dyspneic and anxious, commonly mouth breathe and grunt with each expiration, and, if forced to walk, may collapse and die of asphyctic respiratory failure.

**Auscultation of the lungs** is a valuable aid to diagnosis. The stage of development and the nature of the lesion can be determined, and the area of lung tissue affected can be outlined. In the early congestive stages of bronchopneumonia and interstitial pneumonia, the breath sounds are increased, especially over the anteroventral aspects of the lungs. Crackles develop in bronchopneumonia as bronchiar exudation increases, but in uncomplicated interstitial pneumonia, clear, harsh breath sounds are audible. In viral interstitial pneumonia, wheezes may be audible because of the presence of bronchiolitis. When complete consolidation occurs in either form, loud breath sounds are the most obvious sound audible over the affected lung, but crackles may be heard at the periphery of the affected area in bronchopneumonia. Consolidation also causes increased audibility of the heart sounds. When pleurisy is also present, a pleuritic friction rub may be audible in the early stages and muffling of the breath sounds over the ventral aspects of the lungs in the late exudative stages. If a pleural effusion is present, percussion of the thorax will reveal dullness of the ventral aspects, and a fluid line can usually be outlined. Consolidation can be detected also by percussion of the thorax.

In **chronic bronchopneumonia in cattle**, there is chronic toxemia, rough hair coat, and a gaunt appearance. The respiratory and heart rates are above normal, and there is usually a moderate persistent fever. However, the temperature may have returned to within a normal range even though the animal continues to have chronic incurable pneumonia. The depth of breathing is increased and both inspiration and expiration are prolonged. A grunt on expiration and open-mouth breathing indicate advanced pulmonary disease. A copious bilateral mucopurulent nasal discharge and a chronic moist productive cough are common. On auscultation of the lungs, loud breath sounds are usually audible over the ventral half of the lungs, and crackles and wheezes are commonly audible over the entire lung fields but are most pronounced over the ventral half.

With adequate treatment in the early stages, bacterial pneumonia usually responds favorably in 24 hours, but viral pneumonia may not respond at all or may relapse after an apparent initial beneficial response. The transient response may be attributable to control of the secondary bacterial invaders. In some bacterial pneumonias, relapses also occur that are a result of either reinfection or persistence of the infection in necrotic foci that are inaccessible to antimicrobials. The final outcome depends on the susceptibility of the causative agent to the treatments available and the severity of the lesions when treatment is undertaken. Pleurisy is a common complication of pneumonia and rarely occurs independently of it, and it is described later under that heading.

**Pneumonia and pleuritis** in horses are described separately (see following “Equine Pleuroneumonia” section).

Congestive heart failure or cor pulmonale may occur in some animals that survive a chronic pneumonia for several weeks or months.

**Medical Imaging**

Thoracic radiography and ultrasonography are now commonly performed in veterinary teaching hospitals and specialty clinics and are discussed earlier in this chapter. They can
provide considerable diagnostic assistance in assessing the severity of the lesion and explaining certain clinical manifestations that may be difficult to interpret. Ultrasonography is a useful diagnostic aid in cattle and horses with anaerobic bacterial pleuropneumonia and pulmonary abscessation. Gas echoes within pleural or abscess fluid were found to be a sensitive and specific indicator of anaerobic infection, as was a putrid breath or pleural fluid.

In cattle with pleuropneumonia, ultrasonographic examination of both sides of the thorax may reveal accumulations of anechoic or hypoechogenic fluid in the pleural space in the ventral aspect of the thorax.21 In cattle, pleural effusion associated with pleural effusion may indicate either bilateral pulmonary disease or a noninflammatory cause such as right-sided congestive heart failure or hypoproteinemia.

**CLINICAL PATHOLOGY Respiratory Secretions**

The laboratory examination of the exudates and secretions of the respiratory tract is the most common diagnostic procedure performed when presented with cases of pneumonia. Nasal swabs, tracheobronchial aspirates, and bronchoalveolar lavage samples can be submitted for isolation of viruses, bacteria, and fungi; cyologic examination; and determination of antimicrobial sensitivity. Tracheobronchial aspirates are considered more reliable for the cytologic examination of pulmonary secretions in horses with suspected pneumonia or pleuropneumonia. Bronchoalveolar lavage samples may be normal in horses affected with pneumonia or pleuropneumonia. In suspected cases of pleuropneumonia, the collection and culture of pleural fluid is a valuable aid to diagnosis, and both anaerobic and aerobic bacteria must be considered.

**Thoracentesis**

When pleural effusion is suspected, thoracentesis can be used to obtain pleural fluid for analysis.

**Hematology**

Hematologic examination can indicate if the infection is bacterial or viral in nature and its severity. The hematocrit will be elevated in severely toxemic animals that are not drinking water. Severe bacterial bronchopneumonia and pleuritis is characterized by marked changes in the leukon. Serum fibrinogen or serum amyloid A concentrations are markedly elevated in horses with pleuropneumonia and pleuritic, or other inflammatory, lung disease.22 Some limited studies indicate that the measurement of acute-phase proteins in bovine respiratory disease may be a valuable diagnostic and prognostic aid.

**Serology**

When viral interstitial pneumonia is suspected, acute and convalescent sera are recommended for viral neutralization titer evaluation. For specific diseases such as porcine pleuropneumonia, serum can be taken from a percentage of the herd and submitted for serotyping to determine which serotype is most prevalent in the herd.

**Fecal Samples**

When lungworm pneumonia is suspected, fecal samples can be submitted for detection of the larvae.

**Necropsy**

In outbreaks of respiratory disease wherein the diagnosis is uncertain, necropsy of selected early cases will often assist in making a diagnosis.

**NECROPSY FINDINGS**

Gross lesions are usually observed in the anterior and dependent parts of the lobes; even in fatal cases where much of the lung is destroyed, the dorsal parts of the lobes may be unaffected. The gross lesions vary a great deal depending on the type of pneumonia present. Bronchopneumonia is characterized by the presence of serofibrinous or purulent exudate in the bronchioles and lobular congestion or hepatization.

In the more severe, fibronous forms of pneumonia, there is gelatinous exudation in the interlobular septae and an acute pleurisy, with shreds of fibrin present between the lobes.

In interstitial pneumonia, the bronchiolos are clean, and the affected lung is sunken and dark red in color, and it has a granular appearance under the pleura and on the cut surface. There is often an apparent firm thickening of the interlobular septae. These differences are readily detected on histologic examination.

In chronic bronchopneumonia of cattle, there is consolidation, fibrosis, fibronous pleuritis, interstitial and bullous emphysema, bronchi filled with exudate, bronchiectasis, and pulmonary abscessation.

Lesions typical of the specific infections listed under etiology are described under the headings of the specific diseases.

**TREATMENT**

**Antimicrobial Therapy**

In specific bacterial infections as listed previously, isolation of affected animals and careful surveillance of the remainder of the group to detect cases in the early stages should accompany the administration of specific antimicrobials to affected animals. The choice of antimicrobial will depend on the tentative diagnosis, the experience with the drug in previous cases and the results of drug sensitivity tests. The common bacterial pneumonias of all species will usually recover quickly (24-72 hours) if treated with an adequate dose of the drug of choice early in the course of the disease. Animals with severe pneumonia will require daily treatment for several days until recovery occurs. Those with bacterial pneumonia and toxemia must be treated early on an individual basis. Each case should be identified and carefully monitored for failure to recover, and an assessment should be made. Clinical field trials to evaluate different antimicrobials for the treatment of acute bovine respiratory disease occurring under natural conditions are becoming more common and more meaningful, particularly under commercial feedlot conditions.

**DIFFERENTIAL DIAGNOSIS**

There are two major difficulties in the clinical diagnosis of pneumonia. The first is to decide that the animal has pneumonia; the second is to determine the nature of the pneumonia and its cause. The suspected cause will influence the prognosis, the clinical management, and, more particularly in infectious pneumonias, the kind of antimicrobial therapy used.

There are two kinds of errors made in the clinical diagnosis of pneumonia. One is that the pneumonia is not detected clinically because of the abnormal lung sounds. This is not obvious. The other is to make a diagnosis of pneumonia because of the presence of dyspnea that is attributable to disease in some other body system.

- **In bacterial pneumonia** the major clinical findings are polynea in the early stages and dyspnea later, abnormal lung sounds, and fever and toxemia.
- **In viral interstitial pneumonia** uncomplicated by secondary bacterial pneumonia, there is no toxemia. Pulmonary edema and congestion, embolism of the pulmonary artery, and emphysema are often mistaken for pneumonia but can usually be differentiated by the absence of fever and toxemia, on the basis of the history and on auscultation findings.
- **Diseases of other body systems** can cause polynea and dyspnea. Congestive heart failure, the terminal stages of anemia, poisoning by agents such as hydrocyanic acid, hyperthermia, and acidosis are accompanied by respiratory embarrassment but not by the abnormal sounds typical of pulmonary involvement.

If pneumonia is present, the next step is to determine the nature and cause of the pneumonia. All the practical laboratory aids described earlier should be used when necessary. This is of particular importance when outbreaks of pneumonia are encountered, in which case necropsy examination of selected cases is indicated. In single routine cases of pneumonia, the cause is usually not determined. However, the age
Antimicrobials for treatment of lung disease are preferably those that achieve therapeutic concentrations in diseased lung tissue after administration of conventional doses. This has been convincingly demonstrated for the macrolide (azithromycin, erythromycin), triamidine (tulathromycin), and fluoroquinolone (danofloxacin, enrofloxacin) antimicrobials and fluorfenicol in a variety of species. The beta-lactam antimicrobials (penicillin, cephalosporin) are effective in treatment of pneumonia in horses, pigs, and ruminants despite having chemical properties that do not favor their accumulation in lung tissue.

Routes of administration include oral (either individually or in medicated feed or water), parenteral (subcutaneous, intramuscular, intravenous), or inhalational. Intratracheal administration of antimicrobials to animals with respiratory disease is not an effective means of achieving therapeutic drug concentrations in diseased tissue. Aerosolization and inhalation of antimicrobials has the theoretic advantage of targeting therapy to the lungs and minimizing systemic exposure to the drug. However, although administration by inhalation achieves good concentrations of drug in bronchial lining fluid, the drug does not penetrate ventilated regions of the lungs, in which case parenteral or oral administration of antimicrobials is indicated. Administration of gentamicin to horses and cefotiofur sodium to calves with pneumonia has been investigated. Aerosol delivery of gentamicin to normal horses results in gentamicin concentrations in bronchial lavage fluid 12 times that achieved after intravenous administration. Aerosolized cefotiofur sodium (1 mg/kg) is superior to intramuscular administration in treatment of calves with M. haemolytica.

Treatment of parasitic lung disease, such as that caused by migrating larvae or lungworms, is by administration of appropriate anthelmintics such as ivermectin, moxidectin, or the benzimidazoles. Refer to the sections in this book that deal with these diseases for details of the specific treatments. Treatment of P. jiroveci pneumonia involves the administration of a sulfonamide–trimethoprim combination or dapson (3 mg/kg orally every 24 hours).

The antimicrobials and other drugs recommended for the treatment of each specific pneumonia listed under etiology are presented with each specific disease elsewhere in the book. The common causes for failure to respond favorably to treatment for bacterial pneumonia include the following:

- Advanced disease when treatment was undertaken
- Presence of pleuritis and pulmonary abscesses
- Drug-resistant bacteria
- Inadequate dosage of drug
- Presence of other lesions or diseases that do not respond to antimicrobials

There is no specific treatment for the viral pneumonias, and although many of the Mycoplasma spp. are sensitive to antimicrobials in vitro, the pneumonias associated with them do not respond favorably to treatment. This could be attributable to the intracellular location of the Mycoplasma making them inaccessible to the drugs. Because viral and mycoplasmal pneumonias are commonly complicated by secondary bacterial infections, it is common practice to treat acute viral and mycoplasmal pneumonias with antimicrobials until recovery is apparent.

**Intensive and prolonged therapy** may be required for the treatment of diseases such as equine pleuropneumonia. It may include daily care and treatment in a veterinary clinic consisting of daily lavage of the pleural cavity, including thoracostomy to drain pulmonary abscesses, and intensive antimicrobial therapy and monitoring for several weeks.

**Mass Medication**

In outbreaks of pneumonia where many animals are affected and new cases occur each day for several days, the use of mass medication of the feed and/or water supplies should be considered. Outbreaks of pneumonia in swine herds, lamb feedlots, veal calf enterprises, and beef feedlots are usually ideal situations for mass medication through the feed or water. Mass medication may assist in the early treatment of subclinical pneumonia and is a labor-saving method of providing convalescent therapy to animals that have been treated individually. The major limitation of mass medication is the uncertainty that those animals that need the drug will actually get it in the amounts necessary to be effective. Total daily water intake by animals is a function of total dry matter intake and well-being, and water consumption is therefore markedly reduced in toxic animals. The provision of a reliable concentration of the drug in the water supply on a 24-hour basis is also a problem. However, with careful calculation and monitoring, mass medication can be a valuable and economical method of treating large numbers of animals. The method of calculating the amount of antimicrobials to be added to feed or water supplies is presented in Chapter 7 on antimicrobial therapy.

When outbreaks of pneumonia occur and new cases are being recognized at the rate of 5% to 10% per day of the total in the group, all the remaining in-contact animals may be injected with an antimicrobial in a long-acting base. This may help to treat subclinical cases before they become clinical and thus control the outbreak.

**Other Drugs**

Nonsteroidal antiinflammatory drugs are useful in the treatment of infectious respiratory disease of cattle and horses, and likely other species. The drugs act by inhibiting...
the inflammatory response induced by the infecting organism and tissue necrosis. Meloxicam (0.5 mg/kg subcutaneously, once), when administered with tetracycline, improves weight gain and reduces the size of lesions in lungs of cattle with bovine respiratory disease complex over those of animals treated with tetracycline alone. NSAIDs also improve the clinical signs of cattle with respiratory disease. Use of these drugs is routine in horses with pneumonia or pleuritis.

Corticosteroids have been used for their antiflammatory effect in the treatment of acute pneumonia. However, there is no clinical evidence that they are beneficial, and they might be deleterious.

Bronchodilators have been investigated in the treatment of pneumonia in food animals. The beta-2 adrenergic agonists are potent and effective bronchodilators that can be administered orally, intravenously, or by inhalation. These drugs also enhance mucociliary clearance of material from the lungs. Most administration is orally or by inhalation, but the use of beta-2 adrenergic agonist bronchodilator drugs in food animals is not permitted in most countries because of the risk of contamination of foodstuffs intended for consumption by people. This is particularly the case with clenbuterol, a drug approved in many countries for use in horses that is administered to cattle illicitly as a growth promoter. People can be poisoned by clenbuterol in tissues of treated cattle. Theophylline has been evaluated as a bronchodilator to relieve respiratory distress in cattle with pneumonia. When it was given orally at a dose of 28 mg/kg BW daily for 3 days, along with antimicrobial therapy, to calves with naturally acquired respiratory disease, the respiratory rate and rectal temperature decreased. However, some calves died, presumably from the accumulation of lethal concentrations of plasma theophylline. It is recommended that the drug should not be used unless plasma levels can be monitored.

Supportive Therapy and Housing
Affected animals should be housed in warm, well-ventilated, draft-free accommodation and provided with ample fresh water and light, nourishing food. During convalescence premature return to work or exposure to inclement weather should be avoided. If the animal does not eat, oral or parenteral force-feeding should be instituted. If fluids are given intravenously, care should be exercised over the speed with which they are administered. Injection at too rapid a rate may cause overloading of the right ventricle and death as a result of acute heart failure.

Supportive treatment might include the provision of oxygen, if it is available, especially in the critical stages when hypoxia is severe. In foals, the oxygen can be administered through an intranasal tube passed back to the nasopharynx and delivered at the rate of about 8 L/min for several hours. Oxygen therapy is detailed in the previous general section on treatment of respiratory disease.

ACUTE RESPIRATORY DISTRESS SYNDROME
Acute respiratory distress syndrome is a well-recognized clinical syndrome of humans characterized by acute onset of hypoxemia and pulmonary infiltrates without increases in left atrial pressure (i.e., without evidence of cardiogenic pulmonary edema). Precipitating causes include both direct and indirect lung injury, including sepsis, multiple transfusions, trauma, near-drowning, smoke inhalation, pancreatitis, and more. The underlying lesion is diffuse alveolar capillary damage with secondary severe pulmonary edema. The disease occurs spontaneously in domestic animals, and although the spontaneous disease is not extensively documented, the disease produced experimentally as a model of the human disease is better described.

Acute respiratory distress syndrome (ARDS) in animals occurs in newborns and in adult animals. The disease in some newborn farm animals is related to lack of surfactant, but except for animals born prematurely, this is more the exception than the rule. Most young animals and all adult animals with ARDS have some inciting acute lung injury that then progresses to ARDS. The causes can be infectious (e.g., influenza virus infection, leptospirosis, porcine reproductive and respiratory syndrome virus infection), physical (smoke inhalation or thoracic trauma), toxic, or sepsis.

The pathophysiology of the disease involves a common final pathway that results in damage to alveolar capillaries. The initial injury can be to either the endothelium of pulmonary capillaries or to alveolar epithelium. Damage to these structures leads to extravasation of protein-rich fluid and fibrin with subsequent deposition of hyaline membranes. The capillary injury is attributed to activated leukocytes (macrophages and neutrophils) and cytokines. Accumulation of hyaline membranes and ventilation/perfusion mismatch impairs respiratory gas exchange and cause hypoxemia.

The clinical signs are characteristic of acute, progressive pneumonia. Animals are anxious, tachycardic, tachypneic and have crinkles and wheezes on thoracic auscultation. Severely affected animals can be cyanotic. Thoracic radiographs reveal diffuse pulmonary infiltrates. Hematologic changes are characteristic of the inciting disease but usually include leukopenia. There is arterial hypoxemia.

Treatment includes administration of antinflammarory drugs (NSAIDs with or without glucocorticoids), colloids, antimicrobials, and oxygen. The arterial blood gas response to oxygen therapy is often minimal in severely affected animals. If it is available, mechanical ventilation can be useful, although the prognosis is grave. Inhalation of nitric oxide is beneficial in some humans with the disease, and there are anecdotal reports that it has been used to treat foals with ARDS.

ASPIRATION PNEUMONIA
Aspiration or inhalation pneumonia is a common and serious disease of farm animals caused by inhalation of ingesta, lipid, medications, meconium, or excessive dust. Cases occur after careless drenching, oral administration of medications, or inadvertent intratracheal passage of an intended nasogastric tube during treatment for other illness, for example, administration of mineral oil to horses with colic. Even when care is taken these procedures are not without risk. Other causes include the feeding of calves and pigs on fluid feeds in inadequate troughing, with inhalation occurring in the struggle for food. Dipping of sheep and cattle when they are weak, or keeping their heads submerged for too long, also results in inhalation of fluid. Vomiting in ruminants can be followed by aspiration, especially in cattle with parturient paresis or during the passage of a stomach tube if the head is held high. Rupture of a pharyngeal abscess during palpation of the pharynx or passage of a nasal tube may cause sudden aspiration of infective material. Animals suffering from congenital defects
and paralysis or obstruction of the larynx, pharynx, or esophagus can aspirate food or water when attempting to swallow. Esophageal obstruction is an important risk factor for aspiration pneumonia in horses (see following discussion), with 39 of 109 cases of esophageal obstruction developing aspiration pneumonia. Bluetongue infection (BTV-12) of sheep causes myonecrosis of esophageal musculature and outbreaks of aspiration pneumonia. Aspiration pneumonia is the consistent lesion of crude oil poisoning in cattle and probably results from vomiting or regurgitation.

REFERENCES

Lipid Pneumonia
Lipid pneumonia usually results from aspiration of mineral oil (liquid paraffin) administered for gastrointestinal disease. Pneumonia is sometimes the result of inadvertent administration of the oil into the trachea through a misplaced stomach tube or inhalation during oral administration of oil. However, aspiration of oil can occur even when it is delivered into the stomach through a nasogastric tube, presumably because of regurgitation of oil either around the tube or after the tube has been removed. Administration of oil to sedated or severely depressed animals might increase the risk of aspiration.

Clinical signs include cough, tachypnea, tachycardia, pyrexia, respiratory distress, and abnormal lung sounds. Radiographs can reveal an alveolar or interstitial pattern. Examination of tracheal aspirates reveals a neutrophilic inflammation and the presence of lipid. Lipid can be readily identified by Sudan or oil red O staining of smears of the aspirate in acute cases. Necropsy examination reveals consolidated lungs. On cut section of these areas oil can be visible. Chronic cases have tissue necrosis and severe interstitial pneumonia. Lipid droplets can be identified in affected lung tissue after oil red O staining of sections. The presence and nature of the lipid can be demonstrated by thin-layer chromatography and gas chromatography. The prognosis for recovery is poor. Treatment is supportive and includes antiinflammatory drugs, antimicrobials, and oxygen. There is no specific treatment. Prevention includes careful insertion of nasogastric tubes, verification of their placement in the stomach, and not administering mineral oil to animals with a distended stomach or ones that are heavily sedated or severely depressed.

Esophageal Obstruction
Esophageal obstruction is a common and important cause of pneumonia in horses. Of 109 horses with esophageal obstruction, 39 had clinical signs of aspiration pneumonia. Obstruction of the esophagus in horses, and in other species, leads to the accumulation of saliva and feed material in the esophagus oropharyngeal bacteria. Feed material is irritant and also causes obstruction of the smaller airways. Pulmonary defense mechanisms are weakened or overwhelmed by the contamination, and infection and pneumonia result. The duration of esophageal obstruction is a good indicator of the risk of aspiration pneumonia, although the extent of contamination of the trachea with feed material is not. Affected horses are pyrexic, tachycaardic, and toxemic. Lung sounds can include crackles and wheezes, but the only auscultatory abnormality can be decreased breath sounds in the ventral thorax. Radiography reveals a characteristic pattern of bronchopneumonia restricted, at least initially, to the cranioventral and caudoventral lung lobes in adult horses. Ultrasonography reveals comet tail lesions in the ventral lung fields and variable consolidation. Pleuritis is a not uncommon sequela to aspiration pneumonia. Examination of tracheal aspirates demonstrates neutrophilic inflammation with presence of degenerate neutrophils, bacteria that are both intracellular and extracellular, and plant material. Culture of tracheal aspirates yields one or more of a wide variety of bacteria, including S. zoopneumoniae, Pasteurella sp., Actinobacillus sp., E. coli, and anaerobes. Treatment involves prompt relief of the esophageal obstruction and administration of broad-spectrum antimicrobials, such as a combination of penicillin, aminoglycoside, and anaerobes.Culture of tracheal aspirates yields one or more of a wide variety of bacteria, including S. zoopneumoniae, Pasteurella sp., Actinobacillus sp., E. coli, and anaerobes. Treatment involves prompt relief of the esophageal obstruction and administration of broad-spectrum antimicrobials.

Dusty Feed
Although farm animals fed on dusty feeds inhale many dust particles and bacteria, which can be readily isolated from the lung, this form of infection rarely results in the development of pneumonia. Much of the dust is filtered out in the bronchial tree and does not reach the alveoli. However, this may be of importance in the production of the primary bronchiolitis that so often precedes alveolar emphysema in horses. The inhalation of feed particles in pigs in a very poorly ventilated environment has been demonstrated to cause foreign body pneumonia. Also, a dry, dusty atmosphere can be created in a piggery by overfrequent changing of wood shavings used as bedding, and this can lead to the production of foreign body pneumonia. Liquids and droplets penetrate to the depths of the alveoli and run freely into the dependent portions, and aspiration pneumonia often results.

Meconium Aspiration Syndrome
Aspiration of meconium during parturition is associated with severe lung disease in newborns. Passage of meconium in utero, and subsequent aspiration by the fetus, is a sign of fetal distress. It is suggested that fetal distress results in expulsion of meconium into the amniotic fluid. This is followed by aspiration of contaminated amniotic fluid. The passage of meconium-contaminated amniotic fluid into the lungs may occur before birth when the fetus gasps for air in an attempt to correct hypoxemia or when the calf takes its first breath and aspirates meconium from the oropharynx. Normally, fetal aspiration of amniotic fluid does not occur because the inspiratory forces are insufficient to allow amniotic fluid to reach the lungs, and the lung liquid, a locally produced viscous material present in the trachea and lungs, constantly flows up the major airways to the oropharynx. The result is that the fetus is doubly challenged in that it must deal both with the cause of the fetal distress and the pneumonia induced by aspiration of meconium. Although meconium is sterile, it induces a severe inflammatory response in the lungs.

The meconium aspiration syndrome is best described in newborn calves, although there are numerous reports of its experimental induction in piglets and lambs as a model of the human disease. In a series of calves under 2 weeks of age submitted to a diagnostic laboratory, 42.5% had evidence of meconium, squamous cells, or keratin in the lung. Diffuse alveolitis with exudation of neutrophils, macrophages, and multinucleated cells and obstruction of small airways with atelectasis were common. Treatment of aspiration pneumonia in farm animals is not well described. Administration of antimicrobials is prudent. Antiinflammatory drugs are indicated. Pentoxifylline is used in human neonates with meconium aspiration, but there are no reports of its use for this purpose in farm animals.

REFERENCE

DROWNING
Near drowning has been defined as survival following asphyxia and aspiration of water while submerged. Cases are rare in large
animals, but there is potential with the popularity of swimming as a method of exercising and training horses. There are cases of pneumonia after plunge dipping of sheep, which might be attributable to lung damage as a result of inhalation of dip water contaminated with bacteria. The pulmonary responses to near drowning in sea water differ from that in fresh water. Fresh water can inactivate pulmonary surfactant and lead to collapse of the alveolus with a loss of pulmonary compliance, and the resultant ventilation/perfusion mismatch coupled with alveolar damage can lead to severe hypoxemia. The inhalation of water may also carry bacteria and the risk of secondary bacterial aspiration pneumonia. Affected animals present with an elevated heart rate, tachypnea, and dyspnea. There is a decrease in normal airflow sounds on auscultation, which can occur in all areas of auscultation or be more pronounced in one lung, and rales or crackles may be heard in local areas. Consolidation may be detected with thoracic radiography. The mucous membranes may be congested, cyanotic, or muddy. Arterial blood gas analysis has shown a metabolic acidosis and hypoxemia. The response is typical of acute lung injury (acute respiratory distress syndrome).

Therapy has been based on experience with near drowning cases in humans; horses have been successfully treated by nasal insufflation of humidified oxygen, the correction of the base deficit with sodium bicarbonate and lactated Ringer’s solutions administered intravenously, treatment with bronchodilators and nonsteroidal antiinflammatory drugs, and pulmonary infusion with a surfactant transplant from a recently euthanized horse. Antibacterials are given to cover the risk or the presence of a bacterial pneumonia, and the cover should include the possibility of infection with anaerobic organisms. Respiratory distress can be more severe when the animals are recumbent. Near drowning requires immediate and aggressive therapy, and the recovery can be prolonged.

REFERENCE

PULMONARY ABSCESS
The development of single or multiple abscesses in the lung causes a syndrome of chronic toxemia, cough, and emaciation. Abscesses can be solitary, multiple, military, or coalescing. Small solitary abscesses can be clinically silent, with clinical signs becoming more apparent at the extent of the lesions increases.

ETIOLOGY
Pulmonary abscesses can be part of a primary disease or arise secondarily to diseases in other parts of the body.

Primary Diseases
- *R. equi* pulmonary abscesses of foals
- *S. zooepidemicius* and *Actinobacillus* sp. in adult horses—one-third of infectious causes of abscesses in horses are polymicrobial, and anaerobic bacteria are isolated in 20% of cases
- Solitary abscess associated with strangles in horses, caseous lymphadenitis in sheep
- Tuberculosis
- Actinomycosis rarely occurs as granulomatous pulmonary lesions
- Aerogenous infections with "systemic" mycoses (e.g., coccidioidomycosis, aspergillosis, histoplasmosis, cryptococcosis, and moniliasis)
- *Hlceoccocus ovis* in horses and goats
- *Mycoplasma bovis* in cattle

Secondary Diseases
- Sequestration of an infected focus of pneumonia (e.g., bovine pleuroneumonia or pleuroneumonia in horses)
- Pulmonary abscesses secondary to ovine estrosis
- Emboli from endocarditis, caudal or cranial vena caval thrombosis, metritis, mastitis, omphalophlebitis
- Rumenitis is strongly associated with development of liver abscesses, which in turn are risk factors for lung abscesses in cattle. Of cattle with liver abscesses, 14% have severe lung lesions, and 28% have mild lung lesions.
- Aspiration pneumonia from milk fever in cows, drenching accident in sheep—in which case the abscess is a manifestation of aspiration pneumonia.
- Penetration by foreign body, such as in traumatic reticuloperitonitis, inhalation of a foreign body, or unusual causes such as diaphragmatic hernia with ileal diverticulitis causing a lung abscess

PATHOGENESIS
Pulmonary abscesses are present in many cases of pneumonia and are not recognizable as clinically distinct entities. In the absence of pneumonia, pulmonary abscess is usually a chronic disease, with clinical signs being produced by toxemia rather than by interference with respiration. However, when the spread is hematogenous and large numbers of small abscesses develop simultaneously, respiratory function can be compromised to the extent that it becomes clinically apparent. However, in more chronic cases the abscesses can reach a size sufficient to cause respiratory difficulty by obliteration of large areas of lung tissue. In rare cases, erosion of a pulmonary vessel occurs, resulting in pulmonary hemorrhage and hemothypsis.

In many cases there is a period of chronic illness of varying degree when the necrotic focus is walled off by connective tissue. Exposure to environmental stress or other infection can result in a sudden extension from the abscess to produce a fatal suppurative bronchopneumonia, pleurisy, or empyema.

CLINICAL FINDINGS
In typical cases there is dullness, anorexia, emaciation, and a fall in milk yield in cattle. The temperature is usually moderately elevated and fluctuating. Coughing is marked. The cough is short and harsh and usually not accompanied by signs of pain. Intermittent episodes of bilateral epistaxis and hemothypsis can occur and terminate in fatal pulmonary hemorrhage following erosion of an adjacent large pulmonary vessel. Respiratory signs are variable depending on the size of the lesions, and although there is usually some increase in the rate and depth, this may be so slight as to escape notice. When the abscesses are large (2-4 cm in diameter), careful auscultation and percussion will reveal the presence of a circumscribed area of dullness over which no breath sounds are audible. Crackles are often audible at the periphery of the lesion.

Multiple small abscesses may not be detectable on physical examination, but the dyspnea is usually more pronounced. There can be a purulent nasal discharge and fetid breath, but these are unusual unless bronchopneumonia has developed from extension of the abscess. Radiographic examination can be used to detect the presence of the abscess and give some information on its size and location. Ultrasonographic examination is sensitive and specific in detecting lung abscesses in foals and is useful in adult horses and other species.

Most cases progress slowly, and many affected animals have to be euthanized because of chronic ill-health; others die of bronchopneumonia or emphysema. Persistent fever, tachycardia, and polypnea are common. A rare sequela is the development of hypertrophic pulmonary osteoarthropathy.

The clinical findings of *R. equi* pulmonary abscessation in young foals are presented under that disease.

Solitary lung abscesses are not uncommon in adult horses. Presenting signs are usually low-grade fever and depression. Most horses with lung abscesses cough. There is excessive mucopurulent material in the trachea, and examination of a tracheal aspirate reveals neutrophilic inflammation. Radiographic examination of the chest demonstrates the presence of one or more abscesses. Abscesses are in the caudal lung lobes in 60% of cases. Ultrasonography can be useful in detecting the abscess, provided
that it is confluent with the visceral pleura. The prognosis for life and for return to racing is excellent in horses that are treated appropriately.

**CLINICAL PATHOLOGY**

Examination of nasal or tracheal mucus may determine the causative bacteria, but the infection is usually mixed, and interpretation of the bacteriologic findings is difficult. Culture of tracheal aspirates yields growth of pathogenic bacteria in approximately 70% of samples from horses with lung abscesses. Hematologic examination may give an indication of the severity of the inflammatory process, but the usual leukocytosis and shift to the left might not be present when the lesion is well encapsulated. In lung abscesses in foals and adult horses, hyperfibrinogenemia and neutrophilic leukocytosis are common.

**NECROPSY FINDINGS**

An accumulation of necrotic material in a thick-walled fibrous capsule is usually present in the ventral border of a lung, surrounded by a zone of bronchopneumonia or pressure atelectasis. In sheep there is often an associated emphysema. In rare cases the abscess may be sufficiently large to virtually obliterate the lung. A well-encapsulated lesion may show evidence of recent rupture of the capsule and extension as an acute bronchopneumonia. Multiple small abscesses may be present when hematogenous spread has occurred.

**DIFFERENTIAL DIAGNOSIS**

The diagnosis might not be obvious when respiratory distress is minimal, and especially when multiple small abscesses are present. These cases present a syndrome of chronic toxemia, which may be mistaken for splenic or hepatic abscess. Differentiation between tuberculous lesions and nonspecific infections may require the use of the tuberculin test. Focal parasitic lesions, such as hydatid cysts, can cause a similar syndrome, but are not usually accompanied by toxemia or hematologic changes. Pulmonary neoplasms usually cause chronic respiratory disease, a progressive loss of weight, and lack of toxemia.

**TREATMENT**

Pulmonary abscesses secondary to pneumonia in cattle and pigs are usually not responsive to therapy. The daily administration of large doses of antimicrobials for several days can be attempted but is usually not effective, and slaughter for salvage or euthanasia is necessary. Treatment of pulmonary abscesses in adult horses by administration of broad-spectrum antimicrobials is usually effective. Most (>80%) racehorses with single abscesses return to racing.

Diagnosis and treatment of pulmonary abscess and bronchopleural fistula can be achieved by thoracoscopy or thoracotomy and partial pneumonectomy. As noted previously, almost all horses with solitary pulmonary abscesses recover with antimicrobial therapy.

**REFERENCES**

**HYDROTHORAX AND HEMOTHORAX**

The accumulation of edematous transudate or whole blood in the pleural cavities is manifested by respiratory embarrassment caused by collapse of the ventral parts of the lungs.

**ETIOLOGY**

Hydrothorax and hemothorax occur as part of a number of diseases. Hemothorax can involve rupture of vessels or leakage of blood from abnormal tissues or result from prolonged clotting times. Hydrothorax is a result of excessive accumulation of transudate secondary to altered Starling’s forces or to chylothorax.

**Hydrothorax**

- As part of a general edema resulting from congestive heart failure or hypoproteinemia
- As part of African horse sickness or bovine viral leukosis
- Chylous hydrothorax, very rarely as a result of ruptured thoracic duct
- Secondary to thoracic neoplasia
- Yellow wood (Terminalia oblongata) poisoning of sheep
- Dilated cardiac myopathy of Holstein Fresian cattle

**Hemothorax**

- Traumatic injury to thoracic wall, a particular case of which is rib fractures in newborn foals
- Hemangiosarcoma of pleura
- Lung biopsy
- Strenuous exercise (racing) by horses—intrathoracic, but extrapulmonary, hemorrhage caused death in 6 of 143 Thoroughbred racehorses that died while racing.
- Administration of phenylephrine (intravenously) to horses with left dorsal displacement (nephrosplenic entrapment) of the colon
- Prolonged blood clotting times

**PATHOGENESIS**

Accumulation of fluid in the pleural cavities causes compression atelectasis of the ventral portions of the lungs, and the degree of atelectasis governs the severity of the resulting dyspnea. Compression of the atria by fluid may cause an increase in venous pressure in the great veins, decreased cardiac return, and reduced cardiac output. Extensive hemorrhage into the pleural space can cause hemorrhagic shock.

**CLINICAL FINDINGS**

Clinical signs depend on the evolution of the disease. Acute, severe hemothorax, such as occurs with penetrating injury, during racing, or associated with administration of phenylephrine, presents as sudden death or with signs of acute, severe hemorrhagic shock. Hemorrhage of lesser severity causes increased heart and respiratory rates, pale mucous membranes, and exercise intolerance.

Hydrothorax develops more slowly, and often there is an absence of systemic signs. There can be dyspnea, which usually develops gradually, and an absence of breath sounds, accompanied by dullness on percussion over the lower parts of the chest. In thin animals, the intercostal spaces might be observed to bulge. If sufficient fluid is present, it causes compression of the atria and engorgement of the jugular veins and increased amplitude of the jugular pulse. The cardiac embarrassment is not usually sufficiently severe to cause congestive heart failure, although this disease can already be present.

The accumulation of pleural fluid or blood is evident on radiographic or ultrasonographic examination of the thorax. Large quantities of blood in the pleural cavity have a characteristic swirling, turbulent appearance.

**CLINICAL PATHOLOGY**

Thoracocentesis will yield a flow of clear serous fluid in hydrothorax, or blood in recent cases of hemothorax. The fluid is bacteriologically negative, and total nucleated cell counts are low (<5 × 10⁹/L, <5000 × 10⁹/dL). The pH, Pco₂, and lactate and glucose concentrations of pleural fluid in animals with hydrothorax are similar to those of blood.

**NECROPSY FINDINGS**

In animals that die of acute hemorrhagic shock resulting from hemothorax, the
pleural cavity is filled with blood, which usually has not clotted. Hydrothorax is not usually fatal but is a common accompaniment of other diseases, which are evidenced by their specific necropsy findings.

DIFFERENTIAL DIAGNOSIS

Hydrothorax and hemothorax can be differentiated from pleurisy by the absence of pain, toxemia, and fever and by the sterility of an aspirated fluid sample.

TREATMENT

Treatment of the primary condition is necessary. If the dyspnea is severe, aspiration of fluid from the pleural space causes a temporary improvement, but the fluid usually reaccumulates rapidly. Parenteral coagulants and blood transfusion are rational treatments in severe hemothorax.

PLEURITIS (PLEURISY)

Pleuritis refers to inflammation of the parietal and visceral pleura. Inflammation of the pleura almost always results in accumulation of fluid in the pleural space. Pleuritis is characterized by varying degrees of toxemia, painful shallow breathing, pleural friction sounds, and dull areas on acoustic percussion of the thorax because of pleural effusion. Treatment is often difficult because of the diffuse nature of the inflammation.

ETIOLOGY

Pleuritis is almost always associated with diseases of the lungs. Pneumonia can progress to pleuritis, and pleuritis can cause consolidation and infection of the lungs. Primary pleuritis is usually caused by perforation of the pleural space, such as by a penetrating thoracic injury, and subsequent infection. Most commonly this occurs as a result of trauma, but it can occur in cattle with traumatic reticuloperitonitis and in any species after perforation of the thoracic esophagus.

Secondary pleuritis refers to that which develops from infectious lung disease subsequent to the following conditions. As with pneumonia, the classic triad of host–pathogen(s)–environment is present in development of pleuritic in any species. Risk factors (see following discussion) of crowding, temperature, housing, age, and weight all contribute to increased susceptibility to the disease when the animal is exposed to one or more potential pathogens. Etiologic agents associated with pleuritis or disease syndromes involving pleuritis for specific animals are as follows.

Pigs

- Glasser’s disease
- Pleuropneumonia associated with Actinobacillus (Haemophilus) pleuropneumoniae and Haemophilus influenzae suis1,2

Cattle

- Secondary to Mannheimia haemolytica pneumonia in cattle, especially feedlot cattle, which can be related to a high percentage of fibrotic pleural lesions found in adult cattle examined at the abattoir
- Infection of calves by Pasteurella multocida type B3
- Tuberculosis
- Sporadic bovine encephalomyelitis
- Contagious bovine pleuropneumonia
- Histophilus somni infection

Sheep and Goats

- Pleuropneumonia associated with Mycoplasma spp., including Mycoplasma mycoides subsp. mycoides and Haemophilus spp.
- Caprine pleuropneumonia (Mycoplasma capricolum subsp. capripneumoniae)3
- Streptococcus dysgalactiae in ewes
- Helicobacter ovis in sheep and goats4,5

Horses

The disease in horses is discussed separately in the next section. Rare causes of pleurisy and pleural effusion in horses include lymphosarcoma and equine infectious anemia. Mesothelioma of the pleura causing persistent dyspnea, pleural effusion, and death is also recorded in the horse. Thoracic hemangiosarcoma is recorded as a cause of chylothorax in the horse.

Other Causes

Sporadic and nonspecific diseases may be accompanied by pleurisy. Examples include septicaemia as a result of Pseudomonas aeruginosa and bacteremia with localization causing a primary septic pleural effusion. In horses, the infection is usually S. equi, and the original disease is streptococcal. In goats, it is usually spread from a mycoplasmal pneumonia.

Perforation of the diaphragm occurs in traumatic reticuloperitonitis in cattle and goats. Spread into the pleural cavity can occur without actual penetration of the diaphragm because it enters via the lymphatics. Abomasalopleural fistula secondary to abomasal ulceration can cause pleuritis in cattle.

Chronic pleuritis is an important cause of loss in commercial piggeries. The prevalence can be as low as 5.6% of pigs at slaughter in specific-pathogen-free piggeries and as high as 27% in conventional piggeries. In piggeries with a high incidence of pleuritis, 45% of lungs examined at slaughter had gross lesions of the chronic disease. Examination of a larger number of animals (~4900) from 48 herds revealed a similar frequency of lesions of chronic pleuritis. Risk factors for pleuritis in pigs include the following: risk of a high pleuritic score was increased when the farrowing facilities were not disinfected (odds ratio [OR] = 2.7, 95% confidence interval [CI]:1.2-5.8, p = 0.01), when tail docking was performed later than 1.5 days after birth (OR = 2.6, 95% CI: 1.2-5.7, p = 0.01), when piglets were castrated at more than 14 days old (OR = 2.7, 95% CI: 1.1-6.8, p = 0.03), a temperature range of less than 5°C (41°F) for the ventilation control rate in the farrowing room (OR = 2.7, 95% CI: 1.2-5.9, p = 0.01), a mean temperature in the finishing room less than 23°C (73°F) (OR = 3.0, 95% CI: 1.3-6.8, p < 0.01), and large herd size (OR = 3.1, 95% CI: 1.4-6.9, p < 0.01). The factors affecting pneumonia and pleuritis seemed to be different.

Lesions consistent with pleuritic are common at time of slaughter in veal calves, with one study of calves from 174 farms in France, Belgium, and Italy reporting prevalence of 21% and another of 5825 calves reporting prevalence of 19% in 91 calves examined postmortem.6,7 Risk factors for increased likelihood of lesions included lower calf weight on arrival at the farm, greater number of calves per pen, presence of slatted or rubber flooring (compared with concrete), and season.8

PATHOGENESIS

Contact and movement between the parietal and visceral pleura causes pain as a result of stimulation of pain end organs in the pleura. Respiratory movements are restricted, and the respiration is rapid and shallow. There is production of serofibrinous inflammatory exudate, which collects in the pleural cavities and causes collapse of the ventral parts of the lungs, thus reducing vital capacity and interfering with gaseous exchange. If the accumulation is sufficiently severe, there may be pressure on the atria and a diminished return of blood to the heart. Clinical signs may be restricted to one side of the chest in all species with an imperforate mediastinum. Fluid is resorbed in animals that survive the acute disease, and adhesions develop, restricting movement of the lungs and chest wall, but interference with respiratory exchange is usually minor and disappears gradually as the adhesions stretch with continuous movement.
In all bacterial pleuritis, toxemia is common and usually severe. The toxemia may be severe when large amounts of pus accumulate.

**CLINICAL FINDINGS**
The clinical findings of pleuritis vary from mild to severe depending on the species and the nature and severity of the inflammation. In peracute to acute stages of pleuropneumonia, there are fever, toxemia, tachycardia, anorexia, depression, nasal discharge, coughing, exercise intolerance, breathing distress, and flared nostrils. The nasal discharge depends on the presence or absence of pneumonia. It may be absent or copious, and its nature may vary from mucohemorrhagic to mucopurulent. The odor of the breath can be putrid, which is usually associated with an anaerobic lesion.

**Pleural Pain**
Pleural pain (pleurodynia) is common and manifested as pawing, stiff forelimb gait, abducted elbows, and reluctance to move or lie down. In the early stages of pleuritis, breathing is rapid and shallow and, markedly abdominal, and movement of the thoracic wall is restricted. The breathing movements may appear guarded, along with a catch at end inspiration. The animal stands with its elbows abducted and is disinclined to move. The application of hand pressure on the thoracic wall and deep digital palpation of intercostal spaces usually causes pain manifested by a grunt, a spasm of the intercostal muscles, or an escape maneuver.

**Pleuritic Friction Sounds**
Pleuritic friction sounds may be audible over the thoracic wall. They have a continuous to-and-fro character, are dry and abrasive, and do not abate with coughing. They may be difficult to identify if there is a coincident pneumonia accompanied by loud breath sounds and crackles. When the pleuritis involves the pleural surface of the pericardial sac, a friction rub may be heard with each cardiac cycle and be confused with the friction sound of pericarditis. However, there is usually, in addition, a friction sound synchronous with respiratory movements, and the pericardial rub waxes and wanes with expiration and inspiration. Pleural friction rubs are audible only during the initial stages of the disease; they are not audible when fluid accumulates in the pleural space.

**Subcutaneous Edema**
Subcutaneous edema of the ventral body wall extending from the pectorals to the prepubic area is common in horses with severe pleuritis but is less noticeable in other species. Presumably this edema is attributable to blockage of lymphatics normally drained through the sternal lymph nodes.

**Pleural Effusion**
In cattle, an inflammatory pleural effusion is often limited to one side because the pleural sacs do not communicate. Bilateral pleural effusion might indicate either a bilateral pulmonary disease process or a noninflammatory abnormality such as right-sided congestive heart failure or hypoproteinemia.

**Dullness on acoustic percussion** over the fluid-filled area of the thorax is characteristic of pleuritis in which there is a significant amount of pleural effusion. The dull area has a horizontal level topline, called a fluid line, which can be demarcated by acoustic percussion. As exudation causes separation of the inflamed pleural surfaces and the pleural effusion accumulates, the pain and friction sounds diminish but do not completely disappear. On auscultation there may still be pleuritic friction sounds, but they are less evident and usually localized to small areas.

In the presence of a pleural effusion, both normal and abnormal lung sounds are diminished in intensity, depending on the amount of the effusion. Dyspnea may still be evident, particularly during inspiration, and a pleuritic ridge develops at the costal arch as a result of elevation of the ribs and the abdominal-type respiration. However, the degree of dyspnea is often subtle, and careful clinical examination and counting of the breathing rate is necessary to detect the changes in breathing.

If the pleurisy is unilateral, movement of the affected side of the thorax is restricted compared with the normal side. In cattle, the pleural effusion is commonly unilateral on the right side, but both sides may be affected. Pain is still evident on percussion on deep palpation of the intercostal spaces, and the animal still stands with its elbows abducted and is disinclined to lie down or move, but is not as apprehensive as in the early stages. Toxemia is often more severe during this stage, the temperature and the heart rate are usually above normal, and the appetite is poor. A cough will be present if there is a concurrent pneumonia, and it is painful, short and shallow. Extension of the inflammation to the pericardium may occur. Death may occur at any time and is attributable to a combination of toxemia and anoxia caused by pressure atelectasis.

**Recovery**
Animals with pleuritis characteristically recover slowly over a period of several days or even weeks. The toxemia usually resolves first, but abnormalities in the thorax remain for some time because of the presence of adhesions and variable amounts of pleural effusion in the loculi. Rupture of the adhesions during severe exertion may cause fatal hemotherax. Some impairment of respiratory function can be expected to persist, and racing animals do not usually regain complete efficiency. Chronic pleurisy, as occurs in tuberculosis in cattle and in pigs, is usually subclinical, with no acute inflammation or fluid exudation occurring.

**Medical Imaging**
Radiographic examination may reveal the presence of a fluid line and fluid displacement of the mediastinum and heart to the unaffected side and collapse of the lung. However, in cattle, pleural effusion cannot be located precisely by radiography because only laterolateral radiographs of the thorax can be taken. Ultrasonography is superior for the visualization of small volumes of pleural fluid that cannot be detected by auscultation and acoustic percussion of the thorax.

**Ultrasonography**
Ultrasonography is more reliable for the detection of pleural fluid in horses and cattle than radiography. Pleural fluid is easily detected as hypoechoic to anechoic fluid between the parietal pleural surface, diaphragm, and lung. Transudative pleural fluid appears homogeneously anechoic to hypoechoic. Exudative fluid is commonly present in horses and cattle with pleuropneumonia and often contains echogenic material. Serosanguineous or hemorrhagic fluid is also more echogenic than transudates. Fibrin appears as filmy and filamentous strands floating in the effusion with loose attachments to the pleural surfaces. Pockets of fluid localized by fibrin are commonly imaged in horses with fibrinous pleuropneumonia. Adhesions appear as echogenic attachments between the parietal and visceral pleural surfaces; the adhesions restrict independent motion of the surfaces. The presence of small, bright echoes (gas echoes) swirling in pleural or abcess fluid is associated with anaerobic infection of the pleural cavity. Gas echoes are usually most abundant in the dorsal aspects of the pleural cavity. Other lung and pleural abnormalities that may be visualized include compression atelectasis, consolidation, abscesses, and displacement of the lung as pleural effusion accumulates.

**Pleuroscopy**
Pleuroscopy using a rigid or flexible fiberoptic endoscope allows direct inspection of the pleural cavity. The endoscope is introduced into the pleural cavity in the 10th intercostal space just above the point of the shoulder. The lung will collapse, but pneumothorax is minimized by the use of a purse-string suture placed around the stab incision and blunt dissection of the fascia and muscle layers for insertion of the endoscope. The diaphragm, costosplenic angle, aorta, mediastinal structures, and thoracic wall are clearly visible. By entering the thorax at different locations, the
ventral lung, the pericardium, and more of the diaphragm can be visualized. Lung and pleural abscesses and pleural adhesions may be visible.

**Prognosis**
The prognosis depends on the severity and extent of the pleuritis and the presence of pneumonia. If the disease is in an advanced stage when first recognized and there is extensive fibrinous inflammation, the response to treatment can be protracted and extensive long-term daily care will be necessary. Also, the common failure to culture the primary causative agent, particularly in horses, makes specific therapy difficult.

**CLINICAL PATHOLOGY**

**Thoracocentesis (Pleurocentesis)**
Thoracocentesis to obtain a sample of the fluid for laboratory examination is necessary for a definitive diagnosis. The fluid is examined for its odor, color and viscosity, protein concentration, and presence of blood or tumor cells, and it is cultured for bacteria. It is important to determine whether the fluid is an exudate or a transudate. Pleural fluid from horses affected with anaerobic bacterial pleuropneumonia may be foul smelling. Examination of the pleural fluid usually reveals an increase in leukocytes up to 40,000 to 100,000/L and protein concentrations of up to 50 g/L (5.0 g/dL). The fluid should be cultured for both aerobic and anaerobic bacteria and *Mycoplasma* spp.

**Hematology**
In peracute bacterial pleuropneumonia in horses and cattle, leukopenia and neutropenia with toxic neutrophils are common. In acute pleuritis with severe toxemia, hemococoncentration, neutropenia with a left shift and toxic neutrophils are common. In subacute and chronic stages, normal to high leukocyte counts are often present. Hyperfibrinogenemia, decreased albumin–globulin ratio, and anemia are common in chronic pleuropneumonia.

**NECROPSY FINDINGS**
In early acute pleurisy, there is marked edema, thickening, and hyperemia of the pleura, with engorgement of small vessels and the presence of tags and shreds of fibrin. These can most readily be seen between the lobes of the lung. In the exudative stage, the pleural cavity contains an excessive quantity of turbid fluid containing flakes and clots of fibrin. The pleura is thickened and the central parts of the lung are collapsed and dark red in color. A concurrent pneumonia is usually present, and there may be an associated pericarditis. In the later healing stages, adhesions connect the parietal and visceral pleurae. Type I fibrinous adhesions appear to be associated with pneumonia, whereas type II fibrinous proliferative adhesions are idiopathic.

**DIFFERENTIAL DIAGNOSIS**
The diagnosis of pleuritis is confirmed by the following:

- The presence of inflammatory fluid in the pleural cavity
- Pleural friction sounds, common in the early stages of pleuritis and loud and abrasive; they sound very close to the surface, do not fluctuate with coughing common in the early stages, and may continue to be detectable throughout the effusion stage.
- The presence of dull areas and a horizontal fluid line on acoustic percussion of the lower aspects of the thorax, characteristic of pleuritis and the presence of pleural fluid.
- Thoracic pain, fever, and toxemia are common.

**Pneumonia** occurs commonly in conjunction with pleuritis, and differentiation is difficult and often unnecessary. The increased intensity of breath sounds associated with consolidation and the presence of crackles and wheezes are characteristic of pneumonia.

**Pulmonary emphysema** is characterized by loud crackles, expiratory dyspnea, hyperresonance of the thorax, and lack of toxemia unless associated with bacterial pneumonia.

**Hydrothorax and hemothorax** are not usually accompanied by fever or toxemia, and pain and pleuritic friction sounds are not present. Aspiration of fluid by needle puncture can be attempted if doubt exists. A pleural effusion consisting of a transudate may occur in cor pulmonale as a result of chronic interstitial pneumonia in cattle.

**Pulmonary congestion and edema** are manifested by increased vesicular murmur and ventral consolidation without hydrothorax or pleural inflammation.

**TREATMENT**
The principles of treatment of pleuritis are pain control, elimination of infection, and prevention of complications.

**Antimicrobial Therapy**
The primary aim of treatment is to control the infection in the pleural cavities using the systemic administration of antimicrobials, which should be selected on the basis of culture and sensitivity of pathogens from the pleural fluid. Before the antimicrobial sensitivity results are available, it is recommended that broad-spectrum antimicrobials be used. Antimicrobial therapy can be required for several weeks.

**Drainage and Lavage of Pleural Cavity**
Drainage of pleural fluid removes exudate from the pleural cavity and allows the lungs to reexpand. Criteria for drainage include the following:

- An initial poor response to treatment
- Large quantities of fluid causing respiratory distress
- Putrid pleural fluid
- Bacteria in cells of the pleural fluid

Clinical experience suggests that drainage improves the outcome.

Pleural fluid can be drained using intermittent thoracocentesis or indwelling chest tubes. Intermittent drainage is satisfactory in an animal with a small amount of fluid. Small (12-20 French) chest tubes are temporarily inserted at 2- to 3-day intervals to remove the fluid. Aspiration may not be easy in some cases because the drainage tube may become blocked with fibrin, and respiratory movements may result in laceration of the lung. Drainage may be difficult or almost impossible in cases in which adhesion of visceral and parietal pleura are extensive and fluid is loculated.

Indwelling chest tubes may be required unilaterally or bilaterally depending on the patency of mediastinal fenestration and the degree of fluid loculation. A large-bore (24–32 French) chest tube is inserted and secured to prevent it from sliding out. Unidirectional drainage through the tube is facilitated by a Heimlich valve and monitored regularly. Pleural fluid is allowed to drain or drip passively because suction often results in obstruction of the tube with fibrin or peripheral lung tissue. Loculation of fluid may interfere with proper drainage and necessitate replacement of tubes. Complications include subcutaneous cellulitis or pneumonia.

**Pleural lavage** may assist in removal of fibrin, inflammatory debris, and necrotic tissue; it can prevent loculation, dilute thick pleural fluid, and facilitate drainage (Fig. 12-11). One chest tube is placed dorsally and one ventrally using ultrasonographic guidance; 5 to 10 L of sterile, warm isotonic 0.9% NaCl solution is infused into each hemithorax by gravity flow. After infusion, the dorsal chest tube is capped, the ventral chest tube is reconnected to a unidirectional valve, and the lavage fluid is allowed to drain.

**Thoracotomy** has been used successfully for the treatment of pericarditis and pleuritis and lung abscesses in cattle. Claims are made for the use of dexamethasone at 0.1 mg/kg BW IV or IM to reduce the degree of pleural effusion. In acute cases of pleurisy in the horse, analgesics such as phenylbutazone are valuable to relieve pain and anxiety, allowing the horse to eat and drink more normally.

**Fibrinolytic Therapy**
Pleural adhesions are unavoidable and may become thick and extensive with the formation of loculation, which traps pleural fluid, all of which prevent full recovery. However, some animals will stabilize at a certain level
of chronicity, will survive for long periods, and may be useful for light work or as breeding animals. Fibrinolytic agents such as streptokinase have been used in human medicine to promote the thinning of pleural fluid, provide enzymatic debridement of the pleura, lyse adhesions, and promote drainage of loculi. As reviewed under "Equine Pleuropneumonia" in this chapter, fibrinolytic therapy using recombinant tissue plasminogen activator appears promising in reducing the amount of accumulated fibrin and in hastening recovery of horses with pleuropneumonia.10-12

Prevention of the disease is achieved by prevention of exposure to etiologic agents that cause pleuritis, through specific-pathogen-free piggeries, vaccination,7 and reduction of the effect of noninfectious risk factors.

PNEU莫THORAX

Pneumothorax refers to the presence of air (or other gas) in the pleural cavity. Entry of air into the pleural cavity in sufficient quantity causes collapse of the lung and impaired respiratory gas exchange, with consequent respiratory distress.

ETIOLOGY

Pneumothorax is defined as either spontaneous, traumatic, open, closed, or tension. Spontaneous cases occur without any identifiable inciting event. Open pneumothorax describes the situation in which gas enters the pleural space other than from a ruptured or lacerated lung, such as through an open wound in the chest wall. Closed pneumothorax refers to gas accumulation in the pleural space in the absence of an open chest wound. Tension pneumothorax occurs when a wound acts as a one-way valve, with air entering the pleural space during inspiration but being prevented from exiting during expiration by a valve-like action of the wound margins. The result is a rapid worsening of the pneumothorax. Pneumothorax can be unilateral or bilateral. The complete mediastinum of most cattle and some horses means that in many instances pneumothorax is unilateral, provided that the leakage of air into the pleural space occurs on only one side of the chest.

Rupture of the lung is a common cause of pneumothorax and can be either secondary to thoracic trauma, for example, a penetrating wound that injures the lung, or lung disease. Most cases of pneumothorax in cattle are associated with pulmonary disease, notably bronchopneumonia and interstitial pneumonia. Pleuropneumonia is the most common cause of pneumothorax in horses. Pneumothorax in these instances results from “spontaneous” rupture of weakened lung or development of bronchopleural fistulae.

Trauma to thoracic wall can lead to pneumothorax when a wound penetrates the thoracic wall, including the parietal pleura. In cattle, the thoracic wall may be punctured accidentally by farm machinery being used around cattle, as, for example, when bales of hay are being moved among animals. Penetrating wounds of the thoracic wall are common causes in horses that impale themselves on fence posts and other solid objects. A special case of perforating lung injury occurs in newborns in which the rib is fractured during birth and the lung lacerated by the sharp edges of the fractured rib.1 Bullet and arrow wounds to the chest are not uncommon causes of pneumothorax in regions in which hunting is common.

Pneumothorax also occurs during thoracotomy, thoracoscopy, lung or liver biopsy (in which there is inadvertent damage to the lung), or drainage of pleural or pericardial fluid. Pneumothorax can result from injury or surgery to the upper respiratory tract, presumably because of migration of air around the trachea into the mediastinum and subsequent leakage into the pleural space. Similarly, subcutaneous emphysema, such as commonly occurs with wounds to the axilla, leads to pneumothorax via the mediastinum.2

PATHOGENESIS

Entry of air into the pleural cavity results in collapse of the lung. There can be partial or complete collapse of the lung. Collapse of the lung results in alveolar hypventilation, hypoxemia, hypercapnia, cyanosis, dyspnea, anxiety, and hyperresonance on percussion of the affected thorax. Tension pneumothorax can also lead to a direct decrease in venous return to the heart by compression and collapse of the vena cava.

The degree of lung collapse varies with the amount of air that enters the cavity; small amounts are absorbed promptly, but large amounts compromise tidal volume, minute volume, and gas exchange and can result in asphyxiation.

CLINICAL FINDINGS

There is an acute onset of inspiratory dyspnea, which may terminate fatally within a few minutes if the pneumothorax is bilateral and severe. If the collapse occurs in only one pleural sac, the ribcage on the affected side collapses and shows decreased movement. There is a compensatory increase in movement and bulging of the chest wall on the unaffected side. On auscultation of the thorax, the breath sounds are markedly decreased in intensity and commonly absent. The mediastinum may bulge toward the unaffected side and may cause moderate displacement of the heart and the apex beat.
with accentuation of the heart sounds and the apex beat. The heart sounds on the affected side have a metallic note, and the apex beat may be absent. On percussion of the thorax on the affected side, a hyperecho-
nance is detectable over the dorsal aspects of the thorax.

Affected animals are anxious, tachypneic and in variable degrees of respiratory distress. Because many cases of pneumothorax in cattle and horses are secondary to lung disease, particularly infectious lung disease, there are usually signs of the inciting disease, including fever, toxemia, purulent nasal discharge, and cough. Pneumothorax secondary to chest wall trauma is usually readily apparent, although fractured ribs that lacerate the lung and cause pneumothorax or hemothorax can be easily missed on physical examination, especially in newborns.

Definitive diagnosis is based on demonstration of pneumothorax by radiographic or ultrasonographic examination. Radiography permits the detection of bilateral and unilateral pneumothorax and permits identification of other air leakage syndromes, including pneumomediastinum, pneumoperitoneum, and pneumopericardium. Many cattle with pneumonia and pneumothorax have radiographic evidence of emphysematous bullae. Ultrasonography is also useful in determining the extent of pneumothorax and the presence of consolidated lung and pleural fluid.

Complications of pneumothorax, other than respiratory distress and death, include septic pleuritis secondary to contamination of the pleural space, either secondary to trauma or from ruptured infected lung.

The prognosis depends on the underlying disease and its severity. Of 30 cattle with pneumothorax, mostly secondary to pneumonia, 18 survived, 8 were euthanized, and 4 died. Of 40 horses with pneumothorax, 23 survived, 12 were euthanized, and 5 died. The prognosis is better for animals with traumatic pneumothorax or that secondary to surgery than for animals with pneumothorax attributable to pneumonia.

**CLINICAL PATHOLOGY**

Hematologic and serum biochemical values are indicative of the underlying or concurrent disease—pneumothorax causes no specific changes in these variables. Arterial blood gas analysis reveals hypoxemia and hypercapnia.

**NECROPSY FINDINGS**

The lung in the affected sac is collapsed. In cases where spontaneous rupture occurs, there is discontinuity of the pleura, usually over an emphysematous bulla. Hemothorax might also be evident.

**DIFFERENTIAL DIAGNOSIS**

The clinical findings are usually diagnostic. Diaphragmatic hernia may cause similar clinical signs but is relatively rare in farm animals. In cattle, herniation is usually associated with traumatic reticulitis and is not usually manifested by respiratory distress. Large hernias with entry of liver, stomach, and intestines cause respiratory embarrassment, a tympanic note on percussion, and audible peristaltic sounds on auscultation.

**TREATMENT**

The treatment depends on the cause of the pneumothorax and the severity of the respiratory distress and hypoxemia. Animals should receive treatment for the underlying disease. Animals with closed pneumothorax that are not in respiratory distress or hypoxic do not require specific treatment for the pneumothorax, although the animal should be confined and prevented from exercising until the signs of pneumothorax have resolved. An open pneumothorax, as a result of a thoracic wound, should be surgically closed.

Emergency decompression of the pleural cavity using a needle into the pleural cavity, connected to a tubing and submersed into a flask of saline or water, creates a water-seal drainage. Thoracostomy tubes attached to Heimlich thoracic drainage valves are effective in preventing aspiration of air. Continuous suction, using thoracostomy (e.g., 24 French, 40-cm [16-in.] Argyle trocar thoracic catheter) and a standard three-bottle water seal drainage system or commercial equivalent is preferable if there are large continuing air leaks that may be life-threatening. Reinflation of the lung should be gradual because rapid removal of air can result in pulmonary edema. Inflation of the lung can be monitored by repeated ultrasonic examination. The animal should be kept as quiet as possible and permitted no exercise. Horses with wounds to the axilla should be restrained until the wound has closed because this prevents the aspiration of air into the wound. Prophylactic antimicrobial treatment is advisable to avoid the development of septic pleuritis.

Care should be exercised in performing biopsy of the liver or lung, and the former should be done with ultrasound guidance to prevent inadvertent lung damage.

**REFERENCES**

**DIAPHRAGMATIC HERNIA**

Diaphragmatic hernia is uncommon in farm animals, in which it can be acquired, usually as a result of trauma, or congenital. Of a series of 44 horses and foals examined because of diaphragmatic hernia, 5 cases were determined to be congenital and 39 acquired.

Congenital diaphragmatic hernias are reported in most large animal species, although details of frequency or risk factors are not available. Congenital hernia results from failure of complete formation of the diaphragm during embryogenesis during a process involving the septum transversum, dorsal embryonic mesentery, pleuropertitoneal folds, and body wall mesenchyme. Congenital hernias develop as a result of defects in the diaphragmatic musculature when the septum transversum and pleuropertitoneal folds do not fuse completely or in the dorsal tendinous portion of the diaphragm. Such hernias are characterized by a hernia sac composed of peritoneal and pleural membranes that occurs to one side or the other of midline (usually the right side in horses) in the right ventral (retrosternal hernia) or left dorsal crus. The borders of congenital hernias are usually smooth, fibrous, and thickened and have a characteristic histologic appearance. In some cases, the pericardial sac is incomplete and the diaphragm is rudimentary and in the form of a small fold projecting from the chest wall. Affected animals usually survive for a few hours to several weeks, although many can survive for years with the hernia being clinically inapparent. In pigs, a number of animals in each litter can be affected.

Acquired hernias are usually associated with trauma, such as falls, collisions with motor vehicles, foaling (for both mares and foals), or strenuous exercise. It occurs in cattle, especially in association with traumatic reticuloperitonitis, in which case the hernia is small and causes no respiratory distress, and there may be no abnormal sounds in the thorax.

**CLINICAL FINDINGS**

Clinical findings in cattle include chronic or recurrent ruminal tympany caused by herniation of reticulum preventing its normal function in eructation. Muffled heart sounds can be detectable on both sides of the thorax.

Clinical signs of diaphragmatic hernia in adult horses are usually referable to herniation of reticulum preventing its normal function in eructation. Muffled heart sounds can be detectable on both sides of the thorax.

Clinical signs of diaphragmatic hernia in adult horses are usually referable to herniation of the gastrointestinal tract. Signs of respiratory compromise are not common. There is sometimes a history of trauma or recent parturition, but this is not invariable, and many cases in adult horses occur without such an event being noticed in the recent past. Clinical signs on examination are those typical of colic of varying severity from nonstrangulation incarceration to acute, strangulating incarceration with severe septic shock and collapse. Rectal examination does not reveal evidence specific for diaphragmatic hernia, with the rare exception of a sense that the
abdomen is not as full as one would expect. Thoracic auscultation can reveal the presence of borborygmi in the chest fields, but this should be interpreted with caution because such findings can occur in horses with an intact diaphragm. Examination of peritoneal fluid usually does not reveal abnormalities. Radiographic or ultrasonographic examination can provide a definitive diagnosis (Fig. 12-12).

The hernia is usually left dorsal (approximately 2/3 of cases) and right ventral (approximately 1/3 of cases) in horses. Congenital retrosternal hernia (Morgagni hernia) is almost exclusively right ventral in horses. The presence of intestinal sounds in the thorax can be misleading; they are often present in the normal animal, but their presence, accompanied by dyspnea and resonance on percussion, should arouse suspicion. Radiography, ultrasonography, thorascopy, and exploratory laparotomy are the most useful diagnostic procedures. Radiography reveals the presence of gas- and fluid-filled intestinal contents in the thorax, apparent in cattle as oval rounded masses over the heart. Ultrasonography demonstrates presence of bowel in the thorax. There can be excessive pleural fluid.

The definitive treatment of acquired or traumatic hernia is surgical replacement of viscera in the abdomen and repair of the defect in the diaphragm. Repair of a diaphragmatic hernia through a standing thoracotomy in a cow has been described. Surgical repair has been performed in calves and foals, and in adult horses.

The prognosis is poor to guarded, with short-term survival of affected foals and horses being 7/44 and 8/31. Factors related to survival include the presence and extent of incarcerated intestine, size of the rent (smaller associated with increased chance of survival), and location of the rent. Location of the rent is likely related to survival because small, ventrally located rents are more amenable to surgical correction.

Diseases of the Bovine Respiratory Tract

ENZOOTIC NASAL GRANULOMA OF CATTLE (BOVINE ATOPIC RHINITIS)

Of the three known clinical types of chronic nasal obstruction in cattle, two have been identified etiologically and have clinical or epidemiologic features that distinguish them from enzootic nasal granuloma. One is recorded predominantly in beef cattle and appears to be caused by a fungus, most commonly *Rhinosporidium spp.*, *Drechslera spp.*, *Nocardia spp.*, or *Pseudallescheria boydii*. Another is caused by the parasite *Schistosoma nasalis*. The third type, *enzootic nasal granuloma* (ENG), occurs commonly in southern Australia, less commonly in New Zealand, and is recorded as a sporadic disease in South America and an occasional disease in North America, Britain, and Europe. It is reported as a herd outbreak in Jersey cows in the United Kingdom. Enzootic nasal granuloma occurs sporadically in some herds but may reach an incidence of 30%. In one area, as much as 75% of herds may have the disease. Animals aged between 6 months and 4 years are most commonly affected, and the chronic disease may or may not be preceded by an attack of acute rhinitis. Most cases commence in the summer and autumn months. It is apparent that nasal granuloma develops as a continuous and progressive response to acute episodes of hypersensitivity to an allergen present in the summer months. This accords with the gradual development of the stertorous respiration and the observations, in biopsies of nasal mucosa, of the presence of mast cells in all seasons, but the regression of eosinophils in the winter months.

An extensive survey of Australian dairy-raising areas showed that 22% of cattle had lesions, and that the prevalence was greater in areas where the average annual rainfall was over 70 cm than where it was less than 70 cm; the prevalence varied between 4% and 48%; Jerseys were more commonly affected than Friesians. In New Zealand, 40% of farms and 36% of culled cattle were affected, whereas only 3.6% of young beef cattle showed lesions.

The disease has been identified as an allergic rhinitis and has been produced experimentally. Specific antigens have not been identified as the cause, but cows with nasal granuloma are much more sensitive to a number of common allergens in the environment than are unaffected cows. Additional possible causes include infestation of the nasal cavities with pasture mites (*Tyrophagus palmarum*). An allied condition has been described in the United States as maduromycosis, but there are nasal granulomas plus multiple granulomatous lesions of the skin of the ears, tail, vulva, and thigh. The granulomas contain many eosinophils and fungal elements identified provisionally as *Helminthosporium sp.*

In enzootic nasal granuloma, acute cases are characterized by a sudden onset of bilateral ocular and nasal discharge and swelling of the nasal mucosa causing difficult, noisy breathing. Affected animals shake their heads and snort and rub their noses in hedges. As a result, they commonly block their nostrils with twigs. This form of the disease is commonest in cattle of the Channel...
Island breeds and their crossbreeds. The nasal discharge in these breeds is usually yellow to orange in color.

Established cases of enzootic nasal granuloma have lesions, consisting of granulomatous nodules 1 to 4 mm in diameter and height, in both nostrils. The lesions extend from just inside the nostril posteriorly for 5 to 8 cm. They may be few in number or be packed closely together. Their texture is firm, and the mucosa over them is normal. They have a characteristic histopathology of epithelial metaplasia and hyperplasia, and contain large numbers of eosinophils and mast cells.

The predominant clinical sign is respiratory stertor and dyspnea caused by obstruction to the airflow. The severity of these signs may fluctuate, but in general they progress slowly over several months and then remain static. Although the respiratory distress may be sufficiently severe to cause a loss of condition and marked reduction in milk yield, affected animals do not die. A good proportion of them have to be culled as uneconomic units.

The clinical picture in mycotic nasal granuloma is superficially similar with respect to noisy breathing, respiratory distress, and nasal discharge, but there is no seasonal association. Also, the visible and palpable lesions in the anterior part of the nasal cavities are polyps up to 5 cm in diameter that occur singly or in confluent masses. Their cut surfaces are yellow to green, and they are sometimes ulcerated. Histologically, the lesions are eosinophilic granulomas containing fungal spores and sometimes hyphae. Fungi (Drechslera rostrata) have been isolated from the lesions.

TRACHEAL STENOSIS OF FEEDLOT CATTLE

Tracheal stenosis, also known as “honker cattle,” occurs in feedlot cattle. The etiology is unknown. It is characterized by extensive edema and hemorrhage of the dorsal wall of the trachea, resulting in coughing (honking), dyspnea, and respiratory stertor. Complete occlusion of the trachea may occur. Affected animals may be found dead without any premortem signs.

In tracheal stenosis of feedlot cattle, there is marked submucosal hemorrhage dorsal and ventral to the trachealis muscle, resulting in ventral displacement of the mucosa and partial to complete occlusion of the tracheal lumen. Diffuse hemorrhage in the peritracheal connective tissue and surrounding muscles of the neck is common in animals dying of asphyxia. Histologically, there is hyperemia and hyperplastic tracheal mucosa with focal erosions, squamous metaplasia, and loss of cilia. In acute cases, the mucosa is markedly thickened because of hemorrhage and edema. Culture reveals a mixed bacterial flora.

CAUDAL VENA CAVAL THROMBOSIS (POSTERIOR VENA CAVAL THROMBOSIS) AND EMBOLIC PNEUMONIA IN CATTLE

Embolic pneumonia as a sequel to thrombosis of the posterior vena cava is a relatively common disease of cattle in Europe and the United Kingdom. The disease is rare in cattle less than 1 year old, although it can occur at any age. Most affected animals are in feedlots on heavy-grain diets, and there are peaks of incidence at those times of the year when most cattle are on such diets. There is a relationship between the occurrence of this disease and that of hepatic abscessation arising from lactic-acid-induced rumenitis on heavy-grain diets. The disease is reported with deep digital sepsis in cattle. A similar syndrome occurs in horses, although rarely.

The etiology and pathogenesis of the disease are based on the development of a thrombus in the posterior vena cava and the subsequent shedding of emboli that lodge in the pulmonary artery, causing embolism, endarteritis, multiple pulmonary abscesses, and chronic suppurrative pneumonia. Pulmonary hypertension develops in the pulmonary artery, leading to the development of aneurysms, which can rupture causing massive intrapulmonary or intrabronchial hemorrhage. In most cases the thrombus in the vena cava originate from hepatic abscesses or postdiaphragmatic abscesses. Usually there is an initial phlebitis and the subsequent thrombus extends into the thoracic part of the vessel. When the thrombus occludes the openings of the hepatic veins into the vena cava, there is congestion of the liver and hepatomegaly, ascites, and abdominal distension in some of these cases.

The most common form of the disease is characterized by manifestations of respiratory tract disease. Commonly there is a history of the disease for a few weeks or longer, but some animals are “found dead” without prior recorded illness. Affected animals usually have thin to moderate body condition, reduced appetite, reduced rumen motility, and a positive reticular pain response. There is usually fever and an increase in the rate and depth of respiration, coughing, epistaxis and hemoptysis, anemia with pallor, a hemic murmur, and a low packed cell volume. Respirations are painful and a mild expiratory grunt or groan may be audible with each respiration. Subcutaneous emphysema and frothing at the mouth are evident in some. Deep palpation in the intercostal spaces and over the xiphoid sternum might elicit a painful grunt. The lung sounds can be normal in the early stages, but with the development of pulmonary arterial lesions, embolic pneumonia, and collapse of affected lung, widespread abnormal lung sounds are audible on auscultation. There can be ascites. In one series of cases, the presence of anemia, hemoptysis, epistaxis, and widespread abnormal lungs sounds were characteristic features of the disease. There are accompanying nonspecific signs of inappetence, ruminal stasis, and scant feces.

About one-third of affected cattle become progressively worse over a period of 2 to 18 days with moderate to severe dyspnea, and they die of acute or chronic anemia or are euthanized on humane grounds. Almost half of the cases die suddenly as a result of voluminous intrabronchial hemorrhage. It is probably the only common cause in cattle of acute hemorrhage from the respiratory tract that causes the animal to literally drop dead. The remainder have a brief, acute illness of about 24 hours.

Some evidence of hepatic involvement is often present, including enlargement of the liver, ascites, and melena. Chronic cor pulmonale develops in some with attendant signs of congestive heart failure.

Radiography of the thorax of some affected animals has found an increase in lung density and markings. These are irregular, focal or diffuse, and nonspecific. More distinct opacities are present in some and are referable to embolic infarcts and larger pulmonary hemorrhages. Radiographic abnormalities in the lungs are detected in approximately one-third of cows with caudal vena cava thrombosis. Ultrasonography can be a useful diagnostic aid in detecting changes in the caudal vena cava. The caudal vena cava in affected cows is round to oval rather than the triangular shape in normal cattle, and the hepatic, splenic, and portal veins can be dilated. The presence of thrombi in the caudal vena cava can be detected (Fig. 12-13). There is typically anemia and leukocytosis. Neutrophilia with a regenerative left shift and hypergammaglobulinemia as a result of chronic infection are common. Serum gamma-glutamyl transpeptidase activity is high in about one-third of cases.

**DEFINITION OF THE PROBLEM**

A major problem that large-animal clinicians commonly encounter is a group of cattle that are affected with an acute respiratory disease of uncertain diagnosis.

Acute undifferentiated bovine respiratory disease (BRD) is characterized clinically by dyspnea, coughing, nasal discharge, varying degrees of depression, anorexia, pyrexia ranging from 40 to 41°C (104-105.8°F), evidence of pneumonia on auscultation of the lungs, and a variable response to treatment. Some unexpected deaths may have occurred as the initial indication of the problem. Although in most cases pneumonia is the obvious cause of the disease, determining the etiology is the major diagnostic problem. If lesions typical of any of the common diseases of the respiratory tract of cattle can be recognized clinically, like those of infectious bovine rhinotracheitis (IBR), then on a clinical basis a specific diagnosis can be made.

The affected group may be unweaned dairy heifers, weaned beef calves, or yearlings that have recently arrived in a feedlot; cattle that have been in the feedlot for varying periods of time; young growing cattle on summer pasture; mature cows that have recently been placed on a lush pasture; yearling or mature lactating dairy cattle; or a group of veal calves. The morbidity rate can range from 10% to 50% depending on the age of animals affected, the immune status of the animals, the nature of the stressors involved, and the nature of the disease.

Respiratory disease is the most common illness among cattle in feedlots, affecting on average over 16% of cattle placed. In general, bovine respiratory disease accounts for 65% to 79% of the morbidity and 44% to 72% of mortality in feedlot cattle. Despite of intensive research in the field the incidence of respiratory disease in cattle during the first year of life could not be controlled. The proportion of mortality of weaned dairy heifers attributable to respiratory disease increased from 34.8% of all deaths in 1991 to 46.5% in 2007.

The economic impact of respiratory disease on the U.S. beef industry is estimated to exceed $4 billion annually, including treatment cost, disease prevention, and production loss such as decreased growth performance. Cattle with detectable lung lesions at slaughter on average had a reduced daily weight gain of 0.08 kg/d compared with cattle without lung lesions. Protracted effects of respiratory disease in dairy calves on milk production and fertility in later life are more difficult to estimate, but repeated incidences of respiratory disease in a dairy heifer were found to almost double the risk for not completing the first lactation.

The primary goal of the clinician must be to make the most accurate clinical diagnosis as rapidly as possible, based on the clinical and epidemiologic findings that are identifiable on the farm, preferably when examining the animals on the first visit. Giving a prognosis and the formulation of rational and economic treatment that will minimize morbidity and mortality are the next goals. In any group situation, mass medication of each in-contact animal is a major consideration that will increase costs and must be balanced against the economic losses that might occur if all animals are not treated metaphylactically. The clinical management of the outbreak, which includes treatment of the obvious cases and the prevention of new cases if possible, is dependent in part on the diagnosis. However, differentiation between the diseases based on clinical findings can be unreliable, and it is usually necessary to begin antimicrobial therapy that will be effective against the bacterial pathogens most likely to be present. Even after intensive clinical and...
The respiratory tract of cattle can be broadly divided into those affecting the lower respiratory tract and those affecting the upper respiratory tract. Diseases of the lungs associated with either viruses or bacteria alone or in combination are difficult to distinguish from each other on the basis of clinical findings alone. The presence of toxemia, which causes depression and anorexia in bacterial pneumonias, is a useful guide in categorizing the common diseases when making a differential diagnosis list. Cattle affected with uncomplicated viral diseases of the respiratory tract may show a high fever but are usually not depressed and anorexic because bacterial toxemia is absent.

**Etiology**

The major etiologic agents that cause or may be associated with acute UBRD include the following:

Diseases

Chapter 12  □  Diseases of the Respiratory System

Viruses
  • Bovine herpesvirus-1 (BHV-1) causing infectious bovine rhinotracheitis (IBR)
  • Bovine respiratory syncytial virus (BRSV)
  • Parainfluenza-3 virus (PI-3V)
  • Bovine virus diarrhea virus (BVDV)
  • Bovine coronavirus (BoCV)
  • Bovine adenovirus (BAV)

Bacteria
  • Mannheimia haemolytica
  • Pasteurella multocida
  • Histophilus somni (formerly Haemophilus somnus)
  • Mycoplasma bovis
  • Mycoplasma mycoides causing contagious bovine pleuropneumonia (CBPP)
  • Mycoplasma bovirhinis
  • Mycoplasma dispar
  • Ureaplasma diversum

Uncertain or unknown etiology
  • Atypical interstitial pneumonia

Verminous
  • Dictyocaulus viviparus

Role of Etiologic Agents

The role of the etiologic agents in the cause of BRD is controversial and often uncertain because the major pathogens are ubiquitous in clinically normal animals. The disease is considered to be the result of the effects of stressors causing immunosuppression, which allow colonization of the respiratory tract by opportunistic pathogens. The spectrum of the immune status of the animals is also a major factor. Animals vaccinated well before natural infection may be resistant to clinical disease caused by specific pathogens. Animals that underwent natural infection and developed adequate humoral or cell-mediated immunity may also be immune to clinical disease.

Clearly the viral–bacterial synergism is a major factor in the pathophysiology of the BRD complex. It is well recognized that the effect of a virus that usually is nonfatal combined with various bacteria commonly resident in the upper respiratory tract of healthy individuals can cause fatal bacterial pneumonia. Numerous experimental models of synergism between virus and bacteria have been studied. In cattle, the viruses having received the most attention in this context are PI-3 and BHV-1, which in combination with bacteria such as M. haemolytica or P. multocida can cause clinical disease considerably more severe than experimental infection caused by either viral or bacterial infection alone. Many mechanisms have been suggested behind this viral–bacterial synergism, including impaired neutrophil function or recruitment following initial viral infection, decreased macrophage activity, or altered number and responsiveness of lymphocytes. Most likely several mechanisms are involved in the virus induced suppression of pulmonary antibacterial defense.

Many epidemiologic studies of bovine respiratory disease have attempted to correlate the level of serum antibodies in feedlot calves on arrival at the feedlot and over the first 30 to 50 days of the feeding period with morbidity and mortality as a result of respiratory disease. A low level of antibody to a specific pathogen on arrival followed by significant seroconversion in animals that develop BRD in the first few weeks of the feeding period suggest that the pathogen was an important etiologic factor. Conversely, those animals with a high level of antibody on arrival that do not develop BRD are considered immune. However, some animals with low levels of antibody may remain normal and seroconvert during the early part of the feeding period.

Feedlot cattle commonly seroconvert to the BHV-1, PI-3V, BVDV, and BRSV, and possibly also to Mycoplasma bovis and other Mycoplasma spp., within the first month after arrival. Seroconversion to these pathogens occurs both in animals that develop respiratory disease and those that remain normal within the same group, but the relative importance of each agent and their causative nature is controversial. Seroconversion to M. haemolytica leukotoxin, BRSV, and BVDV were predictive of approximately 70% of all respiratory disease cases in Ontario feedlots. Calves arriving with high serum antibody levels to Histophilus somni had less bovine respiratory disease than calves with lower levels.

Many respiratory pathogens that can cause disease are present in diseased and clinically normal individuals alike during outbreaks of BRD. It has been suggested that UBRD in weaned beef calves is not a highly contagious disease and that although respiratory pathogens may be important etiologic factors, the presence of other contributing factors is as important for the development of clinical disease. Stress resulting from weaning, transportation, processing, crowding, or harsh weather is considered to be an important contributor to outbreaks of BRD. Studies exploring the effect of stress resulting from weaning and maternal separation showed that the viral–bacterial synergism was altered when weaning occurred at the time of a primary viral infection with BHV-1 followed by a secondary bacterial infection with M. haemolytica resulting in significantly increased mortality rates. Similarly calves weaned immediately before transport to a feedlot developed significantly more UBRD compared with calves adapted to weaning for 45 days. This suggests that identifying and avoiding environmental and management risk factors are crucial to control BRD outbreaks.

The relationships between bacterial and viral antibody titers and undifferentiated fever and mortality in recently weaned beef calves in western Canada were examined. Feedlot calves are commonly exposed to M. haemolytica, H. somni, BHV-1, BVDV, and M. bovis in the early feeding period. Seroconversion to M. haemolytica leukotoxin was associated with a decreased risk of undifferentiated fever. Higher arrival BVDV antibody titer was associated with a decreased risk of undifferentiated fever. Higher arrival H. somni antibody titer and increases in H. somni antibody titer after arrival were both associated with a decreased risk of undifferentiated fever. The odds of overall mortality (OR 5.09) and histophilosis mortality (OR 11.31) in clinical cases were higher than in the controls. In summary, protective immunity to M. haemolytica leukotoxin H. somni, BHV-1, BVDV, and Mycoplasma spp. may be necessary to reduce the occurrence of undifferentiated fever.

Chronic, antibiotic-resistant pneumonia, sometimes with polyarthritis, occurs in feedlot cattle. M. bovis, BVDV, and H. somni are commonly found in the tissues at necropsy. This coinfection suggests the possibility of synergism between the BVDV and M. bovis in the pneumonia with the arthritis syndrome.

BVDV has been identified as a contributor to respiratory disease in feedlot calves. On arrival in feedlots, 39% of animals were seropositive for BVDV, and those animals treated for UBRD had larger titer increases to the virus than nontreated animals. BVDV-1b strains have been associated with acute pneumonia in commingled calves that were not vaccinated with BVDV vaccines, and in which M. haemolytica and P. multocida were also present in the pneumonic lesions. Experimental infection of seronegative and immunocompetent calves with BVDV type resulted in primary respiratory disease.

Bovine coronavirus (BoCV) has been implicated as a cause of UBRD based largely on the isolation of the virus from the nasal cavities of cattle with respiratory disease. However, based on seroepidemiology of BoCV titers in feedlot cattle, although higher antibody titers to the virus were associated with a decreased subsequent risk of treatment for UBRD, there was no association between evidence of recent infection (titer increase) and the occurrence of UBRD. Other studies have shown that BoCV infections are not associated with an increased risk of treatment for UBRD. BoCV is widespread in the cattle and can be found in the feces and nasal swabs of recently arrived feedlot cattle and calves with and without clinical signs of BRD. Exposure to BoCV before arrival in the feedlot is common, with 90% of animals being seropositive on arrival. BoCV can be isolated from feedlot cattle in many different locations and most cattle seroconvert to the virus during the first 28
days after arrival in the feedlot. Cattle shedding the virus from the nasal cavity and developing an antibody response to the virus were 1.6 times more likely to require treatment for respiratory disease than cattle that did not shed the virus or develop an immune response. Cattle that shed the virus from the nasal cavity were 2.2 times more likely to have pulmonary lesions at slaughter than cattle that did not shed the virus. In natural outbreaks of shipping fever, more than 80% of affected cattle shed BoCV at the beginning of the epidemic when the *M. haemolytica* infection rate was low.

The role of BoCV in epidemics of shipping fever pneumonia in cattle was examined by the collection of nasal swabs and serum samples before the onset of the epidemic, during the course of the illness, and after death when necropsies were done and samples of lung tissues were examined. Respiratory BoCV was isolated from the nasal secretions before and after transport, from lung tissues of those cattle that died early in the epidemic but not later. *Pasteurella* spp. were isolated from all cattle that had severe pneumonia. All cattle were immunologically naive to both infectious agents at the onset of the epidemic, but those that died after day 7 had rising antibody titers to BoCV and *M. haemolytica*. In contrast, the 18 clinically normal and BoCV-negative cattle had high antibody titers to BoCV from the beginning, and their antibody responses to *M. haemolytica* were delayed.

**Clinical Case Definition and Epidemiology**

**Clinical Case Definition**
The most important part of the clinical and epidemiologic examination is to determine the case definition, which includes the following questions.

**What Is the Clinical Disease That Is Present in the Affected Animals?**

- Which body system is affected and where in that body system is the lesion?
- Do the animals have pneumonia, rhinitis, laryngitis, tracheitis, bronchitis or combinations of these abnormalities?

The clinician should attempt to make a clinical diagnosis by closely examining several typically affected animals and determine whether the lesions are in the lower or upper respiratory tract. The presence of toxemia, depression, fever, anorexia, and agalactia in lactating dairy cattle indicates a primary or secondary bacterial infection. The presence of loud breath sounds (consolidation) and abnormal lung sounds (crackles and wheezes) indicates the presence of pneumonia. Diseases of the upper respiratory tract are characterized by inspiratory dyspnea, stridor, loud coughing, sneezing, wheezing, and lesions of the nasal mucosa.

**Which Animals Are Affected?**

Determining which animals are affected includes age of animals affected, a single animal or group of animals, and vaccination history. Recently arrived feedlot cattle mixed from many different origins are susceptible to fibrinous pneumonia associated with *M. haemolytica*.

**Where Are the Affected Animals?**

Are the infected animals in the feedlot, on pasture, or housed in a barn? If in a barn, with what quality of ventilation?

**When Were the Animals Affected?**

- How soon after arrival in the feedlot did the animals become affected?
- What stressors may have recently preceded the outbreak?
- What risk factors could have predisposed to this outbreak?
- Have the animals been recently shipped and mixed with animals from another source?

Consideration of the clinical and epidemiologic findings can then be correlated, and hypotheses formulated and tested to determine why the disease occurred.

**Occurrence**

Bovine respiratory disease occurs under many different situations, including all age groups, feedlot animals kept outdoors, housed dairy calves, nursing and recently weaned beef calves, dairy and beef cattle heifers, and adult lactating dairy cows. Epidemics of acute respiratory disease have been described in dairy calves from birth to 6 months of age. Outbreaks of BRSV can occur in dairy cattle heifers and adult dairy cattle.

Pneumonic pasteurellosis is most common in recently arrived feedlot calves (shipping fever) and unweaned dairy calves (enzootic calf pneumonia). In calves 3 to 5 weeks after arrival in the feedlot, *H. somni* pleuropneumonia may be more likely. Atypical interstitial pneumonia (pasteurella-induced) is the most likely diagnosis when confronted with an outbreak of acute respiratory disease in mature cattle that have been moved from a summer pasture to a lush autumn pasture within the last 4 to 10 days.

**Risk Factors**

The risk factors that have been identified in outbreaks of respiratory disease in feedlot cattle include the purchase of cattle from auction markets and mixing of cattle from many different sources. An epidemiologic study of fatal fibrinous pneumonia in auction-market-derived feedlot calves in western Canada revealed that peak mortality occurred approximately 16 days after arrival at the feedlot. The risk of fatal fibrinous pneumonia was consistently greater for calves entering the feedlot in November, shortly after the auction sales had peaked, when the feedlot was reaching capacity. Increased mixing at the auction markets was associated with increased fatal disease risk.

The distance calves were transported by truck was not associated with fatal disease risk. When the incidence of fatal fibrinous pneumonia was high, the disease clustered within truckloads or pens. Risk factors positively associated with disease clustering included increased mixing of calves from different farms, month of purchase, number of calves passing through the auction markets, and weather conditions at arrival.

Transportation of feedlot calves increases serum concentration of oxidative stress biomarkers, which are related to episodes of bovine respiratory disease. Transportation stress significantly decreases serum total antioxidant capacity and increases malondialdehyde concentrations in steer calves. It is proposed that stressors such as marketing through an auction barn and transportation precipitate oxidative stress, which reduces the antioxidant defense capacity and increases total body lipid peroxidation, resulting in increased susceptibility to BRD. These biomarkers may be useful to measure the oxidative stress of transported cattle. There is some experimental evidence that acidogenic diets and ketoacidosis may affect lymphocyte function, which may affect vaccine efficacy.

The literature on the risk factors for bovine respiratory disease in dairy heifers and the effect of the disease on productivity has been reviewed with relevance to commercial dairy farming in the Netherlands. Bovine respiratory disease in dairy heifers increases the risk of mortality directly after the disease episode by up to 6 times, reduces growth during the first 6 months of life by up to 10 kg, and increases the likelihood of dystocia after first calving. Both herd size and other diseases in dairy heifers are clearly associated with the risk of bovine respiratory disease. Season and colostrum feeding are important. The most important risk factors for mild and severe pneumonia in dairy calves aged birth to 3 months were inadequate air circulation and the purchase of cattle.

**Diagnosis and Differential Diagnosis**

**Individual Animal Diagnosis**

Although the clinical diagnosis of BRD can readily be made even by cursory examination in severe or advanced cases, the challenge is to identify newly affected animals in early stages of the disease, which is a critical factor for treatment efficacy. In general,
medical treatment is more effective the earlier in the process it can be initiated, and delaying treatment is considered a major factor contributing to treatment failures. A Bayesian estimation of the performance of using clinical observation for diagnosis of BRD yielded an estimated sensitivity and specificity of 0.62 and 0.63 respectively, suggesting that up to 37% of animals diagnosed and subsequently treated for BRD are unaffected by respiratory disease. Another study reported that 68% of feedlot cattle with lung lesions at slaughter were never treated for bovine respiratory disease, further suggesting that current methods of diagnosing bovine respiratory disease based on visual appraisal by feedlot pen riders may not always effectively identify sick animals. The limitations of identifying clinically affected animals that need therapy were a major factor in the development of metaphylactic use of antimicrobials.

The subjective clinical findings of distant examination that have been used by animal attendants in commercial feedlots to identify sick animals that need to be closely examined include:

- **Degree of ruminal fill**: (1, normal; 2, slightly gaunt; 3, moderately gaunt; 4, excessively gaunt)
- **Attitude**: (1, normal; 2, slight lethargy; 3, severe lethargy; 4, nonambulatory)
- **Ocular discharge**: (1, none; 2, slight; 3, moderate; 4, abundant)
- **Nasal discharge**: (1, none; 2, slight; 3, moderate; 4, abundant)
- **The sounds heard on auscultation of the lungs at three sites along a line extending from the cranioventral to caudodorsal lung fields**: (1, normal; 2, slightly harsh; 3, moderately harsh; 4, severely harsh)

Frequently the rectal temperature of animals that appear dull is measured; if temperature is found to be above a predetermined level, they are considered to have BRD if no other clinical findings are detectable that are referable to other organ systems. In most cases, the thorax of these animals is not auscultated for evidence of pneumonia. Although a fever when combined with other clinical signs is a valuable parameter in the process of making a diagnosis, fever of unidentified origin can as well be unassociated with respiratory disease and does not imperatively require treatment. In a feedlot pen of 112 recently arrived bull calves that were fitted with reticuloruminal temperature-sensing boluses, a total of 449 fever episodes were recorded in 110 animals during the first 40 days after arrival. Of these fever episodes, 74% were not associated with any visually apparent clinical signs or respiratory disease, and 75% lasted for less than 48 hours. A negative effect on average daily weight gain of feverish animals with or without clinical signs was recorded with prolonged episodes of fever, with an approximate decrease of 33 g/day for each day of fever. Because of the difficulty in identifying cattle with early stage respiratory disease in large feedlots, several advanced monitoring techniques have been developed and studied for their suitability to help make a rapid and accurate diagnosis in the field situation. The feeding and watering behavior of healthy and sick animals in a commercial feedlot has been examined using radiofrequency technology to record individual animal behaviors. Eating and drinking behaviors are associated with clinical signs of bovine respiratory disease, but there is no obvious predictive association between signs of bovine respiratory disease in recently arrived weaned beef calves and eating and drinking behavior. Calves that were sick had greater frequency and duration of drinking 4 to 5 days after arrival than calves that were not sick. Sick calves had significantly lower frequency and duration of eating and drinking 11 to 27 days after arrival but had greater frequency of eating 28 to 57 days after arrival than calves that were not sick. Calves at slaughter that had a higher percentage of lung tissue with lesions had lower frequency and duration of eating 11 to 27 days after arrival but had greater frequency and duration of eating 28 to 57 days after arrival. Experimentally, the electronic acquisition of feeding behavior data for feedlot cattle, when analyzed using cumulative sums (CUSUM) procedures, offers the potential for predicting morbidity before conventional visual methods of appraisal. The feeding behavior during the first 30 days when cattle are in a receiving pen may be used to detect animal morbidity approximately 4 days earlier than conventional methods typically employed in commercial feedlots. Overall accuracy, positive predictive value and sensitivity of the CUSUM prediction method were 87%, 91%, and 90%, respectively.

Infrared thermography used to monitor infrared heat loss in calves has been studied as a tool for early detection of animals with BRD, with promising results. Measuring heat loss each time calves accessed waterers allowed to combine thermography data and watering frequency, a procedure that was deemed more sensitive, specific, and cost effective than conventional approaches to monitor animals at risk of BRD. Temperature-sensing reticuloruminal boluses have been used to monitor calves at risk of developing BRD. This technology allows remote and continuous recording of the reticular temperature of animals fitted with a temperature-sensing bolus and permits the identification of animals with prolonged fever episodes not associated with apparent clinical signs and thereby potentially improves the sensitivity of the detection of animals with BRD in a field setting.

**Herd-Level Diagnosis**

The clinician is limited in most situations to correlating clinical, epidemiologic, and necropsy findings in making a diagnosis. Diagnostic laboratories may not be readily available, and their resources for microbiological and serologic investigations may be much less than is needed for an accurate determination of causes. In case a diagnostic laboratory is not within reach, on-site postmortem examination of fresh carcasses of untreated animals deceased or euthanized in the early stage of the disease can provide valuable information and diagnostic material for further analysis. Coordinating the necropsy with a pathologist who may attend and guide the procedure via teleconference or assess gross findings on digital material and suggest collection of specific specimens is advisable.

A systematic method of data collection from the customized records of large feedlots has been developed and validated for use in the National Animal Health Monitoring System. The current collection of data from large feedlots provides an acceptable level of sensitivity and specificity for the program, but it is important that the veterinarian makes regular clinical observations to validate the data.

The course of the disease, especially when animals have been treated, alters the gross and microscopic appearance of tissues and the microbiological (bacteriologic, virological) and serologic findings so that the animal’s status is impossible to determine.

**CLINICAL PATHOLOGY**

**Antemortem Diagnostic Procedures**

A number of diagnostic procedures are available that vary in their practicality, their suitability to detect specific pathogens, the rapidity with which test results are available, their economy, the level of stress for the patient, the quality of the material obtained, and the interpretability of the results.

**Nasal/Nasopharyngeal Swabs**

Nasal and nasopharyngeal swabs are frequently used for antemortem sample collection under field conditions because this procedure is technically less demanding and less invasive than a transtracheal wash or bronchoalveolar lavage. Certainly for upper respiratory tract viral infection such as BHV-1 this method has it merits. In contrast, the significance of bacterial isolates or negative test results must be interpreted cautiously. Isolates of *M. haemolytica* from nasopharyngeal swabs were found to be highly representative for the isolates present in lung tissue in clinically affected animals.
However, because most bacterial pathogens of the lower respiratory tract such as *M. haemolytica* can be part of the normal upper respiratory flora, isolation of one or several of these agents from a nasopharyngeal swab does not necessarily indicate that it is the cause of disease.  

Although isolation of *M. bovis* from a nasal swab confirms the presence of this pathogen in the herd, the association of the presence of *M. bovis* in the upper respiratory tract with clinical disease or its presence in the lower respiratory tract reported in the literature is more variable. Some authors reported that *M. bovis* is commonly found in the upper respiratory tract in healthy calves; however, this is not confirmed by others. On the other hand, cultures form nasopharyngeal swabs were found to yield a positive result in only 33% of animals infected with *M. bovis*.  

To collect a nasopharyngeal swab sample, a long, sterile culture swab guarded by an external sheath must be inserted through the nasal cavity of the properly restrained calf. The tip of the swab should be approximately at the height of the medial canthus of the eye before the tip of the swab is extruded beyond the sheath and firmly rotated against the mucosa. The tip of the swab must then be retracted into the sheath before removing the whole swab. Swabs may be submitted for bacterial/mycoplasma culture or virus isolation. Depending on the diagnostic objective, two or three swabs placed into specific transport medium for the analysis requested may be required.

**Transthracheal Wash/ Bronchoalveolar Lavage**  
Transthracheal wash (TTW) and bronchoalveolar lavage (BAL) are antemortem sample collection techniques yielding material suitable for a broader spectrum of diagnostic procedures. Besides of bacterial or fungal cultures, isolation/identification of virus or parasites samples can also be used for cytology. These procedures are technically more demanding and more invasive than swab collection. They require proper restraint, local anesthesia, and aseptic technique. The TTW is performed in the previously clipped and aseptically prepared middle trachea region. A 10-gauge 2-inch needle is advanced through a previously placed stab incision through the anesthetized skin between two cartilage rings into the trachea. Sterile polypropylene tubing is then inserted through the needle and advanced to the level approximately 10 cm beyond the thoracic inlet. Twenty to thirty mL of warm sterile saline or lactated Ringer’s solution are then infused and rapidly aspirated back. This procedure typically yields between 5 and 10 mL of fluid that can either be submitted in the sealed syringe or transferred into a sterile tube. Transtracheal wash samples can also be collected by endoscopy using the biopsy port. To perform a BAL, commercially available kits are available that consist of a long tube with an inflatable cuff at the tip. The tube is passed intranasally into the trachea and further into the lungs, where it is lodged into a bronchus. The airway is then sealed by inflating the cuff, and warm lactated Ringer’s solution is infused (approximately 30 mL for a calf and up to 180 mL for an adult cow) and immediately aspirated.

**Serology**  
Serum samples may be submitted for determination of the levels of specific antibody titers to suspected viral pathogens of the bovine respiratory tract and to *Mycoplasma* spp. Paired acute and convalescent serum samples from both affected and normal animals in the herd are desirable. In a group of animals in a feedlot, or dairy or beef cattle herd, serology for a specific etiologic agent may be followed over a period of time to determine seroconversion and its relationship to occurrence or absence of clinical disease. Although serology is highly sensitive because most respiratory pathogens of cattle induce a strong antibody response, the time delay with which results of paired serum samples become available presents a disadvantage. Moreover, interpretation of serology results in animals with respiratory disease is often complicated by vaccination procedures and the timing of sample collection. Serology is always done in serum and not in plasma.

**Serum Biochemistry and Hematology**  
The suitability of serum concentrations of acute-phase proteins (APPs), such as fibrinogen, serum amyloid A (SAA), or haptoglobin (Hp), as a diagnostic tool to identify calves with BRD has been explored in numerous studies, with variable outcome. Although increased concentrations of SAA and Hp in calves with BRD compared with healthy calves suggest that measuring the serum concentrations of these APPs could assist the early detection of calves with respiratory disease, the discriminative ability of Hp by itself for BRD was found to be no better than determination of the rectal temperature. Haptoglobin concentrations vary considerably between calves even in healthy animals and were significantly affected by sex and rectal temperature. The increase in serum Hp was found to occur within 24 hours of experimental challenge with *M. haemolytica* of BHV-1-infected calves but occurred between 4 and 8 days of infection with BRSV or BVD. For SAA, the wide variation between animals and the less pronounced increase in SAA concentration in animals suffering of respiratory disease impair the ability of this parameter to discriminate between healthy calves and animals affected by BRD.

Leukocyte counts are of little value as predictors of respiratory disease because leukocytosis and neutrophilia occur in some animals, but in others there may be a neutropenia or no significant change.

**Other Procedures**  
With ultrasonographic equipment having become more available in routine food animal practice, the use of this imaging technique as potentially suitable ancillary diagnostic tool to diagnose BRD was studied by several authors. Thoracic ultrasonography is relatively easy to perform with standard equipment under field conditions but requires a certain degree of expertise and routine of the operator to obtain reproducible results. Results of ultrasonographic examination of pneumatic calves were found to be highly correlated with the results of radiographic and postmortem examination. In contrast, the association between ultrasonographic findings and ancillary tests assessing lung and respiratory functions are less obvious. Although the method was found a useful ancillary diagnostic tool to determine type and degree of pleural and pulmonary lesions, ultrasonography results were not found to be associated with animal health outcomes such as subsequent treatment, chronicity, wastage, or mortality.

More invasive diagnostic procedures such lung biopsies have been studied for their usefulness as ancillary diagnostic tool. Although easy to perform with minimal risk to the animal, this procedure was not found useful for characterizing early respiratory disease in feedlot cattle under field conditions.

**Postmortem Samples**  
Postmortem samples may be collected either during on-site necropsy or at the diagnostic laboratory. Animals selected for postmortem sample collection should have the following characteristics:

- Representative of the typical clinical case of the herd
- In the early phase of the disease
- Untreated

Contacting the diagnostic laboratory before euthanizing the animal is advisable to discuss the diagnostic workup best suited for the specific herd, and thus the required material is advisable.

**Bacterial Culture and Antimicrobial Sensitivity**  
The results of antimicrobial susceptibilities of bacterial pathogens isolated from the lung tissues of cattle with pneumonia over a period of years may provide some indication of trends in antimicrobial sensitivities, but the results are of limited value for making decisions about the selection of antimicrobial in affected animals.

The literature on the principles of antimicrobial susceptibility testing of bacterial pathogens associated with bovine respiratory disease has been reviewed. Two different methods are used. The Kirby–Bauer method...
is the traditional in vitro test of bacterial susceptibility or resistance to antimicrobials, which uses a disk containing a standardized concentration of an antimicrobial. Bacteria grow or fail to grow surrounding the disk, and results are interpreted as resistance or susceptibility of the bacteria to certain antimicrobials. The serial-dilution testing uses a broth or agar medium with selected dilutions of antimicrobials in 1:2 dilution steps. Results are expressed as susceptible, intermediate susceptibility, or resistant and also as minimum inhibitory concentrations (MICs), which are considered more reliable. The MIC is defined as "the lowest concentration of an antimicrobial that prevents visible growth of a microorganism in agar or broth dilution susceptibility test.

It is important to adhere to standards set by the National Committee on Laboratory Standards/Veterinary Antimicrobial Susceptibility Testing Subcommittee (NCCLS/VASTS). Veterinary-specific breakpoints are determined by the NCCLS/VASTS through a consensus process based on reviewing pharmacokinetic, MIC, zone-diameter scattergram and clinical trial data relating to an antimicrobial application. The subcommittee selects MIC breakpoints and zone-interpretative criteria that best fit the definitions of susceptible, intermediate susceptibility, and resistant.

The most veterinary-specific breakpoints for pathogens in bovine respiratory disease have been determined for few antibiotics: ceftiofur crystalline free acid, ceftiofur-hydrochloride, ceftiofur-sodium, danofloxacin, enrofloxacin, florfenicol, spectinomycin-sulfate, tulathromycin, and tilimicosin-phosphate. The breakpoints for oxytetracycline and chlortetracycline are adapted from human breakpoints developed for tetracycline.

NECROPSY FINDINGS
Because this clinical syndrome has a multifactorial etiology, necropsy findings will vary with the factors involved in a particular animal or herd, but some form of pneumonia is always present. The most common finding is fibrinous bronchopneumonia with varying degrees of fibrinous pleuritis and pulmonary abscesses (usually bacterial). The pneumonia involves the cranial lung lobes and the ventral portions of the middle and caudal lobes. Affected areas are dark-red and firm (craenoventral consolidation) and may be covered with thick sheets of fibrin on the visceral and parietal pleura. A cut surface of affected lung lobe is dark-red and may be marbled, whereas the bronchi and bronchioles are filled with a purulent exudate. Tracheobronchial and mediastinal lymph nodes are usually enlarged. In subacute or chronic cases, there are areas of coagulative necrosis or encapsulated abscesses within the consolidated lungs, and the fibrin in the pleura is replaced by fibrous tissue resulting in tough adhesions. Microscopically, alveoli are filled with an exudate composed of fibrin mixed with inflammatory cells, mostly neutrophils, macrophages, and fewer lymphocytes. The exudate extends to the lower airways.

With primarily viral infections, the common lesion is an acute, diffuse interstitial pneumonia. The lungs are diffusely red–tan, are enlarged, and do not collapse. All lobes are rubbery, wet, and heavy. Emphysema is present mainly in the diaphragmatic lobes, and there is white froth in the trachea. Microscopically, there will be interstitial pneumonia, necrotizing bronchiolitis, and, in some cases, viral inclusion bodies in epithelial cells or syncytial cells.

Samples for Postmortem Confirmation of Diagnosis
Tissue samples (lung and tracheobronchial lymph nodes) are submitted for histopathology, bacteriology, and virology. However, the length of time usually required to do the diagnostic work and interpret the results means that the procedure is expensive and to an extent inconclusive because the results are available only when the outbreak is over, particularly in feedlot operations.

Interpretation of Results of Clinical Pathology and Necropsy Findings
A large body of information has been generated on the microbiology and, more recently, molecular microbiology of specific pathogens associated with BRD, but only a fraction is applicable clinically. Insufficient effort has been directed toward integrating the information and applying it to the effective control of respiratory disease on the farm. Ideally, investigations of outbreaks of bovine respiratory disease should consist of in-depth examinations of a representative sample of the affected group and normal in-contact animals using a multidisciplinary approach involving clinical, epidemiologic, and laboratory investigation. These procedures, especially those requiring detailed virological and serological examinations, are expensive, and in the light of the economic status of cattle industries, they are not likely to be lightly borne. But it will only be when such a multidisciplinary approach is brought to bear on bovine respiratory disease that we will improve our position with respect to knowing what actually occurs in outbreaks of the disease.

Of paramount importance is the identification of risk factors, which, if valid, gives the clinician a powerful clinical tool for the clinical management and control of BRD.

TREATMENT
The principles of the clinical management of outbreaks of acute undifferentiated bovine respiratory diseases are as follows:

- The clinician must visit the farm and do the clinical and epidemiologic investigations necessary to solve the problem, to assist the owner or the animal attendants with the clinical management of the disease, and to monitor the problem and the herd until recovery occurs. Simply dispensing antimicrobials to the owner without clinical examination of the animals is inadequate and contradicts the intention of the veterinarian–client relationship. The veterinarian is professionally obliged to provide explicit instructions about medication of affected animals and the drug withdrawal requirements and to keep adequate records of affected animals, treatments given, and the results of laboratory examinations. A final report should be prepared by the veterinarian and sent to the owner.

- New cases must be treated as soon as they are detected. Each treated animal should be suitably identified and a record kept of the initial body temperature, the treatment administered and the instructions for follow-up treatment. Treatment failures and disease recurrence a few days after an initial apparent recovery are often attributable to late treatment. Delaying treatment until 48 hours after an experimental aerosol infection of M. haemolytica was found to prolong the course of the disease and increase mortality.

- Unless otherwise determined, when toxemia, causing pyrexia and anorexia, is present a primary or secondary bacterial pneumonia should be suspected, in which case antimicrobial therapy is of prime importance. Antimicrobials should be administered parenterally at least initially. Treatment via medicated feed or water bears the risk of underdosing in anorectic animals that are most severely affected. The regular use of a particular antimicrobial in feedlots may increase the level of resistance to M. haemolytica. Antimicrobials commonly used for treatment of UBRD are summarized in the treatment box of this section.

- Antiinflammatory therapy should routinely be combined with appropriate antimicrobial therapy in severe cases of BRD that are characterized by dyspnea, pyrexia, and anorexia.

A beneficial response to therapy should be apparent within 12 to 24 hours. The body temperature should decline significantly, and the appearance of the animal and its appetite...
should improve. The response to treatment, or lack of it, is valuable information in making a final decision on cause. One of the emerging problems inherent in such broad policies in treatment is public health concern with the amount of antibiotic residue in meat, the spreading of resistance to antimicrobials, and the increased public awareness and concern about indiscriminate antibiotic use in food-producing animals.30 Pressure is now being applied to use antimicrobials only when necessary, which necessitates a more accurate diagnosis.

A number of antimicrobials are registered for the treatment of BRD, of which some are listed in the treatment box of this section. Some of the antimicrobials with a label for treatment of BRD, such as third- and fourth-generation cephalosporins and fluoroquinolones, are also classified as critically important for human and animal health and should therefore be used restrictively. The World Organization for Animal Health (OIE) issued following recommendations for these classes of antimicrobials:31

- Not to be used as preventive treatment applied by feed or water in the absence of clinical signs
- Not to be used as first-line treatment unless justified—when used in a second-line treatment, it should ideally be based on the results of bacteriologic tests.
- Extra-label/off-label use should be limited and reserved for instances where no alternatives are available. Such use should be in agreement with the national legislature in force.

A recent mixed-treatment comparison meta-analysis of antibiotic treatments for BRD attempted a ranking of commonly used antimicrobials based on data published in over 90 publications.32 Based on the publically available information, the authors estimated tulathromycin followed by enrofloxacin, danofloxacin, and florfenicol as the most effective antimicrobials for the treatment of BRD. Gamithromycin was estimated to be less effective but comparable to tilmicosin at label dose. Oxytetracycline, trimethoprim/sulfur, and ceftiofur injected at the base of the ear all ranked poorly in this analysis. For oxytetracycline, the retreatment risk was estimated to be between 64% and 77% and thus far above the risk calculated for other evaluated antimicrobials.32

Antiinflammatory therapy was beneficial in cases of severe BRD that is characterized by marked dyspnea, fever, and feed-intake depression. The best established effects of nonsteroidal antiinflammatory drugs (NSAIDs) in animals suffering of BRD are a more rapid decline of the rectal temperature and faster return to normal feed and water intake. Long-term effects on clinical outcome, disease recurrence, and severity of chronic lung lesions reported in the literature are more variable.33 The precise mechanism through which NSAIDs act in calves with respiratory disease is not entirely understood, but antiinflammatory properties improving respiratory gas exchange and antipyretic and analgesic properties improving the wellbeing and thereby feed and water consumption are believed to be of prime importance. Numerous studies documented a more pronounced improvement in the initial phase of the disease in calves treated with NSAIDs and antimicrobials compared with animals treated with antimicrobials alone, a finding that is significant from an animal welfare perspective. A recent survey among U.S. feedlots revealed that, on average, NSAIDs were part of the standard initial treatment for respiratory disease in 55.9% of the surveyed U.S. feedlots.1 Neverthless, the veterinarian must be aware that the combination of antiinflammatory and antimicrobial therapy complicates the assessment of the antimicrobial effect that should take place no later than 48 hours after first treatment because clinical improvement cannot unequivocally be attributed to the susceptibility of the causative pathogen to the administered antimicrobial drug. Experimental and clinical evaluation of the role of corticosteroid therapy in acute pneumonia in cattle yielded mostly unfavorable results.34 Steroids are powerful antiinflammatory agents, but their effects on the animal’s defensive measures, specifically with repeated use, reduces the value of their use in syndromes of infectious origin unless they have a short duration of action.35

When confronted with an outbreak, one of the major decisions to be made is whether not to recommend metaphylactic antimicrobial mass medication of all in-contact animals in an attempt to treat cases in the preclinical stage.

### Control

**Mass Medication or Metaphylactic Antiinfective Use**

Veterinarians frequently recommend metaphylactic mass medication, and field observations claim beneficial results. Treatment of a whole group of animals

is often preferable to selecting individuals for therapy because of the diagnostic challenge of identifying early cases of BRD.2,3
Although the metaphylactic use of antimicrobials to control BRD is debatable from the point of view of prudent antimicrobial use, this approach was documented to considerably reduce morbidity and mortality rates in a group, thereby having a significant positive effect on animal health and welfare.3,4

The use of tilmicosin at 10 mg/kg BW subcutaneously, florfenicol at 40 mg/kg BW subcutaneously, gamithromycin at 6 mg/kg BW subcutaneously, tulathromycin at 2.5 mg/kg BW, and ceftiofur crystalline-free acid at 6.6 mg/kg BW administered subcutaneously at the base of the ear was found effective in reducing the morbidity rate when given to feedlot calves at high risk of developing respiratory diseases.4,5 The results obtained with long-acting oxytetracycline at a dose of 20 mg/kg BW or higher reported in the literature are more variable.6,7 Although an economical advantage may result from the lower price of oxytetracycline compared with newer antimicrobials, morbidity rates were found to be higher with the use of oxytetracycline compared with tilmicosin.6,8

The mass medication of feed supplies or water of newly arrived feedlot cattle has been investigated as a method of reducing the morbidity and mortality resulting from respiratory disease in a number of studies, but results are equivocal. Although studies suggesting that chlorotetracycline and sulfamethazine in feed are effective in reducing morbidity associated with BRD have been published, issues around study design and data analysis questioned the validity of the results.7 A standard recommendation is to provide 150 mg/kg BW for the first 24 hours and reduce the level to 75 mg/kg BW for the duration of the medication period, which may last 5 to 10 days.

Management of Risk Factors
As a general outline for the control of bovine respiratory disease, the following factors are considered as contributing to disease, and their effects must be minimized with suitable management and disease prevention techniques:

- Young, growing cattle are more susceptible than mature cattle because of a lack of sufficient immunity. The mixing of young cattle of different origins requires increased surveillance to detect evidence of disease. Vaccination of calves at strategic times may be necessary.
- Cattle purchased from various sources and mingled in a feedlot are more likely to develop bovine respiratory disease than cattle that have originated from one source.

Some cattle will be highly susceptible and others relatively resistant because of differences in nasal flora and immunologic, genetic, and nutritional backgrounds. A high level of management and constant surveillance are necessary to recognize, isolate, and treat clinical cases early to minimize morbidity and case mortality.

- Rapid fluctuations in environmental temperatures and relative humidity, not only during the fall and winter months but also during warm seasons, will commonly precede outbreaks of respiratory diseases. Every practical and economical management technique must be used to provide as much comfort as possible and to avoid overcrowding.
- Inadequate ventilation is a major predisposing cause of respiratory disease of cattle raised indoors. This is of major importance in dairy herds during the winter months in temperate climates.
- Weaning calves 3 weeks or longer before sale was found to be beneficial for later development and animal health in several studies.7
- Weaning of beef calves during inclement weather may exacerbate the stress of weaning and commonly results in an outbreak of respiratory disease.
- Stress associated with the marketing of cattle is a major factor. The movement of cattle through saleyards—where they may be overcrowded; mixed with cattle of many different origins; temporarily deprived of adequate feed and water; handled roughly while being sorted, weighed, tagged, blood sampled, vaccinated, or injected with antibiotics and/or vitamins, and then loaded on to uncomfortable vehicles and transported long distances without adequate rest stops—is stressful. The practice of preconditioning cattle before they enter the feedlot must continue to be examined to determine which aspects are most profitable.

Presale vaccination programs are designed to establish an effective immune response to common respiratory tract pathogens well in advance of any natural exposure that may occur while calves travel through the auction market or after they arrive in the feedlot. These programs usually require calves to be castrated, dehorned, and vaccinated against BHV-1, PI-3V, BRSV, and BVDV. Some programs also require vaccination against H. somni and M. haemolytica. Presale conditioning programs involve these procedures but also include weaning and nutritional components. Most such conditioning programs require calves to be weaned and adjusted to a roughage and concentrate diet for at least 30 days before sale.

Vaccines
Although vaccines for the control of acute respiratory disease associated with BHV-1, PI-3V, and Pasteurella spp. are available and widely used in the field, evidence documenting their efficacy under field conditions is scant.8,9 According to a large recent survey conducted in the United States, BVD vaccines are used in 96.6%, BHV-1 vaccines in 93.7%, BRSV vaccines in 89.5%, and PI-3V vaccines in 85.1% of surveyed feedlots to control respiratory disease.1 The use of vaccines against Pasteurella spp. (63.8%) and Histophilus somni (69.7%) is less common. Preshipment vaccination of beef calves 3 weeks before weaning with vaccines containing BHV-1, PI-3V, Pasteurella spp., and H. somni did not reduce the incidence of UBRD compared with those unvaccinated.

Many veterinarians and feedlot owners maintain that vaccination against respiratory disease is an essential component in their disease prevention programs, both to prevent specific disease of the respiratory tract such as clinical infectious bovine rhinotracheitis (IBR) and to reduce losses resulting from respiratory disease in the first few weeks after arrival.

In North America, a large number of bacterial and viral vaccines are available for the control of bovine respiratory disease. There are single-antigen and multiple-antigen vaccines and modified live-virus or inactivated-virus vaccines containing one or more of the following antigens: M. haemolytica, P. multocida, H. somni, BHV-1, PI-3V, BRSV, and BVDV. There are many multiple-antigen vaccines containing combinations of the respiratory viruses, BVDV, H. somni, P. multocida, and M. haemolytica.

Selection of Vaccines
The selection of which vaccine to recommend for the control of BRD in feedlot cattle is currently not possible based on the efficacy information that is available to the veterinarian. The vaccines are used widely, and many anecdotal claims for their effectiveness are made, but there is little scientific evidence that the vaccines are effective and economical in reducing the incidence or the consequences of respiratory disease such as suboptimal weight gain. In most cases the vaccines were approved for sale on the basis of tests for safety in animals, and the potency was measured by a serologic response to the vaccine or experimental challenge in animals under laboratory conditions. Nevertheless, although vaccination is consistently shown to result in antibody production, vaccine-induced titers are not always correlated with protection against disease.10
Efficacy of Vaccines
Meaningful field trials to evaluate vaccines for the control of bovine respiratory disease are difficult to achieve. The case definition of what is a “case of respiratory disease” has been very general, such as the presence of anorexia, depression, and a fever. Therefore, when testing a vaccine for the control of pneumonic pasteurellosis, the conclusions reached may be questionable if the cause of the sick animals in either the vaccinated or control group is not known—thus the importance of case definition. In contrast to field trials, the measures used by the manufacturer in the laboratory challenge of the vaccine have been specific. In a field trial, the control group and the vaccinated groups must be comparable. Where more than one vaccine is used to control respiratory disease in vaccines and controls, it is difficult to evaluate one of the vaccines or the components of a multiple-antigen vaccine unless large numbers of animals are used. Another problem is the difficulty of having the controls and the vaccines experience approximately the same risk of being affected with respiratory disease.

Field trials for bovine respiratory disease vaccines are often unsatisfactory because of inadequate planning, unsatisfactory experimental design, and lack of monitoring. The following comments on the use of vaccines as an aid in the control of acute undifferentiated respiratory disease in feedlot cattle are based on the current information available.

Pasteurella Vaccines
Because fibrinous pneumonia associated with *M. haemolytica* is the most common lesion associated with bovine respiratory disease in feedlot cattle, much of the emphasis has been on the development of effective vaccines for bovine pneumonic pasteurellosis. Based on the immunologic and microbiologic observations of both naturally occurring and experimentally induced pneumonic pasteurellosis, it appears that effective artificial immunization of cattle is possible. High levels of naturally acquired antibody to *M. haemolytica* have been associated with protection against the disease. Antibodies to *M. haemolytica* leukotoxin and certain bacterial surface components appear to be important for resistance to disease. The basis of a recently introduced Pasteurella vaccine is that vaccination of calves with a leukotoxic culture supernatant from pathogenic *M. haemolytica* provided some protection against experimental challenge with the organism.

Vaccination of recently shipped nonpreconditioned calves with the vaccine in Ontario resulted in a slight decrease in morbidity, slight improvement in response rates, and perhaps an important reduction in relapse rates. When the vaccine was combined with an intramuscular modified live BHV-1/PI-3V vaccine, the morbidity rate was increased, the response rate was decreased, and the mortality rate was increased in some groups. It appears that the use of modified live-virus vaccines in recently arrived calves is contraindicated; this is consistent with earlier observations in the Bruce County Project, where fall-placed calves were vaccinated on arrival with a modified live-virus vaccine.

A recent meta-analysis reviewing the evidence behind the recommendation to vaccinate to control BRD in calves identified 18 trials that studied the use of vaccines either against *M. haemolytica* or *M. haemolytica* and *P. multocida.* From these data the authors calculated a risk ratio (RR) of 0.93 (CI 0.89-0.98), indicating a significantly although minimally lower risk of morbidity in vaccinated feedlot cattle compared with controls and thus a potential benefit of using Pasteurella vaccines.

Histophilus somni (Formerly Haemophilus somnus) Vaccine
Few studies have investigated the effectiveness of *H. somni* vaccination of feedlot cattle to control respiratory disease. The antibody response was found to be associated with protection against *H. somni.* When used as part of a preconditioning program, the vaccine tended to have mildly positive or neutral effect on morbidity and mortality related to respiratory disease, whereas the effect appeared to be neutral or even negative when animals were vaccinated on arrival at the feedlot. Observed effects on morbidity and mortality were below the significance level. Little scientific evidence is currently available to support the use of *H. somni* vaccination to control BRD.

Viral Vaccines
Because prior infection of the respiratory tract with either BHV-1, BRSV, or PI-3V may predispose to pneumonic pasteurellosis, the vaccination of beef calves 2 to 3 weeks before weaning and feedlot cattle 2 weeks before shipment to a feedlot has been recommended as part of a preconditioning program. The results are variable, but vaccination of calves at 3 to 6 months of age with an intranasal modified-live BHV-1 and PI-3V vaccine has provided protection against experimental pneumonic pasteurellosis induced by aerosol challenge with BHV-1 followed 4 days later by an aerosol of *M. haemolytica.* It is important to vaccinate the calves at least 2 weeks before they are weaned, stressed, or transported to a feedlot.

A modified-live BHV-1 vaccine given to beef calves before weaning, at weaning, or immediately after arrival in the feedlot was associated with a significant reduction in the treatment rate in one of three groups immunized before weaning and in calves immunized after arrival in the feedlot. There was no significant effect of the vaccine on treatment rate in calves immunized at weaning, in calves immunized after arrival in a bull test station, or in yearlings immunized after arrival in the feedlot. It would appear that the vaccine did provide some protection, but the small reduction may not justify the cost of the vaccination program.

Some feedlot veterinarians recommend that feedlot cattle be vaccinated on arrival with an *M. haemolytica* vaccine, the BHV-1 and PI-3V vaccine, an *H. somni* vaccine, and the BRSV vaccine. The BVDV vaccine is the most commonly used vaccine in feedlots in the United States because BVD virus circulating in feedlots among newly received calves is considered to be an important factor predisposing to BRD. It is expected that control will be achieved if the animals are vaccinated against all the common pathogens that contribute to lesions of bovine respiratory disease. However, there is little, if any, published evidence based on controlled field trials that such blanket recommendations are justifiable.

PNEUMONIC PASTEURELLOSIS OF CATTLE (SHIPPING FEVER PNEUMONIA)

SYNOPSIS

Etiology Mannheimia haemolytica serotype A1 and A6; Pasteurella multocida serotype A2.

Epidemiology Young, rapidly growing cattle, especially recently weaned beef calves placed in feedlot (shipping fever) and unweaned dairy calves (enzootic calf pneumonia). Can occur in nursing calves and mature cows. Stressors include transportation, mixing animals from many different sources, weaning, processing procedures, and ineffective ventilation of housed animals.

Signs Acute respiratory disease, abnormal lung sounds, fever, toxemia, anorexia, sudden death; respond to treatment with antimicrobials.

Lesions Acute fibrinohemorrhagic pneumonia, frequently with pleuritis.

Clinical pathology Culture organism from nasopharyngeal swabs or transtracheal wash/bronchoalveolar lavage fluid.

Diagnostic confirmation Culture organism from lung and histopathology of lung.

Treatment Antimicrobials, NSAIDs.

ETIOLOGY

Pneumonic pasteurellosis is an entity within the bovine respiratory disease (BRD) complex, characterized clinically by acute bronchopneumonia with toxemia and pathologically by lobar, anterioventrally distributed, exudative pneumonia in which fibrin is usually a prominent part of the exudate and fibrinous pleuritis is common.

M. haemolytica of the order Pasteurel lateae, a gram-negative cocobacillus is considered the most important bacterial pathogen in weaned calves, whereas Pasteurella multocida is more commonly isolated from the lower respiratory tract of younger calves with respiratory disease. There are currently 12 recognized serotypes of M. haemolytica (A1, A2, A5, A6, A7, A8, A9, A12, A13, A14, A16, and A17), of which serotype A2 and to a lesser extent A4 are commonly isolated from the upper respiratory tract of healthy ruminants and thus are considered normal inhabitants of the nasopharynx and tonsils of ruminants. Serotypes A1 and, more recently, A6 are most commonly associated with respiratory disease in cattle.1,2

Pasteurella multocida has 5 capsular serogroups (A, B, D, E, and F) and 16 somatic serotypes (1-16). Whereas P. multocida serotypes B and E are associated with hemorrhagic septicemia in cattle and water buffaloes in tropical regions, serotype A3 and, to a lesser extent, D3 are the major pathogens associated with lower respiratory tract infection in cattle.3 Clearly, the presence of P. multocida in the upper respiratory tract does not equal disease because of the ubiquitous nature of this organism, but the proportion of fatal cases of shipping fever attributable to P. multocida appears to be increasing, according to the recent literature.4

The Pasteurella spp. are opportunistic pathogens and the final cause of the pneumonia but rely on predisposing mechanisms allowing the bacteria to enter and colonize the lung and produce the lesions. Viruses or mycoplasmas may act synergistically to allow the bacteria to be pathogenic. Numerous environmental predisposing factors, generally termed as stressors, have been discussed, such as the following:

• Transportation
• Confinement of groups of cattle from different sources
• Extreme temperature changes
• Weaning
• Processing procedures

EPIDEMIOLOGY

Occurrence

Pneumonic pasteurellosis is a common disease of young growing cattle in Europe, the United Kingdom, and North America. The condition has arbitrarily been subdivided into two main categories that are enzootic calf pneumonia (ECP), primarily ascribed to Pasteurella multocida and shipping fever mainly ascribed to Mannheimia haemolytica. Whereas ECP is considered a condition predominantly affecting unweaned dairy calves, shipping fever is discussed as disease of older weanling, stocker, or feeder cattle.1 Nursing beef calves, yearlings, and mature dairy and beef cows may also be affected, but less frequently.

Morbidity and Mortality

Shipping fever is the most common illness among cattle in U.S. feedlots, with an average incidence of 16.2% and a mortality rate of approximately 4%.3 Considerable regional differences in morbidity rates were reported, with feedlots in the central region of the United States reporting twice the percentage of cattle affected compared with other regions (17.8% vs. 8.8% respectively).3 The peak incidence of disease occurs within the first 3 weeks after arrival of the calves in the feedlot.

The incidence of respiratory disease in postweaning dairy heifers in the United States was 5.9%, and respiratory disease was determined to be the most common cause of death in weaned and the second most common cause of death in unweaned heifers (after diarrhea) with 46.5% and 22.5% of death losses respectively in the United States.5 The percentage of death losses attributable to respiratory disease in weaned dairy heifers rose from 34.8% of all deaths in 1991 to 46.5% in 2007.6 An observational study of the epidemiology of fatal fibronasal pneumonia in feedlot calves purchased from auction marts in western Canada and placed in a commercial feedlot between September 1 and December 31 over a 4-year period identified some valid information. Peak fibronasal pneumonia occurred approximately 16 days after arrival at the feedlot; the median number of days between arrival and the first treatment of fatal pneumonic pasteurellosis cases varied from...
3 to 8 days. The fatal fibrinous pneumonia rates varied 11-fold (0.25%-2.73%) between years. The fatal fibrinous pneumonia proportionate mortality varied from 10% to 77%. Fully 75% of the calves that died of fibrinous pneumonia already were sick within 2 weeks after arrival. When the incidence of fatal fibrinous pneumonia was high (greater than 2%), the disease clustered, either within certain truckload groups of calves or within certain pens, or within both. Clustering could have been a result of contagious factors, noncontagious factors, or both.

**Economic Importance**

Pneumonic pasteurellosis is a major cause of economic loss in the feedlot and dairy industry. It is responsible for the largest cause of mortality in feedlots in North America. In addition to the death losses, the costs of treatment (which include the personnel involved in the detection and actual treatment, the drugs used and the vaccines) are considerable. Indirect costs of the disease, which include increased risk of culling or death, losses associated with delayed entry into the milking herd and possibly decreased productivity are difficult to estimate. The average cost of treatments for a single case of respiratory disease in feedlots determined in a recent U.S. survey was $23.40, which was considerably higher than the costs per case of $12.59 reported in similar study from 1999. A study from 1990 estimated the average costs per clinical case with an average $14.71 for unweaned and $1.95 for weaned dairy calves. Long-term costs were estimated at between $15 and $49 for a typical Dutch dairy farm with an overall disease incidence of 60%.

**Risk Factors**

**Animal Risk Factors**

The disease occurs most commonly in young growing cattle from 6 months to 2 years of age but all age groups are susceptible. Calves that are nonimmune to *M. haemolytica* are considered to be more susceptible to the disease than calves that have serum neutralizing antibodies to the organism and its leukotoxin (LKT). Calves that have recovered from the experimental disease are resistant to naturally occurring disease. Auction market calves that originate from many different farms and are mixed at the market are at high risk. Calves may develop the disease before weaning if housed in crowded, poorly ventilated barns, when exposed to rapid changes in temperature and humidity, or when subjected to stress.

The disease occurs commonly in outbreaks 7 to 10 days after cattle have arrived in the feedlot following stressful transportation. This forms a major part of the “shipping fever” complex, which is a major hazard in the practice of rearing beef cattle on range country and then transporting them long distances to other centers for growing and finishing. However, the distance that calves were transported by truck from the auction markets to the feedlot was not associated with an increased risk of fatal fibrinous pneumonia, as determined by one study.

Herd outbreaks in dairy herds are not uncommon, especially when recent introductions have been made or cattle are returned to their home farms after summer grazing. Experimental transportation and handling to mimic stress, followed by an aerosol of *M. haemolytica*, did not result in significant lesions of pneumonia but did make the animals susceptible to BHV-1. Similarly, stress related to weaning and maternal separation at the time of primary BHV-1 infection increased the innate immune response that correlated significantly with mortality following a secondary bacterial infection.

Confinement in drafty or humid and poorly ventilated barns, exposure to inclement weather, transport, fatigue, and deprivation from feed and water are commonly followed by outbreaks of the disease in cattle. In calves kept at a constant temperature of 16°C (60°F), the bacterial populations in the nasopharynx were at a minimum between 65% and 75% relative humidity and tended to rise at humidities outside that range.

An increase in virulence of the bacteria is often evident after animal passage; at the commencement of an outbreak only those animals that have been subjected to devitalizing influences are affected, but the disease may subsequently spread to other animals in the group. There is little tendency for the disease to become an area problem, with sporadic outbreaks occurring with the appearance of conditions favorable to the development of the disease.

**Pathogen Risk Factors**

Pasteurella are considered normal inhabitants of the upper- and opportunistic pathogens of the lower respiratory tract of cattle. Although the precise mechanism is not well understood, concurrent viral infection of the upper respiratory tract is considered a key risk factor. A number of environmental risk factors have been discussed in the literature. In addition to prior infection with viral pathogens that are discussed under “Pathogen Risk Factors,” other predisposing factors generally summarized as “stressors” include the mixing of cattle from different sources; transportation; sudden and extreme temperature changes; cold coupled with wetness, dust, or acute metabolic disturbances; and feed and/or water deprivation (e.g., during transportation). Mixing of recently weaned beef calves from different sources at auction markets was associated with an increased risk of fatal fibrinous pneumonia in calves moved to feedlots in western Canada, especially in November, shortly after auction sales had peaked and when the feedlot was reaching capacity.

The role of stress as a risk factor in shipping fever pneumonia has been examined experimentally. Experimental transportation and handling to mimic stress, followed by an aerosol of *M. haemolytica*, did not result in significant lesions of pneumonia but did make the animals susceptible to BHV-1. Similarly, stress related to weaning and maternal separation at the time of primary BHV-1 infection increased the innate immune response that correlated significantly with mortality following a secondary bacterial infection.

Confinement in drafty or humid and poorly ventilated barns, exposure to inclement weather, transport, fatigue, and deprivation from feed and water are commonly followed by outbreaks of the disease in cattle. In calves kept at a constant temperature of 16°C (60°F), the bacterial populations in the nasopharynx were at a minimum between 65% and 75% relative humidity and tended to rise at humidities outside that range.

An increase in virulence of the bacteria is often evident after animal passage; at the commencement of an outbreak only those animals that have been subjected to devitalizing influences are affected, but the disease may subsequently spread to other animals in the group. There is little tendency for the disease to become an area problem, with sporadic outbreaks occurring with the appearance of conditions favorable to the development of the disease.
fever in feedlot cattle. Up to 80% of affected animals shed bovine coronavirus from their nasal cavities when the infection rate with *Pasteurella* spp. was low.

The virulence factors of *M. haemolytica* and *P. multocida* include the following:

**Surface proteins and carbohydrates**
- Adhesion proteins and fimbrae allowing adherence to the mucosal membranes
- Capsular polysaccharides
- Outer membrane proteins (OMPs), some of which are iron regulated and critically important for iron acquisition by the microorganism
- Lipopolysaccharides (also termed endotoxins, particularly lipid A) that are responsible for pyrexia and hypotensive shock and contribute to pulmonary lesions
- Lipopolysaccharides (e.g., lipoprotein PlpE)

**Toxins and extracellular enzymes**
- Leukotoxin (LKT) of *M. haemolytica*, which induces apoptosis or cell necrosis in ruminant leukocytes
- Glycoproteases that can hydrolyze IgG
- Neuramidase

*M. haemolytica* serotypes A1 and A2 can survive for long periods of time in relatively low-nutrient in vivo fluids. Both strains survived for at least 244 days in ovine and 156 days in bovine tracheobronchial washings, respectively. This may provide an explanation for the long survival of the organism in the nasopharynx of ruminants.

**Immune Mechanisms**

Calves that have recovered from the experimental disease are resistant to naturally occurring disease. Numerous *M. haemolytica* antigens may stimulate the immune response and resistance to disease. These antigens include many of the previously mentioned virulence factors such as capsular polysaccharides, LKT, and surface antigens, including iron-regulated proteins, a serotype-specific outer membrane protein, and several other antigens that are less well defined. High antibody responses to *M. haemolytica* surface-extract proteins are correlated with resistance to experimental pneumatic pasteurellosis. Resistance to experimental challenge with the organism correlates directly with serum LKT neutralizing titers. Aerosol exposure of calves to *M. haemolytica* results in the development of LKT neutralizing antibodies in pulmonary lavage samples and an accompanying increase in serum neutralizing antibody titer. Because aerosol exposure of calves to viable *M. haemolytica* elicits a protective immune response characterized by enhanced clearance of the organism from the lung and by protection against fibrinous pneumonia, it is possible that the presence of preexisting antibodies to LKT in the lungs provides immunity by protecting phagocytic leukocytes from LKT and by promoting phagocytosis and intracellular killing of the organism.

Passive immunization with antibodies to whole *M. haemolytica* or LKT-containing supernatants provides protection against experimentally induced pneumatic pasteurellosis similar to the protection provided by active immunization with these antigens. In contrast, antibodies to lipopolysaccharide provided little protection against challenge.

Cattle exposed to live organisms produce antibodies to both cell surface antigens and LKT, whereas exposure to the killed vaccine results in the production of antibodies primarily to cell surface antigens.

The experimental lung challenge of calves with formalin-killed *P. multocida* does not provide subsequent protection to challenge with live *P. multocida*.

**Method of Transmission**

Transmission of pasteurellas probably occurs by the inhalation of infected droplets coughed up or exhaled by infected animals, which may be clinical cases or recovered carriers in which the infection persists in the upper respiratory tract. *M. haemolytica* and *P. multocida* are highly susceptible to environmental influences and it is unlikely that mediate contagion is an important factor in the spread of the disease. When conditions are optimal, particularly when cattle are closely confined in inadequately ventilated barns, when overcrowded in trucks and trains, or held for long periods in holding pens in feedlots, the disease may spread very quickly and affect a high proportion of the herd within 48 hours. In animals at pasture, the rate of spread may be much slower.

**PATHOGENESIS**

**Colonization of Upper and Lower Respiratory Tract**

Considerable research has centered on determining how the pasteurellas, which are part of the normal flora of the upper respiratory tract, colonize first the upper- and then the lower respiratory tract. Under normal conditions the bovine lung is practically sterile and colonize the lung, they interact with alveolar macrophages. Neutrophils enter the lung within the first few hours after bacterial inoculation.

Bovine alveolar macrophages release superoxide anion when exposed to *M. haemolytica*, and the response is dependent on the presence of opsonizing antibody and the quantity of organisms presented to the phagocyte. This may have a major role in the pathogenesis of the acute lung injury associated with pneumatic pasteurellosis. It is an important mechanism by which this phagocyte can initiate microbicidal activity and may provide clues to further study of the defense mechanisms of the lung.

**Virulence Factors and Cellular and Humoral Reactions**

The lung injury caused by the organisms after entry into the lung is dependent on important virulence factors.

Of the previously mentioned virulence factors, the ones that are considered the most relevant for the pathophysiology of pulmonary pasteurellosis of cattle are as follows:
- Fimbriae
- Capsular polysaccharides
- Lipopolysaccharide (LPS or endotoxin)
- Leukotoxin (LKT) for *M. haemolytica*

The interactions of these virulence factors contribute to the pathogenesis of the disease. Fimbriae enhance the colonization of the upper respiratory tract. The capsular polysaccharides of the organism inhibit complement-mediated serum killing and phagocytosis and intracellular killing of the organism. The capsule also enhances neutrophil-directed migration and adhesion of the organism to the alveolar epithelium. The LPS can alter bovine leukocyte functions and is directly toxic to bovine endothelium. It also modifies cardiopulmonary hemodynamics and elevates circulatory prostanooids, serotonin, cAMP, and cGMP. The organism induces morphologic alterations in bovine pulmonary endothelial cells, the effects of
which can be partially inhibited by indomethacin. Tissue factor is involved in intraalveolar fibrin deposition and coagulopathy associated with pneumonic pasteurellosis in cattle.

The migration and activation of neutrophils in inflamed tissue are regulated by a complex network of interactions among cytokines, leukocytes, vascular endothelium, cellular adhesion molecules, and soluble chemotactic factors. The inflammatory cytokines tumor necrosis factor alpha, interleukin (IL)-1 beta, and IL-8 play a central role in the initiation and orchestration of these interactions. IL-8 is the dominant cytokine expressed within the lungs during the acute phase of pneumonic pasteurellosis.

The lipopolysaccharide (LPS) of P. multocida or M. haemolytica is capable of causing direct injury to bovine pulmonary arterial endothelial cells, which may be a contributing pathogenic mechanism. LPS interacts with numerous cell types and humoral mediator systems, resulting in widespread injury to the lung. LPS can readily cross the alveolar wall either from the air or blood and interact with cells and humoral mediators. LPS can be found in the neutrophils in the alveolus, interstitial tissue, and capillary lumen; in intravascular, interstitial, and alveolar macrophages; in endothelial cells; and on alveolar epithelial cell surfaces. The interaction of endotoxin with cells leads to cell activation and death.

Leukotoxin (LKT) is produced by all known serotypes of M. haemolytica and is a heat-labile protein exotoxin, a pore-forming cytolytin that affects macrophages, lymphocytes, neutrophils, and platelets of ruminants specifically. The bacterium produces LKT, with maximum production occurring during the log phase of growth, peaking after 6 hours of incubation. Following the inhalation of M. haemolytica into the lung, there is an accumulation of neutrophils that, when destroyed by LKT, results in the release of proteolytic enzymes, oxidant products, and basic proteins, which degrade cellular membranes, increasing capillary permeability. This causes fluid accumulation in the interstitium of the alveolar wall, alveolar wall necrosis, and pulmonary edema. LKT also induces histamine release from bovine mast cells.

LKT follows a species-specific dose-dependent activation-inhibition paradox on bovine leukocytes. Exposure to low concentrations of LKT can activate neutrophils and macrophages to stimulate respiratory burst and degranulation, proinflammatory cytokine release, and histamine release from mast cells. At high concentrations, LKT induces apoptosis in bovine leukocytes. Apoptosis is a process of programmed cell death distinguished from necrosis by the orderly shutdown of cell functions. At even higher concentrations, LKT causes transmembrane pore formation, resulting in cell swelling and subsequent cell death.

Supernatants of the organism can also cause rapid cytolysis of platelets. The genes that code for the synthesis and secretion of LKT have been cloned. It is a highly immunogenic protein that is produced by all 15 serotypes of M. haemolytica. Cattle with high LKT antibody titers have higher survival rates in natural and experimental cases of pneumonic pasteurellosis than animals with low antibody titers. LKT antigens and bacterial surface component are now used in commercial vaccines to elicit resistance against pneumonic pasteurellosis.

**Experimental Pneumonic Pasteurellosis**

In an attempt to understand the pathogenesis of bovine pneumonic pasteurellosis, the experimental disease has been reproduced using several different methods; the most commonly used is the sequential aerosol infection of calves with either the PI-3 virus or the BHV-1 virus followed by an aerosol of M. haemolytica 3 days or more later. Exposure of calves to aerosols of PI-3V followed by M. haemolytica at intervals of 3 to 13 days later results in a purulent bronchopneumonia. The virus interferes with the lung clearance of M. haemolytica when an aerosol of the bacteria is given 7 days following the viral infection. There is little interference after only 3 days and a moderate degree at 11 days. Pneumonic pasteurellosis similar to the naturally occurring disease can be reproduced experimentally by exposing calves sequentially to aerosols of BHV-1 and M. haemolytica 4 days apart. The virus infection partly destroys the clearance mechanism of the respiratory tract epithelium and exacerbates the subsequent M. haemolytica infection. Both antigens can be detected by immunohistochemical methods in the bronchovascular fluid cells.

The viral–bacterial synergism is associated with the release of cytokines, which attract more leukocytes and increase leukocyte expression of CD11a/CD18. In this experimental model, vaccination of the animal against the virus before challenge with the viral–bacterial aerosol sequence is protective. The interaction between the BHV-1 virus and M. haemolytica can persist for up to 30 days after infection with the virus. A sequential aerosol infection of BHV-1 and P. multocida, or P. multocida alone, can also result in pneumonia. Experimental in vitro studies indicate that BHV-1 infection does not have a direct effect on the ability of neutrophils to phagocytize M. haemolytica; rather, there is an indirect effect, perhaps through the release of mediators that have an effect on phagocyte function. Large amounts of interferon are produced throughout the course of BHV-1 infection, which reduces chemotaxis and elevates oxidase activity by bovine neutrophils.

The intratracheal injection of P. multocida serotype A3 into 8-week-old calves results in clinical and pathophysiologic findings characteristic of bovine pneumonic pasteurellosis and gross pathologic and microscopic changes similar to field cases. Concentrations of the acute-phase proteins haptoglobin, serum amyloid-A, and alpha-1 acid glycoprotein increased, suggesting a role for these proteins as markers of the onset of and progress of the disease.

The intratracheal instillation of live M. haemolytica into conscious calves results in acute cardiovascular changes consisting of two systemic hypodynamic and pulmonary vasoconstrictive phases.

**Synergism Between Pathogens**

Experimentally, synergism may occur between M. haemolytica and M. bovis in producing pneumonia in gnotobiotic calves but not in conventional calves.

The role of BVDV in outbreaks of pneumonic pasteurellosis is uncertain. In one study the virus did not impair the pulmonary clearance of M. haemolytica. In a different study the endobronchial inoculation of calves with the virus and M. haemolytica sequentially 5 days apart resulted in a severe fibrinopurulent bronchopneumonia and pleuritis involving up to 75% of the total lung volume. Endobronchial inoculation of the organism only caused a localized noninvasive lesion in the lungs.

In summary, pneumonic pasteurellosis can be reproduced experimentally without a preceding virus infection, and it is likely that the naturally occurring disease can also occur without a preceding viral infection.

**CLINICAL FINDINGS**

The spectrum of clinical findings depends in part on whether the disease is occurring in groups of young cattle in a large commercial feedlot, in a small farm feedlot, or in individual animals such as lactating dairy cows, in which illness is more easily recognized based on milk production and feed intake. In the feedlot situation, affected animals must be identified primarily by visual observation followed by closer physical examination.

**Feedlot**

In the feedlot, the disease usually occurs within 10 to 14 days after the animals have been stressed or have arrived in the feedlot. It may occur within 1 day after arrival if the animals have been incubating the disease before arrival. Animals found dead may be the first indication of an outbreak in which many weaned beef calves are obviously affected and some are in the incubation stages of the disease.

When viewed from a distance, affected cattle are depressed, and their respirations are rapid and shallow. There may be a weak protective cough, which becomes more pronounced and frequent if they are urged to
Diseases

In many animals, the disease may persist for several weeks. In these situations, many animals are sick with the disease when they arrive at the feedlot. Some cattle will develop complications, never fully recover, and are culled later.

**Early Identification of Affected Animals in Feedlots**

Where large numbers of cattle are involved, early identification is crucial to successful therapy. Identification of individual animals with early-stage respiratory disease in a large group presents a major challenge. Methods of diagnosing bovine respiratory disease based on visual appraisal by feedlot pen riders may not always effectively identify sick animals. A Bayesian estimation of the performance of using clinical observation for diagnosis of bovine respiratory disease yielded an estimated sensitivity and specificity of 0.62 and 0.63, respectively, suggesting that up to 38% of truly diseased animals may go undiagnosed and conversely that up to 37% of animals diagnosed and subsequently treated for respiratory disease are unaffected by respiratory disease. Improvement of both the diagnosis and the selection of those animals that require treatment will require improvement in the accuracy of the identification of affected animals by visual observation and the use of rapid and reliable clinical examination techniques of individual animals that can identify animals with evidence of pulmonary disease. Close physical examination techniques, such as auscultation of the lungs, are not routinely used in feedlots because of the time required to examine individual animals and the perceived inaccuracy of the examination in making a clinical diagnosis.

More recently, novel approaches to monitor calves at increased risk of developing respiratory disease, such as the use of temperature-sensing reticuloruminal boluses or infrared thermography to monitor heat loss in calves, have been studied, with promising results. There is certainly a need to further improve our clinical diagnostic techniques and to develop new ones that can be applied to making a rapid and accurate diagnosis beside the animal in the field situation.

**Close Physical Examination**

The typical case of pneumonic pasteurellosis reveals a fever of 40° to 41°C (104°-106°F), bilateral mucopurulent nasal discharge, gaunt abdomen with rumen atony, coughing, varying degrees of polypnea and dyspnea, and evidence of bronchopneumonia. In the early stages there are loud breath sounds audible over the anterior and ventral parts of the lungs. As the disease progresses, these breath sounds become louder and extend over a greater area; crackles become audible, followed by wheezes in a few days, especially in chronic cases. Pleuritic friction rubs may be audible, although their absence does not preclude the presence of extensive adherent pleuritis. In severe cases or those of several days duration, the dyspnea is marked, commonly with an expiratory grunt, although the respiratory rate may not be elevated.

The course of the disease is only 2 to 4 days. If treated early, affected cattle recover in 24 to 48 hours, but severe cases and those that have been ill for a few days before being treated may die or become chronic despite prolonged therapy. Some cattle recover spontaneously without treatment.

A mild diarrhea may be present in some cases but is usually of no consequence. On an affected farm, calves may be affected with pneumonia, and young calves may die of septicemia without having shown previous signs of illness.

**CLINICAL PATHOLOGY**

**Bacterial Culture**

Nasopharyngeal swabs taken from calves with early-stage respiratory disease often yield a pure culture of Pasteurella, but *M. haemolytica* serotype A1 is the most common isolate obtained from weaned cattle with acute pneumonic pasteurellosis. The same serotype can usually be isolated from the upper respiratory tract of apparently healthy contact calves. *P. multocida* is the predominant pathogen cultured from swabs or bronchoalveolar lavage fluid in unweaned calves with pulmonary pasteurellosis. In recent years the number of clinical cases of bovine pneumonic pasteurellosis in older calves attributed to *P. multocida* in the absence of other Pasteurellaceae has increased considerably.

The antimicrobial sensitivity of the Pasteurellaceae isolated can be determined, but interpretation of the results is often difficult because it is not known whether the isolates from nasopharyngeal swabs represent those causing the lesions. Significant differences may exist between the antimicrobial sensitivities of isolates from nasopharyngeal swabs and those from the lung tissues. Thus it is not yet possible to recommend routine culturing and antimicrobial sensitivity determination of Pasteurellaceae from nasal cavity or nasopharyngeal mucus from cattle with acuteshipping fever pneumonia. In healthy calves monitored from the farm to the feedlot, there was no relationship between the nasal flora and pulmonary lesions.

**Serum Biochemistry and Hematology**

The suitability of serum concentrations of acute-phase proteins (APPs) such as fibrinogen, serum amyloid A (SAA) or haptoglobin (Hp) as a diagnostic tool to identify calves with BRD has been explored in numerous studies with variable outcome. Although increased concentrations of SAA and Hp in calves with BRD compared with healthy calves suggest that measuring the serum concentrations of these APPs could assist the early detection of calves with respiratory disease, the discriminative ability of Hp by itself for BRD was found to be no better than
determination of the rectal temperature. The concentration of Hp varies considerably between calves even in healthy animals and is significantly affected by sex and rectal temperature. The increase in serum Hp was found to occur within 24 hours of experimental challenge with M. haemolytica of BHV-1 infected calves but occurred between 4 and 8 days of infection with BRSV or BVDV. For SAA the wide variation between animals is a useful marker in culture-negative cases. In nonfatal cases a wall-off reaction by fibrous tissue isolates the necrotic tissue. Determination of the age of the lesions by gross and/or microscopic examination may assist in correlating the occurrence of the disease with specific health management procedures in the herd. In feedlot cattle, determining the age of bacterial pneumonia can help to assess whether or not the pneumonia was present in the animal on arrival or if treatment failure resulted from late detection or from inadequate drug therapy. The degree of necrosis and fibrosis are the main lesions used to age pneumonia.

In general, M. haemolytica causes a fibrinous pleuropneumonia with extensive thrombosis of interstitial lymph vessels and limited evidence of bronchitis and bronchiolitis. In contrast, bronchopneumonia attributable to P. multocida is associated with a suppurative bronchitis, minor thrombosis of interstitial lymph vessels, and considerably less exudation of fibrin.

The organism is easily cultured from acute, untreated cases, but other species of bacteria, including anaerobes, are often found in more chronic cases. More sophisticated tests such as PCR and immunoperoxidase techniques are available for the detection of M. haemolytica but are seldom required in diagnostic cases.

**Samples for Confirmation of Diagnosis**
- Bacteriology—lung, bronchial lymph node (CULT)
- Histology—formalin-fixed lung (LM)

**DIFFERENTIAL DIAGNOSIS**

The differential clinical diagnosis of pneumonic pasteurellosis is summarized in Table 12-6.

As a general guideline the common pneumonias of cattle may be divided into bronchial, interstitial, and hematogenous.

- **The bronchial pneumonias** include pneumonic pasteurellosis and other less common bacterial pneumonias characterized by toxemia and shallow respiration and a good response to early treatment.
- **The interstitial pneumonias** include the viral and parasitic pneumonias and acute interstitial pneumonias characterized by marked respiratory distress and a slow or no response to treatment. In viral pneumonias the animals may die acutely in a few days or recover over a period of several days.
- **The hematogenous pneumonias** are associated with vena caval thrombosis and pulmonary aneurysm and are characterized by acute respiratory distress, hemoptysis, and no response to treatment.

**Pneumonic pasteurellosis of cattle** is an acute, toxemic bronchopneumonia with a high fever and a good response to treatment in the early stages. Depression and anorexia are common. The disease is most common in young beef and dairy calves that have been recently stressed following weaning or mixed in auction markets and shipped to feedlots. The disease can also occur in mature cattle as a primary or secondary pneumonia.

In **viral interstitial pneumonia** of calves, young and adult cattle there is characteristic dyspnea, a moderate fever, only a mild toxemia, and loud breath sounds over the ventral aspects of the lungs followed by crackles and wheezes in a few days, and recovery may take several days. Pneumonia attributable to BRSV may be mild with uneventful recovery or severe with dyspnea and subcutaneous emphysema and a high case-fatality rate.

**Lungworm pneumonia** occurs most commonly in young pastured cattle and is characterized by dyspnea, coughing, only mild toxemia, and a moderate or normal temperature; the course may last several days. Usually many cattle are affected. Crackles and wheezes are usually audible over the dorsal aspects of the lungs, and the response to treatment is usually favorable if treatment is initiated early when signs are first noticed.

Less common causes of acute pneumonia in calves and young cattle include infection with Klebsiella pneumoniae, Streptococcus spp., and Fusobacterium necrophorum, all of which are characterized by a bronchopneumonia indistinguishable clinically from pneumonic pasteurellosis.

**Acute/atypical interstitial pneumonia** (fog fever) usually occurs in outbreaks in pastured cattle that have been moved from dry to lush pasture (or just a different species of pasture or on to a recently harvested cereal grain field); the onset is sudden, and some cattle may be found dead, whereas others are in severe respiratory distress with an expiratory grunt.

**Infectious bovine rhinotracheitis** (IBR) is characterized by rhinitis, usually with discrete lesions in the nares, tracheitis, loud coughing, high fever, and no toxemia unless secondary bacterial pneumonia is present. Recovery usually occurs gradually over 4 to 7 days.

**Contagious bovine pleuropneumonia** resembles pneumonic pasteurellosis but occurs in plague form; there is severe, painful, toxemic pleuropneumonia, and the case-fatality rate is high.

**TREATMENT**

**Antimicrobial Therapy**

The recommendations for the treatment of bovine pneumonic pasteurellosis are based on clinical experience and the results of clinical field trials. Approximately 85% to 90% of affected cattle recover within 24 hours if treated in a timely manner.
Choice of Antimicrobial

Choice of antimicrobial will depend on the cost, availability, expected efficacy based on previous experience with the antimicrobial in a particular area, ease of administration, frequency of administration required, concentrations of the antimicrobial that can be achieved in the lung tissues of affected animals, and length of the withdrawal period required before slaughter or withholding of milk in case of lactating dairy cattle. According to a recent survey among feedlots in the United States, the most commonly used antimicrobials used for the first-line treatment of BRD were tulathromycin (66.3%), followed by fluoroquinolones (43.1%), florfenicol, or third-generation cephalosporins (both 34.8%) and tetracyclines (28.1%). Commonly used antimicrobials registered for the treatment of BRD and their dosages are listed in the treatment table of this section.

Several novel antimicrobials, such as the macrolides tilmicosin, tulathromycin, or gamithromycin, have successfully been used for treatment and control of bovine respiratory pasteurellosis. Other commonly used antimicrobials with proven efficacy include florfenicol, an analog of thiamphenicol, and the chinolones enrofloxacin difloxacin and danofloxacin. Ceftiofur preparations have been evaluated and also found to be effective for the treatment of bovine respiratory pasteurellosis. Ceftiofur crystalline-free acid sterile suspension (CCFA-SS), a long-acting ceftiofur administered subcutaneously in the middle third of the posterior aspect of the ear, is effective, safe, and practical for the treatment of experimental pneumonia pasteurellosis and the control and treatment of bovine respiratory disease in feedlot cattle.

Some of the antimicrobials with a label for treatment of BRD, such as third- and fourth-generation cephalosporins and fluoroquinolones, are also classified as critically important for human an animal health and should therefore be used restrictively. The World Organization for Animal Health (OIE) issued following recommendations for these classes of antimicrobials:

- Not to be used as preventive treatment applied by feed or water in the absence of clinical signs
- Not to be used as first-line treatment unless justified. When used in a second-line treatment, it should ideally be based on the results of bacteriological tests
- Extra-label/off-label use should be limited and reserved for instances where no alternatives are available. Such use should be in agreement with the national legislature in force.

Antimicrobial Sensitivity

The antimicrobial sensitivity of *M. haemolytica* varies, depending on the geographic origin of the animals and the previous use of the drug in the herd or the feedlot. Most isolates of *M. haemolytica* have some degree of multiple antimicrobial resistance, associated with continued use. Surveys of antimicrobial sensitivity trends for pathogens isolated from cattle with respiratory disease from all over the world based on MIC indicate that, overall, resistance to ampicillin, tetracycline, erythromycin, and sulfamethazine is frequently encountered among isolates of *M. haemolytica* and *P. multocida*. The widespread resistance to erythromycin may account for the wide variation in sensitivity to tilmicosin because of cross-resistance. Ampicillin- and tetracycline-resistant *Pasteurella* isolates from dairy cattle (dairy herds and calf ranches) with pneumonia were spatially clustered within certain geographic areas in California. The percentage of *M. haemolytica* isolates resistant to ampicillin was 21.3%; to *P. multocida*, 12.3%. The percentage of *M. haemolytica* isolates resistant to tetracycline was 37%; to *P. multocida*, 52.5%. This reinforces the need to establish regional estimates of percentages of bacterial isolates which are susceptible to commonly used antimicrobials.

It was noticed that *M. haemolytica* serotype A6, the prevalence of which increased significantly over the last decade, exhibited significantly higher antimicrobial resistance rates than serotypes A1 and A2.

Tetracycline resistance (*tet*) genes have been found in isolates of *P. multocida*, *M. haemolytica*, *M. glucosida*, and *M. varigena* from cases of respiratory diseases in cattle and pigs in Germany. Tetracycline resistance in *P. multocida* and *M. haemolytica* is mediated by at least three different *tet* genes, most of which are located on the chromosomes. A new *tet* (H)-carrying plasmid has been identified, and *tet* (B) has been detected in *P. multocida* and *tet* (G) in *M. haemolytica*. More recently, a plasmid carrying chloramphenicol–florfenicol resistance gene floR was identified in *M. haemolytica* isolates from cattle.

Medication of Feed and Water Supplies

There is much interest in mass medication of the drinking water or feed supply or both. The rationale is that the medication of the feed or water would successfully abort an outbreak by treating those animals incubating the disease, provide convalescent therapy to those that have already been treated individually, and deal with mild cases before they become acutely ill and need individual treatment. However, there are problems. The amount of water that cattle drink is directly proportional to feed consumption. If they are inappetent or anorexic, water consumption will decline to only maintenance requirements, and therapeutic levels of drug will not be achieved if the concentration in the water is provided at a level for normal consumption. The other major problem is the provision of a uniform concentration of drug in the water supply, either through automatic water proportioners in the waterline or placing the drug directly into water tanks. Both can be unreliable. The mass medication of feed supplies or water of newly arrived feedlot cattle has been investigated as a method of reducing the morbidity and mortality as a result of respiratory disease in a number of studies, but results are equivocal. Although studies suggesting that chlorotetra-cycline and sulfamethazine in feed are effective in reducing morbidity associated with BRD in calves have been published, issues around study design and data analysis questioned the validity of the results.

Antinflammatory Agents

Antinflammatory therapy was found to be beneficial in numerous studies in cases of severe respiratory disease that is characterized by marked dyspnea, fever, and feed intake depression. The best established effects of nonsteroidal antinflammatory drugs (NSAIDs) in animals suffering of respiratory disease are a more rapid decline of the rectal temperature and faster return to normal feed and water intake. Long-term effects on clinical outcome, disease recurrence, and severity of chronic lung lesions reported in the literature are more variable.

The precise mechanism through which NSAIDs act in calves with respiratory disease is not entirely understood, but antinflammatory properties improving respiratory gas exchange and antipyretic and analgesic properties improving the well-being and thereby feed and water consumption are believed to be of prime importance. Numerous studies documented a more pronounced improvement in the initial phase of the disease in calves treated with NSAIDs and antimicrobials compared with animals treated with antimicrobials alone, a finding that is significant from an animal welfare perspective. Notwithstanding the veterinarian must be aware that this combination treatment complicates the assessment of the antimicrobial effect that should take place 48 hours after first treatment, as clinical improvement cannot unequivocally be attributed to the susceptibility of the causative pathogen to the administered antimicrobial drug. Experimental and clinical evaluation of the role of corticosteroid therapy in acute pneumonia in cattle yielded mostly unfavorable results. Steroids are powerful antinflammatory agents, but their effects on the animal’s defensive measures, specifically with repeated use, reduces the value of their use in syndromes of infectious origin unless they have a short duration of action.

A recent survey among U.S. feedlots revealed that on average NSAIDs were part of the standard initial treatment for respiratory disease in 55.9% of all feedlots, whereas steroids were used in 30.9% of the surveyed U.S. feedlots.
Failure to Respond
The causes of failure to respond to therapy include the following:
- Delayed initiation of treatment resulting in complications such as pulmonary abscess, bronchiectasis, and pleuritis
- Presence of viral or interstitial pneumonia or some other pneumonia that is not responsive to antimicrobials
- Inadequate dose of antimicrobials, inadequate treatment duration
- Antimicrobial resistance of the bacteria

CONTROL
Satisfactory economical control of the disease depends on the successful integration of management and perhaps the use of vaccines and antimicrobials metaphylactically. It is unrealistic to depend on a vaccine, an antimicrobial, or a single management technique to control the disease. Successful control begins with the adoption of effective management techniques, the judicious use of efficacious vaccines, and care in handling and transportation of cattle.

Management Strategies
Preconditioning Programs
Because of the common occurrence of the disease at the time of shipment from the ranch to the feedlot, much attention has been given to reducing the incidence of disease at this time. This led to the development in North America of the concept of preconditioning. The objective of preconditioning was to prepare the weaned calf for the feedlot environment by vaccinating it for all the commonly anticipated diseases before weaning and distributing all stressful procedures such as castration, dehorning, branding, and deworming over a period of time rather than concentrating these at weaning time. Weaning at least 2 weeks before shipment is considered as one of the most desirable preconditioning practices. This was to result in a weaned calf that could not be moved into a feedlot in which the feed bunks and water bowls would not be strange but familiar and the calf would adjust quickly. The most common vaccinations were for BHV-1, PI-3V, BVDV, BRSV, and clostridial disease. In some situations, calves were also vaccinated for H. somni and against pneumonic pasteurellosis.

Weaning Procedures
Bovine calves should be weaned at least 2 to 3 weeks before shipping and well in advance of anticipated inclement weather. A common successful practice is to begin feeding hay and providing water to calves at least 2 weeks before weaning in the same corral or paddock into which they will subsequently be weaned. Following such a weaning program, the calves require only a minimum of adjustment; the only adjustment necessary should be to the loss of their dams. Recently weaned calves should be observed at least twice daily for evidence of respiratory disease and treated promptly if necessary. They should not be transported long distances until they appear to be healthy and are eating liberal quantities of hay and drinking water normally. During transportation liberal quantities of bedding are necessary, and cattle should not be without feed and water for more than 24 to 30 hours. For long trips, calves should be rested for 8 to 12 hours and fed water and hay at intervals of 24 hours. This will minimize the considerable loss of body weight as a result of shrinkage and the effects of temporary starvation.

Creep Feeding
The use of creep feed for calves for several weeks before weaning has been successful but may not always be economical. A high-energy ration containing cereal grains, a protein supplement, and the necessary vitamins and minerals is provided for the calves in a creep arrangement to which the dams do not have access. At weaning time the dams are removed from the calves, and the stress on the calves is minimal. This program has been very successful for purebred herds, where it may be economical, but in commercial herds, it is only economical when the market value of the calves warrants it.

Conditioning Programs
In the absence of preconditioning programs, conditioning programs have become the usual procedure for preparing beef calves or yearlings for the feedlot. This begins with movement of the animals from their farm source to the feedlot. The ideal situation would be to avoid public saleyards and move the cattle directly from the ranch to the feedlot. This avoids the stress of handling, overcrowding, temporary starvation, exposure to aerosol infection from other cattle, and the unnecessary delays associated with buying and selling cattle. However, large intensified feedlots are unable to buy cattle directly from the herd of origin according to their needs at a particular time and thus inevitably purchase large groups of cattle of different backgrounds. This has necessitated the development of conditioning procedures or processing procedures in which,
Chapter 12  Diseases of the Respiratory System

after arrival, the cattle are individually identified; injected with a mixture of vitamins A, D, and E; treated with a residual insecticide; perhaps given an anthelmintic; injected with a long-acting antimicrobial; and vaccinated for clostridial and respiratory diseases. The issue of whether the cattle should be processed immediately after arrival or after a rest period of 2 to 3 weeks remains unresolved because there are few data to support one time over the other. However, the feedlot industry feels that processing immediately after arrival is most economical.

Feeding Newly Arrived Cattle

The feeding and nutritional status of newly arrived cattle is important, but there are few scientific data to formulate a sound economical feeding program that will promote rapid recovery from shipping stress. Good results can be achieved when stressed calves are fed a receiving ration consisting of 50% to 75% concentrate with good-quality hay in a total mixed ration for the 2 to 3 weeks until the cattle have become adapted to their new environment.

Vaccines

General Comments

The use of vaccines against respiratory viruses and to a lesser extent against bacterial pathogens to control shipping fever and enzootic calf pneumonia is widespread. According to a large recent survey conducted in the United States, BVD vaccines are used in 96.6%, BHV-1 vaccines in 93.7%, BRSV vaccines in 89.5%, and PI-3 vaccines in 85.1% of surveyed feedlots to control BRD.23 The use of vaccines against Pasteurella multocida (63.8%) and Histophilus somni (69.7%) is less common. Nevertheless the evidence of efficacy for this practice is equivocal at best. A review of the literature in 1997 on the efficacy of the vaccines available for the control of bovine respiratory disease concluded that there were few documented data to support the use of vaccines against respiratory disease under feedlot conditions. Since that time progress has been made in understanding immunity to pneumonic pasteurellosis, and some vaccines with varying degrees of efficacy have been developed. Various commercial vaccines differ in the rapidity and intensity of serum antibody responses to M. haemolytica whole cells and leukotoxin. Although the vaccines have been evaluated by experimental challenge of vaccinated animals with specific pathogens in a laboratory environment, there is little scientific evidence available that the vaccines are protective against bovine respiratory pasteurellosis as it occurs in the real-world situation.24 Respiratory vaccines have consistently resulted in antibody production against the specific antigen, but obtained titers did frequently not protect against respiratory disease. Failures of vaccination can certainly not exclusively be attributed to the vaccines themselves. Factors such as timing of vaccination or animal stress hampering the immune response to vaccination are likely to contribute to the poor vaccine performance.25 Optimal vaccine response can only be expected in a fully immunocompetent animal, takes 2 to 3 weeks to develop, and may require multiple doses of vaccine to elicit protective immunity.26

Pasteurella Vaccines

Based on the immunologic and microbiological observations of both the naturally occurring and experimental disease, it appears that immunization of cattle is possible. Calves that recover from experimentally induced pneumonic pasteurellosis possess increased resistance to subsequent experimental challenge. Cattle that have recovered from the natural disease are resistant to the disease. The challenge in the development of an efficacious vaccine against pneumonic pasteurellosis has been to determine the most effective protective antigens of the organism. Several different Pasteurella vaccines have been developed based on the virulence factors, including leukotoxin, lipopolysaccharides, capsular polysaccharides, and outer membrane proteins. Each of the vaccines produced may provide some protection against experimental and naturally occurring disease, but none provides a high degree of protection.

Modified live and killed vaccines are currently available. Live streptomycin-dependent P. multocida vaccines have been associated with improved health and weight gain performance compared with unvaccinated calves in some studies. Killed Pasteurella vaccines did not show significant effects on morbidity, mortality, or extent of pulmonary damage and even were reported to result in increased morbidity in some cases.27

Leukotoxin Extract Vaccine

High leukotoxin-neutralizing antibody titers induced by natural infections have been associated with reduced susceptibility to pneumonic pasteurellosis. Vaccination of calves with a leukotoxic culture supernatant from pathogenic M. haemolytica provides some protection against experimental challenge with the organism. The efficacy of the leukotoxin extract vaccine has been evaluated in clinical field trials against naturally occurring bovine respiratory disease in weaned beef calves 6 to 8 months of age entering feedlots in Ontario and Alberta. In an initial field trial in Alberta, auction-market-derived calves were given two doses of the vaccine within 1 to 5 days of arrival. Mortality from all causes was significantly lower in vaccinated calves (4.2% vs. 2.1%), and mortality as a result of fibrinous pneumonia was lower (2.2% vs. 1.1%). In a trial in Ontario feedlots, recently shipped nonpreconditioned calves were vaccinated within 24 hours after arrival. The vaccine resulted in a slight decrease in morbidity, slight improvement in treatment response rates, and a reduction in relapse rates. When the vaccine was combined with a modified live-virus vaccine containing the BHV-1 and PI-3 viruses, the mortality rate increased. However, the number of calves in each group was insufficient to adequately evaluate the differences. In another trial in Alberta the vaccine did not result in a change in morbidity or weight gain. Total mortality rates were increased significantly, and mortality rates from respiratory disease tended to be increased in ranch calves vaccinated at the ranch. In summary, there were no major benefits from vaccination.

A single vaccination of a M. haemolytica bacterin-toxoid given to calves on arrival in the feedlot reduced overall crude mortality, but there were no differences between vaccines and nonvaccines in bovine respiratory disease-specific mortality, morbidity, and/or average daily gain.

Passive Immunity to Mannheimia haemolytica

Vaccination of pregnant dairy cows at 6 and 3 weeks before parturition with a leukotoxin extract vaccine induced leukotoxin-neutralizing serum antibody titers in the cows, increased titers in colostrum, and increased passive leukotoxin colostral antibody titers in the calves. Vaccination was also associated with increased indirect agglutinating serum antibody titers in the cows. The protective effect of the antibodies against naturally occurring disease in the calves was not determined.

Vaccination of beef cows with a combined genetically attenuated leukotoxin M. haemolytica vaccine and an H. somni vaccine once at 4 weeks prepartum increases passive antibody titers to both organisms in their calves. Double vaccination of the calves with preexisting maternal antibodies at 1 and 2 months of age will increase antibody titers to both organisms until 6 months of age. Vaccination of beef calves with low levels of preexisting antibody at 3 and 4 months of age will increase antibody titers to H. somni until 6 months of age and to M. haemolytica until 5 months of age. Thus prepartum vaccination may be an effective measure for the control of pneumonia in calves under 2 months of age, and vaccination of the calves at 3 and 4 months of age may provide additional protection until the calves are 6 months of age.

Evaluation of Efficacy of Mannheimia haemolytica Vaccines

Meta-analysis of the published literature on the efficacy of the various vaccines against pneumonic pasteurellosis of cattle indicates that culture supernatants and/or potassium-thiocyanate-extracted outer membrane protein vaccines perform as well
as live vaccines. Live vaccines are considered to be the best in terms of protective immunity induced against pneumatic pasteurellosis because they replicate at the site of injection and produce the important immunogens that stimulate a protective immune response. However, live vaccines are associated with side effects such as fever, local abscessation, and lameness.

Commercial vaccines have been evaluated by measuring antibodies in 4- to 6-week-old calves vaccinated against leukotoxin, capsular polysaccharide, whole-cell antigens, and iron-regulated outer-membrane proteins. A bacterin-toxoid, a leukotoxin culture supernatant, a modified live *M. haemolytica* and *P. multocida* vaccine, and an outer-membrane extract of the organism were evaluated. All vaccines induced antibodies to the antigens, but there were wide variations between the vaccines: some vaccines demonstrated little if any antibody to leukotoxin or outer-membrane proteins. The highest leukotoxin antibody titer did not reach its peak until 14 days after the booster dose of vaccine, which suggests that a second dose of vaccine is necessary for protection.

The efficacy of three commercial vaccines was evaluated against experimental pneumatic pasteurellosis. Protective immunity was evaluated by assessment of clinical scores and lung lesions after endobronchial challenge with virulent *M. haemolytica*. There was significant correlation between lung and serum antibody levels against leukotoxin, capsular polysaccharide, and outer-membrane proteins. The vaccines did not provide optimal protection, but the bacterin-toxoid vaccine was superior to the others. The culture supernatant containing leukotoxin, lipopolysaccharide, and capsular polysaccharide provided the best protection against experimental disease compared with a sodium salicylate extract containing outer-membrane proteins, lipopolysaccharide, and capsular polysaccharide, and a combination of these two. Leukotoxin is an important virulence factor in the disease, and its use in vaccines provides significant protection. Muramyl dipeptide analogs may increase the humoral and protective response of calves to capsular polysaccharide.

**Adverse Vaccine Reactions**

Some adverse reactions are associated with live vaccines. Systemic infection attributable to *M. haemolytica* occurred 2 to 18 days following vaccination with an avirulent live culture of *M. haemolytica*. Lesions included injection site inflammation, purulent meningitis, and polyarthritis. Abscess formation at injection sites after vaccination with modified live *M. haemolytica* vaccines is also possible. The purified capsular polysaccharide of *M. haemolytica* used in combination with other antigens did not provide protection but rather caused a high incidence of anaphylaxis.

**Histophilus somni Vaccines**

Few studies have investigated the effectiveness of *H. somni* vaccination of feedlot cattle to control respiratory disease. The antibody response was found to be associated with protection against *H. somni*. When used as part of a preconditioning program the vaccine tended to have mildly positive or neutral effect on morbidity and mortality related to respiratory disease, whereas the effect appeared to be neutral or even negative when animals were vaccinated on arrival at the feedlot. Observations on morbidity and mortality were below the significance level. Little scientific evidence is currently available to support the use of *H. somni* vaccination to control BRD.

**Viral Vaccines**

Because prior infection of the respiratory tract with either BHV-1, BRSV, or PI-3V may predispose to pneumatic pasteurellosis, the vaccination of beef calves 2 to 3 weeks before weaning and feedlot cattle 2 weeks before shipment to a feedlot has been recommended as part of a preconditioning program. A modified live-virus BRSV vaccine given to beef calves before weaning, at weaning, or immediately after arrival in the feedlot was associated with a significant reduction in the treatment rate in one of three groups immunized before weaning and in calves immunized after arrival in the feedlot. There was no significant effect of the vaccine on treatment rate in calves immunized at weaning, in calves immunized after arrival in a bull test station, or in yearlings immunized after arrival in the feedlot. It would appear that the vaccine did provide some protection, but the small reduction may not justify the cost of the vaccination program. Vaccination of calves at 3 to 6 months of age with an intranasal modified live BHV-1, BRSV, and PI-3V vaccine provides protection against experimental pneumatic pasteurellosis induced by aerosol challenge with BHV-1 followed 4 days later by an aerosol of *M. haemolytica*. Using this principle of control, it would be necessary to vaccinate the calves at least 2 weeks before they are weaned, stressed, or transported to a feedlot. Vaccination on arrival with modified live-virus vaccines, although commonly done, may be associated with increased mortality.

**Antimicrobial Metaphylaxis**

The early onset of pneumatic pasteurellosis in cattle within a few days after arrival in combination with the limitations of identifying clinically affected animals that need therapy was a major factor in the development of metaphylactic use of antimicrobials. Although the metaphylactic use of antimicrobials to control BRD is debatable from the point of view of prudent antimicrobial use, this approach was documented to considerably reduce morbidity and mortality rates in a group, thereby having a significant positive effect on animal health and welfare. The administration of antimicrobials to high-risk calves immediately after arrival is particularly effective under commercial feedlot conditions. Meta-analysis of the literature on mass medication for bovine respiratory disease indicates that metaphylactic parenteral mass medication of calves with long-acting antimicrobials such as oxytetracycline, florfenicol, tilmicosin, or other novel macro-lide antimicrobials on arrival at the feedlot will reduce bovine respiratory disease morbidity rates.

The use of tilmicosin at 10 mg/kg BW subcutaneously, florfenicol at 40 mg/kg BW subcutaneously, gamithromycin at 6 mg/kg BW subcutaneously, tulathromycin at 2.5 mg/kg BW and ceftiofur crystalline-free acid at 6.6 mg/kg BW administered subcutaneously at the base of the ear were found effective in reducing the morbidity rate when given to feedlot calves at high risk of developing respiratory diseases. The results obtained with long acting oxytetracycline at a dose of 20 mg/kg BW or higher reported in the literature are more variable. Although an economical advantage may result from the lower price of oxytetracycline compared with newer antimicrobials, morbidity rates were found to be higher with metaphylactic treatment with oxytetracycline compared with tilmicosin.

**Mass Medication of Feed and Water Supplies**

The mass medication of feed supplies or water of newly arrived feedlot cattle has been investigated as a method of reducing morbidity and mortality resulting from respiratory disease in a number of studies, but results are equivocal. Although studies suggesting that chlorotetracycline and sulfamethazine in feed are effective in reducing morbidity associated with BRD in calves have been published issues around study design and data analysis questioned the validity of the results. A standard recommendation is to provide 150 mg/kg BW for the first 24 hours and reduce the level to 75 mg/kg BW for the duration of the medication period, which may last 5 to 10 days.

DISEASES OF THE RESPIRATORY TRACT ASSOCIATED WITH MYCOPLASMA SPP.

Several mycoplasmas have been isolated from pneumatic and nonpneumonic lungs of cattle, sheep, and goats (Table 12-6), but attempts to reproduce respiratory tract disease with the isolates have resulted in inconclusive findings.

Sheep
In sheep, *M. ovipneumoniae* is the most important species of mycoplasma affecting the respiratory tract. The pathogen is the cause of *atypical* or *ovine nonprogressive pneumonia*, also known as summer pneumonia in New Zealand and Australia.4 *M. ovipneumoniae* is believed to cause disease by predisposing the lower respiratory tract to invasion by other organisms, such as *M. haemolytica* or *M. paratuberculosis*. *M. ovipneumoniae*, although in low numbers, is frequently isolated from the upper respiratory tract of healthy sheep, which may act as source of infection to young lambs. A high prevalence of *M. ovipneumoniae* in association with *M. haemolytica* in lung tissue of lambs has been reported from Turkey and more recently from Italy.5 Lambs get infected during the first days of life but usually do not show clinical signs before 5 or 10 weeks of age. Clinical disease is commonly triggered by stress, inclement weather, or a secondary bacterial infection.6

The clinical presentation can vary from mildly affected dull lambs with increased respiratory rate, coughing, increased rectal temperature, anorexia, and poor growth to severely affected animals with acute fibrinous pneumonia, lung consolidation, pleuritis, and pulmonary abscesses formation. Most commonly the disease results in chronic, persistent, and irregular cough, with mucopurulent nasal discharge.7 Treatment with fluoroquinolones, tetracyclines, and macrolid antibiotics often results in a rapid improvement that is followed by a relapse once the treatment is discontinued.

The diagnosis is complicated by the common occurrence of *M. ovipneumoniae* in the field. Whereas isolation of the pathogen from the upper respiratory tract is of little diagnostic value, the presence of it in the lower respiratory tract, particularly when associated with lung lesions is highly suggestive of an etiologic role of this pathogen. Paired serum samples obtained 2 to 3 weeks apart from acutely affected animals to determine rising antibody titers give a good indication of an active infectious process and are of more diagnostic value than the simple determination of an antibody titer at one time.

In the United States, *M. ovipneumoniae* has recently been associated with several outbreaks of epizootic pneumonia, a devastating respiratory tract disease of yet unknown etiology in sheep.4 Although a number of other pathogens, such as *Mannheimia haemolytica* and *Pasteurella multocida*, have consistently been isolated from sick animals along *M. ovipneumoniae*; this latter pathogen was the only agent with a significantly higher prevalence in animals from outbreaks (95%) than unaffected control animals (0%).4

Other Mycoplasma spp. occasionally associated with respiratory disease in sheep include *M. arginini*, *M. agalactiae*, *M. putrefaciens*, *M. mycoides* subsp. capri (formerly *M. mycoides* subsp. mycoids LC), *M. capricolum* subsp. capricolum, and *M. bovis*. When found in clinically affected animals, these Mycoplasma spp. are frequently isolated in combination with other pathogens, obscuring their role in ovine respiratory disease. Only *M. capricolum* subsp. capricolum is considered an important pathogen and the major cause of pneumonia in sheep in North Africa.

Goats
Mycoplasma infections in goats most commonly involve the Mycoplasma mycoides cluster organisms that include *M. mycoides* subsp. capri, *M. capricolum* subsp. capricolum, and *M. capricolum* subsp. capripneumoniae, the etiologic agent of the contagious caprine pleuropneumonia (see also “Contagious Caprine Pleuropneumonia”). Although contagious caprine pleuropneumonia is characterized by clinical disease specifically affecting the respiratory tract, the other members of the *M. mycoides* cluster have also been associated with polyarthritis.8

Contagious agalactia is another economically important disease of sheep and goats caused by mycoplasmal infection and occasionally associated with respiratory disease (see also “Contagious Agalactia”). Mycoplasma spp. incriminated as etiologic agents of contagious agalactia are Mycoplasma agalactiae, the classical etiologic agent of the disease, Mycoplasma putrefaciens, and the two species of the *mycoides* cluster, Mycoplasma mycoides subsp. capri and *M. capricolum* subsp. capricolum.

Other Mycoplasma spp. associated with respiratory disease in goats include *M. arginini*, *M. bovis*, and *M. ovipneumoniae*.7

The most common syndrome in goats associated with mycoplasma is a chronic interstitial pneumonia with cough, unthriftiness proceeding to extreme emaciation, chronic nonpainful bony enlargement of joints, and chronic indurative mastitis. The pneumonia in some cases progresses to the point where cor pulmonale develops, with a subsequent appearance of the signs of congestive heart failure.

Cattle
*M. bovis* is a major cause of calf pneumonia (see also “*Mycoplasma bovis Pneumonia*”). In
ETIOLOGY

*Mycoplasma mycoides* subsp. *mycoides* small colony (SC) (*MmmSC*), which is the cause of the contagious bovine pleuropneumonia (CBPP). This pleomorphic organism belongs to the *mycoides* cluster, which consists of six closely related mycoplasma species, that are subdivided into two groups, *capricolum* and *mycoides* (Table 12-8). Only two of the six species cause disease in cattle, *MmmSC*, which is the cause of CBPP, and *Mycoplasma bovis* bovine group 7 (Bg7), which may cause arthritis and bovine mastitis. The four others, two subspecies within the *Mycoplasma mycoides* group and two subspecies within the *Mycoplasma capricolum* group, are responsible for goat respiratory and other diseases. Although *MmmSC* has been isolated from buffaloes, sheep, and goats, which may thus function as hosts, the pathogen only causes disease in ruminants of the *Bos* genus (i.e., bovine and zebu cattle). The disease is not communicable to other species. *MmmSC* is very similar culturally and antigenically to the causative organism of caprine contagious pleuropneumonia, but the two can be differentiated culturally and biochemically.

EPIDEMIOLOGY

CBPP is considered one of the economically most important cattle plagues affecting Africa, and with relaxation of import controls and increase in international trade, it presents a constant risk for disease-free countries. The World Organization for Animal Health (OIE) has categorized CBPP as so-called “List A” disease. List A currently lists a total of 15 diseases notifiable to the OIE that are considered “transmissible diseases that have the potential for very serious and rapid spread, irrespective of national borders, that are of serious socioeconomic or public health consequence and that are of major importance in the international trade of animals and animal products.” The Pan African Programme for the Control of Epi-zootics (PACE), which is implemented in 32 African countries, identified CBPP as the second most common transboundary disease in Africa after rinderpest.

**Occurrence and Prevalence of infection**

Under natural conditions, CBPP occurs in cattle of the species *Bos*. Although buffaloes can be infected by artificial means, only one single case has been reported in an American buffalo and none in African buffaloes or other wild ruminants. Wild and small ruminants are currently not considered to play a relevant role in the epidemiology of CBPP.1,3

Currently CBPP affects around 30 countries in sub-Saharan Africa, of which several are endemic-ally infected. Although the condition was eradicated from many countries during the nineteenth and twentieth centuries through stringent movement control and culling of infected cattle, it has reemerged in the late 20th century. CBPP has also been reported in various small ruminants in sub-Saharan Africa, including sheep, goats, and water buffalo. Of these, water buffalo are considered to be the most important reservoirs of the disease, and sheep and goats are considered to have a relatively small role as reservoirs.3,15

**REFERENCES**

**CONTAGIOUS BOVINE PLEUROPNEUMO-**

**LUNG SICKNESS**, CBPP

**SYNOPSIS**

**Etiology** *Mycoplasma mycoides* subsp. *mycoides* (small colony) (*MmmSC*).

**Epidemiology** A major plague of cattle, endemic in Africa but considered as eradicated in most other parts of the world. Reportable disease to the World Organization for Animal Health (OIE, list A). Insidious nature of disease allows it to spread undetected for months.

**Signs** Fever, agalactia, anorexia, depression, coughing, thoracic pain, back arched, dyspnea, expiratory grunting, pleuritic friction rubs, dull areas of lung, edema of throat and dewlap.

**Clinical pathology** Complement fixation test (CFT), competitive enzyme-linked immunosorbent assay (C-ELISA). Nucleic acid recognition of causative organism with polymerase chain reaction (PCR).

**Lesions** Remarkable pleuritis, marked consolidation and marbling of lung, pleural adhesions.

**Diagnostic confirmation** Isolation of organism from tissue (lung) or pleural or synovial fluid.

**Treatment** Not recommended because of usually poor treatment response and the risk of developing carrier animals.

**Control** Identification and slaughter of sick animals. Vaccination followed by test and slaughter. Antimicrobial therapy of exposed animals may reduce disease transmission but is prohibited in many countries. Establish disease-free areas. Control movement of cattle in control areas.
Chapter 12  ■  Diseases of the Respiratory System

in Africa during the second half of the past century, and several outbreaks have been recorded in southern Europe until the end of last century. Reasons behind the failure to contain CBPP in Africa include the following:

- Changes of ecological/environmental factors, such as availability of water, droughts, and floods, leading to increased movement of livestock over long distances
- Civil strife and political and economic difficulties complicating the strict movement control of apparently infected cattle
- Lack or insufficient resources allocated to CBPP control, particularly limited funding for vaccination, livestock movement control, and mass education of farmers and veterinarians
- Limited potency and field performance of CBPP vaccines
- Reduced disease surveillance (e.g., serologic screening and abattoir studies)
- Distraction by control and prevention of other economically important diseases (e.g., rinderpest or avian influenza)

Historically CBPP spread throughout the European continent during the eighteenth century through uncontrolled movement of livestock caused by transhumance and wars. During the nineteenth and twentieth centuries the disease was introduced into the United States, Asia, Australia, and Japan. CBPP was first introduced into Africa through an infected Holstein Friesian bull imported from the Netherlands to South Africa in 1854. From there the disease spread to other South African countries, causing the death of over 100,000 cattle. By 1939 the disease was eradicated in most South African countries but not in war-torn Angola and Namibia, where it still remains a threat for neighboring disease-free countries.

CBPP was reported from 27 African countries between 1995 and 2002, of which 13 were in West Africa, two in Central Africa, six in East Africa and the remainder in South Africa. In East Africa CBPP is endemic in Burundi, Rwanda, large parts of Tanzania, southern Sudan, Ethiopia, and Somalia. Guinea, Mali, Niger, and Mauritania are endemically infected countries in West Africa and Angola and Zambia in the South African region. Numerous epidemic outbreaks of the disease, spreading from endemic neighboring regions through livestock movement have been reported, including Burundi and Zambia in 1997, Tanzania in 1996 and 1999, and Botswana in 1995 and 1998. The infection prevalence varies considerably in endemic regions of the world. Whereas a seroprevalence of 8% of the cattle population has been reported in Sudan, prevalence rates in the range of 25% have been given for Ethiopia, Chad, Guinea, and Tanzania. For Burkina Faso and Uganda, prevalence rates below 5% have been reported.

In Asia, CBPP has been reported from Assam in India, Bangladesh, and Myanmar. Sporadic outbreaks have been recognized in the Middle East, probably derived from importation of cattle from Africa. The latest Asian outbreaks reported to the OIE occurred in Mongolia, India, and Pakistan in 1973, 1990, and 1997 respectively. In China CBPP first occurred at the beginning of the twentieth century through livestock shipments from Australia. In the early 1950s China implemented its first control measures, including a vaccination program, after having suffered severe economic damage from the plague. The country declared itself free of CBPP in 1996 and is currently officially recognized as CBPP-free by the OIE.

The disease was introduced into Australia in 1858 by dairy cattle imported from England into the colony of Victoria. It spread rapidly throughout Australia by cattle being driven to take up new pastoral lands everywhere, aided by the bullock teams, which provided the only form of transportation of goods and supplies in those days. In 1958 a national eradication campaign was commenced. Australia was declared free from the disease 1973.

The disease was introduced into the United States in 1842 through cattle imports from England. CBPP became so widespread over the following 40 years that the federal government initiated the first intensive campaign to control an animal disease in 1887. By implementing strict quarantine and culling diseased animals the disease could be eradicated by 1892. CBPP was never recorded to occur in South America.

In Europe, after having been eradicated at the end of the nineteenth century, the disease reemerged in Portugal in 1951 and in Spain in 1957. In the 1980s, after an apparent absence of 13 years, CBPP was diagnosed on the borders of France and Spain, from where the disease apparently spread to Portugal, where another outbreak was recorded in 1983. Although the disease could be rapidly controlled in France and Spain, recurrent outbreaks occurred in Portugal until the end of last century. Italy, which had been free of the disease since 1899, saw an outbreak of CBPP between 1990 and 1993 that could never be traced back to its source. Within these 3 years the disease spread over an area 59 km², affecting nearly 100 cattle herds and requiring the slaughter of over 24,000 cattle. The disease was eradicated in 1993. The last reported outbreak in Europe occurred in northern Portugal in 1999. As of 2004, Europe is free from CBPP and the European Union rules prevent the importation of live animals from affected areas. A recent phylogenetic analysis indicated all M. mmmSC strains isolated in Europe since 1980 were derived from a common ancestor, suggesting that a single strain may have spread, largely unnoticed, in southern Europe between 1980 and 1993.

Source of infection

The focus of infection is often provided by recovered "carrier" animals in which a pulmonary sequestrum preserves a potential source of organisms for periods as long as 3 years. For many years, it was thought that conditions of stress attributable to starvation, exhaustion, or intercurrent disease can cause the sequestrum to break down and convert the animal into an active case. Experimental evidence throws some doubt on this explanation, but droplet infection is usually associated with a donor lesion in the lungs. Renal lesions are not uncommon and large numbers of viable M. mmmSC are passed in the urine of infected animals, and inhalation of urine droplets may be a route of infection. The organism has been isolated from the semen and preputial washings of two young bulls that were the result of frozen embryos implanted into Portuguese cows and were

| Table 12-8 Contagious pleuroneumonia-1: Members of the Mycoplasma mycoides group |
|-----------------|-----------------|-----------------|
| Name            | Main disease    | Main (and other) hosts |
| M. mycoides subsp. mycoides SC variant | Contagious bovine pleuroneumonia | Cattle (goats, sheep, buffalo) |
| M. mycoides subsp. mycoides LC variant | Caprine pneumonia, contagious agalactiae | Goats (sheep, cattle) |
| Mycoplasma capri | Caprine pneumonia | Goats (sheep, but rare |
| M. capricolum subsp. capricolum | Caprine pneumonia, contagious agalactiae | Goats (sheep, cattle) |
| M. capricolum subsp. capripneumoniae | Contagious caprine pleuroneumonia | Goats (sheep) |
| M. bovine group 7 (Bg7) | Arthritis, also mastitis, calf pneumonia | Cattle |
being considered for entry into a breeding center.

**Methods of Transmission**

Transmission occurs from direct and repeated contacts between sick and healthy animals. The principal route of infection is by the inhalation of infective droplets from active or carrier cases of the disease. Mediate infection by contamination of inanimate objects is unlikely under natural conditions, but it has been effected experimentally. Infected hay remained infective for up to 144 hours. Other inanimate objects such as placenta and urine can also remain infective for long periods. It has been suggested that urine may be a mode of transmission, especially in European countries with temperate climates, where cattle are reared intensively in restricted geographic areas and many herds share the same watercourse. Spread of the pathogen may also occur by discharges from local tail lesions resulting from vaccination with virulent culture.

A separation of 6 m between animals is usually considered to be sufficient, but transmission over 200 m is suspected to occur. Cattle may be infected for periods of up to 8 months before the disease becomes apparent, underscoring the importance of sufficiently long quarantine period before a herd can be declared to be free of the disease.

CBPP is usually transmitted through movements of live animals; trade in animal products is not thought to be a significant risk.

**Risk Factors**

**Animal Risk Factors**

CBPP occurs only in cattle; a rare natural case has been observed in one buffalo but has not been detected in other wildlife. In sheep and goats, the injection of culture causes a local cellulitis without pulmonary involvement. There is no difference in the susceptibility of *Bos taurus* and *Bos indicus* cattle and both races respond equally to vaccination.

**Immune Mechanisms**

The exact nature of the immunity conferred by vaccination or by naturally occurring disease is not entirely understood, although it can be transferred by the administration of serum from an immune animal. The lack of a cell wall and endotoxins may enable mycoplasmas to colonize the animal without inducing an immune response, and the predilection for the mucosal membranes may also limit the humoral response. For these reasons it is suggested that the organism is a poor immunogen, which may account for the frequent lack of good circulating antibody responses in experimentally infected and vaccinated cattle. There is a poor relationship between antibody titer and the severity of lesions; animals with high antibody titers may have no visible lesions, and those with severe lesions may have low or undetectable titers.

**Management Risk Factors**

The occurrence and incidence of CBPP is heavily influenced by management systems, disease control policies and regulations of a country, knowledge of the disease by farmers and veterinarians, and livestock field officers. The diagnostic capability of veterinary laboratories, disease-surveillance and monitoring systems, adequacy of vaccination programs, government budgets allocated to control programs, the effectiveness of education programs, and the desire of cattle owners and traders to control the disease are critically important management factors that influence the effectiveness of control of the disease in a country.

**Pathogen Risk Factors**

*M. mycoides* subsp. *mycoides* is sensitive to all environmental influences, including disinfectants, heat, and drying, and does not ordinarily survive outside the animal body for more than a few hours. A low incidence can be anticipated in arid regions because of the rapid destruction of the organism in exhaled droplets.

The organism can be grouped into two major, epidemiologically distinct, clusters. One cluster contains strains isolated from different European countries since 1980, and a second cluster contains African and Australian strains collected over the last 50 years.

The current European strains lack a substantial segment of genetic information, which may have occurred by a deletion event. The strains found in reemerging outbreaks of CBPP, which occurred after the eradication of the epidemic in Europe in the middle of the twentieth century, represent a phylogenetically newer cluster that has been derived from a strain of the older cluster of *MmmSC* that is still endemic on the African continent. The genome of *MmmSC* type strain PG1 has been sequenced to map all genes and to facilitate further studies regarding the cell function of the organism.

A variety of potential virulence factors have been identified, including genes encoding putative variable surface proteins, enzymes, and transport proteins responsible for the production of hydrogen peroxide and the capsule that is thought to have toxic effects on the animal. *Galactan* is also associated with pathogenicity of the organism, but its mode of action is uncertain. Galactan can cause necrosis and a connective tissue response in cattle similar to the sequestra in chronically infected animals.

The phylogeny of the *Mycoplasma mycoi-des* cluster according to sequencing of putative membrane protein genes has been examined. Molecular epidemiology of CBPP by multilocus sequence analysis of *MmmSC* strains found a clear distinction between European, south-western African, and sub-Saharan strains. This indicates that the CBPP outbreaks that occurred in Europe were not a result of introduction from Africa and confirms true reemergence. Strains of *MmmSC* isolated from recent outbreaks of CBPP in Africa have been compared with vaccine strains and older isolates. A Botswanan field isolate differed from all other strains of *MmmSC* tested by a variety of criteria. The new isolate may possess a set of protective antigens different from those of other strains of *MmmSC*, including vaccine strains. Such findings have implications for the control of CBPP in Africa.

The last strains isolated from an epidemic are usually of lower virulence than the first strains. Strains are most virulent when first isolated and lose their virulence after subculture.

**Economic Importance**

CBPP is considered as one of the two economically most important diseases of cattle (beside rinderpest) in Africa. Direct losses are from mortality, reduced milk yield, vaccination costs, and disease surveillance. The indirect costs associated with the chronic nature of the disease are more difficult to assess and include decreased weight gain or loss of body weight, impaired working ability, reduced fertility, losses resulting from quarantine, and losses related to restrictions of trade and cattle movement.

Annual losses attributed to mortality, decreased beef and milk production, and loss in draught power occurring in 12 endemically infected sub-Saharan African countries were estimated to be €30.1 million. Costs associated of managing and eradicating the disease after the CBPP outbreak of 1995 in Botswana were estimated at $98 million. The eradication campaign after the most recent European outbreak of CBPP in Portugal at the end last century, which required the slaughter of over 85,000 cattle was estimated to cost more than €200 million.

**PATHOGENESIS**

Even after more than 100 years since CBPP was discovered, the pathogenesis is not well understood. The disease is an acute lobar pneumonia and pleurisy. The organism invades the lungs of cattle and causes a mycoplasmaemia; this results in localization in numerous other sites including the kidneys, joints and brain, resulting in high morbidity and mortality. An essential part of the pathogenesis of the disease is thrombosis in the pulmonary vessels, probably before the development of pneumatic lesions. The mechanism of development of the thrombosis is not understood, but there is no general increase in blood coagulability and no generalized tendency to spontaneous thrombosis.
The production of hydrogen peroxide and other active oxygen species is widely believed to play an important role in mycoplasma pathogenicity, and it has been demonstrated to result in lysis of erythrocytes, the peroxidation of lipids in *M. mycoides* infected fibroblasts, and inhibition of ciliary movement in tracheal organ cultures infected with *M. mycoides* and *M. ovipneumoniae.* European *MmmSC* strains appear to be distinguished from other *M. mycoides* strains by their lack of glycerol phosphate oxidase activity and ability to oxidize glycerol.

Death results from anoxia and presumably from toxemia. Under natural conditions a proportion of animals in a group do not become infected, either because of natural immunity or because they are not exposed to a sufficiently large infective dose. These animals may show a transient positive reaction to the complement fixation test (CFT). Approximately 50% of the animals that do become infected go through a mild form of the disease and are often recognized as clinical cases.

**CLINICAL FINDINGS**

There is considerable variation in the severity of clinical disease from hyperacute to acute to chronic and subacute forms. With acute presentation, high disease incidence of nearly 90% and fatality rates of 50% and higher are observed. Acute disease is the common presentation in outbreaks occurring in previously unaffected regions. Mild or even subacute forms with low mortality rates are common presentation in zones where the disease in endemic. Approximately 25% of the infected cattle have been estimated to remain as recovered carriers with or without clinical signs.

**Acute Form**

After an incubation period of 3 to 6 weeks (in occasional instances up to 6 months), there is a sudden onset of high fever (40°C [105°F]), a drop in milk yield, anorexia, and cessation of rumination. There is severe respiratory distress on exercise. These sequestra may break down when the animal is exposed to environmental stress and may cause an acute attack of the disease. During the Italian outbreak of 1990, less than 5% of cattle in an infected herd had evidence of clinical disease. This was possibly a result of the use of antimicrobials and antiinflammatory agents, which may have masked clinical signs and facilitated the formation of chronic lesions. In Africa, up to one-third of acute cases that recover become potential carriers.

**Chronic and Subacute Forms**

Recovered animals may be clinically normal but in some an inactive sequestrum forms in the lung, with a necrotic center of sufficient size to produce a toxemia causing unthriftiness, a chronic cough, and mild respiratory distress on exercise. These sequestra may break down when the animal is exposed to environmental stress and may cause an acute attack of the disease. During the Italian outbreak of 1990, less than 5% of cattle in an infected herd had evidence of clinical disease. This was possibly a result of the use of antimicrobials and antiinflammatory agents, which may have masked clinical signs and facilitated the formation of chronic lesions. In Africa, up to one-third of acute cases that recover become potential carriers.

**CLINICAL PATHOLOGY**

**Culture and Nucleic Acid Recognition**

**Culture of the organism** is the reference method for detection of the pathogen. However, mycoplasmas are labile, making it necessary to use a special transport medium protecting this microorganism and preventing proliferation of other bacteria. Long-distance transport of samples, particularly when unrefrigerated drastically affects the viability of the bacteria rendering them unfit for culture. Frequently, attempts to isolate *MmmSC* fail because the organism is labile, is present in too little quantities, and is so demanding in its growth requirements. Negative results should therefore always be regarded as inconclusive.

In case of successful culture final identification of mycoplasmas is usually made by means of a biochemical test such growth inhibition, the fluorescent antibody test (FAT) or the immunofluorescence tests (IMF). Specific nucleic acid recognition using the polymerase chain reaction (PCR) has become common practice over the last two decades.

Although most PCR protocols rely on previous culture, preenrichment, or extraction of mycoplasma, PCR is also used without prior culture, directly using samples taken from nasal swabs, bronchoalveolar lavage or transtracheal wash fluid, pleural fluid, blood, urine, or pulmonary tissue. The PCR can identify the organism in bacterial isolates or clinical material within 2 days of extraction and is sensitive and highly specific. An inconvenience of the PCR results from its high sensitivity, which makes it susceptible to false-positive results caused by contamination.

More recently isothermal loop-mediated amplification (LAMP) of DNA sequences specific for *MmmSC* has been developed. The LAMP assay detects *MmmSC* DNA directly from crude samples of pulmonary or pleural fluid and serum or plasma within 1 hour using a simple dilution protocol.

**Immunologic Tests**

A number of immunologic test to identify the causative agent or its antigen in tissue, biological fluids, or cultures are available. Such tests include the indirect fluorescent antibody test (IFA) and the fluorescent antibody test (FAT), which both use hyperimmune rabbit serum against *MmmSC* and labeled antovbine IgG. The growth inhibition test (GIT) is based on direct inhibition of growth of *MmmSC* by a specific hyperimmune serum. Although this is a simple test to perform cross-reactions within the mycoides cluster are common. The antigen immunodiffusion test (AGID) has also been used to detect specific antigens present on the surface of *MmmSC*. The AGID is considered to lack sensitivity, and little is known about its specificity. Because all these tests depend on the presence of a minimum number of organisms, only positive results should be considered conclusive.

**Serologic Tests**

Serologic tests that identify an immune reaction of an individual animal to infection with *MmmSC* include the complement fixation test (CFT) and the competitive enzyme-linked immunosorbent assay (C-ELISA). Both are prescribed tests for international trade according the OIE. This group of diagnostic tests has important limitations because of the nature of the pathogenesis of the disease with its long incubation period and the relatively rapid decline of the antibody titer.

The complement fixation test (CFT) is rapid to perform and easy to interpret. With a sensitivity in the range of 70% to 80% and specificity of 98% it is best suited to diagnose clinically affected animals with acute lesions but less suitable to identify either animals in early stage of the disease, chronically infected or carrier animals with low antibody titers.

The therapeutic use of antimicrobials further increases the risk of a false-negative test results. Vaccinated animals give a positive reaction for about 6 weeks, although this period may be much longer if severe vaccination reactions occur. Because of the limited sensitivity the CFT is considered unreliable on an individual animal level, but it is deemed to be highly effective in detecting infected herds when testing the entire population. The test is widely used in to determine freedom of disease on a herd level. Because false positive results caused by serologic cross-reactions with other species of the mycoides cluster can occur, it is advisable to confirm a positive test result by postmortem and bacteriologic examination.
The C-ELISA has a similar or even greater specificity than the CFT.\textsuperscript{6,17,18} The sensitivity of the C-ELISA was found to be superior to the CFT particularly to detect animals in the chronic stage of the disease, whereas the CFT appears to outperform the C-ELISA in the detection of animals in the acute phase of the disease.\textsuperscript{17,18}

An indirect ELISA based on a recombinant protein, LppQ-NX (LppQ ELISA), has been developed and provides good sensitivity and specificity for the diagnosis of CBPP in naturally infected cattle in an postmortem inspection for the diagnosis of bodies to identify animals in the early stage of the disease, whereas the C-ELISA was the most sensitive test to detect animals in advanced stages of the disease. The LppQ ELISA had a very poor sensitivity (10.8%) to identify animals in the early stage of the disease, whereas in the chronic stage it had a sensitivity ranging above the CFT but below the C-ELISA.

The immunoblotting test (IB) is based on an immunoenzymatic reaction with higher sensitivity and specificity than the CFT. The IB is recommended as a confirmatory test on positive samples previously analyzed with another test because IB is not performed the C-ELISA in the detection of MmmSC, FAT, PCR, C-ELISA).

No single serologic test is capable of detecting all CBPP affected animals in the field. These tests are most useful for diagnosis at the herd level. In the absence of a "gold standard" test for the serologic diagnosis of CBPP, some uncertainties remain unresolved. Suspicious CBPP cases identified by positive serology must be confirmed by further investigations that demonstrate the presence of antigen in the respiratory tissues of animals.

Necropsy Findings
Lesions are confined to the thoracic cavity and lungs, and the lesions are usually unilateral. The pleural cavity may contain large quantities of clear, yellowish-brown fluid with pieces of fibrin. This fluid is ideal for culture of the organism. Caseous fibrinous deposits are present on the parietal and visceral surfaces of the pleura. The interlobular septae are prominently distended with amber-colored fluid surrounding distended lymphatics. This fluid distinctly outlines the lobules, which vary in color, with red, gray, or yellow hepatization. Consolidation of the lungs with a typically marbled appearance is characteristic. In chronic or advanced cases, a sequestrum of necrotic lung varying size from 1 to 10 cm in diameter is surrounded by a fibrous capsule. If these sequestrae rupture and are drained by a bronchus, they can be a source of aerosol infection to cattle. Such a mechanism may contribute to epidemics in closed herds. In affected calves, exudative periostitis, arthritis, bursitis, and fibrous arthritis of carpal and tarsal joints may be present.

Histologically, in the early stages the typical lesion consists of bronchiolar necrosis and edema, progressing to exudative serofibrinous bronchiolitis with extension to the alveoli and adjacent lymphatics. This process extends to the tracheobronchial lymph nodes and pleural lymphatics. The interstitial infiltrates. Immunohistochemically, the MmmSC antigen is present in several renal structures. Samples for Confirmation of Diagnosis

- **Histology**—formalin-fixed lung (LM, IHC)
- **Mycoplasmosis**—effusion fluid in serum tube, lung, bronchial lymph node (MCULT, FAT, PCR, C-ELISA)

Differential Diagnosis
A diagnosis based on a history of contact with infected animals, clinical findings, a complement fixation test, necropsy findings, and cultural examination is necessary.

Diseases that must be differentiated from CBPP include the following:

- **Rinderpest**—Erosive stomatitis, dysentery, and erosions throughout the alimentary tract.
- **Foot and mouth disease**—Salivation, lameness, fever, and vesicular stomatitis.
- **Hemorrhagic septicemia**—Acute disease with death in 6 to 72 hours. Edema of the neck and brisket, lung lesions similar to CBPP. Culture of Pasteurella spp.
- **Theileriosis (East Coast fever)**—Coughing, nasal and ocular discharge, diarrhea, enlargement of peripheral lymph nodes, ulceration of abomasum. No lung lesions.
- **Ephemereral fever**—Ocular discharge, drooling saliva, lameness, enlarged joints, self-limiting disease of short duration; most affected cattle recover quickly; fluctuating fever; secondary pneumonia may occur.
- **Pulmonary abscesses**—Large abscesses containing foul-smelling purulent material; may have total destruction of lung.
- **Tuberculosis**—Tubercular nodules may resemble CBPP sequestra, but they are degenerative cheese-like lesions, often calcified.
- **Farcy**—Abscesses of lungs containing foul-smelling material and enlarged local lymph nodes.
- **Actinobacillosis**—Generalized lesions of lung and other adjacent tissues.
- **Echinococcal (hydatid cysts)**—Pulmonary cysts with a double wall and containing clear fluid, often calcified when old.

Treatment
Official conventional wisdom in the past held that treatment of clinical cases of CBPP with antimicrobials is counterproductive to contain the disease because it gives rise to persistent infection and may produce symptomless carrier animals.\textsuperscript{1,19} Accordingly, the use of antimicrobials is legally banned in many endemically affected countries. Nevertheless, the use of antimicrobials in affected regions is widespread, mainly because, with limited availability of vaccines, it is considered the only available and effective treatment and control measure.\textsuperscript{1,19} In recent years the popularity of antibiotic treatment and the perception of positive results led to some research activity suggesting that antimicrobial use may be of value primarily to control disease transmission.\textsuperscript{1,19} Despite the perception of veterinarians and farmers that antibiotics can alleviate the clinical course of the disease, enabling some
improvement in condition, field studies suggest that antimicrobial therapy had little to no effect on severity of signs, course of the disease, and mortality rate in clinically affected animals. Treatment failures in clinically affected animals may be attributable to inadequate dosage or duration of treatment and to the chronic nature of the condition. Treatment success of antimicrobial therapy to treat mycoplasma infection greatly depends on a timely initiation of the treatment, but clinically affected animals in endemic areas frequently are in an advanced or even chronic stage of disease and thus are unlikely to show strong treatment response. Because of the generally poor treatment response and because these animals present a source of infection for herdmates, clinically affected animals should rather be culled than treated.

In contrast the treatment of in-contact animals appeared to considerably reduce disease transmission, which resulted in a marked decrease in the disease occurrence, morbidity, and mortality rates in affected herds. An increasing body of evidence suggests that use of antimicrobials, primarily as a part of a disease control program, should be reconsidered.

The major classes of antimicrobials that are effective against mycoplasmas are tetracyclines, macrolides, florfenicol, and fluoroquinolones. A number of in vitro and in vivo studies have been published in recent years with results supporting the use of fluoroquinolones, several different macrolides, and tetracyclines to reduce the shedding of MmSC. Beta-lactam antibiotics and sulfonamides are inherently ineffective against the Mycoplasmas that do not have a cell wall and do not synthesize folic acid. Although there are examples of successful eradication of CBPP on the continent, efforts to contain the disease keep failing in many sub-Saharan countries, which lead to a reemergence of the disease in the region over the past decades and regular recurrent outbreaks in countries where the disease has previously been eradicated.

### CONTROL

There are four essential tools in CBPP control and eradication: livestock movement control, stamping out, vaccination, and treatment.

- **Slaughter of all sick and in-contact cattle.** This requires full cooperation of cattle owners and an adequate and timely compensation system. This strategy is impractical in developing countries with a pastoral economy.
- **Slaughter of all sick cattle and vaccination of in-contact cattle.** This strategy is used frequently and usually perpetuates the disease.
- **Vaccination of healthy cattle with slaughter of sick cattle in an epidemic and revaccination of cattle at risk.** This method depends on the ability of the authorities to detect epidemics rapidly, most effectively, by abattoir surveillance and to maintain vaccination for at least 3 years. Vaccination in endemic areas must be done annually, whereas newly infected areas require repeat vaccinations aimed at eradication of the disease.

Although the combination of movement control, quarantine, and culling of infected animals, when strictly enforced, can successfully eradicate CBPP, as is documented by numerous examples of the past centuries, this approach requires a financial and logistic effort that is beyond the means of many endemically infected countries in Africa. In these countries social and civil disturbances interfere with effective disease control. Farmers fleeing civil unrest may move their cattle to endemic areas and then return with them when the threat is over, making strict livestock movement control logistically and politically unenforceable. Culling of infected and in-contact animals requires a system of financial reimbursement for farmers that is far beyond the financial resources of many affected countries.

In view of the epidemiologic situation of CBPP and the socioeconomic structure of many African countries, control of the condition is largely based on vaccination in Africa, whereas treatment of affected animals—although widely practiced—is legally prohibited in many countries.

*The use of antimicrobials is legally prohibited in many countries affected by CBPP.
a stand-alone screening procedure but may be used in the framework of epidemiologic investigations. Serologic surveillance results should primarily be interpreted at a herd level, and positive results should be confirmed by clinical or pathologic examination and identification of the specific pathogen. Because animals in the incubation phase and early stages of the disease may test negative, it is necessary to have two negative tests 2 months apart. After vaccination a positive reaction occurs; this usually disappears within 2 months but may persist for 5 months.

Vaccination
Vaccination against CBPP has been used in countries where rigorous cattle movement control, quarantine, and stamping out cannot be implemented, as is the case in many African countries that cannot afford the prohibitive costs of culling entire infected herds. Although CBPP vaccination is doomed to fail when used as stand-alone strategy to control CPBB, a systematic vaccination strategy in combination with intense surveillance and removal of infected animals can contribute to the containment of the disease and reduction of the infection prevalence to the point where vaccination can be discontinued and remaining infected animals can be culled to achieve complete eradication of the disease.15 Extensive vaccination in Australia reduced the incidence of the disease to an extremely low level, and complete eradication of the disease was achieved shortly afterward. Vaccine application is usually controlled by local legislation.

All effective CBPP vaccines have been based upon live versions of the disease-causing MmmSC, either attenuated or not. Currently the only vaccines in use are live vaccine derived from the T1 strain (T1/44 and T1SR) of live attenuated Mycoplasma mycoides subsp. mycoides SC and attenuated through repeated passage in embryonated eggs before production in artificial growth media.26 Unfortunately these vaccines are characterized by poor and variable efficacy, with only between 30% and 60% of vaccinated animals being protected. In some situations, the T1/44 vaccine induces a good immunity, especially when herds are revaccinated annually, in which case the level of protection exceeds 85%. Induced immunity is short lived, particularly for the T1SR strain, requiring revaccination at least on a yearly basis. Either systemic or local adverse reactions are common, particularly for the T1/44 strain. Within 2 to 4 weeks following injection, an invading edema develops known as the “Willems” reaction. The incidence of these reactions varies from area to another. The reversion to virulence of the T1/44 vaccine has also been observed when it was serially passaged by endobronchial intubation resulting in the development of lesions of CBPP in animals that were infectious to in-contact animals. This suggests that animals given the currently used vaccines (T1/44 and T1SR) subcutaneously could be “reactors” for MmmSC and infect other animals in areas previously free of CBPP.

The value of calfhood vaccination is limited because arthritis, myocarditis, and valvular endocarditis occur 3 to 4 weeks after vaccination of calves less than 2 months old. Vaccination of calves after this age is recommended because it avoids the occasional deaths which occur after vaccination of adults. Historically, pleural exudate from natural cases (natural lymph) was used in an attempt to immunize cattle at risk. Vaccination was carried out by injection into the tough connective tissue at the tip of the tail with a high-pressure syringe. “Natural lymph vaccination” caused severe reactions with sloughing of the tail and extensive cellulitis of the hindquarters, necessitating destruction or causing death of the animal in many instances. Draining infected injection sites may have contributed to the spreading of this disease and others.

Inactivated CBPP vaccines have been field tested but results have been inconclusive. Immunostimulating complex (ISCOM) protein subunit vaccines have been developed, and early results are encouraging. The capsular polysaccharide (CPS) of MmmSC is an important surface antigen and pathogenicity factor previously known as a galactan. The immune response in mice of capsular polysaccharide conjugate vaccines against CBPP indicates that protection against MmmSC mycoplasmaemia in mice is cell-mediated rather than humoral immunity.

Antimicrobial Use
As mentioned previously the use of antimicrobials for treatment and control of CBPP is banned in many countries affected by the disease because it is considered to be counterproductive for the control and eradication of the disease because it may result in subclinically infected animals carrying and possibly shedding the pathogen for prolonged period of time. Despite the ban, the use of antimicrobials is widespread mainly because vaccine coverage vaccine efficacy is limited.24,25 Recent field trials and epidemiologic studies provided evidence corroborating the empirical observation that the use of antimicrobials in infected herds is able to contain disease transmission.15,23 Using a homogeneous model based on publically available data, one study concluded that the potential impact of reducing the infectious period by the use of antimicrobials on disease persistence and mortality was in the same range as the impact of currently available vaccines.25 In single isolated herds of 500 head of cattle, a 50% reduction in length of the infectious period caused the fade-out of the disease in essentially 100% of herds, a 60% decline in the number of cases, and a 73% decline in mortality.26 Accordingly a significant decline in mortality, seropositivity, frequency of morbid lesions, and severity of clinical scores was observed in herds where all incontact animals received a treatment with danofloxacin at a dose of 2.5 mg/kg on 3 consecutive days compared with untreated herds.21 This mounting body of evidence warrants the reconsideration of the use of antimicrobials in an CBPP eradication or control program.

Disease Control on an Area Basis
The prevention of entry of infected animals into a free area is a difficult task. Only the following classes of cattle should be permitted to enter:

1. Cattle that have neither been in an infected area nor in contact with infected animals for at least 6 months. This may be relaxed to permit entry of cattle going to immediate slaughter after a clinical examination and a period of 1 month in a free area.
2. Cattle that have given negative reactions to the CFT or C-ELISA on two occasions within the preceding 2 months and have not been in contact with infected animals during this period. Less rigid measures than these will permit introduction of the disease.

When the disease is already present in an area, two methods of control are possible: vaccination and eradication by test and slaughter of reactors. The method chosen will depend largely on the economy of the cattle industry in the affected area. A vaccination program may be the first step to reduce the incidence of the disease to the point where eradication becomes possible.

In areas where farms are large, fencing is poor, and the collection of every animal cannot be guaranteed, eradication of the disease by test and slaughter is impractical. Vaccination can be practiced whenever the cattle are brought together. Animals moving out of or into infected areas and groups of cattle that contain active cases must be vaccinated. Moving cattle that develop the disease should be halted, clinical cases slaughtered, and the remainder vaccinated. Results are usually good provided the vaccination is carried out carefully, but some further cases as a result of prevaccination infection are to be expected.

When outbreaks occur in small areas where herds can be adequately controlled, complete eradication should be attempted by periodic testing and the destruction of reactors, and in-contact animals should be vaccinated. To avoid unnecessary contact between cattle, retesting is delayed until 5 to 6 months after the first test when vaccination reactions have usually subsided. Under most circumstances all nonreactors should be
vaccinated. This practice is particularly applicable in feeder cattle that will be slaughtered subsequently and when extensive outbreaks occur in closely settled areas where the chances of spread are great. Simple test and slaughter in these latter circumstances will be too slow to control the rate of spread. In either case the herd should not be released from quarantine until two tests at an interval of more than 2 months are completely negative.

World Organization for Animal Health (OIE)—CBPP Status for Countries or Regions

CBPP is a so-called “List A” disease, making it a notifiable disease to the OIE. To qualify as a CBPP-free country or zone according to the rules of the OIE the country must fulfill the following requirements:

- Have a record of regular and prompt animal disease reporting
- Submission of a declaration to the OIE on a yearly basis stating the following:
  - There has been no outbreak of CBPP during the past 24 months.
  - No evidence of CBPP infection has been found during the past 24 months.
  - No vaccination has been carried out during the past 24 months.

This declaration has to be supported by evidence documenting that a surveillance program is in operation and that regulatory measures for the prevention and control of CBPP have been implemented.1 In case a country loses the status as CBPP-free because of an outbreak, one of the following waiting periods applies:

- 12 months after the last case, where a stamping-out policy combined with serologic surveillance and strict movement control is enforced.
- 12 months after slaughter of the last vaccinated animal, where vaccination was used.

As of May 2015 the following countries are recognized by the OIE as CBPP-free: Argentina, Australia, Botswana, Canada, China, France, India, Portugal, Singapore, Switzerland, and the United States.2

In Europe, legislation exists to prevent the spread of CBPP. Any outbreak in a previously CBPP-free country must be reported to the European Commission within 24 hours of confirmation of the disease; the Commission will then inform other member states. Unaffected regions may export only to other member states if cattle come from herds in which all animals over 12 months of age have been serologically negative in the previous 12 months. All animals for export must have been serologically tested negative 30 days before being loaded. Cattle from restricted areas must not be exported to other member states until all herds in the area have passed three clear herd tests on all animals over 12 months of age at intervals greater than 3 weeks apart.

Mycoplasma bovis

PNEUMONIA, POLYARTHRITIS, MASTITIS, AND RELATED DISEASES OF CATTLE

SYNOPSIS

Etiology M. bovis

Epidemiology Occurs in dairy and beef cattle of all ages. Pneumonia, otitis, and polyarthritis primarily seen in feedlot cattle and dairy calves; mycoplasmal mastitis in dairy cows.

Clinical findings Unresponsive pneumonia, polyarthritis, otitis media/interna, mastitis in dairy herds.

Diagnostic confirmation Culture or detection of antigen or bacterial DNA from respiratory secretions, joint fluid, milk.

Treatment Antimicrobial therapy, often with poor treatment outcome.

Control Biosecurity and biocontainment procedures. Prevent entry of infected animals into herds. Purchase animals free of mycoplasma. Pasteurization of milk of cows with mycoplasma mastitis before feeding to calves. Metaphylactic antimicrobial therapy might be justified in herds with high morbidity and mortality rates. Vaccines have been unsuccessful.

ETIOLOGY

Mycoplasma spp. belong to the class of Mollicutes, a group of bacteria enveloped by a complex plasma membrane but lacking a cell wall. They are characterized by their small size, their tiny genome, and their intimate association with host cells that is essential for their survival. Mycoplasmas typically inhabit mucous membranes, including those of the respiratory tract, urogenital tract, the mammary gland, or the conjunctiva.1 M. bovis is a major cause of disease of cattle causing pneumonia, otitis media, arthritis, tenosynovitis, keratoconjunctivitis, mastitis, meningoitis, and reproductive disorders, including abortion.2 It is the etiologic agent of the so-called chronic pneumonia and polyarthritis syndrome (CPPS) of feedlot cattle that has been recognized in the United States and Canada.

Mycoplasma bovis is highly adapted to cattle but has occasionally been isolated from small ruminants, buffaloes, and, in rare instances, even from humans with bronchopneumonia.

EPIDEMIOLOGY

Occurrence M. bovis that was first isolated in 1961 from cow with mastitis in the Unites States, has spread to many countries of the world via animal movements and is now recognized as a worldwide pathogen of intensively farmed cattle.1 Of 1600 isolates of Mycoplasma species recovered from ruminant animals in...
Mycoplasma bovis and Mycoplasma californicum have been described in a mixed dairy cattle and beef cattle herd kept under extremely poor housing and hygienic conditions.

Mycoplasma arthritis of cattle has been reported in a number of countries including Canada, the United States, several European countries and the United Kingdom. Commonly, arthritis occurs in association with respiratory disease or otitis media in calves, or mastitis in adult cattle, and it is proposed that the pneumonia precedes the development of the arthritis. Calves suckling cows with experimental mastitis attributable to this organism may develop mycoplasmal arthritis, and a high incidence is recorded in calves in dairy herds where mycoplasmal mastitis was occurring. In Ireland, infection has occurred in housed adult dairy cattle, without any evidence of pneumonia, producing severe polyarthritis with a clinical incidence in 12 farms that varied from 2% to 66%.

Otitis media/interna has been described in preweaned Holstein dairy calves in dairy herds that have expanded in size. Affected calves were 2 to 5 weeks of age, morbidity was 3% to 10%, and case-fatality rates estimated at 50%. In a retrospective study in calves submitted for necropsy in California, affected calves were 2 weeks to 4 months of age, 92% were from dairy herds, and most cases occurred during late winter and spring. M. bovis, M. bovirhinis, and M. alkalectos were isolated from the ears of affected calves. Outbreaks of suppurrative otitis media and pneumonia associated with M. bovis have been described in calves on a dairy farm in the United Kingdom with a disease incidence of 20%. Outbreaks in beef cattle farms in Japan with morbidity and mortality rates of 8% to 40% and 30% to 100%, respectively have also been reported.

Mycoplasma bovis has been recognized as a pathogen of the bovine mammary gland (see also "Mastitis Caused by Mycoplasma spp.") that is widespread within the dairy cattle population in the United States. A national survey conducted in 2002 in the United States determined a prevalence of mycoplasma culture positive bulk tank milk samples of 7.9%, of which 86% were identified as M. bovis. In contrast the herd prevalence of M. bovis in Canadian dairy herds was estimated to be 1.7%, 1.5% in Belgium, and 0.56% in Japan. M. bovis was not detected in recent survey in dairy herds in New Zealand.

Economic Importance

M. bovis has been associated with respiratory disease in calves and mastitis in dairy cows, that both have a considerable prevalence at least in some parts of the world. Costs related to infection with mycoplasma include expenses for treatment and diagnosis, death and culling losses and implementation of control measures. The chronicity and poor treatment response of most diseases associated with M. bovis contribute considerably to these expenses. The costs to the U.S. beef industry were estimated with approximately $32 million per year as result of decreased weight gain and lost carcass value. Mycoplasma mastitis was estimated to cost the U.S. dairy industry approximately $108 million per year.

Risk Factors

Pathogen Risk Factors

The virulence factors of M. bovis and mechanisms of pathogenicity are not well understood, but the organism’s ability to vary the expression of variable surface proteins (VSPs), a family of lipoproteins on the bacterial surface with high frequency is currently being investigated. The organism has 13 VSP genes involved in antigenic variation that alter the antigenic character of its surface components and may act to enhance colonisation and/or adherence to host cells or to evade the host’s immune defense systems. These VSP proteins and some unrelated proteins such as pMB67 and P48 are the primary antigenic targets of the host’s antibody response, which, however, does not appear to be protective.

M. bovis can induce apoptosis of lymphocytes, and a C-terminal fragment of VSP-L is able to impair the lymphocyte proliferative response to mitogens. The bacterium can furthermore adhere to neutrophils and block the oxidative burst in these cells. Several strains of M. bovis produce biofilm, protecting the organism from heat and desiccation and possibly playing a role in evading the host’s immune response and in resistance to antimicrobial therapy in vivo. M. bovis produces hydrogen peroxide in quantities that vary between strains. Peroxide production can result in oxidative injury to host tissues. The organism is also able to penetrate through lung epithelial junctions and cause systemic infections. There is some evidence of variability of M. bovis strains to cause arthritis.

Animal Risk Factors

The immune status of the individual animal is important in determining the susceptibility to respiratory disease, particularly in young ruminants. An association between failure of transfer of passive immunity and the risk and severity of respiratory disease in young calves is well established. It is however not clear whether maternal antibodies against M. bovis have a protective effect in calves. An association between M. bovis specific serum antibody titers in the first weeks of life and the risk of developing respiratory tract disease could thus far not be established.

Age appears to influence the susceptibility at least to some forms of M. bovis infection. Otitis media is most commonly observed in calves 2 to 6 weeks of age and is uncommon in older calves. Age-related susceptibility is also observed in other species.
Although a genetic effect on the susceptibility to mycoplasma infection in cattle has not been confirmed, the genetic background is considered an important determinant of resistance to mycoplasmal respiratory disease in nonruminants.1

Environmental Risk Factors
With direct animal contact being the main route of infection, introducing infected animals into a herd with no or low M. bovis infection prevalence presents a major risk for disease transmission. Similarly, high infection prevalence within the herd or mingling calves from different origins presents a high risk of infection for young calves. Feeding colostrum or waste milk of cows with clinical or subclinical M. bovis mastitis was shown to result in colonization of the upper respiratory tract with this pathogen and was associated with increased occurrence rates of mycoplasmal otitis.1

Specific and nonspecific immune response that is a critical determinant of the susceptibility to respiratory tract infection can be compromised by a number of environmental factors, such as heat or cold stress, overcrowding, poor ventilation, transportation, inadequate nutrition, or stress related to processing procedures.

Concomitant infection of the respiratory tract with other viral or bacterial pathogens may compromise the nonspecific immune response. M. bovis infection may predispose to superinfection of the respiratory tract with other bacterial pathogens, and previous infection of the respiratory tract with other pathogens may facilitate to progression of M. bovis into the lower respiratory tract. Experimental infection studies have confirmed a synergistic effect of M. bovis with other common pathogens of the respiratory tract, such as M. haemolytica or P. multocida.1

Environmental temperatures have been found to affect the degree of nasal shedding and the incidence rate of clinical disease. Sudden drops of the environmental temperature were associated with increased rates of nasal shedding of M. bovis and higher occurrence rates of respiratory disease caused by M. bovis.1

Methods of Transmission
Direct transmission of M. bovis from infected to uninfected animals is considered the primary route of disease transmission, an assumption that is corroborated by epidemiologic evidence indicating that the seroprevalence in feedlot cattle increases dramatically in the first weeks in the feedlot. Clinically normal cattle in infected herds harbor M. bovis in the upper respiratory tract with no apparent adverse effect and may shed the organism through the nasal discharge for months to years.3 M. bovis might be transmitted with respiratory secretions, via aerosols, direct nose-to-nose contact, or fomites. Although mycoplasmas in general do not easily survive in the environment, M. bovis can survive for prolonged periods outside the host, particularly in cool and humid conditions. Nonetheless the role of fomites and environmental contamination deserves further investigation but, with exception of the transmission of mycoplasma mastitis, is currently considered to be of limited epidemiologic relevance.

Oral ingestion of M. bovis contaminated milk or colostrum results in colonization of the oral cavity and upper respiratory tract with this pathogen and increased occurrence of otitis media.2 Feeding colostrum or milk of cows shedding M. bovis through the mammary gland must therefore be considered as an effective route of disease transmission.

Intrauterine infection of calves appears to occur infrequently. Transmission of mycoplasma mastitis is considered to primarily occur in the milking parlor through contaminated milk.

PATHOGENESIS
As with many mycoplasmas, M. bovis is both immune reactive and immunosuppressive. Upon incubation with M. bovis, alveolar macrophages are activated and produce TNF-alpha and nitric oxide, two powerful initiators of immune activity. M. bovis is also immunosuppressive by inhibiting neutrophil degranulation and oxidative bursts and proliferation of lymphocytes by mitogens. M. bovis also induces bovine lymphocyte apoptosis through the production of a protein that is different from other mycoplasmas both pathogenic and nonpathogenic. The protein is an immuno-inhibitory peptide that can suppress Concavalin A (ConA)–induced proliferation of bovine lymphocytes. This represents a unique immunosuppressive peptide produced by the M. bovis.

Despite its deleterious effects on lymphocytes, infected cattle are able to generate measurable humoral and cellular immune responses against M. bovis. Serologic analysis indicates that M. bovis stimulates increased production of antigen-specific IgG1, whereas very little IgG2 is produced. There is a systemic phase of M. bovis infection, including a potential interaction of the pathogen with endothelial cells. It is one of the most invasive bovine mycoplasmas capable of invading through lung epithelial junctions and causing systemic infections such as arthritis and mastitis following pneumonia. Localized lung vasculitis and the presence of thrombi within subsynovial vessels has been observed, both suggestive of interaction of M. bovis with epithelial cells.

Arthritis is normally regarded as a sequel to pneumonia or mastitis and infection in the respiratory tract or in the mammary gland is believed to lead to bacteremia and localization in joints. However, arthritis can suddenly occur in regions or countries where mycoplasmal pneumonia has been recognized for many years, suggesting that a new strain with different virulence or tropism has been introduced. The intraarticular injection of M. bovis into calves causes severe fibrinopurpurative synovitis and tenosynovitis, erosion of cartilage, and its replacement by polypoid granulation tissue. Erosion of the cartilage is accompanied by chronic osteomyelitis and formation of pannus tissue. Histologically, there is extensive ulceration of synovial membranes of leukocytic infiltration of the subsynovium, congestion, hyperemia, and thrombosis of the subsynovial vessels. Intratracheal inoculation of the organism results in pneumonia and severe lameness, which suggests that M. bovis is involved in pneumonia–arthritis syndrome.

In otitis media/interna of calves there is facial nerve paralysis because of proximity of CN VII to the tympanic cavity. Although hematogenous spreading of the pathogen to the middle and inner ear is considered a possible route of infection of this organ, an ascending infection from the oral cavity through the Eustachian tubes to the middle ear, resulting in clinical otitis media could be experimentally induced by feeding milk replacer contaminated with M. bovis.1,12 Varying degrees of peripheral vestibulocochlear dysfunction occur because of the involvement of the vestibulocochlear receptors and nerve. The spontaneous regurgitation and dysphagia may be associated with lesions involving the glossopharyngeal nerve (CN IX) with or without the vagus nerve (CN X). These nerves may be affected by the inflammation associated with meningitis because both CN IX and CN X travel through the jugular foramen.

CLINICAL FINDINGS
Pneumonia and polyarthritis associated with M. bovis may occur alone or together in cattle of all ages, including dairy and beef calves in their original herds, in growing dairy and beef cattle heifers, and in mature dairy and beef cows.

Chronic Pneumonia and Polyarthritis Syndrome
The disease is most common in feedlot calves within a few weeks after arrival in the feedlot. The morbidity rate may be up to 25%. Affected calves commonly have had a history of respiratory disease with poor to no treatment response to antimicrobial therapy. Auscultation of the lungs reveals areas of loud bronchial tones, crackles and wheezes, and areas of muffled lung sounds indicating consolidation and occlusion of the bronchi with exudate. Depression, inactivity, inappetence, coughing, nasal discharge, fever, and progressive weight loss are common.

Arthritis
Although mycoplasmal arthritis is most commonly seen concurrent with
pneumonia, cattle of any age can be affected. Cases tend to occur sporadically, but outbreaks have been reported in calves and adult cows and as part of CPPS in feedlot cattle. There is stiffness of gait, acute, non-weight-bearing lameness, inappetence, moderate fever, and progressive loss of weight. Swelling of the large movable limb joints and distension of tendon sheaths, associated with fibrinous synovitis and synovial fluid effusions, are characteristic. Both forelimbs and hindlimbs can be affected, and involvement of the carpal joints, the fetlocks and the proximal and distal interphalangeal joints commonly can be clinically detected. In calves, pneumonia is a common finding in the affected group. Some affected cattle spend considerable time in recumbency, lose weight, and develop decubitus ulcers, and they must be destroyed. Mildly affected cases recover spontaneously over a period of several weeks, but severe cases become progressively worse, may develop discharging sinuses over affected joints, and must be culled.

**Otitis Media/Interna**

Otitis media/interna occurs in young beef and dairy calves as enzootic disease or as outbreaks. Feedlot calves are sporadically affected. Clinical findings depend on the extent of the inflammation, which can involve only the middle ear or middle and inner ear. Varying degrees of depression, coughing, nasal discharge, inappetence, and fever are common in affected groups of calves. Head shaking, scratching, or rubbing of the ear are signs of ear pain. Otitis externa that is characterized by purulent exudate in the external ear may occur as a result of a ruptured tympanic membrane. A unilateral head tilt and paralysis of the lip, eyelid, and ear muscles on the same side are common. When the eye on the affected side is threatened, the eyeball may retract, but there is no palpebral fissure closure. An intermittent loss of balance on the affected side may be apparent when the animal attempts to walk. Bilateral peripheral CN VII and VIII deficits (bilateral ear, lip, and eyelid paralyses; bilaterally absent menace and palpebral reflexes; normal gait; balance loss to either side) are suggestive of bilateral otitis media/interna. Dysphagia, spontaneous regurgitation of milk and difficulty in sucking from a bottle or prehending feed may occur. Partially chewed feed may accumulate in the oral cavity, along with difficulty prehension and mastication. Bilateral vestibular disease (balance loss to either side) may occur. Endoscopy of the pharynx may reveal collapse of the nasopharynx, dorsal displacement of the soft palate, and a widely dilated, hypomotile esophagus. Opisthotonus and nystagmus are common, and ataxia, recumbency, and death in several days may occur. The mortality rate is about 50%.

**CLINICAL PATHOLOGY**

Clinical and pathologic signs are not characteristic for *M. bovis* infection, so laboratory diagnosis is necessary for identification. The organism can be detected by culture, identification of specific bacterial DNA by polymerase chain reaction (PCR), or identification of specific bacterial antigen, for example, with a sandwich-ELISA or immunohistochemistry.

**Culture**

Culture methods for the detection of *M. bovis* are typically used on lung tissue, nasal swabs, bronchoalveolar lavage (BAL), or transtracheal wash (TTW) fluid and synovial fluid. Culture methods have the advantage that they can isolate multiple mycoplasma species at the same time and may reveal novel or unexpected species. Nonetheless culture methods require complex growth media, special equipment, and technical skills. They are time consuming, laborious, difficult, and expensive. The sensitivity of mycoplasma culture in clinical material is rather low for several reasons. Infected animals may shed the pathogen intermittently and the distribution within affected tissue is uneven. Poor handling of samples and long shipping times will affect the viability of this labile microorganism. Cultures may also fail in cases sampled animals were previously treated with antimicrobials or samples are contaminated with other pathogens, as is commonly the case with samples collected from the respiratory tract. Although mycoplasma colonies can be identified by their characteristic morphology, they cannot readily be differentiated from each other, making speciation by immunologic methods or PCR necessary.

**DNA Probe and Polymerase Chain Reaction**

Molecular tests to detect bacterial DNA of *M. bovis* have been developed in recent decades and have been widely adopted for clinical diagnostic *M. bovis* infection. The main advantages of these methods are lower costs per sample, a considerably shortened turnaround time, and the compatibility with molecular testing for other pathogens. Because this method does not require the presence of living organisms, it is suitable to be used on previously stored samples. Immunohistochemistry

Immunohistochemical (IHC) techniques can be used to detect the antigen of *M. bovis* in the tissues of cattle. IHC can be performed using formalin-fixed and paraffin-embedded tissue. Histology and immunohistochemistry can be used to analyze the lesions and distribution of the *M. bovis* antigen in the lungs of cattle with pneumonia and can be performed retrospectively.

**Enzyme-Linked Immunosorbent Assay**

A monoclonal antibody-based sandwich ELISA (sELISA) for the detection of *M. bovis* in clinical material has been developed in Europe. The sensitivity of this ELISA is similar to that of conventional culture but can be improved when samples are incubated for a short period before antigen capture.

**Serology**

Because *M. bovis* infection induces a robust humoral response, several methods of detecting antibodies against *M. bovis* have been developed. Available tests that can be used on serum and other body fluids such as milk or synovia include the passive or indirect hemagglutination (HA) test, the indirect ELISA, and the film inhibition test. A variety of ELISA test kits are now commercially available.

Antibodies against *M. bovis* are detectable with the ELISA as early as 6 to 10 days post experimental inoculation. Notwithstanding correlation between antibody titers and clinical disease was found to be poor, and seroconversion in feedlot cattle is observed in healthy and sick calves alike, suggesting that paired serum samples may not be a good predictor of *M. bovis* respiratory disease. Furthermore, serum antibody titers can remain elevated for months to years after an infection, meaning that a high titer may not necessarily be consistent with ongoing or recent infection. Maternal antibodies may result in high antibody titers in young calves, but with a half-life of 12 to 16 days normally wane within the first months of life.

Serology is currently considered to be of limited diagnostic value on an individual animal level but is useful on a herd level to screen a group of animals.

**Sample Collection and Handling**

The choice of the specimen submitted for mycoplasma diagnostics and handling of the sample can have a great impact on the final test result and its validity. A number of ante-mortem diagnostic procedures are available for the diagnosis of respiratory disease that vary in their practicality, their suitability to detect a specific pathogen, the rapidity with which test results are available, their economy, the level of stress for the patient, the quality of the material obtained, and the interpretability of the results. Nasal, nasopharyngeal or conjunctival swabs, bronchioalveolar lavage (BAL), and transtracheal washes (TTW) are the most commonly used procedures to detect *M. bovis* in living animals. Nasal/nasopharyngeal swabs are frequently used under field conditions because this procedure is technically less demanding and less invasive than a TTW or BAL. Although presence of *M. bovis* on swab material is useful to confirm the presence of
the pathogen in a herd, the diagnostic value on an individual animal level is limited because of the high occurrence of upper respiratory tract infection with *M. bovis* in clinically healthy cattle of infected herds. Comparison of paired culture results from nasopharyngeal swabs and BAL samples in cattle with respiratory disease indicate that the correlation between the presence of *M. bovis* in the upper respiratory tract and its presence in the lower respiratory tract or clinical disease is poor. In contrast, excellent agreement between paired BAL fluid samples and corresponding tissue cultures obtained during necropsy have been reported, suggesting that samples collected from the lower respiratory tract such as BAL or TTW fluid are better suited to make a diagnosis on an individual animal.

When using swabs, wooden cotton swabs should be avoided because they can inhibit growth of mycoplasma. The tip of the swab should be inserted approximately to the height of the medial canthus of the eye and must be firmly rotated against the mucosa to harvest many cells to which mycoplasmas are adhered. Swabs should then be stored in aerobic bacterial or mycoplasma transport media. Samples submitted for culture must either be kept refrigerated when shipping time does not exceed 24 hours or otherwise frozen. Because prolonged frozen storage significantly decreases the isolation of *M. bovis*, storage time should not exceed 7 to 10 days.

Tissue samples can be formalin-fixed when used for histology and IHC or must be placed on ice and transported to the diagnostic laboratory immediately for culture.

**NECROPSY FINDINGS**

At necropsy, the characteristic lung lesion of *M. bovis* is a case necrotic bronchopneumonia comprising raised, white, sharply demarcated, friable foci of caseous necrosis within consolidated areas mostly in the cranioventral lung lobes. The necrotic foci often range from 1 to 10 mm in size but can coalesce and grow up to 5 cm in diameter. Larger foci are frequently surrounded by pale firm connective tissue. Between 10% and 50% of total lung surface may be consolidated. When the lung is squeezed, the necrotic material falls out as a single or multiple pieces, and sequestra may be seen.

Microscopically, the specific lesions are areas of coagulative to caseous necrosis originating mostly from bronchioles and bronchi. Well-developed foci of necrosis contain an eosinophilic coagulum at the center surrounded by accumulations of mostly degenerate neutrophils, macrophages and an outer zone of plasma cells, lymphocytes, and degenerate bronchiolar/bronchial epithelial cells. Adjacent lung tissue shows typical suppurative bronchopneumonia and atelectasis. Within the necrotic lesions, and especially in the inflammatory cells at the margin, *M. bovis* antigen or DNA can be detected by immunohistochemistry or molecular techniques respectively.

**Fibrinous polysynovitis** is remarkable at necropsy. One or more joints are swollen (as detected clinically). Acute lesions consist of a serofibrinous exudate within joint cavities and tendon sheaths, and the synovium is reddened and hyperplastic. Later, the exudate becomes purulent or fibrinopurulent, and there may be foci of necrosis as described in the lung. Microscopically, large numbers of lymphocytes and plasma cells are found within the hypertrophic synovial villi. Immunohistochemical and molecular techniques are used for specific diagnosis in the tissues of feedlot cattle. Involvement of the ears by *M. bovis* can lead to *otitis media*. A fibrinous, purulent or caseating exudate is present in one or both middle ears with or without concurrent involvement of the lungs and joints.

**Samples for Confirmation of Diagnosis**

- **Histology**—lung, synovial membrane (LM, IHC)
- **Mycoplasmology**—lung, culture
- **PCR**—lung, synovial membrane or exudate from middle ear

**DIFFERENTIAL DIAGNOSIS**

A diagnosis of infection by *M. bovis* should be considered when pneumonia and arthritis, synovitis, and possibly *otitis* occur at about the same time. The disease must be differentiated from other causes of joint swelling and lameness in feedlot cattle. With *M. bovis* infection there are usually several animals affected in a short period of time, which serves to distinguish it from other sporadic causes of arthritis.

**Differential clinical diagnosis for respiratory disease:**

- **Pneumonic pasteurellosis of cattle** is an acute, toxemic bronchopneumonia with a high fever and a good response to treatment in the early stages. Depression and anorexia are common. The disease is most common in young beef and dairy calves that have been recently stressed following weaning or mixed in auction markets and shipped to feedlots. The disease can also occur in mature cattle as a primary or secondary pneumonia.

- **In viral interstitial pneumonia** of calves, young and adult cattle there is characteristic dyspnea, a moderate fever, only a mild toxemia, and loud breath sounds over the ventral aspects of the lungs followed by crackles and wheezes in a few days, and recovery may take several days. Pneumonia attributable to BRSV may be mild with uneventful recovery or severe with dyspnea and subcutaneous emphysema and a high case-fatality rate.

- **Lungworm pneumonia** occurs most commonly in young pastured cattle and is characterized by dyspnea, coughing, only mild toxemia, and a moderate or normal temperature; the course may last several days. Usually many cattle are affected. Crackles and wheezes are usually audible over the dorsal aspects of the lungs, and the response to treatment is usually favorable if treatment is initiated early when signs are first noticed.

- **Atypical interstitial pneumonia** (fog fever) and atypical interstitial pneumonia of feedlot cattle. The former usually occurs in adult pastured cattle that have been moved from dry to lush pasture (or just a different species of pasture or on to a recently harvested cereal grain field); the latter is incidentally observed in feedlot cattle most commonly in the finishing period; the onset is sudden and some cattle may be found dead, whereas others are in severe respiratory distress with an expiratory grunt. This condition is usually not associated with toxemia.

- **Infectious bovine rhinotracheitis** (IBR) is characterized by h thinis, usually with discrete lesions in the nares, tracheitis, loud coughing, high fever, and no toxemia unless secondary bacterial pneumonia is present. Recovery usually occurs gradually over 4 to 7 days.

- **Contagious bovine pleuropneumonia** (CBPP) resembles pneumonic pastureellosis but occurs in plague form; there is severe, painful, toxemic pleuropneumonia, and the case-fatality rate is high.

**Differential clinical diagnosis for arthritis:**

- **Traumatic aseptic arthritis** may be associated with history of trauma and sudden onset of lameness without signs of systemic disease. Synovial fluid collected by arthrocentesis is colorless or yellow to red-tinged (as a result of hemorrhage). Synovia is clear with moderate cellularity. Culture of synovia is negative.

- **Traumatic septic arthritis** with bacterial contamination of joint cavity commonly involves a single joint with worsening lameness. A skin lesion over the affected joint might be present. Synovial fluid is cloudy, with decreased viscosity, high cellularity, fibrin content, and a tendency to clot.

- **Septic arthritis as a result of hematogenous infection** is a common complication of omphalitis or septicemia (e.g., diarrhea) in calves. Frequently involves several joints and is associated with clinical omphalitis. Common pathogens are *Truusporella* (formerly *Arcanobacterium*) pypogene, *E. coli*, *Salmonella* spp., *Streptococcus* spp.,
The published results of in vitro antimicrobial testing of isolates of M. bovis recovered from various locations are highly variable. The antimicrobial susceptibility of M. bovis strains, cultured from cases of pneumonia, arthritis, and mastitis of cattle, measured in vitro indicate that enrofloxacin, florfenicol, and spectinomycin all exhibited good to excellent activity. The in vitro susceptibility of Belgian field isolates of M. bovis to 10 antimicrobials found that tiamulin was the most active against the organism. The fluoroquinolones, danofloxacin, enrofloxacin, and marbofloxacin were effective against strains of M. bovis, whereas gentamicin was ineffective. In a series of British isolates of M. bovis, most isolates were susceptible to danofloxacin but less susceptible to florfenicol. An industry sponsored study found tulathromycin and florfenicol at label dose to be effective for the treatment of respiratory disease in cattle caused among others by M. bovis under field conditions. Gamithromycin at label dose was found to be effective in treating naturally occurring clinical pneumonia caused by M. bovis. In calves with a high incidence of respiratory disease associated with M. bovis and Pasteurella spp. the use of valnemulin in the milk of the calves for 4 days resulted in improved weight gains and fewer cases of mycoplasmal infection and required fewer treatments with antibiotics than those in the placebo treated group.

Little evidence to support recommendations for an appropriate treatment duration with antimicrobials is available in the literature. Common wisdom holds that early treatment and prolonged therapy are the two most important factors contributing to the success of treatment of mycoplasmal infection. Given that M. bovis infection often becomes chronic, prolonged use of antimicrobials at least until clinical signs resolves appears warranted. This implies that in many cases antimicrobials would have to be administered in an extra-label manner.

In addition to antimicrobial therapy short-term use of antiinflammatory drugs for management of pain and respiratory distress is certainly indicated in severe cases.

In case of early stage septic arthritis involving a single or few joint(s) joint irrigation may be attempted. The objective of this procedure is to drain infected synovial fluid thereby reducing the number of bacteria and removing fibrin, debris, and other harmful products of inflammation. Joint lavage can be performed either by “tidal flush” through the same needle inserted into the infected joint or, preferably, by “through-and-through” lavage in which fluid is injected and drained through different 14-gauge needles that are placed into the joint as far apart as possible. Depending on the size of the joint, a minimum of 250 mL and up to several liters are needed for effective joint lavage. Warmed polyionic solutions (e.g., lactated Ringer’s or isotonic saline solution) are commonly flushed through the joint applying pressure until draining fluid becomes clear. Adding polyvidone-iodine to the irrigation solution to obtain a 0.01% to 0.1% solution has been recommended for its bactericidal effect. Aseptic technique is required to prevent secondary bacterial infection. Because treatment efficacy is greatly impaired by fibrin accumulation in the joint, joint irrigation should mainly be considered in early stages of the disease. Arthroscopic joint debridement has been used to treat septic arthritis in cattle in other species, with good outcome. This approach allows to effectively remove fibrin and debris to synovial membrane but requires adequate surgical equipment and skills. Arthrotomy is rarely done because it is a major surgery with long after care and often unrewarding outcome. In cases of otitis media with ruptured tympanic membrane irrigation of the middle ear has been recommended. Irrigation solutions used include various apparently empirical dilutions of povidone iodine, hydrogen peroxide or chlorhexidine. Perforating the still intact tympanic membrane (myringotomy) with a sharp object has been proposed to allow drainage and irrigation of the middle ear. The advantages and risks of this procedure do not appear to have been properly evaluated.

Procedures that have been recommended to control *M. bovis* transmission in calves include the following:11

- Avoid exposure of calves to milk/colostrum contaminated with *M. bovis*.

- Avoid feeding milk/colostrum from infected cows.

- Pasteurize milk/colostrum of cows of unknown status in infected herds before feeding to calves.

- Feed milk replacer.

- Reduce airborne exposure to *M. bovis*.

- Segregate calves with suspected or confirmed clinical *M. bovis* infection.

- Prevent overcrowding.

- Provide adequate ventilation.

- Promptly treat calves with respiratory disease.

- Prevent fomite transmission.

- Sanitize nipples, bottles, tube feeders, buckets, and so forth.

- Wear gloves when feeding newborn calves and assisting sick calves to nurse, and change gloves between animals.

- Consider all-in, all-out procedure and sanitize pens between calves or separate younger from older calves to prevent disease transmission.

- Consider metaphylactic use of antimicrobials in situations with high morbidity/mortality rates.

- Use nonspecific measures to stimulate calf health.

- Ensure adequate transfer of passive immunity.

- Provide adequate nutrition.

- Minimize stress.

- Control other potentially debilitating pathogens (e.g., other pathogens of the respiratory tract or BVDV).

- Avoid exposure of calves to milk/colostrum contaminated with *M. bovis*.

- Recruit to bulk-tank culture of milk from at least 3 bulk tank samples collected at least 3 to 4 days apart.

- Individual milk samples of newly purchased lactating cows should be submitted for detection of mycoplasma (culture, PCR, C-ELISA) before introducing these animals into the herd. Be aware of low sensitivity of a single milk sample to detect subclinical infection.

- Test for *M. bovis* antibodies in milk or serum to identify infected animals.

- Screen calf health records from herd of origin of newly purchased animals for history of clinical signs consistent with *M. bovis* infection (e.g., polyarthritis or otitis) when available.

**CONTROL Biosecurity**

Effective control consists in maintaining a closed herd or screen and quarantining newly purchased animals. Aggressive surveillance and culling of infected animals is advisable for herds with low infection prevalence. In high-prevalence herds and operations where maintaining closed herds or enforcing a quarantine is impractical, as is the case in feedlots, the focus of the control measures must be on limiting stress, controlling concomitant and potentially debilitating diseases such as bovine viral diarrhea (BVD) and segregating clinically affected animals from new arrivals.

Biosecurity and biocontainment procedures should be implemented to prevent the introduction of infection into the herd and to minimize the spread of infection in the herd. Biosecurity measures applicable to dairy herds include the following:11

- Bulk-tank cultures from the herd of origin of newly purchased dry cows or heifers

- Recruit to bulk-tank culture history of the herd of origin or if unavailable.

- Obtain cultures from at least 3 bulk tank samples collected at least 3 to 4 days apart.

- Individual milk samples of newly purchased lactating cows should be submitted for detection of mycoplasma (culture, PCR, C-ELISA) before introducing these animals into the herd. Be aware of low sensitivity of a single milk sample to detect subclinical infection.

- Test for *M. bovis* antibodies in milk or serum to identify infected animals.

- Screen calf health records from herd of origin of newly purchased animals for history of clinical signs consistent with *M. bovis* infection (e.g., polyarthritis or otitis) when available.

**Vaccination**

Vaccination against *M. bovis* (R-3)

*Tilimicosin (10 mg/kg SC as single dose)*

*Gamithromycin (6 mg/kg SC as single dose)*

*Oxytetracycline long-acting formulation (20 mg/kg IM as a single dose)*

*Enrofloxacin* (7.5–12.5 mg/kg SC as single dose)

*Danofoxacin* (8 mg/kg SC as single dose)

*These are classified as critically important antimicrobials in human and veterinary medicine. Use as first-line treatment is discouraged.*25

**FURTHER READING**

Bovine Coronavirus

Bovine coronavirus (BoCV) is one of the more newly identified viral respiratory pathogens of cattle, being first described in 1993. As a consequence, the clinical significance of BoCV in bovine respiratory disease, and enzootic pneumonia in particular, is still being determined.

The current evidence indicates that BoCV plays a primary and important role in enzootic pneumonia. BoCV was the most commonly identified viral pathogen identified in nasal swabs from calves with respiratory disease in Ireland, being present in 23% of calves. BoCV was identified throughout the year, but at a much lower rate in summer. BoCV was the only virus detected in approximately 75% of respiratory disease outbreaks in two to 3-month calves in Italy.

Parainfluenza-3 Paramyxovirus

The evidence for viruses as primary etiologic agents is based on virus isolation, serologic evidence of active infection, lesions of viral pneumonia, and experimental infection. The parainfluenza-3 (PI-3) virus has been isolated most commonly from affected calves and inoculation of the virus into colostrom-deprived calves results in a pneumonia that resembles the naturally occurring disease.

Mycoplasma bovis and Mycoplasma spp.

Mycoplasma bovis is a major cause of calf pneumonia, and in conjunction with BRSV and BoCV, is considered one of the three most important and common etiologic agents of calf pneumonia. In addition, Mycoplasma dispar, M. bovirhinis, and Ureaplasma diversum, are frequently isolated from the lungs of pneumonia calves. Acholeplasma laidlawii and M. arginini are also found but of dubious significance.

Mixed Viral and Other Pathogen Infections

A survey of viral infections of the respiratory tract of calves over a 3-year period revealed that BRSV, the PI-3 virus and bovine virus diarrhea virus (BVDV) were significantly associated with respiratory disease. Seroenpidemiologic and clinical surveys of calves raised as herd replacements in dairy herds commonly reveals evidence of BRSV and PI-3 virus infections associated with respiratory disease. The rhinoviruses, adenoviruses, reoviruses, and enteroviruses were also isolated but in much lower frequency, and were considered not to be important. Chlamydia spp. has been associated with respiratory disease in calves and usually as part of a mixed infection with viruses and bacteria. A recent metagenomics study identified the presence of bovine adenovirus, bovine rhinovirus A virus, and bovine influenza D virus either alone or in combination in 62% of calves with respiratory disease.
Bacteria

*P. multocida* is frequently isolated from the lungs of calves with enzootic pneumonia. Because it is a commensal of the upper respiratory tract, *P. multocida* is typically considered as an opportunistic pathogen in calves with enzootic pneumonia.* M. haemolytica* and *P. multocida* may both be recovered from the lungs of calves with pneumonia and may act synergistically with the *Mycoplasma* spp. to cause a more severe and fatal pneumonia; however, *M. haemolytica* is not commonly isolated from calves with enzootic pneumonia. Several other bacterial species may also be recovered from pneumonic lungs, including *Histophilus somni* (formerly *Hemophilus somnis*), *Trueperella* (formerly *Arcanobacterium* or *Actinomycyes* or *Corynebacterium*) *pyogenes*, *Fusobacterium* spp., *Streptococcus* spp., and *Staphylococci* spp., particularly from chronically infected animals.

*Bibersteinia trahalosi* (formerly *P. haemolytica* Biotype T) has been infrequently isolated from young dairy calves and adult cows with respiratory disease. It is currently uncertain whether *B. trahalosi* acts as a primary respiratory pathogen in bovine respiratory disease or plays a secondary and opportunistic role. Calves challenge exposed with a virulent isolate of *B. trahalosi* and previously vaccinated with a modified live *M. haemolytica* vaccine had less severe clinical signs of respiratory disease, lower mortality, and reduced lung lesions scores than unvaccinated calves. In contrast, intratracheal inoculation of 2- to 3-month-old dairy calves with leukotoxin positive or negative strains of *B. trahalosi* failed to induce clinical signs of respiratory disease. Interestingly, *B. trahalosi* inhibits the growth of *M. haemolytica* via a proximity-dependent mechanism, leading to speculation that most of the pathology in field cases attributed to *B. trahalosi* pneumonia was actually attributable to *M. haemolytica* infection that has been overgrown. Additional studies are needed to clarify the role of *B. trahalosi* in bovine respiratory disease.

**EPIDEMIOLOGY**

**Occurrence**

Dairy Calves

Enzootic pneumonia occurs most commonly in housed dairy calves from 2 weeks to 5 months of age being raised as herd replacements. Pneumonia can be responsible for up to 30% of all deaths of calves in dairy herds from birth to 16 weeks of age, second to enteritis, which can account for 44% of all deaths. Some farms report many cases of pneumonia, whereas others have none, emphasizing the role that management and environment play in the incidence of enzootic pneumonia.

Pneumonia can be the single largest cause of death in veal calf farms. The calves are purchased at about 10 days of age, assembled into large groups of 25 to 50 per group and fed a milk substitute diet for about 16 weeks and then sent to slaughter. The peak incidence of disease occurs about 5 weeks after arrival in the calf house during which time PI-3 and BRSV are recovered most often.

**Beef Calves**

Enzootic pneumonia occurs in nursing beef calves and can account for significant reductions in weaning weight and a significant cause of economic loss as a result of disease in the neonatal period. In cow–calf herds in northwestern Quebec, one of the major causes of a low percentage of weaned calf-crop was the occurrence of diarrhea and pneumonia in calves under 2 weeks of age. Pneumonia can also occur after beef calves have been housed.

**Morbidity and Case Fatality**

Morbidity rate and case-fatality rates vary depending on the quality of housing and management provided, and the type and amount of viruses and bacteria that predominate in the environment at any one time. The morbidity rate may reach 100%, and the case-fatality rate is usually less than 5%.

On veal calf farms, pneumonia can be the largest single cause of death, with mortality rates up to 3.7% and culling rates at 5.1%. Peak death and cull losses occur during the 7th and 8th week of production.

In Ontario Holstein dairy herds, 15% of calves were treated for pneumonia before the age of weaning. Treatment rates for pneumonia increased slightly until about the 6th week of life and then declined until weaning. Calves that had pneumonia during the first 3 months of life had an increased risk of mortality before they reached calving age. In Holstein herds in New York, the crude incidence rate for respiratory disease within 90 days of birth was 7.4%. In those same herds, dullness of calves and unspecified diagnosis within 90 days of birth increased the hazard rate of death after 90 days of age 4.3-fold above that for heifers without dullness within 90 days of birth. These data indicate pneumonia in dairy calves in the first 3 months of age can have an adverse effect on long-term survival and subsequent growth rate.

**Methods of Transmission**

**Aerosol infection and direct contact** are the methods of transmission and both are accompanied in crowded, inadequately ventilated conditions. Newborn calves raised in individual pens may become infected within 5 to 15 days after an experimentally infected calf is placed in the calf house.

**Risk Factors**

Because most of the pathogens described under etiology can be found in the respiratory tract of normal calves, it has been generally accepted that environmental risk factors, such as ambient temperature, relative humidity, air quality, and population density, are necessary to precipitate the disease. In addition, several animal risk factors make calves susceptible to the pathogens in their environment. There are also pathogen risk factors that determine the disease outcome.

**Animal Risk Factors**

The onset of calf pneumonia occurs between 2 and 4 weeks of age when the concentration of serum IgG, IgG2, and IgA in the nasal secretions are lowest. When the concentrations of serum IgG begin to increase at about 2 to 4 months of age, the incidence of new cases of pneumonia begins to decline. The spectrum of colostral antibodies present in home-raised calves will depend on the spectrum of infection in the adult cows. In herds infected with BRSV, newborn calves acquire colostral antibodies to BRSV, which declines to undetectable levels in an average of about 100 days with a range of 30 to 200 days.

Most calves that recover from clinical enzootic pneumonia are resistant to further attacks of the disease associated with the same infectious agents. Herd immunity to one or more viruses develops, and severe outbreaks of disease usually occur following the introduction of animals that may be carriers of infectious agents to which the resident animals are nonimmune. In commercial veal calf units where market-purchased calves are being introduced on a regular basis, there is commonly a succession of minor epidemics of enzootic pneumonia. The incidence is highest in the recently introduced calves and the disease will occur in a small percentage of resident calves.

In a study of range beef calves from birth to 45 days of age, respiratory disease accounted for a total mortality of 1% and was associated with twins, which may result in a less viable calf at birth that may be neglected and abandoned. The risk of respiratory disease was also higher for male calves. The recent advancement of calving dates of beef cattle herds in the cold areas of North America from April–June to January–March results in crowded conditions in calving yards, which creates the environmental conditions similar to those of housed dairy calves. This has increased the incidence risk for enzootic pneumonia in beef calves.

**Environmental and Management Risk Factors**

Environmental risk factors, such as inadequate housing and ventilation are major contributors to the disease process. These include calving area, calf housing, spatial separation between calves, mixing calves of different age groups, and seasonal effects. Dairy herds that do not house calves in groups before weaning, or that house calves in groups of seven or fewer calves per group, are less likely to be affected with high mortality rate as a result of respiratory disease.
calving area and environment can affect calf health through stress and the degree of exposure to infectious agents. Inadequate ventilation, improper climate control, and poorly constructed facilities can induce stress in calves. Crowding results in close contact and promotes spread of infection, and also results in excess moisture that, in the presence of inadequate ventilation (movement of air) and supplemental heat, causes a high relative humidity and chilling of calves. Many calf barns are old, adapted barns that are occupied for several months without depopulation and disinfection. Monitoring 48 dairy herds over 1 year in the National Animal Health Monitoring System revealed that mortality was lower in herds that used calf hutches compared with those that did not. In commercial veal units, the longer the dissemination and vacancy break, up to 6 to 7 days, the lower the incidence of disease in new calf crops entering the unit. Ventilation is commonly inadequate where dairy calves are raised because of poor design of the building.

Rapid changes in weather, particularly during the winter months, are often followed by outbreaks of acute pneumonia because of inadequate ventilation. A common practice during cold weather is to close the air inlets and turn off the ventilating fans in an attempt to maintain the inside temperature at a comfortable level. This results in increased relative humidity, condensation of moisture on walls and on the calves, leading to wet conditions, and the reduced ventilation results in an increase in the concentration of droplet infection. Attempts to correlate meteorologic data with the daily morbidity rate have not yet provided evidence for the hypothesis that climatic factors have an influence on incidence. This may be because of the difficulties associated with accurately monitoring meteorologic data, and the lack of a direct relationship between the environment outside a calf barn and the microclimate of the calf inside the barn. The disease appears to be most common during the winter months when calves are housed continuously and when ventilation is commonly inadequate.

Humid weather results in a marked increase in the percentage of bacterial colony-forming particles of less than 4 to 7 μm in size. This provides the beginnings of a sound physical framework for the explanation of this and other, as yet empirical, relationships between the microenvironment in calf barns and the etiology and epidemiology of calf pneumonia.

The management risk factors that can influence the incidence rate and mortality of calves with pneumonia include the following:

- Use of prophylactic antimicrobials
- Health management of the dams
- The feeding of a coccidostat to pre-weaned calves may be associated with an increase in the risk of enzootic pneumonia because herds with a history of disease would be more likely to feed a coccidostat.
- Factors associated with mortality to 21 days of life in dairy heifers in the United States include:
  - First colostrum-feeding method, timing and volume
  - Time of separation from dam
  - Calving ease
  - Twin birth

**Inadequate transfer of passive immunity** has consistently been identified as a major risk factor for enzootic pneumonia. Optimizing the feeding of colostrum, as summarized in Chapter 20, is an important method for decreasing morbidity and mortality associated with enzootic pneumonia. Up to 31% of mortality is associated with ineffective colostrum feeding. The longer the calf is left with the dam after birth, the greater the mortality, presumably as a result of greater exposure of the calf to pathogens harbored by the dam. Difficult calving also may interfere with the optimum ingestion of colostrum and absorption of immunoglobulins.

A path model of individual-calf risk factors for calfhood morbidity and mortality in New York Holstein herds indicated that management appeared to affect, directly and indirectly, the risk of respiratory disease within 90 days of birth. Being born in loose housing is strongly related to development of clinical signs of calf diarrhea within 14 days of birth, which in turn increases the risk of respiratory disease within 90 days of birth.

Calves reared as herd replacements may be born inside and raised indoors until they are about 6 months of age and then turned out to pasture for the summer. In the case of veal rearing units, the calves are kept and fed indoors under intensive conditions from a few days of age until they reach 150 kg body weight (BW) at 12 weeks of age. In the barley-beef units, the calves are fed indoors on an intensive basis from weaning until they reach market weight at 10 to 12 months of age. In all of these situations, young, growing calves are raised together in confined conditions that promote the spread of respiratory disease associated with several viruses, Mycoplasma spp., and Pasteurella spp.

Based on serologic surveys, most calves raised in close confinement will have become infected by several viruses, including BRSV, PI-3 virus, adenoviruses, BHV-1, and bovine viral diarrhea virus. If natural exposure to these viruses, Mycoplasma spp., and bacteria is so widespread and inevitable, it raises serious questions about the rationale for vaccination. In most cases the effects of the viruses and Mycoplasma spp. are minimal. The stress factors associated with inadequate ventilation, high relative humidity, chilling, and secondary bacterial complications are responsible for the onset of clinical disease.

**Pathogen Risk Factors**

The infectious agents are ubiquitous in the respiratory secretions of the animals and in their environment, and more numerous in crowded poorly ventilated conditions. The spectrum of infectious agents that are present and acting in a calf population and the severity of clinical disease will vary between farms, between countries, and from season to season. It has been assumed that older calves and mature animals in a herd are the source of infection for the young calves. This assumes major importance in control measures that are commonly designed to rear calves separate from older animals.

**Bovine Respiratory Syncytial Virus**

Infection with BRSV may be subclinical, mildly clinical, or highly fatal. Raising calves in close proximity to older cattle may result in constant exposure to infectious agents to which the mature animals are immune. The disease may be endemic on particular farms in which almost every calf experiences clinical disease. Herd epidemics may occur following the introduction of a different virus, such as BRSV, or following a breakdown in the ventilation system. The disease occurs specifically in nursing beef calves from 1 to 4 months of age while on pasture. Veal calves that are seronegative for BRSV on arrival to the veal unit were twice as likely to develop respiratory disease within the first 3 weeks compared with seropositive calves.

**Bovine Coronavirus**

Information regarding pathogen risk factors is just starting to be identified. Veal calves that are seronegative for BoCV on arrival to the veal unit are 1.7 times as likely to develop respiratory disease within the first 3 weeks as are seropositive calves.

**Parainfluenza-3 Virus**

This is commonly subclinical in a group of calves, and clinical disease may not occur until other pathogens are present or when adverse environmental conditions precipitate clinical disease. Following natural infection of young calves, the PI-3 virus may persist for several weeks. However, the presence of PI-3 infection may predispose to respiratory disease by interfering with normal pulmonary clearance mechanisms and allowing secondary invasion by bacteria or mycoplasmas. PI-3 decreases the phagocytic ability of alveolar macrophages, enhances the production of arachidonic acid signal cascade, a proinflammatory response, and enhances contraction of respiratory smooth muscle, resulting in bronchoconstriction.

The number and types of *Mycoplasma spp.* that colonize the nose and trachea of calves are influenced by the age of calves and...
not by the environmental temperature or relative humidity. *Mycoplasma* spp. start to colonize the upper respiratory tract of calves within days after birth, and the peak isolation rate from their nasal cavities occurs at about 2 to 6 weeks of age, and from the trachea at 6 to 8 weeks of age. Over 92% of calves collected from farms and reared in a controlled environment can harbor *Mycoplasma* spp. in their noses when they are 2 weeks of age. The rate of recovery falls gradually thereafter.

*Mycoplasma dispar* colonizes the respiratory tract of experimentally infected young calves for several months and can be isolated from nasal swabs and transtracheal samples throughout the period of colonization. *M. dispar* and *P. multocida* have been cultured from transtracheal aspirates of dairy calves with pneumonia under 3 months of age. In calves aged 1 to 5 months in calf-rearing farms that purchase calves from dairy farms, the prevalence and level of colonization of the respiratory tract with *Mycoplasma* spp. can be more than 90% over a 2-year period. *M. dispar*, *M. bovirhinis*, and *Acholeplasma laidlawii* have all been isolated from such calves. A high degree of colonization with *M. dispar* among 1- to 2-month-old calves on these rearing farms indicates the ability of the pathogen to spread among the calves and colonize the respiratory tract. *M. dispar* is able to spread very rapidly among groups of calves, and airborne transmission is considered to be an important mode of transmission in addition to direct contact. The infection rate in the calves at the farms of origin is small.

*Pasteurella multocida* is a normal component of the upper respiratory tract of calves but is frequently isolated from the lungs of calves with enzootic pneumonia. It appears that isolation of *P. multocida* from pneumatic lung reflects the overwhelming of the calf immune system rather than a primary pathogenic response. Different strains of *P. multocida* exist in the upper respiratory tract of calves, particularly if calves come from different sources, and *P. multocida* infection can amplify the severity of lower respiratory tract disease in the presence of impaired defense mechanisms.5 *P. multocida* is more frequently isolated from the nasal passages of dairy calves less than 10 weeks of age than similarly aged beef calves; this is thought to reflect differences in housing and management and is consistent with the prevalence of enzootic pneumonia cases in dairy calves.

**Mixed Flora**

Although a mixed flora of viruses, mycoplasma, and bacteria can be isolated from the respiratory tract of calves with pneumonia, and the unpassaged respiratory material can cause disease similar to the naturally occurring disease, the inoculation of pure cultures of *M. bovis*, *M. dispar*, and *Ureaplasma* spp., or pure cultures of BRSV, BoCV, or PI-3, into calves does not produce the severe clinical disease seen in the field. The failure of pure cultures of a pathogen to produce a severe pneumonia may be for one of three reasons:

- Combinations of organisms are required for disease
- Laboratory passage of the pathogens, necessary for purification causes their attenuation
- Material in the respiratory secretion other than the pathogens identified is required for disease, which may include agents that were not detected by routine culture techniques.

**Economic Importance**

The economic losses associated with enzootic pneumonia may be considerable. One estimate reports that the disease accounts for 50% of all calf mortality and a reduction of 7% in live weight gain. In commercialveal units, the presence of enzootic pneumonia may be associated with a prolonged time in the unit because of reduced daily weight gain.

The economic loss attributable to calfhood morbidity and mortality is well recognized by the dairy industry. However, the long-term effects of morbidity from diseases such as enzootic pneumonia on health and performance may constitute an even greater economic loss to the herd. Calfoothdiseases occurring in the first 3 months of life may have serious long-term consequences. Heifer calves that are treated for pneumonia during the first 3 months of life are 2.5 times more likely to die after 90 days of age than heifers that are not treated for pneumonia. Heifer calves without respiratory disease are twice as likely to calve, and calved for the first time 6 months earlier, compared with calves with respiratory illness as calves. Some studies have found no significant independent association with calfhood disease status with first lactation milk production. However, the population selected did not include all heifers affected as calves; a heifer could have a suboptimal rate of growth or unthrifty appearance and would be removed from the herd before milk production was measured.

**PATHOGENESIS**

**Viruses**

The respiratory viruses can cause a viral interstitial pneumonia affecting the cranial lobes of the lung that may be subclinical, mildly clinical, or severe and highly fatal. The pathogenesis of BRSV and BHV-1 pneumonia is described elsewhere in this chapter. The pathogenesis of experimental respiratory bovine coronavirus infection has not been well described.

**Parainfluenza-3**

Subclinical viral pneumonia associated with the PI-3 virus uncomplicated by secondary bacterial invasion is usually of minor importance. In subclinical PI-3 infection in calves, seroconversion will occur, and at necropsy there are microscopic lesions consisting of bronchiolitis, bronchial and bronchiolar epithelial hyperplasia, alveolar epithelialization, and giant-cell syncytial formation. In the mild form there are slight clinical signs such as coughing and polyphnea. In the severe form of viral pneumonia, such as in respiratory syncytial viral infection, there is severe dyspnea, with mouth breathing and an inspiratory grunt, but a marked absence of toxemia compared with a bacterial pneumonia. Death can occur without secondary bacterial bronchopneumonia. Atellectasis and consolidation of the anterior lobes of the lungs are characteristic and account for the loud bronchial tones audible on auscultation over the anterior ventral aspect of thorax.

The experimental intranasal inoculation of the PI-3 virus into colostrum-deprived calves results in a pneumonia that is grossly and histologically similar to the naturally occurring disease. Within 2 to 4 days following infection there is bronchiolitis and bronchitis and cellular exudate in the bronchiolar lumina. These lesions become more severe and are accompanied by alveolar cell thickening and hyperplasia. Beginning at about 14 days following infection, there is healing of the bronchiolar and alveolar lesions. The bronchiolar exudate becomes organized by fibroblasts, and mononuclear cells predominate in the alveolar exudate. Bronchiolitis obliterans is widespread, but reepithelialization of damaged bronchial mucosa and alveoli occurs.

Experimentally, the PI-3 virus can affect alveolar macrophages, which may impair the lung clearance mechanisms and allow *M. haemolytica* to produce a secondary bacterial bronchopneumonia. However, aerosols of PI-3 followed by *M. haemolytica* 7 days later do not necessarily result in significant pulmonary disease.

After the primary viral pneumonia is established, bacterial invasion may occur and the resulting pneumonia will vary with the species of bacteria that are present. Secondary bacterial pneumonias usually respond to treatment, although relapses are common if the viral pneumonia is extensive. Viruses are capable of reducing the resistance of mucous membranes, allowing bacteria such as pasteurellae to invade tissues. They are also capable of destroying the cilia on the bronchial mucosa that act as an escalator and help to keep the lower respiratory tract free of potential pathogens. In animals where there is an uncomplicated viral pneumonia with very extensive lesions, there may be minimal clinical signs and almost complete resolution.

**Mycoplasma**

The pathogenesis of *M. bovis* pneumonia is described elsewhere in this chapter.
The endobronchial or intratracheal inoculation of gnotobiotic calves with *Mycoplasma* spp. does not usually result in significant clinical disease. However, 2 or 3 weeks following inoculation, there is microscopic evidence of pneumonia. The lesions produced by experimental inoculation of calves with *M. bovis*, *M. dispar*, or *Ureaplasma* spp. are characterized by peribronchiolar and perivascular "cuffing," catarrhal bronchiolitis, and atelectasis. Intranasal inoculation of *Ureaplasma diversum* into SPF calves results in thick cuffs of round cells surrounding the bronchi, bronchioi, and blood vessels and a lobular catarrhal pneumonia. However, clinical signs of pneumonia are not observed. Inoculation of *M. canis* results in only a slight pathologic change that disappears 9 days after infection. *M. dispar* produces an alveolitis without cuffing lesions. It is thought that the *Mycoplasma* spp. are synergistic with each other, viruses, and bacteria in producing the lesions of subclinical and clinical enzootic pneumonia.

**Bacteria**

The pathogenesis of *P. multocida* and *M. haemolytica* pneumonia is described elsewhere in this chapter, and the pathogenesis of *Histophilus somni* pneumonia is described in Chapter 22.

**CLINICAL FINDINGS**

Regardless of the identity of the causative pathogen, the clinical findings in almost all enzootic pneumonias of calves are similar. In the experimental viral pneumonia, a febrile reaction occurs on about day 5 and is followed by the appearance of rhinitis, pneumonia, and mild diarrhea. The fever is only moderate (40–40.5°C [104–105°F]). A harsh, hacking cough, easily stimulated by pinching the trachea, is characteristic.

**Clinical scoring systems** have been developed to assist in the field diagnosis of respiratory disease in calves with enzootic pneumonia. Factors considered of potential clinical utility, such as rectal temperature, presence and nature of nasal and ocular discharges, presence and nature of a cough, respiratory rate, and degree of depression, are assigned a whole integer score and the individual scores added to provide a summative score. Ultrasonographic examination of the cranioventral lung fields may provide helpful additional information. Current scoring systems for dairy calves have not been well validated, and the use of a summative clinical score is statistically illegal, even when weights are assigned to measured factors. Despite these limitations, appropriately designed and validated clinical scoring systems show promise as providing a practical method for implementing effective treatments earlier to calves with respiratory disease.

In naturally occurring cases, the clinical findings are similar, although the fever is usually higher. This may be attributable to bacterial invasion in the early stages. The nasal discharge is only moderate in amount and is mucopurulent. On auscultation of the thorax the major abnormalities can be detected over the ventral aspects of the apical and cardiac lobes. The breath sounds are loud and harsh and represent breath sounds transmitted through consolidated lung. The intensity of the heart sounds is increased because of shrinkage of lung tissue in the cardiac area. The usual course ranges from 4 to 7 days. Some peracute cases of uncomplicated viral pneumonia die within 1 day after the onset of signs. Infections with the PI-3 virus generally cause mild respiratory disease characterized by coughing, nasal discharge, slight fever, and recovery in a few days.

*M. bovis* pneumonia in young calves is characterized by the sudden onset of severe dyspnea, fever, and rapid deterioration in spite of therapy.

In BRSV pneumonia there may be a sudden onset of acute pneumonia in 80% to 90% of a group of calves. The clinical findings are characteristic of a severe viral pneumonia. Affected calves are usually mentally alert, and there is only a mild fever. There is polyypnea and dyspnea, which in a few days become worse, with mouth breathing and an expiratory grunt. Loud breath sounds, indicating consolidation, are audible over the anterior lobes of the lung. Squeaky, wheezing sounds as a result of the bronchiolitis are also commonly audible over the periphery of the consolidated areas. Loud, crackling sounds as a result of interstitial emphysema may also be audible over the dorsal aspects of the lungs. Death may occur in 2 to 4 days in spite of intensive therapy.

When secondary bacterial bronchopneumonia occurs, the fever, dyspnea, and toxemia are usually more severe. When secondary infection with *Pasteurella* spp. occurs, the temperature rises to 41° to 41.5°C (106-107°F), the area of lung affected is much increased, and loud harsh breath sounds as a result of edema are followed by crackles and a pleuritic friction rub. These cases usually respond rapidly to adequate treatment. When *Trueperella pyogenes* is the secondary invader, consolidation is marked, and there is a profound toxemia and loud breath sounds. In cases where *Fusobacterium necrophorum* is present, the clinical findings are similar, and pulmonary abscesses are likely to develop. The calf has lost a substantial amount of weight and stands with its neck stretched out in an attempt to decrease upper airway resistance (Fig. 12-15). Necrotic lesions are often present in the mouth and pharynx in these cases, and the pulmonary infection probably originates from here. With both of these latter infections there may be some response to antibiotic treatment, but there is a predisposition to relapse soon after treatment is terminated. Coughing, dyspnea, anorexia, and emaciation continue, and the animal eventually has to be destroyed.

**CLINICAL PATHOLOGY**

The etiologic cause of a case of bovine respiratory disease cannot be differentiated in most cases based on clinical examination in conjunction with consideration of history and signalment. As a result, it is sometimes helpful to submit appropriately collected and transported samples to a laboratory for analysis. Detailed methods for primary respiratory pathogens are described elsewhere in the appropriate section of this book. The acute-phase reactants, such as serum haptoglobin and haptoglobin-matrix metalloproteinase 9 (Hp-MMP 9), are biomarkers...
of inflammation and may therefore indicate the presence or absence of active lung pathology in calves at risk of developing respiratory disease. However, the clinical utility of serum biomarkers needs to be compared with tests that can be conducted rapidly and calf-side, such as rectal temperature, presence and nature of nasal and ocular discharges, or ultrasonographic examination of the cranioventral lung fields, before they are widely adopted.

The oxygen tension \( (P_{O_2}) \) in arterial (preferably) or venous blood is decreased in calves with respiratory disease, primarily as a result of ventilation-perfusion mismatch. The partial pressure of oxygen in arterial blood \( (P_{O_2}) \) is negatively associated with the extent of lung lesions in calves with experimentally induced BRSV infection, with a 0.6% to 0.8% increase in the proportion of affected lung for every 1 mm Hg decrease in \( P_{O_2} \) from the reference value. As such, arterial \( P_{O_2} \) provides an excellent method for quantifying the proportion of diseased lung and monitoring the response to treatment.

Isolation of Pathogens
Nasopharyngeal swabs, transtracheal aspirates, and lung lavage samples may be taken for isolation of viruses, mycoplasmas, and bacteria, and the methods have been described in detail. Special laboratory media are required to isolate Mycoplasma spp. Determination of drug sensitivity to the bacteria may be valuable, particularly when a number of calves are involved in an outbreak. The isolation of BRSV from natural infections is difficult because of the labile nature of the virus. The immunofluorescent antibody test for antigen detection is one of the most rapid, reliable, and sensitive tests for BRSV from tracheal aspirates, nasal swabs, and lung samples.

After experimental infection with PI-3, the median time to shedding is 1 day, the median time to peak shedding is 4 days, and the median time until shedding ceased is 10 days.

Serology
Serologic tests have been more extensively used for confirmation of suspected BRSV infections. The standard serologic test is a virus-neutralization test using microtiter plates. Others include a modified indirect fluorescent antibody test, indirect hemagglutination, and an ELISA test, the latter of which is considered to be sensitive and specific and has the advantage of giving test results within several hours, whereas the virus-neutralization test requires 5 to 6 days for completion. The complement fixation test is less specific and less sensitive than the ELISA test.

NECROPSY FINDINGS
In uncomplicated viral pneumonia, irrespective of the specific cause, there are areas of atelectasis and emphysema in the apical and cardiac lobes, with little macroscopic involvement of the diaphragmatic lobes. In the later stages, a dark red consolidation featuring a hobnail appearance of the pleural surface affects most of the ventral portions of the apical and cardiac lobes. The lesions are always bilateral. Histologically, there is a bronchointerstitial pneumonia. Acute inflammation of the nasal mucosa, particularly on the turbinate and ethmoid bones, is usually accompanied by a marked, mucopurulent exudate. In PI-3 infection, intra- and extraplasmic inclusion bodies are widespread in the lungs; after experimental infection, they are present on day 5, but they have disappeared by day 7 after infection.

In respiratory syncytial viral pneumonia there is severe interstitial pneumonia and interstitial emphysema. Histopathologically, there is severe bronchiolitis and alveolitis with multinucleated syncytia (which often contain eosinophilic intraerythroplastic inclusion bodies), and alveolar epithelial cell hyperplasia.

When bacterial or mycoplasmal invasion has occurred, the lesions vary with the agent present. Extensive hepatization with mottled red and gray lobules and considerable interlobular aggregations of serofibrinous fluid, often accompanied by a fibrinous pleuritis, is characteristic of \( P. multocida \) infection. Extensive consolidation and suppuration occur with \( T. pyogenes \) and \( F. necrophorum \) infections. In the latter case there may be necrotic lesions in the mouth and upper respiratory tract.

Confirmation of this diagnosis at necropsy is somewhat awkward because the population of pathogens responsible may change between the time of disease onset and the death of the calf. In severe outbreaks it may be necessary to euthanize animals early in the course of the disease or to perform serologic surveys for respiratory pathogens among surviving herdmates.

Samples for Confirmation of Diagnosis
- **Histology**—lung (several sections), trachea, turbinates (LM, IHC)
- **Virology**—lung (several sections), trachea (FAT, ISO)
- **Mycoplasmaology**—lung (MCULT, FAT)
- **Bacteriology**—lung (CULT)

Differential Diagnosis
Clinically, the diagnosis of pneumonia is usually readily obvious, but the causative agents are usually not determined. Young calves raised indoors and affected with a cough, nasal discharge, and pneumonia are usually affected with enzootic pneumonia associated with the agents described under etiology. The common diseases of the respiratory tract of young calves that may resemble enzootic pneumonia include the following:

**Bacterial pneumonia caused by** \( M. haemolytica \) or \( H. somni \) in young calves is characterized by severe toxemia, fever, dyspnea, grunting, and a poor response to therapy.

**M. bovis pneumonia** is characterized by sudden onset of dyspnea, fever, depression, and poor response to therapy in a group of calves.

Calf diphtheria usually affects a single calf and is characterized by inspiratory dyspnea, stridor, toxemia, fever, and obvious lesions of the larynx.

Lungworm pneumonia occurs in young calves at pasture, and marked dyspnea, coughing, and a few deaths are characteristic. A fever is common in lungworm pneumonia, and there are loud breath sounds over the ventral aspects of the lungs, and loud and moist crackles over the dorsal aspects.

Acute myocardial dystrophy in young calves, following turnout on pasture, is characterized by sudden onset of weakness, polyneuropathy, and dyspnea as a result of pulmonary edema and lesions of the diaphragm, tachycardia and arrhythmia, and skeletal muscular weakness.

Aspiration pneumonia occurs occasionally in calves that have been force-fed colostrum or milk. There is a sudden onset of marked dyspnea, anxiety, distress, and death may occur within a few minutes. However, some calves survive, and there is marked dyspnea with abdominal breathing and loud breath sounds and crackles over both lung fields, especially over the ventral aspects; and subcutaneous emphysema. Several animals are usually involved. Affected animals fail to respond to treatment with antimicrobials, and the case-fatality rate is usually over 75%. There may be a history of mild respiratory disease in the affected group about 10 days previously. In pasteurellosis, depression, toxemia, fever, loud breath sounds over the ventral aspects of the lungs, and a favorable response to treatment are characteristic.

Chronic enzootic pneumonia is characterized by bronchiectasis and pulmonary abscessation, causing unthriftiness and a poor response to therapy.
TREATMENT

Antimicrobial Therapy
Uncomplicated enzootic pneumonia associated with mycoplasma or viruses is unlikely to respond to treatment, but antimicrobial therapy daily for 3 days is indicated because of the high probability of secondary bacterial pneumonia. Any of the antimicrobials used commonly for the treatment of acute undifferentiated bovine respiratory disease (shipping fever) are effective, with a preference for antimicrobials that are effective against Mycoplasma spp. and P. multocida, H. somni, and M. haemolytica. These are described in detail in the section on pasteurellosis earlier in the chapter.

Early treatment is necessary to avoid the development of incurable secondary complications, such as pulmonary abscesses, pleuritis, bronchiectasis, and supplicative pneumonia. In commercial veal calf units, the case-fatality rate can be kept to a low level by early and adequate treatment. In some cases, it may be sufficient to treat animals once only, but a proportion of cases are likely to relapse after an initial response. Such cases require repeated daily therapy for 3 to 5 days. If the number of relapses in an area or on a farm is excessive, all cases should receive multiple treatments.

Adjunctive Therapy
Bronchodilators and NSAIDs as adjunctive therapy for enzootic pneumonia in calves are used, but their efficacy is questionable.

Correction of Adverse Environmental Conditions
The clinical management of an outbreak of enzootic pneumonia in calves must include correction of adverse environmental conditions that may have precipitated the disease.

CONTROL

Environmental and Management Practices
Control of the disease in housed calves is dependent on effective animal and environmental management. Overcrowding, drafty or inadequately ventilated housing, exposure to inclement weather, and sudden changes in environmental temperatures are major risk factors. Recently purchased calves should be isolated for several weeks before being introduced to the group.

Ideal Environmental Conditions
Control is especially difficult and expensive in countries where the calves are housed for several months during the winter months in northern climates. The most comfortable ambient temperature for young calves ranges from 13°C to 21°C (55–70°F) with a relative humidity of 70%. To achieve these environmental conditions requires a suitable insulation material in the walls and ceilings, ample bedding to absorb moisture from feces and urine, and adequate movement of air to remove aerosol particles that may be infectious. This requires an adequate air inlet and outlet system, adequate capacity fans, and supplemental heat during very cold periods.

The installation of recirculating air filter units can lead to a substantial reduction in the concentration of airborne bacteria to which calves are exposed. Field studies in veal calf units indicate that mean aerial bacterial concentration in filtered barns can be reduced by 45%, the number of calves requiring treatment reduced by 19%, the number of repeat courses of treatment and the total antibiotic usage reduced by 29% and 35%, respectively. At slaughter, the average area of lung consolidation in calves from filtered barns can be reduced by 35%. In general, air filtration can result in a reduction in both the incidence and severity of clinical and subclinical pneumonia in calves and in improved weaning gain.

In spite of ideal hygiene and management, it may not be possible to prevent the development of new cases if the infection already exists in a herd, or if cattle from other herds are moved into the herd. At present, it is feasible only to be vigilant and treat new cases urgently and vigorously because a strict hygiene program may not be feasible in the average commercial herd. If management is inadequate and the general resistance of the animals is low, losses resulting from calf pneumonia with significant bacterial or mycoplasmal invasion can be sufficient to make calf-rearing unprofitable.

Calf Barns or Hutches
When economics permit, the ideal situation is to construct a calf barn completely removed from the main adult cow barn to minimize the spread of infection from adults that may be symptomless carriers. After the Colostrum feeding period, calves are removed from the calving barn and placed in individual pens in the calf barn. The raising of young veal calves indoors in calf “hutches” or “igloos” is highly satisfactory and economical, even in countries where the outside temperatures go well below freezing. With adequate bedding, protection from the prevailing winds and adequate nutrition, calves will grow satisfactorily. Dairy herds that have had difficulty controlling enzootic pneumonia of calves have found this system to be an excellent alternative to the construction of a stand-alone, well-ventilated calf house. Nutritional deficiencies, usually of energy and protein, are common in young calves and often accentuate the severity of the pneumonia. Young calves should receive a balanced calf starter grain ration supplemented with essential vitamins and minerals and good-quality hay beginning by at least 3 weeks of age.

Vaccines and Immunization
There is insufficient information available from field trials to make firm recommendations for the use of vaccines for the control of enzootic pneumonia in calves. It is difficult to evaluate the results of vaccination trials because investigators use so many combinations of vaccines and different vaccination schedules, and there are many different management variables and differences in methods of evaluation. In addition, many vaccination trials are not randomized controlled trials. Recommendations regarding vaccination protocols for BRSV, BHV-1, M. haemolytica, P. multocida, and M. bovis are presented elsewhere in this chapter; recommendations for a BVDV vaccination protocol are presented in Chapter 9, and recommendations for an H. somni vaccination protocol are presented in Chapter 22.

Any successful vaccine would have to be multivalent and would have to be effective when given before 2 months of age or earlier in the “window of susceptibility” to coincide with the decline in passive (maternal) immunity, the increase in active immunity, and the occurrence of enzootic pneumonia in calves (Fig. 12-16).

There is good field evidence that the colostral immunologic status of the calf has a significant effect on the susceptibility of the calf to pneumonia. There is a clear association between low levels of IgG1, IgG2, and IgA of calves at 2 to 3 weeks of age, and subsequent susceptibility to pneumonia at 2 to 3 months of age. Calves with signs of pneumonia had low levels of IgG1 compared with nonpneumonic calves that had relatively higher levels. In addition, calves with high levels of serum immunoglobulin do not respond normally to vaccine and any vaccine for enzootic pneumonia would have to be administered during this relatively refractory period. However, for veal calves, which are purchased at a few days of age and with low levels of immunoglobulin, this may not be a problem. A 2015 meta-analysis concluded that in natural exposure trials, 2-week-old to 4-month-old dairy calves vaccinated with commercially available vaccines against BHV-1, BVDV, BRSV, and PI-3 for protection against respiratory disease had no reduction in morbidity or mortality compared with age-matched unvaccinated controls.24

Vaccines currently available for BoCV are only licensed to control neonatal diarrhea in calves. Their efficacy in controlling respiratory disease is unknown but is likely to be poor. This is because respiratory isolates belong to subclades 2a, 2b, and 2c, whereas enteric isolates and a vaccine strain for control of enteric disease in calves belong to the antigenically different clade 1.23

The intranasal inoculation of calves with virulent or a modified strain of PI-3 virus stimulates the development of both serum antibody and nasal secretion antibody. The nasal secretion antibody is dose dependent. Challenge exposure of these calves provides protection against clinical disease. These factors should be considered in the development and administration of PI-3 viral
vaccines if the objective is to establish an optimal concentration of antibody in the nasal secretion. The parenteral administration of two sequential doses, 2 weeks apart, of an inactivated PI-3 vaccine virus with adjuvant will induce high levels of serum antibody and prevent virus excretion in nasopharyngeal secretions after challenge. Successful immunization of calves against PI-3 infection may be useful for protection against pneumonic pasteurellosis if PI-3 precautions are taken. This is presented in greater detail in the section on pneumonic pasteurellosis. A single dose of an experimental vaccine for Mycoplasma bovis pneumonia, inactivated with saponin, given subcutaneously to 3- to 4-week-old calves followed by experimental challenge 3 weeks later with a virulent strain of Mycoplasma bovis provided protection against clinical pneumonia. Unvaccinated calves developed clinical signs of disease as a result of lung lesions. The vaccine also reduced the spread of Mycoplasma bovis to internal organs. Calves tested 6 months after immunization had high levels of humoral immunity. The successful use of saponin in vaccines has been demonstrated for other mycoplasma infections, such as contagious bovine pleuropneumonia (CCPP) and contagious agalactia. The saponin may preserve the major antigens seen in untreated whole cells.

**Fig. 12-16** Development of the immune response in the calf from conception to puberty. The window of susceptibility is the optimal time for vaccination against enzootic pneumonia and represents the time during which passive (maternal) immunity is waning and active immunity is increasing. ETIOLOGY
Bovine respiratory syncytial virus (BRSV) is a cause of a viral pneumonia primarily in calves under 6 months of age and also in yearlings and adult cattle. BRSV is a pneumovirus in the family Paramyxoviridae. Antigenic and genetic subtypes have been identified. Using monoclonal antibodies against a glycoprotein (G protein on the surface of the virus), four subgroups have been identified: A, B, AB, and untyped. There are six genetic subgroups based on G and five subgroups based on F (a fusion protein on the surface of the virus that causes fusion of cell membranes with resultant formation of syncytia) or N (nucleoprotein). The evolution of BRSV into subtypes may have been driven, in part, by selection pressure applied by vaccination.

BRSV is genetically and antigenically related to human respiratory syncytial virus (HRSV). Other pneumoviruses include ovine respiratory syncytial virus (ORSV) and caprine respiratory syncytial virus (CRSV), with BRSV being most closely related to CRSV. BRSV provides a good model for HRSV, and consequently many studies related to identifying virulence factors and understanding the immunopathogenicity of BRSV infection have been conducted.

EPIDEMIOLOGY
BRSV was first reported in Europe in 1970 and was subsequently reported in the United States in 1974. Distribution is currently worldwide. A case could be made that BRSV is the most important viral cause of respiratory disease in calves less than 6 months of age and in adult dairy cattle. BRSV is a rare cause of respiratory disease in adult beef cows.

Occurrence
Prevalence of Infection
The virus is ubiquitous in the cattle population and new infections occur most commonly in autumn and winter months and may result in severe respiratory disease. In longitudinal studies in dairy herds, 90% of primary infections occur in calves and heifers; very few occur in cattle over 2 years of age, and all cattle in the herds are seropositive when they are over 3 years of age. Recurrent infections occurring annually at the same time, and in cows of all ages, without new introductions into the herd, are characteristic of BRSV infections in a herd. The virus appears to circulate during summer at very low levels or not at all, with almost all isolations coming from winter and spring. Persistent BRSV infection in some of the cows in a herd might be a means for the virus to survive during the summer, but a steady state of reinfection of seropositive cows throughout the year at a low level might also maintain a reservoir of infection. Monthly data on the prevalence of BRSV antibodies in dairy herds suggest that persistent infection in seropositive cows is more likely than population persistence.

When the prevalence of infection in the cattle population is high, the incidence of clinical disease is much lower. It can be assumed that most mature cattle have been exposed to the virus, but unexposed cattle are susceptible to developing clinical disease after infection. Surveys in the United States, England, Denmark, Sweden, and France found seropositive rates in herds ranging from 50% to 80%. Cattle entering feedlots may seroconvert to the virus, which may be associated with an increased risk to subsequent treatment for respiratory disease. A high percentage of young beef bulls aged about 6 months and entering performance test stations may seroconvert to BRSV and adenovirus, both of which may be associated with clinical respiratory disease.

Occurrence of Clinical Disease
In general, clinical infection is most common in calves under 6 months of age and some BRSV infections are undoubtedly associated with enzootic pneumonia of housed dairy calves. In dairy herds, recent introductions of young cattle purchased from public salesyards may introduce the infection to homefarm cattle that have had no previous exposure to the viruses or those in which their immunity to a previous infection with the virus has declined. Thus adult dairy cows may be affected with a highly fatal pneumonia attributable to the virus. A high prevalence of infection exists in Swedish cattle, and annual outbreaks of disease have occurred in adult cattle, with pregnant or recently calved cows being most severely affected. Outbreaks have occurred in beef cattle on pasture. The disease occurs in nursing beef calves 1 to 8 months of age on pasture with their dams without any history of previous stress. A common occurrence is in weaned beef calves 6 to 8 months of age within 2 to 3 weeks following weaning and commingling in confinement. Yearling cattle in feedlots are also susceptible.

In North America, herd epidemics of clinical disease usually occur during the fall and winter months. Nursing beef calves may be affected with clinical disease during the summer months. Some outbreaks have occurred in nursing beef calves between 1 and 2 months of age while they are still in nursery pastures or in the calving areas.

A spontaneous outbreak of respiratory disease in goats attributable to BRSV has been described, and sheep can be infected with the virus.

Morbidity and Case Fatality
The morbidity rate in herd epidemics of clinical disease can vary from 30% to 50% or higher. The case-fatality rate is usually low, 3% to 5%, but may be higher.

Methods of Transmission
The mode of transmission has not been defined, but aerosol infection and direct contact are probable. Infection spreads rapidly among susceptible cattle.

Risk Factors
Animal Risk Factors
Naturally occurring BRSV infection affects both dairy and beef cattle, and those under 6 to 10 months of age are most susceptible to clinical disease. Nursing beef calves with colostral BRSV antibody are not protected from infection, but the incidence and severity of clinical disease is inversely related to the level of maternal antibodies in calves younger than 3 months. The highest percentage of reinfections occurs most commonly in cows during their first lactation. Older animals may have a more effective immunity because of previous exposure.

Seroepidemiologic surveys in feedlot cattle found that seroconversion to the virus may occur in up to 70% of animals within 1 month after arrival. Animals with low titers to the virus on arrival are at increased risk of subsequent treatment for respiratory disease, which suggests that the virus may be a factor in bovine respiratory disease. In some situations in feedlot cattle, high BRSV serum antibody levels on arrival were related to a lower risk of respiratory disease.

Environmental Risk Factors
The highest incidence of clinical disease occurs in autumn and winter months. Outbreaks have been associated with changes in weather, especially declining ambient temperatures and atmospheric pressure.

Pathogen Risk Factors
BRSV has a narrow host range, affecting primarily cattle. Important antigenic differences between BRSV isolates have been described. Subgroups A and AB are associated with severe respiratory disease and circulate in the Dutch cattle population. In natural outbreaks of infection in closed dairy cattle herds and veal calf units in Denmark, using DNA sequence data, identical viruses were isolated within a herd during outbreaks, but viruses from recurrent infections varied by up to 11% even in closed herds. It is possible that a quasispecies variant swarm of BRSV persisted in some of the calves in each herd and that a new and different highly fit virus type (master and consensus sequence) became dominant and spread from a single animal in connection with each outbreak.
Antigenic subtypes may have relevance both in explaining differences in virulence between subtypes and in the development of new vaccines for the control of clinical disease. The production and characterization of monoclonal antibodies to a vaccine strain of BRSV has been described. The respiratory syncytial virus of goats and sheep, caprine respiratory syncytial virus, and ovine respiratory syncytial virus are antigenically related, but not identical, to BRSV.

The BRSV may act synergistically with a concurrent experimental challenge of the virus and 3-methylindole to produce more severe pulmonary disease similar to BRSV pneumonia seen in feedlot cattle, than either agent alone. But vaccination of cattle with BRSV vaccines does not protect the potential synergism between the 3-MI and BRSV infection.

Whether or not the virus persists in individual animals in spite of the presence of maternal or naturally acquired antibodies has been a major question. Serologic findings indicate persistence of the virus, but the virus could not be detected in lung lavage fluid or nasal swabs. Experimentally, the virus persisted in tracheobronchial and mediastinal lymph nodes for up to 71 days after infection. In vitro, the virus was still able to replicate in bovine B-lymphocyte cell lines 6 months after infection. This may explain the absence of the virus between epidemics, recurrent infections in the same individuals and inapparent reinfection of adults.

Immune Mechanisms

After a natural BRSV infection, the protection is short-lived and multiple reinfections are common. In endemic areas, the absence of BRSV-associated disease in adult cattle is possibly as a result of repeated infections. This places a constraint on vaccine development because one or two vaccinations would have to induce immunity that only repeated natural infections can provide. BRSV infections can occur in the presence of high to moderate levels of maternal antibodies. Maternal antibodies, which are directed against the F, G, and N proteins of BRSV, are commonly present in calves but do not protect against infection. However, the incidence and severity are inversely related to the level of specific maternal antibody, and natural infection does not prevent reinfection but appears to offer good protection against clinical disease after infection. Primary BRSV infections in calves less than 1 month of age are less severe than those in calves 2 to 4 months of age, probably as a result of decreased proinflammatory TNF-α production in calves less than 1 month of age.

The BRSV colostral antibody of dairy calves varies dependent on season of the year when the calves are born. Dairy calves born during the winter months in the Netherlands have lower BRSV colostral antibody titers than those born during the summer months. Whether this may be attributable to the seasonal periodicity of BRSV circulation or to other factors influencing antibody development or colostrum intake is uncertain. Calves born in the summer have higher antibody titers at 14 to 19 weeks of age, most likely attributable to BRSV exposure. Calves born during the season of infection may be primed with BRSV field virus during the period of maternally derived immunity and may be better protected against disease by cellular immunity during the next season of infection.

IgM and IgA are the predominant antibody isotypes in the respiratory tract after BRSV infection, with IgA especially prominent after reinfection. Both serum antibody responses and local antibody responses are suppressed by maternal antibodies. After natural BRSV infection of cattle, antibodies are predominantly directed against the epitope A, whereas after experimental infection, or vaccination with an inactivated vaccine, antibodies against epitope B and nonneutralizing epitope C are markedly increased compared with the same epitopes in naturally infected cattle.

The subgroups of the virus are based on antigenic differences of the G protein, and BRSV infection protects against reinfection by homologous strains of the virus. It is also known that a complete BRSV can partially protect against a BRSV infection with a strain that contains an antigenic dissimilar G protein. Therefore incorporation of representative viruses of different BRSV subgroups in vaccines for cattle does not seem necessary to achieve cross-protection. Vaccination of calves with a formalin-inactivated BRSV vaccine followed by challenge exposure to virulent virus increased the severity of clinical disease and lesions compared with calves nonvaccinated and challenged. Vaccination did not induce neutralizing antibodies, but IgG antibodies were detected with ELISA. Immunization with formalin-inactivated BRSV vaccine mainly primes a Th2-like inflammatory response characterized by a significant eosinophilic influx in the bronchia alveolar lung field and lung tissues and high levels of immunoglobulin E serum antibodies.

PATHOGENESIS

BRSV causes rhinitis, tracheitis, bronchitis, bronchiolitis, and mild interstitial pneumonia. In naturally occurring cases, the main lesions are bronchitis and bronchiolitis in the cranioventral portions of the lungs combined with widespread emphysema and edema throughout the lungs. BRSV infection causes airway obstruction and hyperactivity that may persist for up to 30 days following viral exposure. In naturally occurring cases, the cranioventral lung fields are particularly poorly ventilated, and there is arterial hypoxemia associated with mismatching of ventilation and perfusion. Radiographic and radionuclide lung perfusion imaging reveals the presence of bullous emphysema and areas of marked atelectasis.

The pathogenesis of acute fatal pneumonia as a result of BRSV is not clear. The characteristic lesions are exudative or necrotizing bronchiolitis, atelectasis, interstitial edema, and emphysema. The acute fatal disease is commonly preceded by a mild respiratory disease several days previously, which suggests that hypersensitivity may be a pathogenic mechanism causing lung injury. The second stage may follow initial improvement or recovery from the first stage and is associated with the onset of extreme respiratory distress. The virus-specific IgE antibody may play a role in the pathogenesis of the severe disease as part of a hypersensitivity reaction. The IgM and IgA antibodies are not involved in a hypersensitivity reaction. In experimentally induced infection in calves, there is considerable injury to bronchial epithelium including hypertrophy, hyperplasia, and formation of syncytia, which facilitates movement of virus between cells. In the alveoli, BRSV infection results in necrosis of type I pneumocytes; the response of type II pneumocytes includes hypertrophy, hyperplasia, and syncytial formation. It is suggested that an immune-mediated mechanism may be responsible for the widespread lesions over the entire lung.

The severe, highly fatal form of the disease, also known as the “malignant” form, or paroxystic respiratory distress syndrome (PRDS), is associated with extensive pulmonary mast cell degranulation. In a series of naturally occurring paroxystic respiratory disease in calves, paired serum samples were taken 3 weeks apart and lungs examined at necropsy. The serum concentration of tryptase was used as a marker of mast cell degranulation. Tryptase is a preformed serine protease stored in mast cell granules and causes significant changes in the respiratory tract smooth muscle tone and vascular permeability. The substances released by the mast cells are at least partially responsible for the pulmonary edema, in particular by means of venoconstriction and the increase in the vascular permeability induced by the histamine. The edema and bronchoconstriction caused by the mast cell leukotrienes impede bronchial flow, which causes ventilatory asynchronism. The mechanical constraints caused by the asynchronism are aggravated because the bovine lungs consist of a number of compartments, which prevents any collateral ventilation and any dissipation of interlobular pressure gradients. The breaking point is reached when the level of the mechanical constraints exceeds the level of tissue resistance, causing interstitial emphysema.

Calves that die of the BRSV-associated PRDS have a uniform pattern of gross
lesions. The trachea and bronchi are filled with a white-to-pink froth, and the lungs are heavy and voluminous and fail to collapse. The most characteristic lesions were the dramatic lung distension by edema, alveolar hyperinflation, and severe interstitial and subpleural emphysema, often with large dissecting bullae on the dorsal edge of the diaphragmatic lobes.

Microscopically, the most characteristic lesions are bronchitis, bronchiolitis, alveolar edema, mononuclear cell infiltration, hyaline membrane deposition, and scattered hyperplasia of type-2 pneumocytes. There is a clear gradient in the severity of inflammatory changes in the airway along a craniocaudal axis, with lesions being more frequent and severe in the cranial parts except for hyper-inflation and emphysema. Extensive mast cell degranulation occurs in the diaphragmatic lobes, where neither the virus nor the epithelial syncytia nor the bronchiolitis typically observed in cranioventral zones are found.

**Experimental Reproduction of BRSV Pneumonia**

Experimental reproduction of the disease has been difficult; in most cases, infection results in only mild clinical disease with limited lesions.

Severe respiratory tract disease and lesions can be reproduced experimentally in conventionally reared calves, and the virus can be recovered from tissues. Severe disease similar to the naturally occurring disease can be induced with a single aerosol of a low-passage clinical isolate of the virus. Moderate to severe BRSV-induced pneumonia can be reproduced in colostrum-fed calves, and nasal shedding of the virus and demonstration of the antigen in the lungs at necropsy provides evidence that the virus causes the disease.

In neonatal calves with experimental acute infection with BRSV, there is increased pulmonary resistance and decreased compliance, which explains the severe dyspnea observed in some calves. There is no evidence that transplacental infection occurs. Experimental infection of young lambs with BRSV can result in severe pathologic changes with only mild clinical disease.

In experimentally infected calves, the virus can be detected in the bronchiolar epithelial cells and in alveolar cells, including bronchiolar ciliated and mucus cells, and bronchiolar ciliated and nonciliated epithelial (Clara) cells. Syncytia are often observed in the bronchiolar walls and in the alveoli, and such syncytia were always replicating the virus. However, syncytial cell formation is not unique to infection with BRSV because it may also occur in other viral infections of the lung. Ultrastructural studies of experimental BRSV pneumonia reveal that BRSV replicates primarily in the superficial layer of respiratory ciliated epithelium and to a lesser extent in type II pneumocytes. BRSV infection of ciliated cells in the airway can result in the loss of cilia and ciliated cells, which may interfere with lung clearance mechanisms and predispose to bacterial pneumonia. The severity of clinical signs following experimental BRSV infection in calves is positively associated with the magnitude of decreased clearance of an inhaled protein marker, indicating that BRSV-induced ciliated epithelial damage affects the effectiveness of the mucociliary escalator.6

Experimental BRSV infection in calves induces an acute-phase-protein response. Strong and reproducible acute-phase proteins haptoglobin and serum amyloid A will peak at 7 to 8 days after inoculation of the virus. The proinflammatory cytokine, tumor necrosis factor (TNF-α), can be detected in the bronchoalveolar lung lavage fluids, and high levels appear on the days when severe lung lesions and clinical signs are obvious. It may be involved in mechanisms leading to increased permeability of endothelium.

**CLINICAL FINDINGS**

The clinical findings vary considerably from herd to herd and from year to year. In dairy cattle, disease occurs most commonly in young calves under 6 to 10 months of age, although outbreaks of severe disease in mature dairy cattle also occur. Clinical signs of infection in older cattle, particularly those with previous exposure to the virus, are less severe. In large dairy herds, episodes of infection usually mild and often unnoticed, despite cattle having a fever, slight inappetence, and a corresponding decrease in milk production. Primary infections in lactating dairy cattle may cause a considerable decrease in daily milk production. However, reinfections are not associated with an important loss of milk production.

A **sudden outbreak of acute respiratory disease** in a group of animals is a characteristic of a primary BRSV infection. The disease is more severe in animals with no previous exposure to the virus. A dry, non-productive cough, severe dyspnea and polypnea, and bilateral nasal discharge are characteristic. A fever of 40° to 42°C (104-108°F) is common and milk production in lactating cows declines markedly. Feed consumption in the affected group declines for a few days. The fever usually persists for 3 to 5 days in spite of therapy with antimicrobials. Toxemia is not a feature unless there is secondary bacterial pneumonia. On auscultation of the lungs there are loud breath sounds over the ventral aspects, indicating consolidation, and wheezes that indicate bronchiolitis. These are the findings of a viral interstitial pneumonia. Most animals recover within 5 to 7 days. Approximately 1% to 2% of affected animals will develop a fatal viral pneumonia characterized by severe dyspnea with abdominal breathing and an expiratory grunt, the head stretched out horizontally, mouth breathing with foamy salivation, marked anxiety, persistent fever, and death within 2 to 5 days after onset. Feed and water consumption are decreased because of severe dyspnea, which results in a gaunt abdomen and dehydration. Affected animals are reluctant to move or lie down. The loud breath sounds audible over the ventral two-thirds of both lung fields indicate that extensive consolidation is becoming pronounced. Subcutaneous emphysema over the withers may also occur. Occasionally, some animals that are not being observed closely will die with peracute pneumonia within a few days and represent the index case of an outbreak.

In outbreaks of BRSV infection in young dairy cattle under 12 to 16 months of age, the first clinical abnormalities usually noticed are coughing and a mild nasal discharge in 50% to 75% of the animals. Inappetence with a fever of 40°C (104°F) or higher lasts for about 3 days followed by recovery in most cases. Coughing, nasal discharge, and conjunctivitis may persist for several days or a few weeks in 10% to 30% of the animals with no long-lasting complications. Abdominal breathing, and loud and abnormal lung sounds may occur in approximately 50% of the animals, but these commonly resolve within 10 days.

In an outbreak of BRSV in recently weaned beef calves 6 to 8 months of age, nasal and lacrimal discharge, polypnea and dyspnea, fever of 40° to 42°C (104-108°F), decreased feed intake, coughing, and lethargy are common. In a small percentage of affected animals, within a few days the dyspnea becomes marked, with mouth breathing and the production of frothy saliva created by the labored respirations. Subcutaneous emphysema over the withers as a result of severe interstitial emphysema also occurs. Loud breath sounds, wheezing, and crackling sounds are audible over the ventral aspects of the lungs. Death may occur within a few days after the onset of the dyspnea. Secondary bacterial bronchopneumonia may occur but is uncommon.

**CLINICAL PATHOLOGY**

It is difficult to obtain a definitive etiologic diagnosis of BRSV infection because the virus is highly labile in tissue samples, and virus detection in specimens is poor because of inadequate laboratory techniques. The virus replicates slowly, classical virus isolation is laborious, and several blind passages are often necessary before any cytopathic effect can be seen. Nasopharyngeal swabs for virus isolation and paired serum samples are necessary to make a definitive etiologic diagnosis. Successful laboratory diagnosis of BRSV is generally based on one of the following four criteria:

- **Virus isolation**
- **Detection of BRSV antigen in suspected tissues**
Indications of BRSV seroconversion
- The high prevalence of antibody titers to the virus and the need for skilled personnel to process and interpret the diagnostic tests have hindered development of a routine diagnostic test. Successful isolation of the virus from typical clinical cases of disease is often unsuccessful and can take 11 to 21 days because of the late appearance of any noticeable cytopathic effect. Because of these difficulties, isolation of the virus is not commonly recommended as a routine diagnostic approach.

Virus Isolation or Detection
After experimental infection, the median time to shedding is 3 days, the median time to peak shedding is 5 days, and the median time until shedding ceased is 9 days. The ideal sample for isolation of the virus is a transtracheal aspirate in the very early stages of the disease. The sample also provides cells for immunofluorescent antibody (IFA) staining. Nasopharyngeal swabs are also useful, but sampling technique must ensure good contact with the most caudal part of the pharyngeal cavity, and the samples must be placed in viral transport medium and shipped on cold packs and not frozen.

The PCR assay is rapid and sensitive and is the preferred method for the analysis of clinical specimens because of advantages in speed, sensitivity, sample lability, and cost. The presence of the virus can be determined by using PCR on moistened cotton nasal swabs taken in the acute phase of a suspected outbreak. The virus can be detected and quantified in cell cultures using real-time quantitative RT-PCR and quantitative competitive RT-PCR assays. A rapid patient-side immunomigration assay designed to detect HRxV can accurately detect BRSV in field studies, thereby providing a rapid calf-side diagnostic test.

The fluorescent antibody test for virus detection is one of the most rapid, reliable, and sensitive tests for the diagnosis of BRSV infection. For tracheal aspirates, an aliquot of the sample is centrifuged onto a microscopic slide to obtain a cell preparation for the IFA test. The virus can be detected in tissues with monoclonal or polyclonal antibodies and avidin–biotin complex immunohistochemistry. This is typically done on formalin-fixed, paraffin-embedded tissues.

Serology
The standard serologic test for specific BRSV antibodies is the virus-neutralization (VN) test, usually done with microtiter plates. Paired acute and convalescent samples from both affected and normal animals in the herd are desirable. The majority of dairy calves do not have detectable maternal antibodies directed against BRSV after 5 months of age; consequently, a positive titer in cattle aged 6 months or more indicates exposure to infection within the population. The indirect ELISA is a rapid and reliable test for detecting antibodies to BRSV in milk, bulk-tank milk, and serum. A microneutralization ELISA has been developed that correlates well with other assays and is useful in assessing antibody responses to the virus both in naturally occurring disease and in vaccination studies.

Arterial Blood Gas Analysis and Blood L-Lactate Concentration
The partial pressure of oxygen in arterial blood (Pao2) is negatively associated with the extent of lung lesions in calves with experimentally induced BRSV infection, with a 0.6% to 0.8% increase in the proportion of affected lung for every 1 mm Hg decrease in Pao2 from the reference value. As a consequence, measurement of Pao2 provides clinical useful information regarding the proportion of damaged lung and the response to treatment. In contrast, arterial blood L-lactate concentration was not useful in predicting the proportion of damaged lung and usually remained within the reference interval, even in the presence of severe hypoxemia.

NECROPSY FINDINGS
Affected lungs are voluminous and heavy, and they fail to collapse when the thoracic cavity is opened. The cranioventral portions of the lung are consolidated and usually dark red or plum-colored. The interlobular septa are edematous, and mucoid exudate can often be expressed from small bronchi. Severe interstitial emphysema and edema are prominent over the dorsal and caudal lobes. Subpleural emphysema is often obvious in the cranial and caudal lobes. The caudodorsal lung regions may be “meaty” in consistency. The caudal lobes are often markedly distended because of interstitial emphysema, and large bullae are common. The interlobular septa of the caudal lobes are usually distended because of emphysema and edema. Subcutaneous emphysema over the withers, thorax, and neck are common. Secondary bacterial bronchopneumonia with pleuritis may occur.

Histologically, there is bronchiolitis and bronchitis. Large multinucleated syncyta are present, projecting from the bronchiolar walls or lying free in the lumen. Hyperplasia is necrosis of the bronchiolar epithelium are common. Exudates consisting of neutrophils, macrophages, desquamated epithelial cells, and syncyta are present in the bronchiolar lumina. Small airways are often occluded with exudate. Alveolar changes include cellular infiltration and thickening of alveolar septae with multinucleate giant-cell syncytia in the alveoli. Epithelial syncytia containing eosinophilic intracytoplasmic inclusion bodies are often present on alveolar walls. The presence of epithelial syncytia is a useful feature, but the numbers and prominence of these structures can vary considerably. Other viruses can also induce these syncytia. In the caudodorsal lung regions, there is severe emphysema, often with rupture of alveolar walls and alveolar edema, sometimes with hyaline membrane formation and swelling of alveolar epithelial cells.

In experimental BRSV pneumonia, the findings include bronchitis, bronchiolitis, proliferative and necrotizing bronchiolitis, interstitial pneumonia with areas of atelectasis and alveolar edema, epithelial syncytium formation on bronchiolar and alveolar walls, and pneumocyte hyperplasia. Viral antigen can be demonstrated by immunoperoxidase or immunofluorescent staining of bronchiolar and alveolar epithelium.

Isolation of the BRSV from natural field cases has always been difficult because of the long duration required for the appearance of characteristic cytopathic effects. Fluorescent microscopy can be used for detection of the antigen in the cranioventral lung areas, but PCR is a more sensitive technique. It is advisable to collect and sample several areas of lung because viral antigen/nucleic acid will be most abundant in areas of acute infection. The virus can also be demonstrated in formalin-fixed paraffin-embedded bovine lung tissue using immunohistochemical techniques.

Samples for Confirmation of Diagnosis
- Histology—fixed lung (several sites) (LM, IHC)
- Virology—chilled lung (several sites) (FAT, PCR); nasal swab (ELISA, PCR)

DIFFERENTIAL DIAGNOSIS
The differential diagnosis includes those infectious diseases of the respiratory tract of young cattle that commonly affect groups of animals in a short period of time.

It is not usually possible to make a definitive etiologic diagnosis based on the clinical findings. However, the combination of the epidemiologic and clinical findings is usually suggestive of an acute viral respiratory disease. It is not usually possible to be more specific than making a clinical diagnosis of acute undifferentiated respiratory disease.

- Acute respiratory disease attributable to BRSV in weaned beef calves is characterized by marked dyspnea, anorexia, mouth breathing, fever, subcutaneous emphysema, loud breath sounds, and death in a small percentage of animals in a few days or less. In some cases there may be a history of respiratory disease in the affected group several days previously.
- Infectious bovine rhinotracheitis (IBR) is characterized by outbreak of coughing.
TREATMENT

Antimicrobial Therapy

Broad-spectrum antimicrobials given daily for 3 to 5 days for secondary bacterial pneumonia are commonly administered but may not be necessary. Recovery usually occurs gradually over a period of 3 to 5 days. Severely affected animals will become worse in spite of therapy.

Corticosteroids and Nonsteroidal Antiinflammatory Agents

Corticosteroids and NSAIDs are used on the basis that widespread dissemination of the virus into the caudodorsal lung field is proinflammatory and results in extensive emphysema and severe respiratory distress. There is no evidence that such treatment is efficacious. Currently, there are no effective postinfection treatments for HRSV infection in humans, other than supportive care.11

CONTROL

The ubiquitous nature of the virus, the persistency of infection in herds, the movement of cattle between herds, the expansion of herds, the replacement practices used in herds, and recurrent infections make control difficult. However, in BRSV-seronegative herds, effective biosecurity measures, including maintaining a closed herd, preventing nose-to-nose contact with cattle on adjacent farms, quarantining and testing new additions to the herd, and providing boots for visitors, may be effective in preventing infection from entering the herd. A rational approach to control would be management of the herd to minimize stressors such as inadequate ventilation. Herd replacements brought into the herd should be quarantined from the rest of the herd for 2 to 3 weeks before mixing with the remainder of the herd.

Vaccines and Immunization

An effective vaccine must be able to stimulate an effective immune response in the presence of maternally derived antibody resulting from colostrum ingestion. This is because the majority of adult cattle are seronegative, and clinical disease appears to be most common in calves aged 2 to 4 months. Currently, several types of immune response, influenced by vaccination protocol and vaccine composition, appear to provide protection against BRSV, and optimal protection in the face of maternally derived antibodies may require both live and inactivated vaccines.12 However, immune responses to parenterally administered modified live-virus (MLV) vaccines appears to be substantially inhibited in neonatal calves. As a result, the parenteral administration of a MLV BRSV vaccine is not expected to engender a protective immune response to BRSV infection.13 Several MLV and inactivated virus vaccines are available for the control of respiratory disease resulting from BRSV infection, but appropriately controlled randomized clinical trials evaluating the efficacy of the vaccine under naturally occurring conditions against BRSV infection or clinical disease are lacking. Protection induced by BRSV vaccines is short lived and usually less than 4 months.

A MLV vaccine administered by the intranasal route appears to provide the best vaccine candidate, based on our current understanding of the pathogenesis of BRSV infection. Such a vaccine was first made commercially available in 2007. However, administration of a MLV vaccine runs the risk of reversion to virulence and spread. The risk of reversion is reduced if gene deletion is employed.12 In addition, maternal antibodies appear to inhibit priming of protective immune responses when intranasal BRSV vaccines are administered.11,14 Cattle vaccinated with MLV BRSV vaccines generally develop high concentrations of virus neutralizing antibodies (VN) and F (fusion) inhibiting antibodies, compared with low to moderate concentrations of total BRSV-specific IgG. A 2015 meta-analysis concluded that in experimentally induced exposure trials, beef or dairy calves vaccinated with modified live BRSV vaccines had no reduction in morbidity or mortality compared with unvaccinated controls. This meta-analysis included calves vaccinated by the intranasal route.15 Cattle receiving inactivated virus vaccines develop lowered concentrations of VN antibodies and higher concentrations of virus-specific (nonneutralizing) IgG than cattle administered an MLV vaccine. The clinical significance of this difference has not been determined. Inactivated BRSV vaccines have been successful when tested by experimental challenge of vaccinated calves, which contrasts to the enhanced disease that may occur in children vaccinated with a formalin-inactivated alum adjuvanted HRSV vaccine. A 2015 meta-analysis concluded that in experimentally induced exposure trials, dairy calves less than 6 months of age vaccinated with inactivated BRSV vaccines had no change in morbidity but decreased mortality compared with unvaccinated controls.16

None of the 81 commercial BRSV vaccines available in 2014 enable the differentiation of infected from vaccinated animals (DIVA).15 Subunit BRSV vaccines provide an attractive alternative to MLV BRSV vaccines in that there is no potential for reversion to virulence, and vaccinated animals can be distinguished from naturally infected animals based on serologic testing.12,16 The use of BRSV-immunostimulating complexes (ISCOMs) has been evaluated in calves with BRSV-specific maternal antibodies. The vaccine overcame the suppressive effect of colostral antibodies and induced a strong clinical and virological protection against a BRSV challenge. Clinical protection was associated with a marked reduction in virus replication in the upper and lower respiratory tract and rapid antibody and T-helper-cell responses, which may be attributable to the effects of the adjuvant in antigen presentation.17

INFECTIOUS BOVINE RHINOTRACHEITIS (RED NOSE), BOVINE HERPESVIRUS-1 INFECTION

SYNOPSIS

Etiology Bovine herpesvirus-1 subtypes: BHV-1.1 (respiratory); BHV-1.2a and 1.2b (genital); BHV-1.3 (renamed BHV-5; encephalitic).

Epidemiology Worldwide occurrence in cattle; high prevalence of infection; low incidence of disease; transmitted directly; latent infection characteristic; economic losses as a result of deaths and abortions, latent infection in breeding animals cause international trade problems and entry into artificial insemination units.

Signs Rhinitis with typical nasal lesions, tracheitis, fever, conjunctivitis, coughing, nasal discharge, and recovery in few days; severe systemic disease in newborn calves, abortion outbreaks.

Clinical pathology Isolation or detection of virus with tissue culture or polymerase chain reaction (PCR); serology with serum-neutralizing titer, enzyme-linked immunosorbert assay (ELISA). Bulk-tank milk antibodies.

Lesions Rhinotraceitis, bronchopneumonia, nonsuppurative encephalitis, alimentary tract necrosis in calves with systemic disease, aborted fetuses autolyzed.

Differential diagnosis All diseases associated with bovine respiratory tract disease: pneumonia pasteurella, viral interstitial pneumonia, Haemophilus pleuropneumoniae, allergic rhinitis.

Treatment Antimicrobials for secondary bacterial infections.

Control Vaccination of young breeding herd replacements using modified live virus or inactivated virus vaccines. Subunit and marker vaccines are preferred to conventional vaccines. Some countries have eradicated infection by identifying and eliminating seropositive animals.

ETIOLOGY

The bovine herpesvirus-1 (BHV-1), or the infectious bovine rhinotracheitis (IBR) virus, is an alpha-herpesvirus and the cause of the respiratory disease, abortion, conjunctivitis, and other clinical forms of the disease complex. Genetic analyses of various clinical isolates have found at least four distinct BHV-1 subtypes: a respiratory subtype, two genital subtypes, and an encephalitic subtype designated as BHV-1.1, BHV-1.2a, BHV-1.2b, and BHV-1.3, respectively. BHV-1.3 as a neuropathic subtype has been renamed as three genotypes, BHV-5a, BHV-5b, and BHV-5mon/a/non-b.1 Antigenic differences between isolates of the virus may account for some of the diverse epidemiologic and pathologic patterns of behavior of this herpesvirus, although development of rhinotracheitis or vulvovaginitis/balanoposthitis depends more on the route of infection than on the subtype of the virus.

Four ruminant alpha-herpesviruses are related to BHV-1 and have the potential for cross-infection of cattle in Europe: bovine herpesvirus-5, caprine herpesvirus-1 (CpHV-1), cervine herpesvirus-1 (CvHV-1), and cervine herpesvirus-2 (CvHV-2). Buffalo herpesvirus-1 and elk herpesvirus are also closely related to BHV-1. BHV-5 is the cause of fatal meningencephalitis in calves. CpHV-1 causes enteritis and generalized infection in neonatal kids. Most CpHV-1 infections in adults are subclinical, the virus can cause vulvovaginitis, balanoposthitis, or abortion. CvHV-1 can cause ocular disease in red deer and is widespread in free-living and farmed red deer. CvHV-2 has been isolated from reindeer in Finland, and serologic evidence of infection with a virus similar to BHV-1 has been reported in caribou in Canada. Although these viruses differ considerably in their virulence, they are closely related both genetically and antigenically, and they can establish latent infections similar to that of BHV-1. An immunofluorescence assay using monoclonal antibodies can discriminate between these related herpesviruses. Bovine herpesvirus-4 has been associated with mastitis in cattle.

EPIDEMIOLOGY

Prevalence of Infection and Occurrence of Disease

Reproductive disease as a result of BHV-1 was first reported in Germany in 1841 as the cause of infectious pustular vulvovaginitis (IPV) and infectious pustular balanoposthitis (IPB). A more virulent disease form attributable to BHV-1.1 (infectious bovine rhinotracheitis) emerged in Colorado feedlots in the United States in 1950, and this subtype has been widely disseminated, most likely as a result of the export of live cattle. It is thought that this subtype developed because of an adaption to multiply in respiratory epithelium associated with large susceptible populations congregated on one feedlot. The virus is now distributed worldwide, but it has been eradicated from Austria, Denmark, Finland, parts of Germany, Sweden, parts of Italy, Switzerland, and Norway. Control programs are running in several other countries. The respiratory form of clinical disease is most common in feedlot cattle and cattle on dairy and beef farms without a routine vaccination program.

Wildlife

Bovine herpesvirus infections exist in wild ruminants. Infections may be endemic in white-tailed deer in certain parts of Canada, and it is suggested a mild form of the disease occurs in these animals. Mule deer are susceptible to infection, the disease has occurred naturally in a goat, and antibodies to the virus have been found in pronghorn antelope in western Canada and in Tanzania in game animals and cattle. According to serologic surveys, the virus is widespread in African wildlife, particularly the buffalo, which may be a reservoir of infection among the wildlife population. The virus has been recovered from the wildebeest in Africa, which suggests further that wildlife may serve as reservoirs. Antibodies to the alpha-herpesviruses were found in reindeer, roe deer, and in red deer in Norway. In Saskatchewan, Canada, 52% of Woodland caribou were seropositive for BHV-1.

Morbidity and Case Fatality

The uncomplicated form of the respiratory disease in cattle is not highly fatal, with most losses being mainly attributable to secondary bacterial bronchopneumonia. The morbidity and case-fatality rates in dairy cattle are about 8% and 3%, respectively, whereas in feedlot cattle the morbidity rate is usually 20% to 30% in unvaccinated cattle and may rarely reach 100%. The case-fatality rate in feedlot cattle is invariably associated with secondary bacterial tracheitis and bronchopneumonia and may reach 10%, but is usually no more than 1%. Morbidity and mortality are higher in feedlot cattle than in dairy herds because of the frequent introduction of susceptible animals into an enzootic situation. The case-fatality rate in the systemic form of the infection in newborn calves is almost 100%.

Methods of Transmission

The main sources of infection are the nasal exudate and coughed-up droplets, genital secretions, semen, and fetal fluids and tissues. Aerosol infection is the method of spread of the respiratory disease. Experimentally,
BHV-1 can be shed from calves into the environment and transported by air over a distance of at least 3.9 m to sentinel calves housed in a separate building. The virus is stable for at least 1 month at 4°C (39°F), 50 days at 22°C (72°F), 10 days at 37°C (98.6°F), and 21 minutes at 56°C (132°F), and can survive 30 days in feed. Venereal transmission is the method of spread of the genital diseases. The virus may survive for up to 1 year in semen frozen at −196°C (−321°F).

Introduction of animals into a group often precedes an outbreak of the disease. However, it can arise simultaneously in a number of dairy farms in an area and spread from these farms to adjacent farms until the entire area is affected. The same pattern of occurrence simultaneously in a number of foci is seen in feedlots, and from these foci infections it spreads to other pens in the lot. An outbreak usually reaches its peak in week 2 or 3 and ends by week to 6.

Risk Factors
Animal Risk Factors
Age and Breed Susceptibility
All ages and breeds of cattle are susceptible, but the disease occurs most commonly in animals over 6 months of age, probably because of their greater exposure. There is no seasonal variation in incidence, except possibly higher occurrence in feedlot cattle in the fall and winter months when large numbers of susceptible animals are assembled. The disease complexes associated with the virus occur most commonly in animals that lack acquired immunity from previous natural infection or vaccination. An unvaccinated herd of breeding cattle or a group of feedlot animals is highly susceptible to epidemics of respiratory disease and abortion. Newborn calves are highly susceptible to the systemic form of infection if the level of specific antibody to the virus in the colostrum is inadequate or if there is failure of transfer of passive immunity.

The analysis of the relationship between interferon genotype and severity of clinical disease in cattle experimentally inoculated with BHV-1 revealed that certain alleles of the interferon were significantly associated with the more severe clinical phenotype. A different subtype of BHV-1 than was used for the primary inoculation. The virus of IBR is similar to the virus causing IPV in cows and IPB of bulls. It has been suggested that the IPV was transmitted to North America from Europe in infected cattle, but continued to cause lesions in only the genital tract until its introduction into dense populations of cattle in feedlots encouraged rapid passage through many hosts and thus encouraged adaptation to the respiratory tract. Only rarely do the respiratory and genital forms of the disease occur together. However, by routine methodology it is difficult, and usually impossible, to distinguish between isolates obtained from the reproductive tract and the respiratory mucosa. Likewise, with the exception of temperature-sensitive mutants, vaccine strains cannot be distinguished from field isolates.

The virulence of several strains of one genotype can vary widely. The outcome of BHV-1 infection can vary from subclinical to a systemic infection in neonatal calves that is often highly fatal. Vaccine strains of BHV-1.1 have been associated with outbreaks of meningoencephalitis in feedlot cattle within 7 to 10 days after routine vaccination intranasally with a vaccine intended for the intramuscular route. Newborn calves under 3 days of age are susceptible to the highly fatal systemic form of IBR if vaccinated intramuscularly with a modified live-virus BHV-1 and PI-3 vaccine. An outbreak of a subclinical form of IBR has been described in a dairy herd of high health status and managed under high standards of biosecurity, and known to be serologically negative for the virus for the previous 15 years. Although 70% of the cows had seroconverted to the virus, no clinical signs were observed, with the exception of an ocular discharge in a few cows, and their performance and productivity were unaffected. The causative virus was isolated after reactivation with corticosteroids and had the DNA profile of a BHV-1 strain normally associated with severe respiratory disease.

The glycoprotein E (gE) gene is a virulence factor of BHV-1 is important in the development of gE-negative marker vaccines used in eradication programs in Europe. These marker vaccines, either inactivated or live attenuated, are deleted in the gene coding for the nonessential glycoprotein E (gE) of BHV-1 to allow serologic differentiation between vaccinated and infected cattle.

Immune Mechanisms
Immunity to the virus is complex and consists of relationships between local and systemic antibody and cell-mediated immunity. Following natural infection or vaccination with the modified live-virus (MLV) vaccines, both cell-mediated and humoral components of the immune system are activated. The level of humoral immunity has been used as an indicator of previous infection and an indirect measure of resistance to clinical disease. However, the level of serum neutralizing (SN) antibody is not a reliable indicator of resistance to clinical respiratory disease. Animals with low levels of antibody may be immune because of cell-mediated immunity. The level of cell-mediated immunity can be evaluated using the delayed-type hypersensitivity test. Experimentally, the virus-neutralizing (VN) titers are lower in calves inoculated with both the IBR and parainfluenza-3 (PI-3) viruses than in calves infected with a single virus. This suggests that mixed viral infections may result in greater immunosuppression, although infectious virus synthesis may be suppressed by interference.

Following intranasal infection or the use of a MLV IBR virus vaccine intranasally, local secretory antibody and interferon are produced. The interferon appears in 3 days and persists for 10 days. The presence of the interferon does not protect calves against experimental challenge 3 days after vaccination. However, the presence of even low levels of antibody in the serum or nasal secretion, which appears by day 7 following vaccination, provides varying degrees of resistance to clinical disease for 9 months.
Colostral Immunity
Calves acquire colostral antibodies from dams with humoral antibody. The duration of the colostral immunity varies from 1 to 6 months of age depending on the initial level acquired by the calf. Maternal antibody in the calf may interfere with the successful vaccination of calves before 6 months of age.

Economic Importance
BHV-1 infection can cause major economic consequences in a dairy or beef cattle breeding herd or in a beef feedlot. Losses are incurred because of epidemics of abortion, infertility as a result of IPV and IPB in bulls, loss of production and deaths from the respiratory tract, eyes, and reproductive tract. Systemic spread to many organs by viremia occurs and neuronal spread. In addition, the virus can establish latency in neuronal or lymphoid cells. Upon reactivation, the viruses reestablish the lytic cycle of replication. The innate immune response is primarily activated in animals infected with IBR though Toll-like receptors 2 and 4, and the development of an effective cytotoxic T-cell response is critical for the elimination of cells infected with virus.  

Respiratory Disease
The BHV-1 virus infects the nasal cavities and upper respiratory tract, resulting in rhinitis, laryngitis, and tracheitis. The pharyngeal tonsil is readily infected by the virus and may be an important lymphoid tissue for defense against systemic invasion by the virus. The virus is highly susceptible to the virus, which causes a peracute infection that is usually fatal. Infection in the last trimester of gestation may result in mummification, abortion, stillbirth, or weak calves with the usual lesions of IBR and the lesions of the stomachs and intestines that have been produced by experimental administration of the virulent virus to newborn calves. The systemic form of the infection in newborn calves is characterized by severe inflammation and necrosis of the respiratory and alimentary tracts, including the pharynx, esophagus, lungs, larynx, lymph nodes, and liver, and nephritis and encephalitis. There is severe laryngeal edema and respiratory distress that results in difficulty in swallowing and aspiration pneumonia. A severe, highly fatal syndrome characterized by diffuse erosion and ulceration of the upper alimentary tract, including the oral cavity, has occurred in beef feedlot cattle.

Latency
The BHV-1 virus can become latent following a primary infection with a field isolate or vaccination with an attenuated strain. The virus may remain latent indefinitely, and recrudescence, reactivation, and shedding of the virus can occur following the use of large doses of corticosteroids that mimic the effects of stress. Transportation of cattle with latent infection can reactivate the virus, resulting in reexcretion of the virus and a rise in neutralizing antibodies. Attenuated vaccine strains can remain in a latent stage, and vaccination does not provide protection against the establishment of latent infection with a wild strain. Vaccination also does not inhibit reexcretion of a wild strain that was in the latent form at the time of vaccination.

Encephalitis
The mechanism by which the brain is infected is presumed to be spread of the virus from the nasal mucosa via the trigeminal peripheral nerve to the trigeminal ganglion, resulting in a nonsuppurative encephalitis. However, a viremia has been suspected. Severe encephalitis can be produced experimentally in colostrum-deprived calves with neurovirulent type BHV-1.3. Experimental infection with BHV-1.1 produces respiratory disease and a mild encephalitis. Intranasal inoculation of young calves and adult cows with BHV-1 can result in nonfatal trigeminal ganglionitis and encephalitis, which may be an important mechanism for latent infection.

Abortion
Systemic invasion by the virus is followed by localization of the virus in several different tissues. The virus may be transported by peripheral leukocytes to the placenta and transferred to the fetus to cause abortion. The fetus is highly susceptible to the virus, which causes a peracute infection that is usually fatal. Infection in the last trimester of gestation may result in mummification, abortion, stillbirth, or weak calves with the usual lesions of IBR and the lesions of the stomachs and intestines that have been produced by experimental administration of the virulent virus to newborn calves. The systematic form of the infection in newborn calves is characterized by severe inflammation and necrosis of the respiratory and alimentary tracts, including the pharynx, esophagus, lungs, larynx, lymph nodes, and liver, and nephritis and encephalitis. There is severe laryngeal edema and respiratory distress that results in difficulty in swallowing and aspiration pneumonia. A severe, highly fatal syndrome characterized by diffuse erosion and ulceration of the upper alimentary tract, including the oral cavity, has occurred in beef feedlot cattle.
calves that do not have antibody response after infection but develop a cell-mediated immune response after infection detected by a specific interferon gamma assay. The failure to easily detect such animals presents an epidemiologic threat for the control of BHV-1 infections. Marker glycoprotein E–negative vaccines can also establish latency not only in naive but also in passively immunized neonatal calves after a single intranasal inoculation. This indicates that gE-negative vaccines, when used in calves with passive antibodies, can result in seronegative vaccine virus carriers.

The experimental intrapreputial infection of young bulls with BHV-1.2 caused acute balanoposthitis, latent infection, and detection of viral DNA in regional neural (sacral nerve ganglia, pelvic sympathetic plexus) and nonneural tissues (lymph nodes) 50 days after experimental reactivation. Following experimental infection in calves the BHV-5 also can result in latent infection of surviving animals.

Parturition may also be a stimulus for reactivation and shedding of a thermosensitive vaccine strain of the virus in vaccinated animals. Reactivation and shedding of the virus has also been observed in cattle that recovered from the respiratory form of the disease and 5 months later were experimentally infected with Dictyocaulus viviparus. The placenta may harbor the virus in a latent stage for up to 90 days without transmitting the virus to the fetus. Recrudescence may be differentiated from primary infection and reexposure by the intranasal route based on the distribution of antiviral antibody activity among serum IgM, IgG1, and IgG2 isotypes.

Predisposition to Pneumonia
The role of the virus in affecting the lung clearance mechanism of cattle in the pathogenesis of pneumonic pasteurellosis has been reviewed and is presented in the section on shipping fever pneumonitis in cattle. Experimental aerosol exposure of calves with the BHV-1 virus impairs the function of alveolar macrophages, which allows Mannheimia haemolytica to persist and proliferate in the lung and produce the characteristic lesion. In vitro studies indicate that the BHV-1 virus can interfere with the function of effector cells, such as macrophages, neutrophils, and lymphocytes. Aerosol exposure of calves to BHV-1 can affect the composition of alveolar phospholipids, which can alter the function of lung surfactant and compromise pulmonary defense mechanisms. The BHV-1 can cause alteration in the glycoconjugate composition of bovine nasal epithelial surfaces, which may promote M. haemolytica proliferation in the early stages of pneumonia pasteurellosis. The virus also causes varying degrees of obstructive lung disease, resulting in increased resistance to breathing, retention of carbon dioxide, and increased resting lung volume. Excessive airway constriction and impairment of bronchial relaxation occurs, which may compromise lung defense mechanisms and allow development of secondary bacterial pneumonia. A severe fatal BHV-1 pneumonitis can occur.

Experimentally, active BHV-1 infection triggers cytokine expression on bronchial epithelial cells that facilitates recruitment of neutrophils. BHV-1 infection also affects bovine peripheral blood neutrophils, enhances the binding of M. haemolytica leukotoxin to bronchoalveolar leukocytes, and increases their killing. The virus increases the number of bronchoalveolar leukocytes, resulting in many more leukotoxin-responsive cells being present in the lung. The net effect is that BHV-1 infection amplifies the detrimental effect of M. haemolytica in the lung.

Reproductive Failure
The intraterine inoculation of the BHV-1 into cattle results in an acute necrotizing endometritis in the uterine body and caudal portions of the uterine horns but minimal lesions in the anterior parts of the horns. Experimental inoculation of the virus into heifers on the day after estrus and insemination can result in lesions of the ovaries consisting of focal necrosis and cellular infiltration. Commercially available vaccinal strains of the BHV-1 virus can produce similar lesions. The ovarian lesions have marked effects on luteal function, and plasma progesterone values in the first estrus after inoculation are markedly lower than those in subsequent normal cycles. Whether the BHV-1 virus causes reproductive failure as a result of necrosis of the corpus luteum or embryonic infection remains to be determined. Recently hatched bovine embryos can be infected with any of several strains of BHV-1 and such infection in vitro is embryocidal. Experimentally induced infection during early pregnancy (7-28 days) will cause oophoritis and, in some cases, embryonic mortality. The effects of the virus on the genital tract and on reproductive performance in cattle have been reviewed.

Bovine Mastitis
BHV-1 and BHV-4 have been associated with mastitis in cattle. Both viruses, including the foot-and-mouth disease virus, and the PI-3 virus have been isolated from milk. BHV-4 has been isolated from cows with clinical mastitis that also developed antibodies against the virus at the time of the mastitis, and no bacteria were isolated from the milk samples. Bovine umbilical cord endothelial cells were used to culture the virus. Experimental inoculation of the ductus papillaris of the teat has resulted in replication of the virus and subclinical mastitis after BHV-4 infection. Simultaneous intramammary and intranasal inoculation of lactating cows with BHV-4 did not induce clinical but subclinical mastitis. It is unlikely that BHV-4 is a major mastitis pathogen.

CLINICAL FINDINGS
Rhinitis (Red Nose), Tracheitis, and Conjunctivitis
After experimental infection there is an incubation period of 3 to 7 days, but in infected feedlots the disease occurs 10 to 20 days after the introduction of susceptible cattle.

There is considerable variation in the severity of clinical signs following natural infection, dependent on the strain of the virus, the age susceptibility, and environmental factors. In North America, where the disease is endemic, the clinical disease is usually mild in dairy cattle and in range beef cattle. A severe form of the disease can occur in feedlots where crowding and commingling from several sources occur. A severe form of upper respiratory tract disease and encephalitis has been reported in neonatal beef calves. Clinical disease is most common after 6 months of age in colostrum-fed calves as a result of waning colstral IgG (passive immunity).

There is sudden onset of anorexia, loud coughing, fever (up to 42°C [108°F]), severe hyperemia of the nasal mucosa with numerous clusters of grayish foci of necrosis on the mucous membranes of the nasal septum visible just inside the external nares, a serous discharge from the eyes and nose, increased salivation, and sometimes a slight hyperexcitability. A marked fall in milk yield may be the earliest indication in dairy cattle. The respirations are increased in rate and are shallow, but only an increase in the loudness of breath sounds is audible on auscultation of the lungs unless secondary pneumonia is present. A severe primary viral, or secondary bacterial, tracheitis may cause inspiratory dyspnea with abnormal tracheal breath sounds transmitted to the lungs. Respiratory distress is evident on exercise. A short, explosive cough is characteristic of some outbreaks but not in others. Sudden death within 24 hours after first signs appear can result from extensive obstructive bronchiolitis.

In dairy cattle, many animals in a herd become affected within a few days. The disease is usually mild, characterized by inappetence, coughing, profuse bilateral serous nasal discharge, excessive salivation, nasal lesions, moderate fever, moderate drop in milk production, and recovery in a few days. Several animals may have the conjunctival form of the disease with obvious conjunctivitis and profuse ocular discharge. The affected animals as a group do not return to full production for 10 to 14 days. The outbreak of respiratory disease will be followed by abortions in several days up to 90 days after the index case occurred.

In feedlot cattle the illness is often more prolonged, the febrile period is longer, the
nasal discharge becomes more profuse and purulent, and the convalescent period is longer. Some deaths may occur in the acute febrile period, but most fatalities are attributable to a secondary bronchopneumonia and occur after a prolonged illness of up to 4 months in which severe dyspnea, complete anorexia, and final recumbency are obvious signs. Some recovered animals may have a persistent snoring respiration and a grossly thickened, roughened nasal mucosa accompanied by nasal discharge.

**Ocular Form of IBR**
Conjunctivitis is a common finding in typical "red nose," but outbreaks of conjunctivitis may occur as the major clinical finding. One or both eyes may be affected, which is easily misdiagnosed as infectious keratoconjunctivitis (pink eye) associated with Moraxella bovis. However, the IBR lesions are confined to the conjunctiva and there are no lesions of the cornea except diffuse edema. The conjunctiva is reddened and edematous, and there is a profuse, primarily serous, ocular discharge. The cornea is initially unaffected, but occasionally may be damaged as a result of secondary bacterial infection. Calves less than 6 months of age may develop encephalitis, which is marked by incoordination, excitement alternating with depression, and a high mortality rate. Salivation, bellowing, convulsions, and blindness are also recorded.

**Systemic Disease in Newborn Calves**
In newborn calves under 10 days of age, the systemic form of the disease is severe and highly fatal. Sudden anorexia, fever, excessive salivation, and rhinitis, often accompanied by unilateral or bilateral conjunctivitis, are common. The oral mucous membranes are usually hyperemic, erosions of the soft palate covered by tenacious mucus are common, and an acute pharyngitis covered by tenacious mucopurulent exudate is characteristic. The larynx is usually edematous, and respiratory distress is common. Bronchopneumonia is common, and loud breath sounds, crackles, and wheezes associated with consolidation are present. Outbreaks of the disease commonly occur in highly susceptible herds where the herd immunity has declined, the dams are not vaccinated, and there is minimal, if any, specific colostral immunity. Diarrhea and dehydration, referred to as the alimentary form of BHV-1 infection, occur in some affected calves. The cause of the diarrhea is uncertain, but it may be related to the ruminal lesions.

**Abortion**
Abortion is a common sequela and occurs some weeks after the clinical illness or parenteral vaccination of nonimmune pregnant cows with the MLV vaccine of bovine tissue culture origin. Abortion may occur up to 90 days following vaccination if the virus becomes latent in the placenta and infects the fetus much later than usual. This raises the possibility that vaccination even with safe vaccines may appear to be the cause of abortion if natural infection preceded vaccination. It is most common in cows that are 6 to 8 months pregnant. Retention of the placenta often follows, but residual infertility is unimportant. However, endometritis, poor conception, and short estrus can occur after insemination with infected semen. The infectious bovine rhinotracheitis virus has been isolated from semen 12 months after storage.

Infected pustular vulvovaginitis is characterized by frequent urination, elevation of the tail, and a mild vaginal discharge. The vulva is swollen, and small papules, then erosions and ulcers, are present on the mucosal surface. Mucosal ulcers may coalesce, and sloughing of brown necrotic tissue may occur. Recovery usually occurs in 10 to 14 days unless there are complications. Balanoposthitis is characterized by similar lesions of the glans penis and preputial mucosa.

**Clinical Pathology**

**Virus Isolation or Detection**
After experimental infection, the median time to shedding is 2 days, the median time to peak shedding is 4 days, and the median time until shedding ceases is 14 days. Isolation of the virus from nasal swabs using tissue culture combined with a fourfold rise in antibody titers between acute and convalescent phase sera are desirable for a positive diagnosis of the disease. When using nasal swabs, cotton and polyester swabs are recommended rather than calcium alginate swabs, which are viricidal within 2 hours. The virus can be detected in nasal swabs by the use of an ELISA, direct and indirect immunofluorescence techniques, immunoperoxidase, and by electron microscopic examination that may reveal herpes-like viral particles. The sensitivity of the direct immunofluorescence techniques is comparable to the cell culture technique. The ELISA is highly sensitive. A combination of the indirect immunofluorescence test and virus isolation from both ocular and nasal swabs of several animals will increase the recovery rate.

The PCR assay is as sensitive as virus isolation and is a practical alternative for the rapid detection of the virus. The results are available in 1 day, compared with virus isolation, which requires 7 days. The PCR assay can be used for detection of virus in semen and is considered equivalent to that of standard virus isolation and dot blot hybridization. The PCR assay with Southern blot hybridization is considered to be highly sensitive and can detect the virus in semen before they develop any detectable antibody. The PCR assay can also detect 5 times as many positive semen samples as the virus isolation on egg yolk–extended semen. PCR is considered the diagnostic test of choice for routine diagnosis of BHV-1 in aborted fetuses.

Using restriction endonuclease analysis of viral DNA, it is now possible to distinguish field isolates of the virus from vaccine strains, which may be useful in the investigation of vaccine-induced epidemics of the disease.

**Serology**
Several serologic tests are available for the detection of antibody and a rise in titer between the acute and convalescent phases of the infection.

The primary immune response to BHV-1 experimental inoculation of cattle is characterized by the formation of IgM and IgG antibodies, primarily IgG1, by postinoculation day 7. Secondary immune responses are characterized primarily by the formation of IgG2 antibody. A secondary immune response resulting from abortion induced by intraamniotic virus inoculation is characterized by a substantial increase in IgM antibody. A secondary BHV-1 exposure by the intranasal route does not result in secondary IgM antibody formation.

The VN test has been widely used and is the standard by which other techniques have been evaluated. The ELISA is a specific, sensitive, and practical test for detection of BHV-1 antibodies and has advantages over the SN test. The IgM–ELISA test is useful for the diagnosis of recent infection with BHV-1 in calves.

The detection of latent BHV-1 infection in cattle is important in control programs and in international trade activities. Therefore tests to detect specific antibodies in serum must be highly sensitive to detect low levels of BHV-1–specific antibodies. This emphasizes the need for international standardization of tests to detect BHV-1–specific antibodies in cattle. In endemic herds, BHV-1 transmission is not continuous but is sufficient to produce detectable antibodies. A serologic test negative carrier status (latent infection) occurs when there is no reexposure to stimulate humoral immunity. In other words, it remains very challenging to identify latently infected cattle when they are housed in a population with minimal BHV-1 transmission.

An immunofluorescence assay using monoclonal antibodies can discriminate between the four ruminant alpha-herpesviruses related to the BHV-1. They include the bovine herpesvirus-5, caprine herpesvirus-1 (CpHV-1), cervine herpesvirus-1 (CvHV-1), and cervine herpesvirus-2 (CvHV-2). Buffalo herpesvirus-1 and elk herpesvirus are also closely related to BHV-1.

Bulk-tank milk testing for BHV-1 antibodies may be useful in eradication and monitoring programs because it offers the possibility of rapid and inexpensive screening. The correlation between the bulk milk test and the within-herd prevalence of
infection, although it was not clear whether BHV-1 was the primary cause of death in all cases. The encephalitic form lacks gross lesions but is characterized microscopically by non supplicative inflammation, neuronal degeneration and gliosis, located particularly in the cerebral cortex and the internal capsule. Inclusion bodies are sometimes present. Both immunoperoxidase and PCR tests are capable of detecting BHV-5 antigen in formalin-fixed brain tissues affected with bovine herpesvirus encephalitis.

Aborted fetuses show moderately severe autolysis and focal necrotizing hepatitis. Microscopically, foci of necrosis rimmed by very few leukocytes are visible in the liver and many other organs. Occasionally, intra nuclear inclusion bodies can be seen. Viral antigen can be demonstrated in sections of the lung, liver, spleen, kidney, adrenal gland, placenta, and in mummified fetuses using the avidin–biotin complex system. Using this system, the viral antigen can be found in fetal tissues from which the virus could not be isolated in cell culture.

Samples for Confirmation of Diagnosis

- **Histology**—formalin-fixed samples:
  - **abortion/neonate**: lung, liver, trachea, kidney, adrenal gland, rumen, esophagus, pharynx; **respiratory form**: nasal turbinate, trachea, pharynx, lung; **encephalitic form**: half of midsagitally sectioned brain (LM, IHC)
  - **Virology**—abortion/neonate: lung, liver, kidney, rumen; **respiratory form**: lung, trachea, nasal swab; **encephalitic form**: half of midsagitally sectioned brain (FAT, ISO, PCR)

Differential Diagnosis

Infectious bovine rhinotracheitis is characterized by acute rhinotracheitis, coughing, profuse nasal discharge, nasal septum lesions, bilateral conjunctivitis, anorexia, fever, and gradual recovery in a few days. Secondary bacterial tracheitis and pneumonia can occur. It must be differentiated from the following:

- Pneumonic pasteurellosis is characterized by marked toxemia and depression, coughing, anorexia, gauntness, fever, abnormal lung sounds, and good response to antimicrobials.
- Bovine virus diarrhea is characterized by depression, anorexia, salivation, oral erosions and ulcers, persistent diarrhea, dehydration, and death in a few days.
- Malignant head catarrh is characterized by remarkable mental dejection, prominent lesions of nares, severe erosive lesions in oral cavity, interstitial keratitis, enlarged peripheral lymph nodes, high persistent fever, hematuria, terminal encephalitis, and death in several days.
- Calf diphtheria occurs usually in a single animal and there is depression, fever, inability to suck or eat, inspiratory dyspnea and stridor, fetid oral and laryngeal lesions, and severe toxemia.
- Viral pneumonia of calves occurs in a group of calves and is characterized by mild depression, inappetence, fever, coughing, dyspnea, abnormal lung sounds, no nasal lesions, and recovery in a few days.

- Allergic rhinitis occurs in cattle on pasture in summer months and is characterized by sneezing and wheezing with inspiratory dyspnea, mouth breathing, normal temperature, and profuse thickened nasal discharge that caseous and greenish-orange in color.
- Systemic form of IBD in newborn calves must be differentiated from acute pneumonia, septicemia, and toxemias.

**TREATMENT**

**Antimicrobial Therapy**

Broad-spectrum antimicrobials are indicated if secondary bacterial tracheitis and pneumonia are present. Affected cattle should be identified, isolated, and monitored frequently for evidence of secondary bacterial disease accompanied by anorexia and toxemia and treated accordingly. The tracheitis is particularly difficult to treat; antimicrobials daily for several days are necessary.

**CONTROL**

The diseases associated with the virus may occur unpredictably at any time, and even closed herds with no introductions may remain free of the disease for several years and suddenly experience an outbreak. The current strategies for control are natural exposure, biosecurity, vaccination, or eradication of the virus from a herd or even the cattle population of a country.

**Natural Exposure or Vaccination**

**Natural Exposure**

Cattle that have recovered from a natural infection with the virus are immune to further clinical disease. However, to depend on natural exposure of the herd is risky because not all animals will become infected and become immune. Abortion storms occur in herds that are not vaccinated and depend on natural exposure. Vaccination is therefore recommended in areas where the prevalence of infection is high and eradication is not feasible because of the extensive nature of the cattle population and movement of animals from one area to another. The virus is sensitive to many disinfectants including 1% quaternary ammonium bases, 1% phenolic derivatives, and 10% Lugol’s iodine.
Biosecurity

Biosecurity is any practice or system that prevents the spread of infectious agents from infected animals to susceptible animals or that prevents the introduction of infected animals into a herd, region or country in which the infection has not yet occurred. Biosecurity is an integral part of any successful livestock enterprise and reduces the risks and consequences of introducing an infectious disease. The components of biosecurity include management and placement programs, farm layout, decontamination, pest control, and immunization. All of these factors directly affect productivity and profitability.

The introduction of new infections into herds can be prevented or minimized by purchasing animals directly from herds known to be free of a particular disease. The adoption of this principle requires awareness of the possibility of purchasing unknown infected animals and testing animals for the infection before entry into the herd. It may also require keeping the introduced animal in quarantine for several weeks after arrival before it is mixed with the other animals.

Veterinarians need to work with their clients to develop a specific disease control and biosecurity protocol for each farm. The benefits of a rigidly enforced biosecurity program need to be stressed. Veterinarians can assist producers in developing methods to handle livestock and to purchase replacement stock by designing protocols that concentrate on general and specific aspects, such as design and construction of isolation rates.

Closed Herd

A closed farming system to prevent the introduction of infectious diseases into dairy farms is technically possible and is economical. A closed dairy farming system could prevent the introduction of BHV-1 and can be a good starting point for eradication of infectious diseases from the herd.

In the cattle industry, animals are moved freely from their farms of origin to veterinary clinics, cattle shows and sales, auction markets, 4H club events, and community grazing pastures. Cattle are commonly returned to their farms of origin after being at shows and sales, veterinary clinics and other events where animals from other farms are mixed. Animals may commingle with those from adjacent herds (broken fences or cattle breaching fences from one pasture to another). Breeding bulls may be leased from one farm to another, and then returned to the farm of origin. The mixing of animals that occurs in all of these circumstances provides opportunities for the transmission of important infectious agents.

Vaccination

With currently available diagnostic tests, it is not possible to identify animals that have a latent BHV-1 infection. The next best strategy is to use a well-planned vaccination program.

Rationale for Vaccination

Vaccination protects animals from severe clinical signs of infection and assists in control and eradication programs. The rationale for vaccination is based on the following:

- The virus is ubiquitous and the occurrence of the disease unpredictable.
- Economic losses from abortion, neonatal disease, and respiratory disease can be high.
- Colostral immunity in calves wanes by 4 to 6 months of age.
- The vaccine will prevent abortions caused by the virus and provide protection against respiratory disease if given at least 10 days before natural exposure.

Several attenuated live and inactivated BHV-1 vaccines are currently available, with attenuated vaccines being administered intranasally or intramuscularly. The vaccine strains have usually undergone multiple passages in cell culture to induce attenuation.

Modified live-virus (MLV) vaccines offer three advantages over inactivated vaccines:

- Induction of a rapid immune response
- Relatively long duration of immunity
- The induction of local immunity

Protection from infection and disease has been observed within 40 to 96 hours following intranasal or IM vaccination with MLV vaccines. This rapid development may be attributable to interferon induced locally, but intranasal vaccination also induces secretory IgA antibody and cell-mediated immunity. Vaccination trials have found that the traditional MLV vaccines are safe and effective in preventing clinical disease and are more effective than inactivated vaccines.

Both the intranasal and intramuscular stimulate the production of humoral antibody. The intranasal vaccine stimulates the production of local interferon and local antibody in the nasal mucosae, is safe for use in pregnant cows, and is highly effective for the prevention of abortion caused by the virus. The intramuscular vaccine of bovine tissue culture origin is abortigenic, especially in nonimmune cows. The intranasal vaccine provides protection against respiratory disease induced by experimental challenge 72 hours after vaccination. In general, the intranasal vaccine provides effective protection against the respiratory form of the disease but occasionally disease occurs in vaccinated animals. The intranasal vaccines do not cause a significant systemic reaction and have been used in the face of an outbreak where all in-contact animals are vaccinated in an attempt to reduce the number of new cases. A major requirement of the intranasal vaccine is that the vaccine virus must multiply on the nasal mucous membranes. If the vaccine is not administered into the nasal cavities carefully, or if the animal is difficult to handle or snorts out the vaccine, vaccination will not occur. The careful administration of a temperature-sensitive vaccine in 2 mL of diluent into one nostril is as effective as a two-nostril vaccination method using a total of 5 mL of diluent. Serum antibody titers were similar for beef cattle vaccinated in high (>32°C, >90°F) or moderate (21°C, 69°F) ambient temperatures with an intranasal vaccine. The preexistence of some local antibody from natural exposure or coinfection with a virulent strain of the virus may also restrict the multiplication of the vaccine virus, especially the temperature-sensitive mutants.

Temperature-Sensitive BHV-1 Modified Live Vaccine. An intranasal BHV-1 vaccine containing an MLV strain whose growth is restricted to the upper respiratory tract has been developed in Europe. The vaccine strain is chemically treated to produce a temperature-sensitive characteristic, so that it cannot replicate at the body temperature of the animal. Prebreeding vaccination of replacement heifers with the vaccine provides fetal protection. The vaccine is efficacious and safe for use in pregnant cattle. Intranasal vaccination stimulates both systemic and local cell-mediated immunity and antibody.

Disadvantages of Modified Live Vaccines.

The extensive use of MLV vaccines has reduced the incidence of clinical disease but there are some potential disadvantages. MLV vaccines must be stored and handled properly to avoid loss of potency. The parental MLV vaccine is potentially abortigenic and cannot be used on nonimmune pregnant cattle. The virus in MLV vaccines can also become latent following vaccination. Fatal, generalized BHV-1 infection has been associated with vaccination of beef calves under 3 days of age with MLV containing BHV-1 and PI-3. An outbreak of meningoencephalitis occurred in purchased Holstein Friesian male calves vaccinated intranasally at 1 and 3 weeks of age with a commercial MLV vaccine containing BHV-1, bovine virus diarrhea virus (BVDV), PI-3, bovine adenovirus type-7 and bovine respiratory syncytial virus (BRSV). Parenteral vaccination was recommended as the proper vaccination protocol. The isolated virus was classified as BHV-1.1.

Shedding of Virus by Vaccinated Animals.

There is some concern that MLV-vaccinated calves may shed the vaccine virus, which could then spread to pregnant cattle, resulting in abortion. In calves vaccinated with the intranasal vaccines, the virus replicates in the respiratory tract and is shed for 7 to 14 days. In nonimmune calves, replicating virus can...
be detected 9 hours after vaccination, with peak shedding occurring at 4 days. However, the intranasal vaccination of feeder calves at 7 months of age does not result in transmission of the vaccine virus to nonvaccinated animals comingle with vaccinated calves. Calves vaccinated with a live temperature-sensitive mutant of BHV-1 vaccine were protected against clinical illness from experimental challenge, but excreted the virus 2 months later following treatment with corticosteroids. This emphasizes the general principle that the use of a MLV vaccine implies a continuing commitment to vaccination that may reduce the incidence of disease but is unlikely to eradicate the infection.

**Inactivated Vaccines.** Inactivated virus vaccines were developed because of some of the disadvantages of MLV vaccines. The vaccines contain high levels of inactivated virus or portions of the virus particle (glycoproteins) supplemented with an adjuvant to stimulate an adequate immune response. Inactivated vaccines are given intramuscularly or subcutaneously. They do not cause abortion, immunosuppression, or latency, although they do not prevent the establishment of latency by field strains. They do not cause shedding and are safe for use in and around pregnant animals. They are also relatively stable in storage.

Inactivated vaccines, however, may not be as efficacious as MLV vaccines because of the potential for destruction of some of the protective antigens during the inactivation process. They require two doses of the vaccine and protection is not observed until 7 to 10 days following the second dose of the vaccine, which is usually given 10 to 14 days after the primary vaccination.

A major disadvantage of both the MLV and inactivated vaccines is that neither allows for differentiation between vaccinated and naturally infected animals. These factors render conventional vaccines ineffective for a concurrent vaccination and eradication strategy and inappropriate for use in breeding bulls for export market or artificial insemination units that demand BHV-1-free animals. These limitations, along with major advances in molecular biology and protein purification techniques, have encouraged the development of genetically engineered attenuated vaccines and nucleic acid–free subunit vaccines.

**Subunit Vaccines.** A subunit vaccine contains only one or more of the antigens of the pathogen necessary to evoke protective immunity, and lacks the components that might cause unwanted side effects. The major surface glycoproteins of the BHV-1 are the antigens responsible for stimulating protective immunity. To produce a subunit vaccine containing only surface glycoproteins, the proteins are isolated from the virus of virus–infected cells, or the peptides can be synthesized. The major glycoproteins of BHV-1 originally designated gI, gII, and gIV are now named gB, gC, and gD, and they induce high levels of antibody in cattle that are fully protected from experimental disease. The level of immunity based on serum antibody titers and protection against experimental challenge is much greater with the individual glycoproteins than are those immunized with commercially available inactivated vaccines.

**BHV-1 subunit vaccines provide a number of advantages:**
- They do not contain live virus and therefore cannot be shed to other animals, cause abortion, or establish latent infections.
- They prevent infection and disease.
- They are not immunosuppressive.
- Serologic assays, based on one or more antigens not present in the vaccine, provide a potential to differentiate vaccinated from naturally infected animals.

Prevention of infection by the use of a BHV-1 subunit vaccine combined with the use of a diagnostic test to identify infected cattle offers the potential for vaccination of breeding bulls for artificial insemination units and export and for eradication of the virus.

**The potential disadvantages of subunit vaccines include the following:**
- Because of the amount of glycoprotein needed, two immunizations may be necessary for protection.
- Subunit vaccines will have to be compatible with the commonly available multivalent vaccines.
- The efficiency of subunit vaccines is highly dependent on the use of an effective adjuvant.

**Marker vaccines or DIVA (differentiation of infected from vaccinated animals)** attenuated or inactivated vaccines are based on deletion mutants of one or more viral proteins, which allows the distinction between vaccinated and infected animals based on respective antibody responses. This vaccine approach was very successful in eradication programs for pseudorabies. A marker vaccine must be accompanied by a diagnostic test, which enables distinction of infected from vaccinated animals. These tests detect antibodies against a **glycoprotein that is lacking in the vaccine**. The desirable characteristics of the companion diagnostic test include the following:
- Antibodies are detectable in 2 to 3 weeks after infection, both in vaccinated and unvaccinated cattle.
- Antibodies must persist for at least 2 years, preferably lifelong.
- A low level of virus replication gives rise to detectable antibody formation.

- Cattle repeatedly given the matching marker vaccine remain negative in the test.
- The test should be suitable to detect antibodies in milk.
- The test has high sensitivity and specificity in comparison with conventional antibody tests.

Mutants of BHV-1 have been developed by deleting one or more of the nonessential glycoproteins. Marker vaccines offer the advantage of evaluating the effect of vaccination on the circulation of the field virus under naturally occurring conditions. Using a gE-deleted BHV-1 strain, both a killed virus and MLV marker vaccine have been developed. These vaccines induce all the relevant immune responses against BHV-1–specific immune reactions, including antibodies against gE. Both vaccines have the capacity to reduce, and even to stop, the spread of BHV-1. A serologic test that detects gE–specific antibodies in serum and milk is also available. These vaccines have been tested according to the current European requirements for the development of bovine vaccines. The live vaccine is safe in pregnant cattle and is considered safe for all kind of breeding cattle, including bulls. The live-virus marker vaccine is also efficacious in the presence of maternal antibody, and vaccination of very young calves, irrespective of their BHV-1 status, can be recommended. An inactivated BHV-1 gE-negative vaccine resulted in only a slight decrease of about 1.4 liters per cow in milk production after a double vaccination. One concern with this use of modified live BHV-1 gE-negative vaccines is the potential for recombination of vaccine-virus and field-virus strains resulting in the emergence of virulent BHV-1 virus that is gE-negative on serologic testing. This potential can be mitigated by development of double mutant vaccine strains, such as a gE and thymidine kinase mutant Bo-HV-1 strain.

**Combination or Multivalent Vaccines.** The vaccines available for the control of diseases associated with BHV-1 infection are mostly multivalent antigen vaccines containing other respiratory pathogens such as PI-3, BRSV, and BVDV. Some also contain the antigens for the control of leptospirosis and campylobacteriosis. Vaccines containing only BHV-1 are not in common use. A Canadian field trial to compare the serologic responses in calves to eight commercial vaccines against BHV-1, PI-3, BRSV, and BVDV found some differences. Antibody responses to BHV-1 were higher in calves vaccinated with MLV vaccines than in those vaccinated with the inactivated vaccines. There were no differences in seroconversion rates and titers to BHV-1 between intranasal and MLV IM vaccines following a single vaccination. However, after double vaccination with MLV BHV-1 vaccines, both seroconversion rates and changes in titers to the virus were higher.
in calves vaccinated IM than in those vaccinated intranasally. Whether or not these differences in antibody titers reflect differences in vaccine efficacy against naturally occurring disease in the field situation is unknown.

The vaccination of calves with multivalent vaccines containing MLV or MLV and inactivated BHV-1 is associated with virus-specific interferon gamma production and protection from clinical disease as a result of challenge 5 days after a single vaccination.

**Immunization and Latency.** Immunization with vaccines, as with natural infection, does not prevent subsequent infection and the possibility of latency.

**Vaccination Programs in Herds**

**Beef Breeding Herds.** Beef calves should be vaccinated 2 to 3 weeks before weaning as part of a preweaning preconditioning program. Calves vaccinated with the parental MLV BHV-1 vaccine before castrational BHV-1 antibody titers reach low levels do not develop an immediate, active serologic response, as indicated by serologic titers, but are sensitized to the virus. Revaccination at a later date, when maternal antibodies have decreased to undetectable levels, results in a marked serologic response. Heifer and bull replacements are vaccinated at least 2 weeks before breeding. When outbreaks of the respiratory disease occur in unvaccinated beef herds, all cattle in the herd may be vaccinated with the intranasal vaccine. Whether or not beef herds should be vaccinated annually following the initial vaccination is uncertain. There are field reports of outbreaks of abortion as a result of the virus in beef cattle that were vaccinated 3 years previously, which suggests that revaccination of breeding females every 2 years may be indicated. Because both natural infection and vaccination results in latent infection, it may be that the persistence of the virus, combined with natural exposure, may result in persistence of antibody. The duration of protective immunity following vaccination is uncertain, but usually lasts 1 year. Antibodies last for at least 5.5 years in heifers following experimental infection and complete isolation during that time.

The MLV BHV-1 vaccine given intranasally or parenterally can enhance the prevalence of infectious bovine keratoconjunctivitis in beef calves vaccinated between 4 and 10 months of age, when the risk for the ocular disease is highest. The explanation for the pathogenic mechanism is uncertain.

**Feedlot Cattle.** Feedlot cattle should be vaccinated at least 10 days before being placed in the lot, especially one in which the disease may be enzootic. If this is not done, a high incidence of the respiratory form of the disease may occur in recent arrivals. If vaccination before arrival is not possible, the next best procedure is to vaccinate the cattle on arrival and place them in an isolation starting pen for 7 to 10 days, during which time immunity will develop. A 2015 meta-analysis concluded that in natural exposure trials, beef calves vaccinated with commercially available vaccines against BHV-1, BVDV, BRSV, and PI-3 had slightly less than half the risk of developing clinical signs of pneumonia and approximately 1/5th the risk of dying from respiratory disease. Moreover, vaccination with modified live or inactivated IBDV vaccine decreased the risk of developing clinical signs of respiratory disease by 39% to 46%, respectively, in beef and dairy calves to experimental challenge compared with unvaccinated controls. Collectively, this is strong supportive evidence that vaccination against IBDV is effective in beef calves in North America.

**Dairy Cattle.** The necessity of vaccinating dairy cattle will depend on the prevalence of the disease in the area and in the herd and the movement of cattle in and out of the herd. A closed herd may remain free of BHV-1 infection indefinitely and vaccination may not be indicated. But to avoid unpredictable abortion storms as a result of the virus in dairy herds, heifer replacements should be vaccinated for the disease 2 to 3 weeks before breeding. Vaccination of a large dairy herd with a persistent BHV-1 infection has been successful in controlling the respiratory form of the disease. The intranasal vaccine has been used extensively in newborn calves in problem herds, but its efficacy at such an age is unknown. The parenteral vaccination of beef calves under 3 days of age with an MLV BHV-1 and PI-3 vaccine caused high mortality. If the systemic form of the disease poses a threat to a potential calf crop, the pregnant cows could be vaccinated with the intranasal vaccine in late pregnancy; this will increase the level of colostral antibody available to the newborn calf and will provide newborn calves with protection against the highly fatal systemic form of the disease. A 2015 meta-analysis concluded that in natural exposure trials, dairy calves vaccinated with commercially available vaccines against BHV-1, BVDV, BRSV, and PI-3 had similar risk of developing clinical signs of pneumonia and dying from respiratory disease than unvaccinated controls. The markedly different effect of vaccination in dairy calves to that seen in beef cattle may be because respiratory disease occurs most frequently before 6 months of age in dairy calves. However, as indicated previously, vaccination with modified live or inactivated IBDV vaccine decreased the risk of developing clinical signs of respiratory disease to experimental challenge by 39% to 46%, in beef and dairy calves, respectively, compared with unvaccinated controls. Collectively, there is moderate supportive evidence that vaccination against IBDV is effective in dairy calves in North America.

**Bulls intended for use in artificial insemination centers** present a special problem of disease control because the virus in semen can have severe consequences on reproductive performance. Bulls that are seropositive to the virus must be considered as carriers and potential shedders of the virus, and should not be allowed entry to these centers. Not all bulls that are seronegative can necessarily be considered free of the virus, and regular attempts at the isolation of the virus must be made from preputial washing and semen. Bulls that become infected while at the centers should be kept isolated, culled, and replaced with clean bulls. Bulls from herds that routinely vaccinate against BHV-1 should not be vaccinated with conventional vaccines if destined for an artificial insemination center. Cattle destined for export should not be vaccinated in case importing countries prohibit the introduction of seropositive cattle. This will not guarantee that such animals will not become positive from natural infection. The use of marker vaccines has some potential in breeding bulls intended for artificial insemination units and for export.

**Eradication**

Eradication of the BHV-1 virus from a single herd or the cattle population in a country can be considered as an alternative to vaccination, particularly when the initial prevalence of infection based on serology is low. Serologically positive animals are removed or culled, and only seronegative animals introduced into the herd. Control is focused on segregation and elimination of seropositive animals and reduction of animal movement to prevent spread. This approach is not feasible in countries with extensive cattle populations and where management practices result in movement of cattle from one region to another.

**Eradication Using Marker Vaccines.** Some countries are beginning an immunization program with the marker vaccines, which will protect the cattle against disease but still allow differentiation between vaccinated animals and those that have been naturally infected and are potential carriers of the latent virus. These infected animals could be eliminated over a period of time. Successful eradication depends not only on the efficacy of the vaccine but also on the quality of the tests. False-positive test results can lead to unnecessary culling of cattle, an increase of costs, and reduced cooperation of farmers in the eradication program. As an example, a compulsory eradication program for BHV-1 began in The Netherlands in 1998. The program required that farms either vaccinate all cattle twice yearly or be approved for a certified BHV-1-free or specific-pathogen-free (SPF) status. To become a certified BHV-1-free herd, cattle have to be sampled individually and all seropositive animals
culled as soon as their status is known. The BHV-1-free herd status is monitored by monthly bulk milk samples. The spread of BHV-1 between herds can be prevented using a surveillance system of sampling herds annually, both individual milk samples and blood samples.

Herd with BHV-2 infected (seropositive) animals are required to vaccinate with a glycoprotein E (gE)-negative BHV-1 vaccine. The vaccine can be either an inactivated or live vaccine both on a spontaneous BHV-1 mutant without the complete gE gene. These so-called marker vaccines or DIVA vaccines allow the identification of cattle infected with the wild-type BHV-1 within a vaccinated population using a gE-blocking ELISA or a commercially available gE-blocking ELISA that both specifically detect gE antibodies. The eradication program is based on the presumption that all BHV-1 wild-type strains express gE and induce antibodies that can be measured with a gE-blocking ELISA.

**Loss of Certification.** The probability of and risk factors for the introduction of BHV-1 into SPF Dutch dairy farms has been examined. A total of 95 SPF dairy farms were monitored for 2 years, during which time 14 introductions of infectious diseases occurred on 13 of the 95 farms, for a total incidence rate per herd-year at risk of 0.09. Outbreaks were usually associated with allowing cattle to return to their farm, cattle grazed more often at other farms, and protective clothing less often provided to the veterinarians. For a successful eradication program, farms should remain BHV-1 free, which can be achieved by a more-closed farming system. A more-closed farming system is one that rules out the possibility of direct contact with other cattle from other farms. Also, the farmer requests that professional visitors such as veterinarians and artificial insemination (AI) technicians to wear protective farm clothing when handling cattle. Protective farm clothing includes coveralls or overcoats and boots that can be worn over “off-farm” clothing and that the farmer provides to the visitors before handling cattle. A sanitary barrier is a covered area outside the barn in which visitors put on protective farm clothing over their off-farm clothes. A sanitary barrier has a “dirty” side, where visitors leave their off-farm boots, and a “clean” side, where visitors wear protective clothing and can enter the barn. All of these measures would be economical.

**Control**

Vaccination of beef calves ≥ 6 months of age against BHV-1 (preferably with modified live glycoprotein E–negative vaccine) or with modified live or killed vaccine against BHV-1, BVDV, BR SV, and PI-3 (R-1)

Vaccination of dairy calves less than 6 months of age against BHV-1 (preferably with modified live glycoprotein E–negative vaccine) (R-2)

Vaccination of dairy calves less than 6 months of age with modified live or killed vaccine against BHV-1, BVDV, BR SV, and PI-3 (R-3)

**LUNGWORM IN CATTLE**

**SYNOPSIS**

**Etiology** The nematode Dicyocaulus viviparous is the only lungworm of cattle. The disease it causes has many local names, including the following:

- **Parasitic bronchitis**
- **Verminous pneumonia**
- **Verminous bronchitis**
- **Husk**
- **Hoose**

Bovine lungworm has a very wide distribution through temperate and cold areas and, depending on climatic conditions and season, can cause serious losses.1 The disease reaches its greatest importance in mild, damp regions of the British Isles and parts of western Europe. D. viviparous is also carried by the European bison, in which it causes a disease with similar pathologic lesions to those in cattle.2,3 Deer carry similar parasites, including D. eckerti and D. capreolus. It is uncertain whether deer play a role in the transmission of D. viviparous but lungworm species are generally host specific.

**LIFE CYCLE**

Adult lungworms live in the trachea and bronchi. The females are prolific egg producers, and it has been estimated that a single infested calf may contaminate a pasture with 33 million larvae. The eggs are coughed up and swallowed. They hatch in the air passages or alimentary canal, and larvae are passed in the feces. These develop in the dung pat through to the infective third stage, which is protected by cuticles retained from both first and second molts. Because the ensheathed larvae cannot feed, glycogen granules are stored in the intestinal cells. Moisture is essential for the survival and development of the larvae, and a moderate temperature of 18° to 21°C (65–70°F) permits their full development to the infective stage in 3 to 7 days. Larvae survive best in cool, damp surroundings, especially when the environment is stabilized by the presence of

**TREATMENT AND CONTROL**

**Treatment**

Antimicrobial treatment for animals with a fever to address concurrent bacterial pneumonia (see treatment recommendations in this chapter for Mannheimia hemolytica) (R-1)

**Lesions**

Large volumes of consolidation in diaphragmatic lobes of lung, emphysema, worms up to 8 cm long in bronchi (only in patent phase of disease).

**Diagnostic confirmation**

Clinical pathology as noted; at necropsy, distribution of lesions in lungs and demonstration of worms in bronchi.

**Treatment**

Eprinomectin, avermectins/milbemycins and benzimidazoles are active against all parasitic stages of D. viviparous; eprinomectin and avermectins also have a persistent protective effect; levamisole also used.

**Control**

Vaccination; early-season anthelmintic prophylactic programs using suitable intraruminal boluses or multiple doses of avermectins/milbemycins; keep susceptible animals off potentially dangerous pasture.
of long herbage or free water. Under optimum conditions, larvae may persist for over 1 year. They can overwinter in climates as cold as Canada and Germany. When warmer spring weather arrives, the larvae resume their motility but quickly die once their food stores are depleted.

Transmission occurs when cattle ingest third-stage larvae while grazing. These migrate through the intestinal wall to reach the mesenteric lymph nodes. From here they pass via the lymphatics to the venous bloodstream and through the heart to the lungs, where they break into the alveoli. They migrate up the bronchioles to their predilection site in the larger air passages and start to lay eggs some 3 to 4 weeks after infection. Most adult worms succumb to immune expulsion within a few weeks. These events determine the progression of the clinical syndrome and their approximate timing is as follows:

1. Penetration phase (ingestion to arrival of larvae in lung), days 1 to 7
2. Prepatent phase (larvae in lung), days 7 to 25
3. Patent phase (mature worms in lung) days 25 to 55
4. Postpatent phase (lungworms disappearing from lung), days 55 to 70

EPIDEMIOLOGY

Bovine parasitic bronchitis is a sporadic and largely unpredictable disease. This is because immunity develops more quickly than is the case with many other nematode infections, but nevertheless can remain incomplete for many weeks and may wane in the absence of reinfection. In most grazing seasons, immunity will develop fast enough to protect calves against the accumulating numbers of infective larvae on the grass. The farmer may not even realize that the land is contaminated. Clinical outbreaks occur when weather patterns, management, or other factors result in sudden exposure to a pasture challenge sufficient to overwhelm any immunity that has already developed. In comparison with the gastrointestinal nematodes of cattle, relatively few worms (i.e., a few hundred or thousand) are required to produce clinical signs. Thus the disease is almost entirely confined to grazing cattle and occurs most frequently in young animals in their first year on grass, although outbreaks are becoming more common in adults. The epidemiology of lungworm disease is largely concerned with factors determining the number of infective larvae on the pasture and the rate at which they accumulate.

Infective D. viviparus larvae are relatively inactive and are incapable of traveling more than 5 cm from the dung pat. Factors that disperse the larvae more widely over the pasture include mechanical spread by the following:

- Rain
- Earthworms
- Wheeled vehicles
- Human and animal feet

A fungus, Pilobolus, plays a particularly important role in this process and can transfer larvae across field boundaries. Fungal spores on grass pass through the grazing animal and germinate in the feces. Dictyocaulus larvae climb onto the sporangium (fruiting body), which fills with water and bursts, propelling the fungal spore and the lungworm larvae for distances of up to 3 m.

Dairy calves are most vulnerable to lungworm disease because they are often reared indoors until 4 to 5 months of age and then placed on paddocks grazed each year by successive calf crops. If the paddocks are heavily contaminated, acute disease may occur in 1 week or so. Usually, however, only sufficient larvae survive the winter to induce low-grade asymptomatic infections in the susceptible calves, which then start to reactivate the pasture and recycle the infection. With the high stocking densities commonly used, pasture challenge can reach pathogenic levels within 2 to 4 months. This model does not satisfactorily explain all outbreaks, and it has been suggested that larvae may be washed into the soil to emerge later (e.g., onto hay aftermath). Beef calves at grass with their dams are less likely to be affected as this system provides fewer opportunities for large numbers of larvae to accumulate, but outbreaks can occur particularly after weaning in the autumn.

In older animals, larvae ingested in the autumn become hypobiotic and resume their development in the following spring. This event occasionally causes disease in housed cattle but such infections are usually asymptomatic and provide a source of pasture contamination when these carrier animals are put out to graze. This is thought to be the main source of infection in more severe climates where overwintering larvae may not survive on the pasture, but carrier animals have also been incriminated in disease outbreaks in, for example, Louisiana in the United States.

Immunity to reinfection occurring after initial exposure to D. viviparus is variable in degree and duration. It normally provides protection during the first grazing season and is boosted by exposure to overwintered larvae at the beginning of each subsequent grazing season. Cattle removed from infected pastures for long periods can suffer clinical disease when reexposed. Recently the number of outbreaks of parasitic bronchitis in yearling and adult cattle in the United Kingdom, Denmark and some other countries has been rising. Reasons for this are speculative but include the following:

- A decline in the use of vaccination
- Changes in weather patterns and management systems
- Use of highly effective anthelmintic strategies in the first grazing season that may prevent adequate antigenic exposure

PATHOGENESIS

Migrating D. viviparus larvae provoke little damage until they reach the lungs. Thereafter, passage of larvae up the bronchioles causes them to become blocked by mucus, eosinophils, and other inflammatory cells, leading to collapse of the alveolae that they supply. Coughing and dyspnea occur if a sufficiently large volume of lung tissue is affected. This is accompanied by pulmonary edema and interstitial emphysema. As no structural damage has yet occurred, treatment at this stage in the disease produces an immediate clinical response. Later, however, when mature parasites are in the major bronchi, eggs and fragments of worms killed by immunity are aspirated and provoke a foreign-body pneumonia. Secondary bacterial infections establish and sequelae such as bronchiectasis occur. Such lesions are slow to resolve, and treated animals will require a long recovery period. Later still, once all or most of the worms have been expelled, the alveolar lining cells of some 25% of recovering animals become cuboidal and nonfunctional. The reason for this is unknown but may be a response to substances released by the dead worms. Because this reaction is irreversible, many animals affected in this way will die.

The response of the lung varies widely depending on the number of larvae ingested, the nutritional status and age of the host, and whether or not it is exposed to lungworm infection for the first time. Vaccinated animals or those that have recovered from clinical or subclinical infection may cough and even become tachypneic if grazed on contaminated pasture. This is known as the “reinfection syndrome” and occurs as many larvae reach the lungs before succumbing to the immune response. Exposure of older previously infected animals to massive challenge may invoke a severe or fatal hypersensitivity reaction.

CLINICAL FINDINGS

Outbreaks vary in severity from sporadic coughing with no apparent production loss to acute cases with a rapidly fatal outcome. Individuals within a group are usually affected to varying degrees. Poorly nourished animals appear less able to withstand lungworm infection. Nevertheless, it is not unusual for severe infestations to be fatal in well-fed calves.

Acute cases have rapid shallow abdominal breathing of sudden onset that may reach a rate of 60 to 100 breaths/min. There is a frequent bronchial cough, a slight nasal discharge, a temperature of 40 to 41°C (104–105°F) and a heart rate of 100 to 120 bpm. The animal is bright and active and will attempt to eat, although respiratory distress often prevents this. Progress of the disease is
rapid, and within 24 hours dyspnea may become very severe, accompanied by mouth breathing with the head and neck outstretched, a violent respiratory heave and grunt, cyanosis, and recumbency. On auscultation, lung consolidation is evidenced by loud breath sounds, and crackles are heard over the bronchial tree. The cracking of interstitial emphysema commences over the dorsal two-thirds of the lung but is never as evident as in less acute cases. Fever persists until just before death, which usually occurs in 3 to 14 days and is greatly hastened by exercise or excitement. The case-fatality rate in this form of the disease is high, probably of the order of 75% to 80%.

**Subacute disease** is more common in calves than the very acute form. The onset is usually sudden, the temperature is normal or slightly elevated and there is an increase in the rate (60-70 breaths/min) and depth of respiration. An expiratory grunt is heard in severe cases and expiration may be relatively prolonged. There are frequent paroxysms of coughing. The course of the disease is longer, 3 to 4 weeks, and auscultation findings vary widely with the duration of the illness and the area of lung involved. In general, there is consolidation and bronchitis ventrally and marked emphysema dorsally. Affected animals lose weight very quickly and are very susceptible to secondary bacterial bronchopneumonia. The mortality rate is much less than in the acute form, but many surviving calves have severely damaged lungs. Consequently, they may remain stunted for long periods, and breathing may be labored for several weeks. Some surviving calves may show a sudden exacerbation of dyspnea around 7 to 8 weeks after the initial onset of disease. In these relapsed cases the prognosis is grave.

**Adult dairy cattle** are usually immune but sporadic outbreaks do occur as a result of waning immunity. Mortality is low but morbidity can be high, with reduced milk yields causing significant economic loss. Coughing is a constant feature, but other clinical signs are variable and may include dyspnea, nasal discharge, and weight loss. Sudden exposure of immune adults to massive challenge can cause severe interstitial pneumonia.

**CLINICAL PATHOLOGY**

The presence of *D. viviparus* larvae in feces confirms lungworm infestation, but their absence does not necessarily exclude the possibility of parasitic bronchitis. No larvae will be passed in the early stages of disease when the causal worms are still immature, nor will they be a constant finding when partially immune animals (e.g., dairy cows) succumb to challenge. In general, larvae can be found about 12 days after signs appear (i.e., around 24 days after infestation occurs). They are few in number at first but may become more numerous later.

**Enzyme-linked immunosorbent assay (ELISA) tests** using adult or larval worm antigen for the detection of *D. viviparous*-specific antibodies in serum and in milk (including bulk tank milk) have been developed. Care is required with interpretation because antibodies to adult antigen may not be detectable until several weeks after primary challenge and do not correlate with the immune status of the animal. Eosinophilia is a fairly consistent finding but not pathognomonic.

**An alternative method**, if disease is suspected but the lungworms are still in the prepatent stage, is to examine pasture clippings for larvae. This is a laborious procedure because large amounts of herbage (0.5–1 kg) must be used, and the yield of larvae is low.

**NECROPSY FINDINGS**

Adult *D. viviparous* are up to 8 cm long and easily seen when the trachea and bronchi are cut open. Worms may also be recovered by lung perfusion. Up to several thousand may be present in severely affected animals. In prepatent disease, however, careful microscopic examination of bronchial mucus is necessary to find larvae. Adult worms may be few or absent if the case is of sufficient duration for immune expulsion to have taken place.

**In acute cases**, morphologic changes include the following:

- **Enlargement of the lungs as a result of edema and emphysema**
- **Widespread areas of collapsed tissue of a dark pink color**
- **Hemorrhagic bronchitis with much fluid filling all the air passages**
- **Enlargement of the regional lymph nodes**

Histologically, the characteristic signs are as follows:

- **Edema**
- **Eosinophilic infiltration**
- **Dilation of lymphatics**
- **Filling of the alveoli and bronchi with inflammatory debris**
- **Larvae in the bronchioles and alveoli**

**In subacute cases**, interstitial emphysema is usually gross. Areas of dark pink consolidation are present in the diaphragmatic lobe and may also occur in other lobes. They can occupy two-thirds of the lung volume. There is froth in the bronchi and trachea. The regional lymph nodes are enlarged. Histologically, eggs and larvae can be seen in the air passages, the bronchial epithelium is much thickened, the bronchioles are obstructed with exudate, and the alveoli show epithelialization and foreign-body giant-cell reaction.

**The reinfection syndrome** is characterized by the presence of numerous 5-mm gray-green nodules formed by lymphoreticular cells clustering around dead larvae.

**DIAGNOSTIC CONFIRMATION**

*D. viviparus* larvae may be demonstrated by placing feces on a fine sieve or dental gauze on the top of a water-filled funnel (the Baermann technique). The larvae that swim into the water and collect at the bottom of the funnel are less than 0.5 mm long, sluggish, and often appear curved or coiled. Their most important diagnostic feature is the presence of easily visible refractile granules in the intestinal cells. Because not all animals will be shedding larvae, samples should be taken from all, or at least a representative proportion, of the group. Grass samples are washed in water with a surfactant and the sediment Baermannized as described previously. A technique that effectively separates larvae from plant debris by migration through agar gel has been reported. Gathering grass close to dung pats maximizes chances of finding larvae. Cattle with parasitic bronchitis are likely to have eosinophilia, and serologic tests can be used to rule out some other respiratory diseases, such as infectious bovine rhinotracheitis (IBR).

**In view of the uncertainties** associated with laboratory tests for parasitic bronchitis and the need for prompt treatment, diagnosis often has to be based on clinical history, signs, and auscultation. Affected animals have usually grazed alongside potential carriers or had access to pasture previously used by susceptible calves or older carrier animals. The timing of the outbreak may coincide with that expected from recycling of an infection initiated by overwintered larva (often 2-4 months after turnout) or recent exposure to heavily contaminated land. Many of the clinical signs of parasitic bronchitis are common to pneumonias of bacterial and viral origin. One feature that may be of value in differentiation is the relative softness and paroxysmal nature of the cough in parasitic infection.

**DISEASES OF THE BOVINE RESPIRATORY TRACT**

- **Bacterial bronchopneumonia**
- **Acute and chronic interstitial pneumonia**
- **Viral pneumonia**
- **Acute interstitial pneumonia (fog fever)**
- **Heavy infestations with ascarid larvae on pastures contaminated with pig feces**

In adult cattle, the major problem in diagnosis is to differentiate the acute form of the disease from acute interstitial pneumonia attributable to other causes. Clinically, the diseases are indistinguishable, and a history of movement onto a new pasture 1 to 2 weeks before the onset of the disease may be common to both. It is necessary to demonstrate *D. viviparous* antibodies in blood, worms at necropsy, and larvae in the herbage or in the feces of animals that previously grazed the pasture.
**TREATMENT**

**TREATMENT AND CONTROL**

**Treatment**
- Eprinomectin (0.5 mg/kg TOPp, 0.2 mg/kg SC) (R-1)
- Ivermectin (0.2 mg/kg, SC, PO; 0.5 mg/kg, TOPp) (R-1)
- Doramectin (0.2 mg/kg, SC, IM) (R-1)
- Moxidectin (0.2 mg/kg, PO, SC; 0.5 mg/kg, TOPp) (R-1)
- Albendazole (10 mg/kg, PO) (R-2)
- Oxendazole (7.5 mg/kg, PO) (R-2)
- Febantel (7.5 mg/kg, PO) (R-2)
- Fenbendazole (5 mg/kg, PO) (R-2)
- Netobimin (7.5 mg/kg) (R-2)
- Levamisole (7.5 mg/kg) (R-3)

**Control**
- Eprinomectin extended-release formulation (1.0 mg/kg, SC) (R-2)
- Ivermectin long-acting formulation (0.63 mg/kg, SC) (R-2)

**Vaccination**
- Live irradiated infective D. viviparus larvae (1000 larvae/calf, PO) (R-2)

PO, orally; SC, subcutaneously; TOPp, topical pour on formulation.

Anthemtics may be used prophylactically to prevent disease from occurring, as a curative treatment once disease strikes, or to prevent reinfection following an outbreak. Avermectins and milbemycins are particularly useful for prophylaxis and prevention of reinfection because they are not only highly effective against the lungworms present in the animals at the time of treatment but have prolonged activity against subsequent incoming larvae. The duration of this persistent effect varies with compound and formulation.

Most modern broad-spectrum drugs are active against D. viviparus. Dosage rates and label claims vary from country to country according to local conditions and regulatory requirements. Avermectins and milbemycins (macroyclic lactones) are particularly potent against immature and mature stages; doses of ivermectin, for example, as low as 0.05 mg/kg, are effective. At commercial dose rates, ivermectin by injection or as a pour-on formulation provides residual protection for up to 28 days; corresponding figures are up to 35 days for doramectin by injection and 42 days both for doramectin as a pour-on formulation and moxidectin by either route of administration. These compounds are given at 0.2 mg/kg by injection and 0.5 mg/kg as a pour-on formulation. Eprinomectin is the compound of choice for adult dairy cattle because it has a nil milk withdrawal period and provides residual protection of up to 28 days when given topically (0.5 mg/kg). Albendazole (10 mg/kg), febantel (7.5 mg/kg), fenbendazole (5 mg/kg), netobimin (7.5 mg/kg), and oxendazole (4.5 mg/kg), which are given orally, are active against all stages of the parasite but have no residual activity. Levamisole (oral or injection—7.5 mg/kg; pour on—10 mg/kg) also has activity against lungworm but no persistent effect.

Sustained-release intraruminal devices (“boluses”) provide extended periods of protection. For example, fenbendazole is released for up to 140 days from one bolus. There are also pulse release boluses containing oxendazole that release five or six anthelmintic doses at 3-week intervals. Most boluses normally protect against disease but may allow some worms to establish (in the case of the fenbendazole bolus) or to reach the lungs between pulses (oxendazole bolus), which may allow immunity to develop. Formulations of eprinomectin extended-release injection have been developed that have greater than 98% efficacy against D. viviparus and provide protection from reinfection for up 150 days in cattle. Similarly, an ivermectin long-acting injectable formulation has been shown to have up to 100% efficacy against D. viviparous in cattle for at least 77 days.

For veterinarians in the field, the outcome of therapeutic treatment is often unpredictable because it depends on the amount of structural damage in the lungs. Best results are obtained early in the course of disease when most pathologic changes can be quickly resolved. In severe cases, treatment may initially exacerbate clinical signs because the death and disintegration of many worms in the air passages releases antigens and adds to the mass of foreign material that can be aspirated. Because of animal welfare considerations and the high risk of mortality, anthelmintic treatments are often combined with an anthistamine or nonsteroidal antiinflammatory drug (NSAID) such as flunixin to reduce the severity of the reaction to the larvae and an antibiotic or sulfonamide to prevent secondary bacterial infection. Severely affected animals should be brought indoors for nursing and all other members of the group removed from the contaminated pasture and placed on clean grazing ground.

**CONTROL**

Two major strategies of control derive from the premise that the main factor governing the occurrence of disease is the density of D. viviparus larvae on pasture grazed by susceptible cattle. First, cattle grazing potentially contaminated pasture can be quickly resolved. In severe cases, treatment may initially exacerbate clinical signs because the death and disintegration of many worms in the air passages releases antigens and adds to the mass of foreign material that can be aspirated. Because of animal welfare considerations and the high risk of mortality, anthelmintic treatments are often combined with an anthistamine or nonsteroidal antiinflammatory drug (NSAID) such as flunixin to reduce the severity of the reaction to the larvae and an antibiotic or sulfonamide to prevent secondary bacterial infection. Severely affected animals should be brought indoors for nursing and all other members of the group removed from the contaminated pasture and placed on clean grazing ground.

For veterinarians in the field, the outcome of therapeutic treatment is often unpredictable because it depends on the amount of structural damage in the lungs. Best results are obtained early in the course of disease when most pathologic changes can be quickly resolved. In severe cases, treatment may initially exacerbate clinical signs because the death and disintegration of many worms in the air passages releases antigens and adds to the mass of foreign material that can be aspirated. Because of animal welfare considerations and the high risk of mortality, anthelmintic treatments are often combined with an anthistamine or nonsteroidal antiinflammatory drug (NSAID) such as flunixin to reduce the severity of the reaction to the larvae and an antibiotic or sulfonamide to prevent secondary bacterial infection. Severely affected animals should be brought indoors for nursing and all other members of the group removed from the contaminated pasture and placed on clean grazing ground.

Sensible grazing management is important in all systems but cannot be relied upon, per se, for controlling parasitic bronchitis in view of the unpredictable nature of the disease. Although natural immunity provides adequate protection on many farms, it cannot be accurately measured nor predetermined. With the possible exception of beef suckler systems, calves should not be run with or follow older cattle because these may harbor asymptomatic patent infections and contaminate the pasture. An important consideration is that clean pasture can be contaminated by larvae from neighboring fields carried on windborne fungal spores (see epidemiology paragraph earlier). Although the numbers of larvae spread in this way are likely to be small, they can initiate the epidemiologic cycle culminating in disease after some weeks.

Vaccination of calves with two doses of 1000 infective larvae attenuated by irradiation is a long-established and effective method of preventing disease. Only healthy calves should be vaccinated and they should be at least 8 weeks old. The vaccine is given 6 and 4 weeks before turnout. Exposure to lightly contaminated pasture will boost immunity, but low-grade patent infections may develop in some animals. Vaccinated and nonvaccinated calves should not be grazed together because the former may contaminate the pasture, enabling lungworm to cycle through the susceptible animals. The vaccine gives a high level of protection under most conditions, but vaccinated calves should not be put onto heavily contaminated pasture. Coughing may occur when immune responses kill lungworm larvae in the lungs. Overt disease can occur in cases of overwhelming challenge. To avoid such problems on severely affected farms, vaccinated calves should be allowed only gradual access to pasture. An experimental recombinant subunit vaccine, based on the parasite's paramyosin as a recombinant antigen, that overcomes the disadvantages of the attenuated vaccine has been developed.

In some endemic areas, for example, in the south of Ireland, which has mild winters and an early start to the grazing season, the ideal vaccination program described earlier may be inconvenient and it is possible, by cautiously avoiding periods when massive pasture contamination is likely to occur, to vaccinate at pasture. Calves are sometimes vaccinated at less than 8 weeks old to allow spring-born calves to graze during late summer and autumn, but optimal protection may not be afforded in all cases.

Strategic anthelmintic programs provide an alternative to vaccination. The aim is to suppress the infection initiated by overwintered larvae and thereby prevent subsequent contamination of the pasture. This can be done by application of a suitable intraruminal bolus at or just before spring turnout or by giving two or three doses of an avermectin/milbemycin during the early grazing season.
These systems are designed to control parasitic gastroenteritis and lungworm. Clinical field experiments have demonstrated good results with ivermectin, fenbendazole, and oxfendazole boluses and with ivermectin treatments given at 3, 8, and 13 weeks after turnout, or doramectin administered at turnout and again 8 weeks later. Calves may become vulnerable after the period of anthelmintic cover if pasture contamination occurs (e.g., because of fungal spread). An extra anthelmintic treatment may be indicated in regions with a very long grazing season. Calves that are exposed to infection but protected by chemoprophylaxis during their first grazing season generally have substantial resistance to reinfection in their second year. Nevertheless, field experiments have shown that immunity can be compromised to a degree related to the level of protection provided. There is concern that such intensive treatment may provoke anthelmintic resistance, but no resistant strains of *D. viviparus* have yet been reported.

**REFERENCES**

**ATYPICAL INTERSTITIAL PNEUMONIA OF CATTLE (ACUTE BOVINE RESPIRATORY DISTRESS SYNDROME, ACUTE PULMONARY EMPHYSEMA, AND EDEMA)**

**SYNOPSIS**

**Etiology** Uncertain; a number of etiologies such as *D,L*-tryptophan in forage, inhalation of toxic gases and fumes, hypersensitivity to molds, mycotoxins, and plant poisonings or feed supplementation with melengestrol acetate have been discussed.

**Epidemiology** Occurs primarily in adult cattle moved from dry to lush pasture and incidentally in feedlot cattle. Outbreaks or incidental cases of AIP in adult cattle moved from dry to lush pasture in autumn. In feedlot cattle incidental cases are observed toward the end of the finishing period.

**Signs** Outbreaks of acute respiratory distress in pasture form of disease within days of moving to lush pastures; severe dyspnea, open-mouth breathing with extended head and neck, respiratory grunt, subcutaneous emphysema, and rapid death. Subacute form less severe and may survive but develop cor pulmonale later.

**Clinical pathology** None clinically applicable.

**Lesions** Enlarged firm lungs that do not collapse, diffuse congestion and edema, interstitial and bullous emphysema, cranioventral consolidation, hyaline membrane formation, alveolar epithelial hyperplasia, fibrosis.

**Diagnostic confirmation** Lesions at necropsy.

**Treatment** Symptomatic, no effective treatment available.

**Control** Grazing management. Use of antimicrobials to control conversion of tryptophan to 3-methylindole in pastured animals.

Atypical interstitial pneumonia (AIP) of cattle has been known for many years under many different terms, including acute interstitial pneumonia, acute pulmonary emphysema and edema (APEE), acute bovine respiratory distress syndrome (ABRDS), bovine pulmonary emphysema, pulmonary adenomatosis, bovine asthma, pneumoconiosis, and “fog fever.” The syndrome that is characterized by diffuse or patchy damage to alveolar septa is known to occur in an acute and chronic form. The acute presentation, frequently occurring as an outbreak in adult pastured cattle a few days after they are moved from heavily grazed summer pastures to lush fall pastures, is also referred to as “fog fever.” A similarly acute to peracute syndrome in feedlot cattle, primarily affecting animals toward the end of the finishing period, is known as acute or atypical interstitial pneumonia of feedlot cattle. A more chronic form occurring sporadically, often with secondary bacterial involvement, has also been described.

The term atypical interstitial pneumonia refers to some clinical characteristics of the syndrome that set it apart from the common acute infectious respiratory tract diseases, especially the viral diseases also causing interstitial pneumonia. Clinically the syndrome is atypical, especially compared with the bacterial pneumonias:
- Presentation can be acute or chronic.
- Acute or chronic respiratory distress in absence of toxemia
- Syndrome is progressive and generally nonresponsive to treatment.
- Pathology consists of varying degrees of pulmonary emphysema, edema, hyaline membrane formation, and alveolar epithelial cell and interstitial tissue hyperplasia.

**ETIOLOGY**

The precise etiology of the condition is currently not entirely understood, but because of the obvious epidemiologic differences between the conditions occurring in pastured, housed, and feedlot cattle, it is assumed the AIP can have several different etiologies, all leading to the characteristic lung lesions. The etiologies presented in the following subsections have been proposed.

**Ingestion of Excessive Amounts of D,L-Tryptophan With the Forage**

Clinical cases of AIP are frequently reported in adult cattle that have been moved from a dry to a lush pasture in the autumn season. Specific forages have not been implicated, but affected cattle have often been consuming alfalfa, kale, rape, turnip tops, rapidly growing pasture grass, and several other feeds. The levels of tryptophan in lush pasture are sufficient to yield toxic doses of 3-methylindole, the product of tryptophan fermentation in the rumen. A 450-kg cow eating grass at an equivalent DM intake of 3.5% of BW/day with a tryptophan concentration of 0.3% of DM would ingest 0.11 g tryptophan/kg BW/day. The total amount ingested over a 3-day period would approximate the single oral dose of 0.35 g/kg BW needed to reproduce the disease experimentally. However, pasture levels of tryptophan are not necessarily higher in those associated with the disease compared with normal pastures.

*D,L*-tryptophan is converted in the rumen to 3-methylindole (3mI), which, when given orally or intravenously, also produces the lesions characteristic for AIP in cattle and goats. In some naturally occurring cases of AIP in beef cows changed from a dry summer range to a lush green pasture, there is a marked increase in the ruminal levels of 3mI, whereas in other cases the levels are not abnormal. Failure to detect abnormally high levels in the rumen and plasma of naturally occurring cases may be related to the rapid metabolism and elimination of 3mI.

Ingestion of *D,L*-tryptophan has generally been discounted as a possible cause for AIP in feedlot cattle because of its sporadic occurrence and the lack of an epidemiologic association between occurrence of the disease and ration changes. Nevertheless, significantly higher concentration of a 3mI metabolite in the blood of animals affected by AIP compared with healthy control animals were measured in one study, suggesting a possible etiologic role of *D,L*-tryptophan in AIP in feedlot cattle.
Hypersensitivity to Molds

AIP has also been associated with chronic hypersensitivity to moldy hay based on the presence of serum precipitins of the thermophilic antigens of Thermopolyspora polyspora, Microsporosa faeni, and Thermactinomyces vulgaris in cattle with allergic alveolitis, a condition also termed as “bovine farmer’s lung.” In Switzerland, a high incidence of serum precipitins against Microsporosa faeni (60%) and moldy hay antigen (80%) was demonstrated in exposed but apparently healthy cattle from an area where the chronic presentation of bovine farmer’s lung is common. Outbreaks of acute respiratory disease in adult cattle as a result of acute allergic pneumonitis can occur 15 hours after the introduction of severely moldy hay. Serologic investigation and provocative challenge may reveal a hypersensitivity to moldy hay based on the presence of serum precipitins of the Thermopolyspora polyspora (60%) and Microsporosa faeni with or without prior sensitization by subcutaneous injection of the antigen.

Although clinically allergic pneumonitis and AIP share a very similar presentation, there are significant pathologic differences indicating that allergic pneumonitis and AIP are different conditions. Although hyaline membrane formation, which is characteristic for AIP, is rarely seen with allergic pneumonitis, the latter is typically associated with microscopic granuloma formation that is not seen with AIP.

Inhalation of Toxic Gases and Fumes

Incidental cases of AIP have been reported in cattle exposed to different noxious gases and fumes, such as silo gas, nitrogen dioxide, chlorine gas, or zinc oxide fumes. The experimental inhalation of nitrogen dioxide gas is capable of causing acute interstitial pneumonia in cattle and severe alveolar edema and emphysema in pigs, but it seems unlikely that animals of either species would be exposed naturally to a significant concentration of the gas for a sufficiently long period to produce such lesions. Pigs that survived experimental exposure to silo gas did not have the lesions seen in silo-fillers’ disease in humans, and experimental exposure of cattle to nitrogen dioxide gas produces lesions that do not occur in naturally occurring AIP. Acute pulmonary emphysema and deaths have occurred in cattle exposed to zinc oxide fumes produced by the welding of galvanized metal in an enclosed barn housing cattle.

Parasitic Infestation

For many years it was thought that massive infestation of the lungs by large numbers of lungworm larvae in a lungworm-sensitized animal could cause an allergic reaction resulting in the development of AIP. The possibility of such hypersensitivity as being associated cannot be totally ignored, but at the present time there is no evidence to support such a theory. Such hypersensitivity may occur when the level of larval infestation of pasture is extremely high, but it is not involved in the great majority of cases. In most cases of naturally occurring AIP, there is no laboratory evidence of lungworm infestation of affected and in-contact animals. Reinfection of cattle with lungworm will occur 2 to 3 weeks following introduction to an infected pasture and cause acute respiratory distress that may be indistinguishable clinically from AIP.

The migration of abnormal parasites, particularly Ascaris suis, has been observed to cause an acute interstitial pneumonia in cattle that were allowed access to areas previously occupied by swine.

Myco toxosis and Plant Poisonings

The ingestion of sweet potatoes infested with the mold Fusarium solani has been incriminated as a cause of AIP in cattle. Growth of the mold on the potatoes produces the toxins ipomeamarone and ipomeamaronal and a lung edema factor. The latter is a collective term for a group of substances capable of causing death associated with severe edema and a proliferative alveolitis of the lungs of laboratory animals. It produces a respiratory syndrome that is clinically and pathologically indistinguishable from AIP.

The fungus Fusarium semitectum growing on moldy garden beans, Phaseolus vulgaris, which were discarded on pasture, was associated with acute pulmonary emphysema in cattle that consumed the beans and their vines. The fungus produces a pulmonary toxin. The pulmonary toxin 4-ipomeonal (ipomeanol) accumulates in mold-damaged sweet potatoes and induces pulmonary edema, bronchiolar necrosis, and interstitial pneumonia in many mammalian species. Outbreaks have occurred in lactating cows following ingestion of sweet potatoes damaged by Myzus persicae. Other Fusarium spp. have been found in peanut-vine hay, which has been associated with acute respiratory distress and atypical interstitial pneumonia in adult beef cattle. The population mortality rate as a result of respiratory disease was about 12% and the case-fatality rate 77%. Clinical signs occurred within a few days to 2 months after the animals were fed the peanut-vine hay.

A weed, Perilla frutescens, is considered to be a cause of the disease in cattle in the United States and wherever the plant is found. High morbidity and high case-fatality rates are characteristic, and the plant contains a perilla ketone that can be used to produce the disease experimentally.

Turf-quality perennial ryegrass straw (Lolium perenne) infected with the endophyte (Acremonium lolii), which yields toxic substances, including lolitrem-B, has been associated with atypical pneumonia in weaned beef calves. However, feeding the suspect hay resulted in typical ryegrass staggars but not atypical interstitial pneumonia.

Melen gestrol Acetate

Melengestrol acetate (MGA), a feed additive commonly fed to feedlot heifers to suppress estrus, has been associated with AIP based on epidemiologic evidence. Data obtained from Canadian feedlots indicated that the great majority of cases of AIP occurred in heifers and that discontinuing MGA treatment resulted in a reduced number of emergency slaughters, most of which were attributable to AIP. Further work did not reveal any effect of oral MGA administration on plasma 3ml concentration. If MGA does play a role in the etiology of AIP, the mechanism through which this occurs is not clear.

Bacterial and Mycoplasma spp. Infections

There is no evidence that any of the common bacterial pathogens of cattle such as Mannheimia haemolytica, Pasteurella multocida, Histophilus (Haemophilus) somni, or Mycoplasma spp. are primarily associated with AIP. In a series of feedlot cattle with clinical findings consistent with AIP, the pathogens were present in the lung tissues of some animals at necropsy, but their presence was not considered as a primary cause of the pneumonia but rather secondary to the initial injury of the lung that was undetermined.

Viral Infections

Certain viral infections of the lung may result in interstitial pneumonia. In the interstitial pneumonias caused by the bovine respiratory syncytial virus (BRSV) there is a bronchiolitis and alveolitis, and these should be termed bronchiointerstitial pneumonias. The BRSV is an important cause of outbreaks of acute interstitial pneumonia in beef calves 2 to 4 weeks after weaning. Pathologic evaluation of the lung tissues of feedlot cattle that had acute interstitial pneumonia found that BRSV was not a causative agent. In a series of cases of interstitial pneumonia in feedlot cattle in Saskatchewan, the presence of the BRSV antigen was demonstrated in only 7% of cases, and there was more severe bronchiolar epithelial necrosis than in the other cases that were negative for the virus.

Epidemiology

AIP occurs primarily in adult cows and bulls, usually 4 to 10 days after they are moved abruptly from a dry or overgrazed summer pasture to a lush autumn pasture. The new pasture may or may not have been grazed during that summer, and the species of grass or plants does not seem to make a difference, but usually there is some lush regrowth of
confirmed cases were in heifers, and plasma concentrations of 3mI metabolites (adducts) were higher in heifers with AIP than in controls. Most of the heifers were receiving melengestrol (MGA) orally to suppress estrus. The odds of an animal with acute interstitial pneumonia being a heifer were 3.1 times greater than the odds that an animal with the disease was a steer. In some large feedlots the estimated relative risk was 4.9.

Other types of atypical interstitial pneumonia occur sporadically and may affect only a single animal or several over a period of time. There is not necessarily a seasonal incidence except in areas where cattle are housed and fed dusty and moldy hay during the winter months. AIP has been reported to occur in weaned beef calves about 4 weeks after weaning.

**PATHOGENESIS**

Because of the number and variety of circumstances in which acute or chronic interstitial pneumonia occurs, it is difficult to suggest a basic underlying cause, or to explain the mechanisms for the development of the lesions and the variations that occur from one circumstance to another.

The 1-isomer of tryptophan contained in feed is metabolized by ruminal microorganisms to indoleacetic acid, which is then converted to 3-methylindole (3mI). The conversion of L-tryptophan to 3mI is maximal at a ruminal pH near neutrality. The 3mI is absorbed from the rumen and metabolized by a mixed-function oxidase system to an active intermediate, which has pneumotoxic properties.

Bioactivation of 3mI by alveolar Clara cells leads to profound cellular injury in Clara and type-1 alveolar epithelial cells and, ultimately, atypical interstitial pneumonia. It is postulated that the compound responsible for causing the injury is the electrophilic metabolite of 3mI, 3-methylenedoleine (3mEIN), which forms stable adducts with cellular macromolecules. (Adducts are compounds formed by an addition reaction.)

Concentrations of 3mEIN in lung tissue and blood were higher in feedlot cattle that had died of AIP than in healthy feedlot cattle. However, lung tissue concentrations of 3mEIN were similar in samples from cattle with interstitial pneumonia and bronchopneumonia. Mean concentration of 3mEIN-adduct increased to a maximum value on day 33 and then decreased to a minimum on day 54 after arrival in the feedlot. Plasma 3mI concentrations initially decreased and remained low until after day 54. Neither 3mEIN-adduct concentrations nor plasma 3mI concentrations were associated with deleterious effects on weight gains.

The reaction that occurs is a nonspecific but fundamental reaction of the pulmonary parenchyma to a wide variety of insults that may be ingested, inhaled, or produced endogenously. Pulmonary edema is the first morphologic change occurring in ruminants given 3mI. The edema is preceded by degeneration, necrosis, and exfoliation of type I alveolar septal cells. During the acute stage, there is flooding of the alveoli with serofibrinous exudate, congestion, edema of alveolar walls, and hyaline membrane formation. Varying degrees of severity of interstitial emphysema also occur. The interstitial emphysema may spread within the lymphatics to the mediastinum and into the subcutaneous tissues over the withers, over the entire dorsum of the back, and, occasionally, over the entire body, including the legs. If the acute phase is severe enough, there is marked respiratory distress and rapid death from hypoxemia. Unlike the bacterial pneumonias, the emphasis is on edema and proliferation rather than on necrosis.

The lesions have been produced experimentally in cattle, sheep, and goats following oral or IV administration of 3mI. Calves appear to be more resistant to experimental toxicity with 3mI than adults, which supports the observation that the naturally occurring disease is uncommon in calves grazing the same pasture in which adults are affected.

In case the animal survives the acute stage a proliferative stage follows that is marked by proliferation of alveolar type II cells. There is alveolar epithelialization and interstitial fibrosis, the latter being progressive and irreversible. The central features of chronic interstitial pneumonia are intraalveolar accumulation of mononuclear cells, proliferation and persistence of alveolar type 2 cells, and interstitial thickening by accumulation of lymphoid cells and fibrous tissue. Diffuse fibrosing alveolitis is a form of chronic interstitial pneumonia of uncertain etiology, but it is possibly the chronic form of AIP.

AIP has been recorded in sheep, and there was extensive alveolar epithelialization. In Norway, an acute respiratory distress syndrome has occurred in lambs moved from mountain pastures onto lush aftermath pasture. The lesions were those of AIP and alveolar epithelial hypersensitivity to molds in the grass is being explored. The experimental oral administration of 3mI to lambs will result in acute dyspnea and lesions similar to those that occur in cattle and adult sheep following dosing with 3mI. However, the lesions in experimental lambs are different from those that occur in lambs affected with the naturally occurring disease.

**CLINICAL FINDINGS**

This acute form of AIP in feedlot cattle is usually obvious. Within 4 to 10 days after adult cattle have been moved onto a new pasture, they may be found dead without any premonitory signs. In the experimental disease, the typical clinical signs of respiratory disease appear within 24 to 36 hours.
after the oral administration of L-tryptophan to adult cattle and within 4 days, 50% of the dosed cows will die. One or several cattle may exhibit labored breathing, often with an expiratory grunt, open-mouthed breathing, head and neck extended, frothing at the mouth, and anxiety. Severely affected cattle do not graze, stand apart from the herd, and are reluctant to walk. If forced to walk, they may fall and die within a few minutes. Moderately affected cattle continue to graze, but their respirations are increased above normal. Coughing is infrequent regardless of the severity. The temperature is normal to slightly elevated (38.5–39.5°C [101–103°F]) but may be up to 41 to 42°C (106–108°F) during very warm weather. There is a similar variation in the heart rate (80-120/min), and those with a rate of more than 120/min are usually in the terminal stages of the disease. Bloat and ruminal atony are common in severe cases. Subcutaneous emphysema is common over the withers and may extend to the axillae and ventral aspects of the thorax. The nostrils are flared, and the nasal discharge is normal. Diarrhea may occur but is mild and transient.

Loud, clear breath sounds audible over the ventral aspects of the lung, indicating consolidation without bronchial involvement, are the characteristic findings on auscultation in the early stages of the disease. The intensity of the breath sounds may be less than normal over the dorsal parts of the lung if involvement is severe, but in animals that survive for several days the loud crackles characteristic of interstitial emphysema are of diagnostic significance. Most severely affected cases will die within 2 days of onset, but less severe cases will live for several days and then die of diffuse pulmonary involvement. Those that survive longer than 1 week will often have chronic emphysema and remain unthrifty. Of those moderately affected cattle that recover in a few days, some will develop congestive heart failure a few months later, as a result of chronic interstitial pneumonia (cor pulmonale). Calves running with their adult dams will usually not be affected.

AIP in nonpastured cattle such as feedlot cattle usually occur sporadically, but several animals may be affected over a period of time. There may or may not be a history of a change of feed or the feeding of moldy or dusty feed. In many cases, a few days will elapse after the appearance of signs before the owner is aware of the affected animals. The animal may have been treated with an antimicrobial for a bacterial pneumonia with little or no response. Dyspnea, increased respiratory effort sometimes with a grunt, deep coughing, a fall in milk production, an absence of tox!emia, a variable temperature (38.5–40°C [101–104°F]) and a variable appetite are all common. On auscultation there are loud breath sounds over the ventral aspects of the lungs and crackles over both dorsal and ventral aspects. The presence of moist crackles suggests secondary bacterial bronchopneumonia. Subcutaneous emphysema is uncommon in these, and most will become progressively worse.

Yearling cattle with acute interstitial pneumonia that may be viral in origin may become much worse and die in a few days in spite of therapy. Mature cattle affected with the chronic form of AIP will survive in an unthrifty state with the chronic disease for several weeks and even months.

The major clinical features of all these other interstitial pneumonias are obvious respiratory disease, lack of toxemia, poor response to treatment, progressive worsening, and abnormal lung sounds distributed over the entire lung fields.

**Differential Diagnosis**

AIP is usually obvious when presented with an outbreak of acute respiratory disease in adult cattle that have recently been moved onto a new pasture. The onset is sudden; several cattle may have been found dead, and many are dyspneic. Clinical differential diagnoses for AIP include:

- **Pneumonic pasteurellosis (shipping fever, enzootic pneumonia of calves)** that is characterized by fever, toxemia, mucopurulent nasal discharge and less dyspnea; young cattle are more commonly affected, and there is a beneficial response to therapy within 24 hours.
- **Organophosphatic insecticide poisoning** may resemble AIP because of the dyspnea, but additionally there is pupillary constriction, mucoid diarrhea, muscular tremor and stiffness of the limbs, and no abnormal lung sounds.
- **Nitrate poisoning** may occur in cows moved into a new pasture with high levels of nitrate. Many cows are affected quickly; they are weak, staggering, gasp, fall down, and die rapidly. The chocolate brown coloration of the mucus membranes, the lack of abnormal lung sounds, and the response to treatment are more common in nitrate poisoning.
- **Other interstitial pneumonias** in cattle are generally not associated with a change of pasture in the autumn and are difficult to diagnose clinically and pathologically, especially when they occur in a single animal. The chronic and subacute types of interstitial pneumonia are difficult to differentiate from each other and from other pneumonias of cattle.
- **Extrinsic allergic alveolitis (bovine farmer's lung)** occurs in housed cattle exposed to dusty or moldy feeds for a prolonged period and is characterized by a history of chronic coughing, weight loss, poor milk production, occasionally green-colored nasal discharge, and dry crackles over most aspects of the lungs. Not infrequently, acute cases occur, and animals die within a week after the onset of signs.

- **Verminous pneumonia** caused by *Dysticola multispiralis* occurs in young cattle on pasture in the autumn months and causes subacute or acute disease that may resemble AIP clinically but not epidemiologically. Identification of the larvae in the feces or tissues of affected animals should be attempted.
- **Verminous pneumonia** caused by aberrant migration of *Ascaris suis* larvae may be indistinguishable from acute interstitial pneumonia, but a history of previous occupation of the area by pigs may provide the clue to the diagnosis, which can only be confirmed on histologic examination of tissues.

**Clinical Pathology**

There are no abnormalities of the hemogram or serum biochemistry that have any diagnostic significance. Examination of feces and forage for lungworm larvae will aid in differentiation from verminous pneumonia if past the prepatent period.

** Necropsy Findings**

In AIP the lungs are enlarged and firm and do not collapse on cutting. In the early stages of acute cases they contain much fluid that is more viscous than usual edema fluid. The pleura is pale and opaque and appears to be thickened. In peracute cases, the entire lungs are homogeneously affected in this way. Such cases usually have edema of the larynx.

In the more common acute case, the lung has a marbled appearance. Adjacent lobes may be affected with any one of four abnormalities. Areas of normal, pink lung are restricted to the dorsal part of the caudal lobes. There are areas of pale tissue indicative of alveolar emphysema, areas of a dark pink color affected by early alveolar exudation, yellow areas in which the alveoli are filled with coagulated protein-rich fluid, and dark red areas where epithelialization has occurred. The latter two lesions are firm on palpation and resemble thymus or pancreas. They are more common in the ventral parts of the cranial lobes.

In chronic cases, as a sequela to the acute form described previously, the obvious differences in the age of the lesions suggest that the disease progresses in steps by the periodic involvement of fresh areas of tissue. In all cases there is usually a frothy exudate, sometimes containing flecks of pus, in the bronchi and trachea, and the mucosa of these passages is markedly hyperemic.

Histologically, the characteristic findings are an absence of inflammation, except in the case of secondary bacterial invasion, and the presence of an eosinophilic, protein-rich
fluid that coagulates in the alveoli or may subsequently be compressed into a hyaline membrane. This is more apparent in acute cases, and if animals live for a few days, there is evidence of epithelialization of the alveolar walls. In longstanding cases, there is extensive epithelialization and fibrosis. There is a lack of obvious lesions of the small airways, which differentiates interstitial pneumonia from bronchopneumonia.

Bacteriologic examination of the lungs is often negative, although in longstanding cases in which secondary bacterial pneumonia has developed, Pasteurella multocida, Mannheimia haemolytica, Streptococcus spp., and Trueperella (formerly Arcanobacterium) pyogenes may be found. A careful search should be made for nematode larvae.

TREATMENT

The treatment of AIP in cattle is empirical and symptomatic because there is no specific therapy available. The lesion is irreversible in severe cases, and treatment is unlikely to be effective. When outbreaks of the disease occur on pasture, the first reaction is to remove the entire herd from the pasture to avoid the development of new cases. However, almost all new cases will usually occur by day 4 after the outbreak, and removal from the pasture usually will not prevent new cases. Conversely, leaving the herd on pasture usually will not result in additional cases. Severely affected cattle should be removed from the pasture with extreme care, very slowly, and only if necessary, and they should be moved to shelter from the sun. Immediate slaughter for salvage may be indicated in severe cases. Mild or moderately affected cases will commonly recover spontaneously without any treatment if left alone and not stressed, a fact that has not been given due consideration when claims are made for the use of certain drugs. Several different drugs have been advocated and used routinely for the treatment of AIP in cattle. However, none has been properly evaluated, and definitive recommendations cannot be made.

Treatment of the chronic interstitial pneumonias is unsatisfactory because the lesion is progressive and irreversible.

CONTROL

There are no known reliable methods for the prevention of AIP in pastured cattle, but there are some strategies that merit consideration.

Grazing Management

If lush autumn pasture contains toxic levels of the substance that causes the acute disease, it would seem rational to control the introduction of cattle to the new pasture. This can be done by controlling the total grazing time during the first 10 days: allow the cattle to graze for 2 hours on the first day, increasing by increments of 1 hour per day, and leave them on full time at the end of 10 to 12 days. If possible, this may be accomplished by rotating cattle back and forth, either between the summer and fall pastures or between the fall pasture and a drylot where ample supply of dry, mature hay is available. Dry, mature hay may be offered ad libitum to adult cattle in the morning before going on pasture for at least 4 days into the grazing period to reduce consumption of pasture forages. Such a management procedure is laborious and may not be practical depending on the size and terrain of the pasture and the holding yards that are available.

Inhibition of 3-Methylindole Production in Rumen

Controlling the conversion of D,L-tryptophan in forage to 3ml is a plausible control strategy. Experimental tryptophan-induced AIP can be prevented by oral administration of chlortetracycline or polyether antibiotics such as monensin. The daily oral administration of 2.5 g/head of chlortetracycline beginning 1 day before and for 4 days following administration of a toxin of L-tryptophan will prevent clinical signs. The daily oral administration of monensin at the rate of 200 mg/head/day beginning 1 day before and for 7 days after an abrupt change from a poor-quality hay diet to a lush pasture reduced the formation of 3ml during the 7 days of treatment, but the effect of the drug was diminished on day 10, 3 days after its withdrawal. Because the effects of monensin on ruminal 3ml are diminished within 48 hours after withdrawal of the drug, effective prevention of acute pulmonary edema and emphysema may require continuous administration of monensin for the critical period of approximately 10 days after the mature animals are exposed to the lush pasture. The daily feeding of monensin in either an energy or protein supplement will effectively reduce ruminal 3ml formation in pasture-fed cattle.

Lasalocid at a dose of 200 mg per head once daily in ground grain for 12 days reduced the conversion of tryptophan to 3ml and prevented pulmonary edema. Any combination of these management practices may reduce 3ml production to a greater extent than just providing monensin or implementing grazing management techniques alone.

Other Forms of AIP

The control of nonpasture cases of AIP depends on the suspected cause and removal of it from the environment of the animals. Every attempt must be made to control the concentration of dust and moldy foods to which cattle are exposed. Feed supplies must be harvested, handled, and stored with attention to minimizing dust and molds. In the preparation of mixed ground feed for cattle, the fineness of grind must be controlled to avoid dusty feed particles that may be inhaled. Because of the creation of dust, the grinding and mixing of dry feeds such as hay, straw, and grains should not be done in the same enclosed area in which cattle are housed. If dusty feeds must be used, they should be wetted to assist in dust control.

ENZOOTIC NASAL ADENOCARCINOMA OF SHEEP AND GOATS (ENZOOTIC NASAL TUMOR)

Intranasal adenocarcinoma has been recorded as a sporadic disease of sheep and goats for many years and is now recognized as a contagious neoplasm in these species. The disease in sheep and goats is associated with related but different retroviruses, the ovine nasal adenocarcinoma virus (ENT-1) and the caprine adenocarcinoma virus (ENT-2), respectively. These retroviruses are highly conserved, with North American and European isolates being 96% homologous. They are homologous with the retrovirus that causes jaagsiekte (JSVIR) but can be distinguished by unique sequences of the genome. Nasal adenocarcinoma is not a...
component of the disease jaagsiekte, nor are pulmonary tumors present in sheep and goats with nasal adenocarcinoma. Infections with the viruses of enzootic nasal adenocarcinoma and jaagsiekte can occur in the same sheep, and this can potentiate the proliferation of jaagsiekte virus in the infected sheep.

Enzootic nasal adenocarcinoma is recorded in the United States, Canada, Europe, Japan, India, China, and Africa. It is believed to occur on all continents except Australia and New Zealand, but it is not present in the United Kingdom. The disease occurs sporadically but is often clustered in certain flocks and herds, and it is assumed to transmit by the respiratory route. The prevalence in affected flocks varies in different countries. It is generally less than 2% but can be as high as 10% to 15%.

There is no seasonal occurrence and no apparent breed or genetic predisposition. There is no apparent influence of nasal myiasis on the prevalence of nasal adenocarcinoma in infected flocks.

Clinical disease is recorded occurring as early as 7 months of age, but most occurs in mature sheep between 2 and 4 years of age. Affected animals are afebrile, have a profuse seromucous or seropurulent nasal discharge, and sneeze and shake their heads frequently. There is depilation around the nostrils. The tumor may be unilateral or bilateral.

As the disease progresses, there is dyspnea, stertorous breathing with flaring of the nostrils at rest, and open-mouthed breathing following exercise. Some animals develop facial deformity and protrusion of one or both eyes from tumor growth, and the tumor may protrude from the nostril (Fig. 12-17). There is progressive loss of weight, emaciation, and death after a clinical course of 3 to 6 months. There is no detectable immune response in affected animals.

At postmortem, the tumor masses are in the ethmoid turbinates, with metastasis to regional lymph nodes in some cases. The tumors may be unilateral or bilateral and are gray or pink in color with a granular surface. The tumors originate in the serous glands of the turbinates and have the histologic features of adenocarcinoma.

The disease has been transmitted experimentally in both goats and sheep, with challenge of young kids resulting in disease at 12 to 16 months of age.

CONTAGIOUS CAPRINE PLEUROPNEUMONIA

SYNOPSIS

Etiology Mycoplasma capricolum subsp. capripneumoniae.
Epidemiology Highly contagious disease of goats, outbreaks in wild small ruminants do occur
Clinical findings Pleuropneumonia.
Lesions Pleuropneumonia with no enlargement of the interlobular septa.
Diagnostic confirmation Culture, polymerase chain reaction (PCR) on pleural fluid. Latex agglutination test.
Treatment Antimicrobials.
Control Herd biosecurity; vaccination provides strong immunity but of short duration.
ETIOLOGY
Contagious caprine pleuropneumonia (CCPP) is a classical disease of goats, associated with *Mycoplasma capricolum* subsp. *capripneumoniae* and commonly confused with other serious pneumonias of goats and sheep (first isolated in 1976 and previously known as mycoplasma strain F38) (Tables 12-6 and 12-9). The disease was first described in Algeria in 1873 and presents primarily as a pleuropneumonia. The organism is difficult to grow, which can lead to poor differentiation of the CCPP from pneumonic disease induced by other mycoplasmas (*M. capricolum* subsp. *capricolum* and *M. mycoides* subsp. *capri*). Highly specific PCR tests can differentiate infections within the *M. mycoides* cluster of goats and will provide more information on the distribution and epidemiology of these diseases.

EPIDEMIOLOGY
Occurrence
CCPP is one of the most serious fatal diseases of goats in Africa and Asia and has serious socioeconomic effects for subsistence goat herders. It is known as Abu Nini in the Sudan. The exact distribution is uncertain, but clinical disease has been reported from 38 countries, mostly from Africa and Asia, with recent detections in Mauritius (2009), Turkey (2009), and China (2012). However, the causative organism has only been isolated in some of these countries because of the difficulty growing it and lack of mycoplasmal laboratories. CCPP has many similarities clinically and at necropsy to contagious bovine pleuropneumonia, caused by *M. mycoides* subsp. *mycoides* SC, but it is not transmissible to cattle. Sheep can be infected experimentally and seroconvert, and they have been reported with respiratory disease in Eritrea. Captive and free-ranging wild ungulates, including deer, gazelles, and ibex, can also become infected and suffer disease. *M. capricolum* subsp. *capripneumoniae* is highly infectious. In newly affected flocks the illness is acute and severe following a brief incubation period (generally 6-10 days, but up to 28 days), with morbidity rates of 90% and case mortality rates of 60% to 100%. The disease is less severe and more sporadic in endemically exposed flocks.

Transmission
The disease is readily transmitted by inhalation, but the organism does not survive for long in the environment. Infection is brought into the flock by asymptomatic carrier or clinically affected animals.

Agent
Mycoplasmas are among the fastest evolving bacteria, with high mutation rates. *Mycoplasma capricolum* subsp. *capripneumoniae* shows a degree of heterogeneity not found among other members of the *M. mycoides* cluster. Based on sequencing of several genes, including 16S rRNA and H2 locus and other proteins, 24 haplotypes were identified in 25 strains of *Mycoplasma capricolum* subsp. *capripneumoniae* and placed within six genotypic clusters (A to F), with two distinct evolutionary lineages identified. Lineage 1 contains two groups with strains from East Africa, Qatar, Niger, and Mauritius; lineage 2 is subdivided into three groups with strains from the United Arab Emirates, China, and Tajikistan.

CLINICAL PATHOLOGY
Antigen can be detected in lung tissue and pleural fluid by PCR based upon the 16S rRNA genes. A real-time PCR offers advantages over conventional PCR including speed, greater specificity and sensitivity, and elimination of post-PCR processing. Serologic tests used to identify carrier animals include complement fixation, ELISA, and a latex agglutination test. The latter is robust, available commercially, and suitable for field use. Monoclonal antibody is used in serologic tests to identify caprine isolates by the disc growth inhibition method, which will include *M. agalactiae*, *M. capricolum* subsp. *capricolum*, and the other members of the *M. mycoides* cluster associated with goats. A competitive ELISA using monoclonal antibodies is highly specific for CCPP.

NECROPSY FINDINGS
The necropsy findings are similar to those of contagious bovine pleuropneumonia except that there is no thickening of the interlobular septa. Lesions are restricted to the lungs (often one lung) and pleura, with hepatization, increased pleural fluid, and a fibrinous pleuritis, which differentiates the disease from that caused by *M. mycoides* subsp. *capri*. Histologically, there is acute serofibronous to chronic fibrino-nectritic pneumonia with interstitial intralobular edema, rather than a thickening of the interlobular septa that occurs with other mycoplasmal infections. Inflammatory exudate consists mainly of neutrophils. There is also peribronchiolar lymphoid hyperplasia.

Samples for Confirmation of Diagnosis

- **Bacteriology**— Pleural fluid and lung tissue from the interface of the hepatized and normal lung tissue. These mycoplasmas are fragile and should be freeze dried or placed in transport medium if there is to be a significant transport time (>2 days). Conventional or real-time PCR can be performed on samples of pleural fluid dried on filter paper.
- **Serology**— CFT, Latex agglutination, competitive ELISA.

**DIFFERENTIAL DIAGNOSIS**

The other pulmonary mycoplasmas from which this disease needs to be differentiated are those associated with *Mycoplasma mycoides* subsp. capri (formerly *M. mycoides* large colony type) and *M. capricolum* subsp. capricolum.

**TREATMENT**

Clinical cases respond to a range of antibiotics, including intramuscular tyllosin (10 mg/kg BW), oxytetracycline (15 mg/kg/d), or tilmicosin, marbofloxacin, and danofloxacin.6,8 The severity of the disease is reduced, but treated animals are still sources of infection.

**CONTROL**

Effective biosecurity measures are needed to prevent the introduction of the disease into a flock via contact with infected carriers. Killed vaccines effectively reduce morbidity and mortality rates. These have been widely used in many countries, although they can not yet commercially available and may not be permitted in some jurisdictions.9

**CHRONIC ENZOOTIC PNEUMONIA OF SHEEP (CHRONIC NONPROGRESSIVE ATYPICAL PNEUMONIA, SUMMER PNEUMONIA, PROLIFERATIVE EXUDATIVE PNEUMONIA)**

**SYNOPSIS**

- **Etiology**— Multifactorial, with *Mycoplasma ovipneumoniae*, viruses and secondary bacterial infections implicated.

- **Epidemiology**— Affects sheep under 12 months of age. Seasonal occurrence, summer and autumn in southern hemisphere. Common disease affecting most flocks, but severity varies between farms.

- **Clinical findings**— Insidious onset. Coughing, nasal discharge and uneven weight gain in a mob.

- **Lesions**— Consolidation of anteiroventral lobes of lung. Pleuritis.

- **Diagnostic confirmation**— Postmortem lesions.

- **Treatment**— Antimicrobials for severely affected individual sheep.

- **Control**— No effective control procedure established.

Enzootic pneumonia is defined here as the common, lowly pathogenic disease of sheep, particularly lambs, which is common in all sheep populations. The disease is recognized by different names in different areas of the world. It can be differentiated from the acute fibrinous pneumonia and pleurisy associated with *Mannheimia (Pasteurella) haemolytica*, which is often called enzootic pneumonia in the British literature, and from the chronic progressive pneumonias, maedi and jaagsiekte.

**ETIOLOGY**

Although the disease is well known, its cause is not well defined. This is partly because of its nonfatal character, which leads to incomplete examination of early cases; most of those submitted for examination or necropsy are distorted by secondary bacterial infections. It has a multifactorial etiology, with a mix of (mainly) *Mycoplasma ovipneumoniae*, Bordetella parapertussis, chlamydia, parainfluenza-3 (PI-3) virus, adenovirus, a respiritory syncytial virus, and reovirus nominated as causes. *M. haemolytica* is a common secondary infection and may lead to more acute, suppurative respiratory disease. The disease, which might be most accurately identified as chronic undifferentiated enzootic pneumonia of sheep, is probably a collection of etiologically specific diseases.

**M. ovipneumoniae**

*M. ovipneumoniae* is now considered to be one of the more important parts of the disease complex, and may be the initiating cause.1 It is commonly isolated in large numbers from the lungs of affected sheep, but it can also be isolated from the nasal cavity of some normal sheep and less occasionally from normal lung.1 Experimental challenge with pure cultures of the organism produces minimal lesions, but aerosol or intrabronchial challenge with homogenates of affected lung that contain the organism produces proliferative interstitial and lymphoid pneumonia lesions indistinguishable from the natural disease. *M. ovipneumoniae* is a facultative pathogen that requires compromised lung defense mechanisms to initiate lesions; infection with this organism subsequently predisposes the lung to secondary infection with organisms such as *Past. haemolytica*. There is considerable heterogeneity in *M. ovipneumoniae*, and several different strains may be isolated from a pneumonic lung.2 Differences between strains in pathogenicity are not determined. Other mycoplasm, including *M. mycoides* subsp. *mycoides*, *M. mycoides* subsp. *capri*, *M. pui subspecies*, and *M. arginini*, may be associated with chronic enzootic pneumonia in tropical zones, but *M. arginini* is considered to have no role in atypical pneumonia of lambs in the United Kingdom.3

**B. parapertussis**

*B. parapertussis* is a common isolate from the nasal cavities and lungs of sheep with chronic enzootic pneumonia in New Zealand and is also believed to have an initiating role in the disease. It produces a cytotoxin that damages ciliated epithelium in the trachea and experimental challenge of colostrum-deprived lambs produces mild pulmonary lesions similar to those seen early in the natural disease. *B. parapertussis* also can predispose pneumonic pasteurellosis.

**Parainfluenza-3 (PI-3) Virus**

PI-3 is a cause of a mild undifferentiated pneumonia in sheep, and surveys around the world have shown that it is a widespread infection. The disease is clinically mild and marked by the presence of interstitial pneumonia. Antibodies to PI-3 are present in lambs soon after birth, but the half-life is short, and lambs are susceptible by the time they are weaned and mixed with other lambs, which is when clinical disease often occurs. In the experimentally produced
disease in lambs there is a slight seromucosal nasal discharge, coughing, increased sensitivity to tracheal compression, and fever of 40° to 41°C (104–106°F). At necropsy there is obvious hyperemia of the upper respiratory mucosa, including the trachea; the bronchial lymph nodes are enlarged; and there are small foci of catarrhal inflammation of pulmonary parenchyma of the apical and cardiac lobes. However, challenge of lambs at 2 weeks of age with this virus and \textit{M. haemolytica}, although producing disease, did not result in prolonged disease lasting to slaughter, and it was concluded that these agents, without other factors, were not the cause of enzootic pneumonia. This conclusion is supported by the results of vaccine trials with PI-3 against enzootic pneumonia.3

**Bovine Respiratory Syncytial Virus**

BRSV has resulted in pneumonia following experimental challenge of sheep and is evidenced clinically by fever and hyperpnea and pathologically by multifocal pulmonary consolidation and necrosis of epithelial cells. There is little evidence for BRSV as a cause of significant respiratory disease in sheep.

**Other Agents**

\textit{Adenovirus} and a type-3 \textit{reovirus} have been used experimentally to produce pneumonic lesions, and a vaccine has been produced to protect lambs against the adenovirus infection. Similarly, sheep herpesvirus, \textit{caprine herpesvirus-1}, will produce an interstitial pneumonia in experimentally challenged SPF lambs, but there is no evidence of a causal association with chronic enzootic pneumonia.

Autoantibodies to upper respiratory cilia have been detected in sheep colonized with \textit{M. ovipneumoniae}, and it is suggested that they contribute to the pathogenesis of coughing in this disease.

**EPIDEMIOLOGY**

**Occurrence**

Enzootic pneumonia affects animals up to 12 months but may commence as early as 6 weeks of age. The disease can occur in both lambs at pasture and housed lambs. In many affected flocks, 80% of 4- to 5-month-old lambs have clinical signs and lesions, and the disease is credited with causing a significant depression in growth rate after weaning, use of plunge or shower dips, and transport or mustering of sheep in hot dry conditions. Cases commence within 1 to 3 weeks after transport. In contrast, in the United Kingdom and Europe this disease occurs primarily in the late winter and early spring; in the more intensive production systems of the northern hemisphere, the disease is commonly associated with environmental problems of housing. In Ireland, an association has been made between the occurrence of lesions at slaughter and the extent of rain and wind-chill experienced by the sheep in the 2 months before slaughter.

**Economic Importance**

Death loss from this disease is minor, but economic loss is considerable and includes reduced growth rate, prolonged periods on the farm before reaching slaughter weight, the drug and labor costs associated with treatment, slaughterhouse wastage, and downgrading of carcasses with pleural adhesions and an effect on carcass quality. The situation is similar to that with enzootic pneumonia of pigs.

**CLINICAL FINDINGS**

The disease is insidious in onset and can persist in a group of lambs for 4 to 7 months. The disease has mild clinical manifestations, with the primary signs being poor and uneven weight gains, an increased nasal discharge, coughing, increased respiratory rate, and respiratory distress with exercise. Increased intensity and a higher pitch of breath sounds are heard on auscultation over the region of the bronchial hilus, and sounds of fluid in the airways are heard in some cases at rest but can usually be elicited by inducing the lamb to cough. There may be periods of fever.

There is a relationship between the proportion of the lung affected with pneumonia and average daily gain, and in one study weight gain was reduced by 50% when greater than 20% of the lung was affected. The weight loss is most apparent clinically soon after the disease commences.

**NECROPSY FINDINGS**

At postmortem there are clearly demarcated areas of consolidation in the anterioventral lobes, and there may be pleuritis with pleural adhesions. The diagnosis is on gross lesions and the presence of typical lesions on histologic examination.

**TREATMENT AND CONTROL**

Treatment is not usually undertaken unless there is secondary infection to produce acute respiratory disease. Nevertheless, lincomycin (5 mg/kg IM), given twice or three times at intervals of 2 days, and oxytetracycline (20 mg/kg, IM), given twice at 4-day interval, both gave good clinical cure and increased growth rates in a study in Greece.7 Control is based on the avoidance of stress factors that can exacerbate existing infection.

**FURTHER READING**

**REFERENCES**

**OVINE PROGRESSIVE PNEUMONIA (MAEDI, MAEDI-VISNA)**

Ovine progressive pneumonia and maedi are North American and European terms for slow virus diseases of sheep in which a chronic progressive pneumonia is a major manifestation. The name maedi is derived from the Icelandic term for dyspnea. Maedi-visna virus can also produce visna, which is a disease of the nervous system and is discussed elsewhere under that heading. Additional manifestations of infection are arthritis, inducative mastitis, and ill-thrift. These diseases have a close relationship with caprine arthritis encephalitis. La Bouhite and Graff–Reinert disease are local names for maedi in France and South Africa, respectively. In the United States it was originally described as Montana progressive pneumonia, and in Holland as zwoergersiekte.

**SYNOPSIS**

\textbf{Etiology} Ovine retroviruses

\textbf{Epidemiology} Most sheep infected as lambs. Persistent infection. High prevalence of infection in many countries but low prevalence of clinical disease. Transmission is via infected colostrum and milk, but lateral transmission also occurs.

Continued
ETIOLOGY

Maedi-visna virus (MVV) and ovine progressive pneumonia virus (OPPV) are single-stranded RNA nononcogenic ovine lentiviruses within the retrovirus family. They have a tropism for monocytes, macrophages, and dendritic cells, but not T-lymphocytes. This is an important determinant of their pathogenesis because they induce a persistent infection in sheep that can cause lymphoproliferative changes in the lung, mammary tissues, brain, and joints. There is a high degree of relatedness with the lentivirus associated with caprine arthritis encephalitis (CAE), and these ovine and caprine lentiviruses share nucleotide homology and serologic properties. Consequently, MVV, OPPV, and CAE viruses are now regarded as a viral continuum and referred to as small ruminant lentiviruses (SRLV).1

Isolates of MVV from naturally infected sheep are genetically heterogeneous, antigenic drift is common, and antigenic variation of the surface protein facilitates the persistence of the virus in the host, both as latent and chronic infections. There is evidence for variation in pathogenic potential between isolates and hosts, and it is estimated that only about 30% of infected animals develop disease.2

There is some evidence that the North American strains of ovine lentivirus may have originated from cross-species transmission of caprine arthritis—encephalitis virus rather than from maedi lentivirus. However, the similarity in clinical manifestation of maedi and ovine progressive pneumonia and the evidence that the causative viruses are part of a continuum permit the discussion of these diseases as a single entity.

EPIDEMIOLOGY

Occurrence

The earliest reports of the disease were from South Africa and the United States, but it now occurs in all major sheep-producing countries with the exception of Australia, New Zealand, and Iceland. Maedi virus was present in Iceland, being introduced in 1933 through the importation of infected Karakul sheep, but was eradicated in 1965. Because of the susceptibility of the local sheep and management practices that favored transmission, it developed to a problem of major national significance. In individual flocks the annual mortality was often 15% to 30%, and in these circumstances sheep farming was not economically viable. Approximately 105,000 sheep are believed to have died of the disease, and 650,000 sheep had to be slaughtered to eradicate it from the country.

The international movement of sheep has facilitated the spread of the disease, and it is believed to have been introduced into Denmark, Norway, Sweden, and Great Britain since the 1970s through the importation of infected sheep. However, as yet no other country has experienced the severity of disease that occurred in Iceland.

Host Range

Sheep and goats are the only species known to be susceptible to MVV, and infection cannot be established by experimental challenge in cattle, deer, pigs, dogs, horses, chickens, mice, and rats. Rabbits are susceptible, but infection is limited to the acute stage before the production of antibody; chronic infection, as seen in sheep and goats, does not occur. Hybrid mouflon—domestic sheep and calves have been experimentally infected with CAE virus, although the infection was cleared naturally in the latter, and SRLV nucleic acid detected in wild ibexes in close contact with goats.2

A serologic survey of wildlife in the United States found no evidence of infection in bighorn sheep, elk, white-tail deer, or antelope. All breeds of sheep appear to be susceptible to infection, but there may be differences in breed susceptibility, based on differences in seroprevalence in flocks with more than one breed of sheep. These differences are not consistent and so they may reflect differences in the susceptibility of family lines within a breed. Variations in the gene encoding an ovine transmembrane protein (TMEM 154) are associated with increased or decreased susceptibility of sheep to SRLV; sheep with glutamate at position 35 have increased susceptibility, whereas those with lysine or a deletion have decreased susceptibility.3 The average frequency of highly susceptible alleles across 74 sheep breeds was 0.51, with more than 25% of mainstream breeds being greater than 0.8.4 In contrast, frequency of highly susceptible alleles across 3 hill breeds was 0.26 to 0.42, suggesting that they would be less affected by MVV infection.5

Prevalence

The prevalence of infection varies between farms, breeds, and countries. In the United States, infection is more common in the western and midwestern and uncommon in the southern states. An estimate of flock seroprevalence (flocks with 1 or more positive sheep) of 48%, and overall seroprevalence of 24%, was recorded in samples collected in 2001 from sheep in 29 states. More recently, samples collected in Wyoming in 2011 found a flock prevalence for OPPV of 47.5% and overall seroprevalence of 18%, with open range (unfenced) flocks at significantly higher risk compared those that were fenced in (an odds ratio of 3.5). In Canada, a random survey found a flock prevalence of 63%, with 19% of sheep over 1 year of age being seropositive, and more recently a flock prevalence of 25% in Manitoba. Serologic surveys that use the AGID test will markedly underestimate prevalence, demonstrated by a study in Alberta where 27% of culled ewes were positive on histopathology, but using the AGID there was a seroprevalence of only 13%.6

In the United Kingdom, MVV was introduced more recently, and so this country has lower flock and within-flock prevalence rates (estimated at 3% and up to 15%, respectively, in 2010). However, there is concern that the prevalence of maedi-visna may be increasing, demonstrated by a steady increase in the number of introduced infections in approximately 2600 flocks that participate in a maedi-visna accreditation scheme. These breakdowns are usually caused by flocks not adhering to the biosecurity rules of the scheme, such as introducing sheep into a nonaccertified flock on the same holding.7

There is considerable variation in the prevalence of seropositive sheep between flocks. Rates of seropositivity increase with age, and so within-flock seroprevalence is influenced by the average age of the flock. Flock seroprevalence also has been positively associated with the use of foster ewes, allowing lambs older than 1 day to have contact with other lambing ewes, flock size, close contact during confinement for lambing, stocking density on pasture, and the length of time that the flock has been in existence. Within flock seroprevalence is much higher in flocks that are also infected with pulmonary adenomatosis compared with those that are not.

Transmission

The disease is spread most commonly by inhalation of infected aerosols and the ingestion of infected colostrum or milk. Vertical transmission following in utero infection is possible but relatively uncommon. Virus is also shed in the semen of infected rams if there are leukocytes in the semen, and so this risk may be increased in rams that are also infected with *Brucella ovis*.

Lambs may contract the infection at or shortly after birth, either from contact with infected ewes or from ingestion of infected colostrum and milk. The virus then infects...
dendritic cells at the mucosal surface, and these migrate to local lymph nodes, where virus is transferred to macrophages and spreads systemically. Alveolar macrophages play a similar role when infection occurs via the respiratory route. Lambs born to seropositive ewes have a significantly greater risk of infection than those from seronegative ewes, and lambs born to ewes that have been infected for a long time are at greater risk of infection. The chance of transmission to lambs from infected ewes increases with the period of contact, but it can occur within the first 10 hours of life.

Lateral transmission can occur in older sheep, and this was probably important in the transmission of the disease in Iceland and the Basque area of Spain, and it has been a significant component of the spread of infection of the virus in flocks in the United Kingdom. In some flocks, the spread of infection can be rapid, and the majority of the flock can seroconvert within a few years of the introduction of infected sheep. The spread of infection is often rapid in flocks that are concurrently infected with the retrovirus causing pulmonary adenomatosis. There are many macrophages in the lungs of these sheep, and so these cells will also be infected with MVV if it is present. In dual-infected sheep, the copious lung fluid produced by sheep with pulmonary adenomatosis contains MVV and can increase the risk of lateral transmission of maedi-visna.

**Economic Importance**

Economic loss from this disease is associated with increased mortalities, decreased longevity, decreased value of culled animals, and reduced productivity associated with subclinical infections, such as failure to thrive or to rear lambs. Losses are usually more severe in intensive housed operations, and they can be catastrophic in flocks that derive a large proportion of income from the sale of breeding animals (stud or seedstock flocks).

Clinical disease occurs in sheep 2 years old or older, usually in sheep 3 to 4 years of age. Severe disease is more likely when the within-flock prevalence exceeds 50% and has a case-fatality rate of 100%. Up to 30% of infections are subclinical, and so clinical disease may not be obvious or common in flocks that have a low prevalence. A high proportion of infected sheep, premature culling, and high mortality rates have occurred in flocks in Iceland, the Netherlands (particularly the Texel breed), the United States, the United Kingdom, and other European countries, especially in intensively managed dairy flocks.

It is possible that the major economic loss associated with infection with these viruses rests with the effects of subclinical infection on productivity of infected flocks. Subclinical infection of breeding ewes in some flocks has been associated with a reduction in conception rate and lowered birth weights and/or reduced growth rates in their lambs. The reduction in growth rate of the lamb is associated with indurative mastitis and a lowered milk intake. This may be expressed by a decreased growth rate of lambs from only older ewes. In other flocks there has been no evidence of effect on the birth weight or growth rate of lambs born of infected ewes. Subclinical infection has no effect on mature ewe body weight or greasy fleece weight.

**PATHOGENESIS**

SRLV infections are classed as immunopathologic diseases, whereby the host immune response is responsible for most of the pathology rather than the virus itself.

The virus infects cells of the monocyte/macrophage lineage and attaches to cells by the binding of its envelope glycoprotein to specific receptors on the cell surface. The virus replicates its RNA genome via a DNA intermediate provirus that is integrated into the chromosomal DNA of infected cells. With initial infection there is virus replication; this is followed by an immune response that restricts viral replication but fails to eliminate the virus completely. The immune response occurs between 2 and 8 weeks after infection, with antibody to different viral antigens emerging at different times during this period, although some sheep do not develop an antibody response until several months after infection. The ability to establish latent infection of monocytes, which then transfer virus to other organs, may be related to the fact that SRLV are relatively poor at inducing type I interferon (IFN), an important mediator of immunity to viral infection.

In monocytes, replication is restricted and does not proceed beyond the synthesis of provirus in most infected cells. The principal site of virus replication is the macrophage, and pulmonary secretions and milk containing infected macrophages are the main source of virus for natural transmission. Diseases such as pulmonary adenomatosis, which increase the number of macrophages in lung secretions, will facilitate transmission of ovine progressive pneumonia virus via aerosols.

The replication of virus initiates viral-specific immune responses (immune activation), and immune-mediated lesions develop in various organs. Production of viral antigen attracts more monocytes, which become latently infected, and so a cycle of latent infection and immune activation, with lymphocytic hyperplasia, is established. The infected macrophages in the affected tissues are surrounded by a slowly progressing inflammatory response, creating a focus of mononuclear cell aggregation. Many tissues can be involved, but the lungs, mammary gland, central nervous system and joints are most affected. Any or all of these organs can be affected in a single sheep, but genetic differences in host susceptibility and the virus often lead to a predominance of a single syndrome in a flock. For example, Border Leicesters in the United States and Texels in Holland appear more susceptible to lung infection (maedi), whereas Icelandic sheep are more susceptible to the central nervous disease (visna).

In the lung there is a gradual development of a lymphocytic interstitial pneumonia dominated by CD8+ T lymphocytes, hyperplasia of smooth muscle, and fibrosis. There is no healing or shrinkage of tissue, so the lungs increase in size and weight, alveolar spaces are filled, and dyspnea and anoxia gradually develop. The pathologic lesions develop very slowly during the preclinical and clinical stages of the disease, so that they are widespread and there is little ability to compensate when clinical signs do appear. In the central nervous system there is infiltration of the meninges and white matter with lymphocytes. The demyelination that occurs in visna is believed to result from the direct effect of the virus on oligodendrocytes and astrocytes and is believed to be the result of an inflammatory response provoked by the presence of viral antigen in these cells. Similar infiltrations occur in the udder. Lymphoid follicles are found in the alveolar parenchyma, often with atrophy of the alveolar tissue. Numerous lymphocytic follicles also occur around the lactiferous ducts, some of which may be occluded by lymphocytic aggregates protruding into their lumens.

**CLINICAL FINDINGS**

There is a long incubation period. Clinical disease, if it occurs, does not develop before 2 years of age, and most clinically affected sheep are older than 3 years. The clinical signs develop insidiously and progress slowly, and there is a long clinical course.

The earliest signs are usually listlessness and loss of body condition that progresses to emaciation. The presenting syndrome can be one of an increased cull rate of ewes in poor condition. Signs of respiratory involvement are not evident in the initial stages of the disease, but there is exercise intolerance, and affected sheep will fall back behind the flock when the flock is moved. Dyspnea, with an increase in respiratory rate (80–120/min at rest) and flaring of the nostrils, or open-mouth breathing, develops later, but there is no evidence of excess fluid in the lungs. There may be coughing and some nasal discharge, but in most instances this occurs in sheep with secondary bacterial pneumonia. The body temperature is in the high normal range, and there may be inflammation of the third eyelid. Clinical illness lasts for 3 to 10 months, and the disease is always fatal. Clinically affected sheep are more prone to other diseases, such as pregnancy toxaemia. In some sheep, clinical respiratory disease is minimal, and the major manifestation is wasting and the thin ewe syndrome.
Indurative mastitis ("hard bag" or "hard udder") also has an insidious onset, with ewes usually in their third or later lactation before the disease becomes clinically obvious, although histologic changes will be apparent far sooner. In early stages, hardening of the udder is more easily detected at drying off. In advanced cases the udder is enlarged and uniformly very firm, but the teats are limp. There is very little milk in the teat cistern, although it appears normal. Mammary involvement may occur, along with signs of respiratory infection, or affected ewes may show no other clinical abnormality. The lambs of ewes with less severe involvement may have a reduced growth rate.

Arthritis is occasionally seen in naturally infected sheep, usually when they are from 1 to 6 years of age. These sheep become lame and emaciated, with obvious swelling of the carpal joints.

**CLINICAL PATHOLOGY**

There is a progressive, moderate hypochromic anemia, with hemoglobin levels falling from 12 to 14 g/dL to 7 to 8 g/dL, and some depression of the red cell count. There is a tendency to leukocytosis, which in experimental infections is quite marked between exposure and the onset of clinical disease, but the count returns to normal when clinical signs appear. There is also hypergammaglobulinemia. There is an increase in the number of lymphocytes and neutrophils in bronchoalveolar lavage fluid, with more CD8+, fewer CD4+, and an inversion of the CD4+/CD8+ cell ratio.

In clinical cases, diagnosis is by the presence of the appropriate clinical syndrome, supported by the presence of a positive serologic test for the virus. A positive serologic test, by itself, has limited value for the diagnosis of individual sheep because there is a high prevalence of seropositivity in most flocks, especially in older animals. A positive test indicates that the animal is infected, but does not indicate that signs or lesions are attributable to infection with the virus.

**Detection of Antigen**

PCR is a sensitive method for detection of small amounts of viral nucleic acid, but it may not be available for routine diagnosis in some jurisdictions. It has been used to detect antigen in the third eyelid of infected sheep.

**Serologic Tests**

Assessing flock status (the presence or absence of infection) and the status of an individual sheep currently relies on serologic testing. The agar gel immunodiffusion (AGID) and ELISA tests are used in most countries. The AGID test is easy to perform and inexpensive, and thus it is often the most commonly used routine diagnostic test. It has a high specificity but often a lower sensitivity than the indirect and competitive ELISA tests, which may vary depending on the antigen used. Sensitivities of these tests vary from 64% to 97%, and thus they will be unsuited for diagnosis of infection in individual animals or use in test and cull programs if at the lower end of this range. The value of serologic testing rests primarily with the establishment of the infection status of the flock. A negative test in an individual sheep could mean that the sheep is free of infection, but this result can also occur in an infected animal that has not yet responded to infection.

A commercial indirect ELISA using a recombinant core protein and a synthetic transmembrane protein as antigens was developed in the Netherlands. Although it had high sensitivity and specificity, it was labor intensive and expensive, and so a pooling procedure that required modifications to the test was developed. Subsequently, testing of bulk milk tank samples by ELISA or PCR was confirmed as a cost-effective alternative for flock testing and capable of detecting early infection in dairy flocks. The ELISA detected a within-herd prevalence of less than 1% when samples were tested undiluted and less than 3% when using samples diluted 1 in 10. All the bulk milk samples from known SRLV-free flocks (138) tested negative, whereas 50% of samples from flocks with an unknown SRLV status (111) were positive. Agreement between the ELISA and two real-time PCR tests on a subsample of 59 milk samples was 90% for the LT-PCR and 98% for the leader-gag PCR.

**NECROPSY FINDINGS**

Lesions may be present in the lungs and associated lymph nodes, brain, joints, mammary gland, and blood vessels, but gross lesions in most sheep are confined to the lungs and, in some cases, the mammary glands. In advanced cases, the lungs are larger and 2 to 4 times as heavy as normal lungs. They collapse much less than normal when the chest is opened, and are gray-blue to gray-yellow in color. There is a diffuse thickening of both lungs, with abnormal color and consistency in all lobes and consistent enlargement of the bronchial and mediastinal lymph nodes. Histopathologic changes are characteristic of a chronic interstitial pneumonia, with proliferation of lymphoid tissue and the presence of numerous lymphoid follicles. There is infiltration of lymphocytes and macrophages in the interalveolar septa, which are thickened, and the bulk of the alveolar space is replaced by the thickened alveolar walls. Larger airways are unaffected. There is a complete absence of healing, consistent with the progressive nature of the disease, and vasculitis is often present.

Lesions of arthritis, encephalitis, and mastitis are often present. The mastitic lesion comprises an interstitial accumulation of lymphocytes and the presence of periportal lymphoid nodules with atrophy of alveolar tissue. Culture of the virus is difficult, and confirmation of the diagnosis is often limited to the presence of characteristic microscopic lesions, preferably supported by a positive serologic titer to the virus. Immunohistochemistry is highly specific, but it may not be routinely available.

**Samples for Confirmation of Diagnosis**

- **Virology**—lung, mammary gland, synovial membrane, brain (PCR, ISO)
- **Bulk or individual milk**—(PCR, ELISA)
- **Serology**—heart blood serum (AGID, ELISA, PCR)
- **Histology**—formalin-fixed lung, bronchial lymph node, mammary gland, synovial membrane, half of brain section midsagittally (LM, IHC)

**DIFFERENTIAL DIAGNOSIS**

There are several chronic pneumonias requiring differentiation from maedi:

- Jaagsiekte
- Parasitic pneumonia
- Chronic supplicative pneumonia
- Caseous lymphadenitis
- Postdipping pneumonia
- Enzootic pneumonia
- Melioidosis
- Chronic wasting conditions:
  - Johne's disease
  - Caseous lymphadenitis

**TREATMENT**

No treatment has been successful. Secondary bacterial infections can be treated with commonly used antibiotics, such as tetracyclines, but there will be no improvement in the underlying chronic pneumonia.

**CONTROL**

In the past, the only control attempted was eradication by complete destruction of all sheep in a flock or area and subsequently restocking. However, it is possible to greatly reduce the prevalence, and even eradicate the disease, by either (a) testing all sheep and removing seropositive sheep from the flock, or (b) by removal of lambs at birth and rearing them in isolation from other sheep.

Many jurisdictions have developed accreditation programs for flocks to establish that they have a low risk of infection with MVV. Once flocks are seronegative they are subjected to testing at various intervals, typically 1 to 3 years depending on an assessment of the biosecurity risk and the presence of untested sheep on the same farm holding.
Test and Cull
Test and cull involves the detection and culling of seropositive animals and is the preferred method when lateral transmission is the dominant mode of transmission in the flock. All sheep (and goats) on the farm are serologically tested once or twice a year, and seropositive animals and their progeny of the flock. All sheep (and goats) on the farm are serologically tested once or twice a year, and seropositive animals and their progeny of the flock. 

Test and Cull
Test and Cull

Flock Biosecurity and Other Control Methods
Once infection is introduced it is difficult and expensive to eradicate; thus, establishing and maintaining good biosecurity is a cost-effective way of preventing the introduction of maedi-visna and other important infectious diseases, such as foot rot. Unfortunately, the specificity and sensitivity of most currently available serologic tests are inadequate to reliably determine the infection status of an individual. Consequently, the results of flock tests from a potential source of replacement sheep should be examined, along with postmortem and other animal health records if these are available. Rams and replacement ewes should be acquired from accredited free flocks in countries where these programs exist and should be transported directly from the source farm rather than through markets or farms of unknown status.

Other control procedures that attempt to limit or delay the spread of infection and, consequently, the occurrence of clinical disease within an infected flock have limited success. Lambs born in sheds and close confinement paddocks is conducive to spread of disease, and so ceasing or modifying this practice is recommended for infected flocks. In flocks that have a high incidence of clinical disease, culling animals before the age at which they develop clinical signs can reduce the economic impact of the disease.

In countries where the disease is endemic, there is often a great deal of movement of animals between farms, especially rams but also replacement ewes. Thus restricting movement of animals between farms and preventing comingling in common grazed areas should help limit the spread of the disease.

Vaccination and Genetic Selection
There is currently no effective vaccine against the SRLV’s, including MVV and OPPV, and in some cases candidate vaccines have enhanced viremia and/or the immune-mediated pathology of the disease. The difficulty in developing effective vaccines is common among the lentiviruses, with various approaches, including attenuated vaccines, vector vaccines, and proviral DNA vaccines, having little success. The reasons are obscure but probably relate to the underlying dysfunction in T-cell-mediated immune responses.

However, marker-assisted genetic selection, to identify those sheep less susceptible to infection, has the potential to supplement existing control measures. For example, in a trial involving 187 lambs, the probability of infection following natural exposure to OPPV was 3.6 times greater in crossbred lambs with susceptible or heterozygous diploidy of the ovine transmembrane protein gene 154 (TEM154 diploidy “1 3” or “3 3”) compared with lambs with diploidy “1 1.” This is an active research area, and it is expected that additional markers will be identified with additional investigations.

OVINE PULMONARY ADENOCARCINOMA (JAAGSIEKTE, PULMONARY ADENOMATOSIS)

SYNOPSIS
Etiology Jaagsiekte sheep retrovirus.
Epidemiology Disease of mature sheep with geographic clustering but low prevalence. Spread probably mainly by respiratory route.
Key signs Dyspnea, profuse watery pulmonary discharge, loud fluid sounds on auscultation, long clinical course with progressive emaciation.
Pathology Tumors in lung.
Diagnostic confirmation Histologic changes are diagnostic and histopathologic confirmation, including immunohistochemistry, is the only method currently available.
Treatment None.
Control Culling and strict biosecurity.

Jaagsiekte is Afrikaans for “driving disease” because of the tendency for affected sheep to show clinical signs when driven. The disease manifests clinically as a chronic progressive pneumonia and is a contagious disease of sheep resulting from the development of a bronchoalveolar adenocarcinoma in the lungs.
ETIOLOGY

The disease is associated with an infectious beta-retrovirus, jaagsiekte sheep retrovirus (JSRV) of the family Retroviridae. JSRV has two forms, an exogenous infectious form that alone can produce the disease and an endogenous RSRV-related provirus that is present in all sheep genomes.1 The disease has been transmitted experimentally with partially purified retrovirus from infected lungs, by infection with cloned JSRV, and supportive evidence for retrovirus as the causative agent includes an inverse dose relationship between reverse-transcriptase activity in the infectious inoculum and the incubation period of the experimental disease.

The presence of retrovirus has been demonstrated in the lungs of sheep with jaagsiekte in different countries, there is serologic cross-reactivity, and strains from different countries have been sequenced. A herpesvirus has also been isolated in several countries from the lungs of sheep with jaagsiekte, but epidemiologic studies show that it is not the causative agent.

EPIDEMIOLOGY

Occurrence

The disease has worldwide distribution and is recorded in most countries that have significant sheep populations, with the exception of Australia and New Zealand. Until recently there has been no practical method to detect infected sheep, and estimates of the prevalence of jaagsiekte are largely based on clinical or postmortem observations. The prevalence of the disease appears to vary depending on the breed of sheep and the type of flock management. In most endemically infected flocks, annual losses attributable to jaagsiekte are between 2% and 10%, although the tumor is present in a much higher proportion of the flock, and infection without lesions is also common. Annual mortality can be higher in flocks where the infection has recently been introduced and before the disease becomes endemic. PCR analysis of peripheral blood leukocytes of sheep in infected flocks shows significantly higher rates of nonclinical infection.

Prevalence varies between countries, and there can be areas of high prevalence within countries; in Britain, the Borders and the east coast of Scotland, and East Anglia in England, appear to be foci of infection from which other outbreaks arise. The prevalence may be higher than generally recognized; in a biased sample, histologic evidence of jaagsiekte was detected in 25% of cases of pneumonia in sheep submitted to a diagnostic laboratory in Scotland over a 6-year period. In a more recent study, ovine pulmonary adenocarcinoma was confirmed in 0.8% of fallen (culled) adult sheep at a slaughterhouse.2

The disease is also a significant cause of mortality in adult sheep in South Africa and Peru, but it is a minor disease in the United States and Canada. It occurred in epizootic proportions in Iceland during the same period of time as the maedi-visna epizootic but has been eradicated by a rigorous slaughter policy.

Animal and Environmental Risk Factors

Mature sheep, 2 to 4 years of age, are most commonly affected, but the disease can occur in younger animals. There are reports of the occurrence of jaagsiekte in goats at very low prevalence rates in India and Greece, and the disease has been experimentally transmitted to goat kids. The lesions produced were small and circumscribed, and goats have low susceptibility to infection.

Jaagsiekte has a prolonged clinical course and is uniformly fatal. In some reports there is a greater prevalence of onset of clinical disease in the winter months, but in others there is no seasonal variation in clinical onset. Ewes may show a sudden onset of clinical disease in late pregnancy.

The incubation period in natural cases is 1 to 3 years, but it may be as short as 5 to 12 months after experimental transmission. Clinical disease is rare in sheep younger than 2 years and is most common at 3 to 4 years of age. Very rarely, cases occur in lambs 3 to 6 months old, and disease can be reproduced in lambs of this age by challenge of very young lambs. A genetic or familial susceptibility to the disease is suspected.

Because of the method of spread, the disease is likely to assume more importance in systems of sheep husbandry where there are significant periods of close contact, as, for example, occurs with intensified lamb-rearing systems. Close housing during the winter is a potent predisposing cause and probably accounted for the occurrence of the disease in epidemical form in Iceland. However, the disease occurs commonly in range sheep in other countries. Sheep that have a combined infection with jaagsiekte and the maedi-visna lentivirus have an increased ability to transmit maedi-visna infection, and flocks with the combined infection can suffer high losses from pneumatic disease.

Transmission

Experimental transmission has been effected by pulmonary or IV injection, or by intratracheal inoculation of infected lung material. The incubation period of the experimental disease in young lambs is much shorter than that in mature sheep. The disease has also been transmitted by inhalation of infected droplets when sheep are kept in close contact, and it is assumed that the natural mode of transmission is by droplet infection from respiratory secretions, which are copious in sheep with clinical disease. A longitudinal study of the natural transmission showed that infection established readily and rapidly in young lambs and also horizontally in adult sheep, but that the majority of infected sheep did not show clinical disease during their commercial life span.

PATHOGENESIS

The virus replicates in the type II pneumocytes in the alveolus. Type II pneumocytes and Clara cells in the terminal bronchioles are transformed, and their growth produces intraalveolar and intrabronchiolar polyloid ingrowths. These cells are surfactant-producing secretory cells, and there is also copious production of fluid. The excessive surfactant-like protein produced in the tumor provides a stimulus for the accumulation of macrophages seen in association with this disease. The adenomatous ingrowths of alveolar epitheliums enroach gradually upon alveolar airspace so that anoxic anoxia occurs. The lesions produced by experimental inoculation are identical with those of the naturally occurring disease.

CLINICAL FINDINGS

Affected sheep are afebrile and show progressive respiratory distress with loss of weight. Clinical signs are not evident until a significant proportion of the lung is compromised by the tumor.1 Occasional coughing and some panting after exercise are the earliest signs, but coughing is not a prominent sign in this disease unless there is concurrent parasitic pneumonia. Subsequently there is emaciation, dyspnea, lacrimation, and a profuse watery discharge from the nose, with death from 6 weeks to 4 months later. A diagnostic test, colloquially known as the wheelbarrow test, in this disease is to hold the sheep up by the hindlegs in affected animals a quantity of watery mucus (up to about 200 mL) runs from the nostrils. Moist cracks are audible over the affected lung areas and may be heard at a distance, so that a group of affected animals are said to produce a sound like slowly boiling porridge. There is no elevation of body temperature unless there is secondary infection, and the appetite is normal. Advanced cases may have cor pulmonale. Pasteurellosis (Mannheimia haemolytica) is a common complication and often the cause of death.

CLINICAL PATHOLOGY

No immune reaction can be detected in affected animals, and there is no serologic test. Sheep in advanced stages of the disease may show neutrophilia and lymphocytopenia. The pulmonary fluid contains round orpherical clusters of epithelial cells, which have the hyperplastic adenomatous epithelium typical of pulmonary lesions and increased numbers of macrophages. Earlier reports of a consistent elevation in circulating immunoglobulin concentrations have not been substantiated. JSRV can be detected by exogenous JSRV-specific PCR in peripheral blood leukocytes and can be used to demonstrate that JSRV is not present in flocks or regions.2
**NECROPSY FINDINGS**
Lesions are usually restricted to the thoracic cavity. As in maedi, the lungs are grossly increased in size and in weight (up to 3 times normal). There are extensive areas of neoplastic tissue, particularly of the anterolateral regions of one or both lungs, with smaller lesions in the diaphragmatic lobes. The affected areas are solid and slightly raised above the adjacent normal lung. This, with the excess frothy fluid in the bronchi, is characteristic. The bronchial and mediastinal lymph nodes are enlarged and hyperplastic, and they occasionally contain small metastases. Pneumonic pasteurellosis is a frequent complication, and secondary pulmonary abscesses and pleurisy may develop. Histologically, the alveolus is lined by cuboidal and columnar epithelial cells that form characteristic adenomatous ingrowths of alveolar epithelium into the alveolar spaces.

Differences between the pathology of classical (progressive) and atypical (nonprogressive) forms of the disease are seen using immunohistochemistry, with an influx of T-cell subsets and expression of MHC class II in the latter.4

**Samples for Confirmation of Diagnosis**
- Histology—formalin-fixed lung, bronchial lymph node (LM)

**DIFFERENTIAL DIAGNOSIS**
Chronic pneumonias requiring differentiation from jaagsiekte:
- Maedi
- Parasitic pneumonia
- Chronic suppurrative pneumonia
- Caseous lymphadenitis
- Postdipping pneumonia
- Enzootic pneumonia
- Melioidosis

**TREATMENT**
No treatment is available.

**CONTROL**
In Iceland, where the disease assumed epizootic proportions, eradication was achieved in the 1950s by complete slaughter of all sheep in the affected areas. In areas where the prevalence is lower, the disease can be satisfactorily controlled, but not eradicated, by slaughter of clinically affected sheep. There is evidence that the disease is spreading in sheep populations in some countries, such as the United Kingdom, and flocks that are free of disease should attempt to obtain replacement sheep from flocks that are free of jaagsiekte. Infected flocks can reduce the prevalence of disease by culling sheep at the onset of clinical signs and also culling the progeny of affected ewes. PCR can detect infection in the preclinical stages, but there has been no trial to establish if eradication from a flock can be achieved with this technology.

Exclusion of the disease from unaffected flocks requires strict biosecurity measures.

**REFERENCES**

**NASAL BOTS INFESTATION**
Infestation of sheep and goats with larvae of the nasal bot fly (*Oestrus ovis*) has a serious effect on the productivity and welfare of both sheep and goats. Adult activity induces stress responses and significant behavioral change. Larval infestation induces moderate to severe pathology that reduces productivity.

Similar flies are known to affect horses, donkeys, and mules (*Rhinoestrus spp.*) in the Mediterranean region and to affect camels (*Cephenemyia titillator*) in Africa and Australia. Wild ungulates are affected by nasal bots in the Mediterranean basin, central America, southern Africa, and eastern Europe. The larvae inhabit the nasal passages and sinuses, eventually being expelled through the nares. Goats are less dramatically affected than sheep. The slightly dorsoventrally flattened, segmented larvae are light cream in color, but as they reach maturity dark bands appear on each segment. Species affecting horses and camels have distributions that are similar.

**ETIOLOGY**
The sheep nose bot affects sheep and goats in most regions, but it is particularly significant in the Mediterranean basin, central America, southern Africa, and eastern Europe. The larvae inhabit the nasal passages and sinuses, eventually being expelled through the nares. Goats are less dramatically affected than sheep. The slightly dorsoventrally flattened, segmented larvae are light cream in color, but as they reach maturity dark bands appear on each segment. Species affecting horses and camels have distributions that are similar.

**LIFE CYCLE AND EPIDEMIOLOGY**
The adult fly is stout, mottled gray in color, and about 1 cm long. Its mouthparts are rudimentary, and it does not feed. In North America, flies emerge in the late spring and mate, and the females begin larviposition activities approximately 2 to 3 weeks later. Adult flies attempting to deposit larvae on the nares annoy the sheep and cause them to bunch or seek shelter. Stamping of the feet and shaking of the head are common. Sheep may bunch together and press their heads into the fleece of others. Fly activity occurs primarily during the warmer parts of the day but still may result in the loss of a good deal of grazing time. Behavioral changes in goats are less dramatic, presumably because of their browsing habit.

Larval development takes place in the dorsal turbinates and frontal sinuses. The period of development can vary 3 weeks to several months, after which they migrate to the nostrils. Larvae feed on the mucosal secretions and cells eroded from the mucosal epithelium. The larvae are thick, yellowish-white in color, and when mature there is a dark dorsal band on each segment. The ventral surface has rows of small spines on each segment. Mature larvae exit the host, usually during a bout of sneezing, and

---

Inflammation of these surfaces tissues is evident and increases as the larvae become mature. Changes to the epithelial structure are noted, including the erosion of the surface ciliary covering and a breakdown in epithelial cell integrity. Abrasive action of the body armature and the activity of proteolytic enzymes excreted/secreted by the larvae are responsible for the pathology. Secondary effects include the induction of lung lesions and the activation of latent “off” infections. Diagnostic confirmation. Behavioral changes during fly season and nasal discharge

**Differential diagnosis** Unthriftiness usually caused by helmith infection.

**Treatment** Macrocyclic lactone endectocides, clorsulon.

**Control** Treatment given when fly activity has ceased.
actively burrow beneath the upper layers of soil and ground litter. Pupation occurs at these locations, and development of the adults requires 4 to 5 weeks but may take longer at low temperatures. In temperate areas there may be one or two generations per year, but several generations may be completed in hot areas. *O. ovis* are adapted to the various climates prevailing wherever sheep and goats are kept. When winters are cold, the larvae can overwinter by remaining dormant in the first instar (hypobiosis), but in warmer climates development may continue throughout the winter. In those regions where summer temperatures are extreme, the larvae will also undergo hypobiosis.

*O. ovis* are an important zoonosis because the females may larviposit in the eye, in the nose, or on the lips of humans. In some countries ophthalmomyiasis or infection of the upper respiratory tract is a common occurrence.

### Pathogenesis

The stress of the larviposition attacks can be significant with reduced grazing time and overheating resulting from bunching. Herdsmen find the animals are more nervous and difficult during the fly activity periods.

Larvae induce a gradually increasing rhinitis and sinusitis as the infestation persists. Marked changes in the structure of the epithelial tissues are noted, with a marked cellular degeneration and a loss of the ciliary epithelial tissues are noted, with a marked cellular degeneration and a loss of the ciliary epithelial tissues. The changes are a result of both lular degeneration and a loss of the ciliary epithelial tissues with a marked cel -

An ELISA for detection of antibodies to larvae secretions has been developed but is not currently used.²

### Treatment

Clostabil 5 mg/kg and ivermectin 0.2 mg/kg, in addition to other macrocyclic lactones, are effective, and the use of these compounds for fluke or worm control also controls nasal bots.

### Control

Treatment should preferably be applied after the cessation of fly activity, although it may be necessary to apply treatments during pro-longed fly activity to give relief.³

### Recommendation

Treatment should be applied once or twice a year. This is not absolutely necessary but will increase both endurance and the animal’s well-being. Population control of the flies is probably not likely.

### Lungworm Infestation in Sheep and Goats

#### Synopsis

**Etiology** The nematode parasites *Dictyocaulus filaria*, *Muellerius capillaris*, and *Protostrongylus rufescens*.

**Epidemiology** Infective *D. filaria* larvae are found on grass, but *M. capillaris* and *P. rufescens* are transmitted when molluscan intermediate hosts are accidentally ingested by grazing animals.

**Signs** *D. filaria* and *P. rufescens* can cause bronchitis and loss of condition. *M. capillaris* is asymptomatic in sheep but may be pathogenic in goats.

**Clinical pathology** Characteristic larvae in feces.

**Lesions** *D. filaria* and *P. rufescens*: scattered patches of consolidation; *M. capillaris*: small fibrous nodules up to 5 mm in diameter.

**Diagnosis confirmed** Characteristic larvae in feces.

**Treatment** Avermectins/milbemycins, benzimidazoles or levamisole.

**Control** No specific measures available.

### Pathogenesis

The relative pathogenicity of each lungworm is dependent on its predilection site. *D. filaria* lives in the trachea and bronchi so aspirated eggs, larvae, and debris can affect a large volume of lung tissue. It is therefore the most pathogenic species and provokes changes resembling those described for *D. viviparus*. The volume of damaged lung is however usually insufficient to cause severe dyspnea. Adult *P. rufescens* are found in smaller bronchioles, and so associated lesions are much smaller. *M. capillaris* is found in the lung parenchyma, where it becomes encysted in fibrous nodules. Lesions are thereby confined to its immediate surroundings. Consequently, this worm is generally considered to be relatively innocuous. Heavy mixed protostrongylid infections can impair pulmonary gaseous exchange.

### Clinical Findings

Lambs 4 to 6 months of age are most severely affected with lungworms, but sheep of all
ages are susceptible. Clinically *D. filaria* is associated with bronchial irritation that results in coughing, moderate dyspnea, and loss of condition. There may be added fever and evidence of toxemia if secondary bacterial infection occurs. It is highly pathogenic in young goats. *P. rufescens* infestations in sheep and goats cause clinical signs similar to those of *D. filaria*.

**CLINICAL PATHOLOGY**

Laboratory diagnosis depends on the detection of first-stage larvae in the feces by the Baermann technique. *D. filaria* larvae have refractile granules in their intestinal cells and a conical tail. *P. rufescens* has a wavy tail as does *M. capillaris*, which, in addition, has a spine just anterior to the tail.

**Necropsy Findings**

*D. filaria* lesions are similar to those of the subacute form of parasitic bronchitis in calves with exudate in the bronchioles, scattered patches of consolidation, and thickening of the alveolar septa, but widespread lesions are not common. *M. capillaris* is found in small fibrous nodules up to 5 mm in diameter. Most of these are in the parenchyma of the lung immediately under the pleura. Many of them are calcified and often contain only one live or dead worm. Infestation of goats leads to a diffuse infection quite different from the nodular reaction in sheep and to the production of an interstitial pneumonia. Whether this is attributable solely to *M. capillaris* infection or whether a chlamydial or viral agent is involved has not been determined. However, cases of nodular reaction in goats attributable to *M. capillaris* larvae have been reported.

**Diagnostic Confirmation**

The presence of larvae in the feces confirms lungworm infection, but their number is often no indication of the degree of infestation.

**Differential Diagnosis**

Lungworm infestation in sheep needs to be differentiated from maedi and jaagsiekte.

**Treatment**

</tbody>
</table>

Ivermectin, moxidectin, the benzimidazoles, and levamisole are effective against *D. filaria* at normal dose rates. Ivermectin, in addition, has a label claim for *P. rufescens*. It is doubtful whether treatment of sheep for *M. capillaris* is ever justified. In goats, one or two doses of ivermectin (0.2 mg/kg, SC or PO) or elevated doses of benzimidazoles destroys the adult worms but not the immature stage, but regular daily oral doses of fenbendazole (up to 5 mg/kg/d) in the feed for 1 to 2 weeks or albendazole (1 mg/kg in the feed for 2 weeks) are highly effective against all stages. The label dose of albendazole (7.5 mg/kg BW, once in sheep and 10 mg/kg BW once in goats) is effective in treating adult lungworms, but is not effective against the immature stage.

**Control**

An attenuated vaccine for *D. filaria* is available in a few countries where this worm is a particular problem. With most forms of sheep husbandry, there are few precautionary measures that can be taken, particularly against lungworms with molluscan intermediate hosts.

**Diseases of the Equine Respiratory Tract**

**Abnormalities of the Upper Respiratory Tract of Horses**

Impairment of ventilation by abnormalities of the upper respiratory tract is an important cause of poor performance in athletic horses. Abnormalities that impair athletic capacity are those that reduce the effective diameter of the upper airway, thereby increasing the work needed to maintain the same level of tidal volume and minute ventilation or, as is the case clinically, reducing the minute ventilation achieved by the horse during maximal exercise. In other words, a reduction in effective diameter of the upper airway increases work of breathing at all exercise intensities, and at maximal intensity, when the effort expended on breathing cannot be increased, decreases maximal minute ventilation. The result is diminished oxygenation of arterial blood and delivery of oxygen to muscle and other tissues, exacerbated hypercapnia, and reduced athletic capacity during high-speed exercise.1-3

The work of breathing is, simplistically, determined by the volume of air moved and the pressure required to do so. The relationship between pressure and resistance in the airway is described mathematically by a rearrangement of Poiseuille’s law:

\[ \text{Resistance to flow} = \frac{\text{pressure drop}}{\text{flow}} = \frac{8 \times \text{viscosity of the air} \times \text{length of the airway}}{(\pi \times \text{[radius]}^4)} \]

Given that the viscosity of air is constant and the length of the airway does not change for an individual horse, the radius of the airway has a huge effect on resistance to flow. Notice that a change in pressure is inversely proportional to the fourth power of the radius (r^4), with the consequence that relatively small changes in radius have large effects on the pressure needed to generate a given flow of air. For this reason, abnormalities of the upper airway that cause only small reductions in airway diameter can have clinically important effects on ventilation during high intensity exercise.

Another consequence of changes in airway diameter and structure is the generation of abnormal airflow patterns that result in production of abnormal respiratory sounds. Such sounds can vary from gurgling through to roaring and can be of diagnostic importance.4

Advent of first rigid and then flexible endoscopes allowed greater refinement of diagnosis of disorders of the upper respiratory tract of horses when examined at rest. A further advance was the ability to examine the upper airway during intense exercise. This was first achieved in horses running on a treadmill and has now progressed to examination of horses running over ground. Although there are advantages to each mode of examination (at rest, treadmill, over ground), greatest diagnostic utility is achieved by examination of horses exercising over ground and performing their customary activity wearing their usual tack and with their rider.5-8

Laryngeal hemiplegia caused by recurrent laryngeal neuropathy is a well-recognized abnormality of the upper airway associated with impaired performance by racehorses. In many of its forms, it is readily identified in horses at rest. However, more subtle abnormalities or those that develop as the horse fatigues are best detected, or can only be detected, on examination during strenuous exercise. It is now clear that most abnormalities of the upper airway of horses, with the exception of laryngeal hemiplegia, can only reliably be detected by examination of exercising horses.5-8

Abnormalities developing during strenuous exercise by horses are best referred to as “dynamic” abnormalities. This term should not be used to denote the mode of examination (ie, “dynamic endoscopy”), which should be specified as “over ground” or “treadmill.” Terms describing abnormalities detected during endoscopic examination of the upper airway of horses have recently been standardized (Table 12-10).10

The use of endoscopy during exercise has revealed that dynamic abnormalities of the upper airway are often complex and involve...
multiple structures.\textsuperscript{9,11} Up to 50% of horses examined during high-speed exercise have multiple abnormalities of the upper airway. Furthermore, examination of exercising horses has revealed abnormalities not apparent during examination of resting horses, including the full spectrum of manifestations of recurrent laryngeal neuropathy, palatal instability including intermittent dorsal displacement of the soft palate, vocal fold collapse, aryepiglottic fold collapse, axial deviation of the aryepiglottic folds, dynamic nasopharyngeal collapse, collapse of the corniculate process of the arytenoid cartilage, bilateral arytenoid and vocal fold collapse, and epiglottic retroversion.\textsuperscript{9}

Fig. 12-18 Endoscopic view of dorsal displacement of the soft palate in a resting Thoroughbred racehorse.

PALATAL DYSFUNCTION (INSTABILITY, DORSAL DISPLACEMENT OF THE SOFT PALATE)
The soft palate of equids is unique in that it provides an airtight seal between the oropharynx and nasopharynx during respiration, rendering equids obligate nasal breathers. During swallowing the soft palate is transiently displaced dorsally to permit passage of the bolus and the normal act of deglutition. Abnormalities of the soft palate that result in alteration of the normal act of deglutition are associated with impaired respiration and exercise intolerance.\textsuperscript{1-3} Displacement of the soft palate other than during deglutition is abnormal and can be intermittent, which is usually associated with exercise, or persistent, which is usually associated with disruption of the nerve supply to the pharynx.

Palatal Instability and Intermittent Dorsal Displacement of the Soft Palate During Exercise
Dysfunction of the palate during exercise results in a range of structural abnormalities that reduce the functional area of the rima glottidis (the opening of the larynx) and thus impair ventilation during high-speed exercise. Dysfunction during exercise ranges from palatal instability to intermittent dorsal displacement of the soft palate.\textsuperscript{1} Palatal instability and dorsal displacement of the soft palate cause an expiratory obstruction to airflow through the larynx and pharynx.\textsuperscript{3}

Palatal instability is evident as dorsoventral billowing of the soft palate during high speed exercise and flattening of the epiglottis against the palate. Palatal instability is significantly associated with dorsal displacement of the soft palate during exercise.\textsuperscript{1} Dorsal displacement of the soft palate is an extreme of palatal instability and results when the caudal border of the soft palate displaces dorsal to the epiglottis (Fig. 12-18). Palatal instability is also associated with axial deviation of the aryepiglottic folds and abnormalities in the conformation of the epiglottis.\textsuperscript{1,3}

Estimates of the prevalence of the disease in the wider population are unreliable because of the transient nature of the instability and displacement and the fact that it only occurs during exercise. Additionally, examination of large numbers of horses to determine prevalence in populations of horses has not been performed, with most reports being prevalence rates in horses selected for high-speed endoscopic examination. It is estimated to occur in 0.5% to 1.3% of Thoroughbred racehorses, and of 52 Thoroughbred racehorses examined using over ground endoscopy, 25% had dorsal displacement of the soft palate, 40% had axial deviation of the aryepiglottic fold, 35% had vocal fold collapse, and 33% had abnormal arytenoid function.\textsuperscript{6} Forty-eight percent of the horses had multiple abnormalities. Nineteen of 57 Thoroughbred yearlings had intermittent dorsal displacement during a single examination using over ground endoscopy.\textsuperscript{7} Dorsal displacement was detected in 10 of 46 Standardbred racehorses examined using overground endoscopy during racing—these horses were presumably considered healthy before examination.\textsuperscript{6} Three
percent of performance horses (nonracing) had dorsal displacement of the soft palate as the sole abnormality during exercise.\textsuperscript{9} Palatal instability and intermittent dorsal displacement of palate are a common part of complex dynamic abnormalities of the upper respiratory tract in harness horses, with 70\% of examined horses having a complex disorder.\textsuperscript{5} Similarly, 19\% of performance horses (nonracing horses) had complex upper respiratory tract abnormalities during exercise.\textsuperscript{9}

The cause of intermittent displacement of the soft palate during exercise is unknown, although a number of mechanisms, including palatal myositis, ulcers of the caudal border of the soft palate, caudal retraction of the larynx, and lower respiratory disease, are suggested. Retropharyngeal lymphadenopathy can cause neurogenic paresis of the pharyngeal and palatal muscles, with dorsal displacement of the soft palate the most obvious sign of pharyngeal collapse during exercise. The immediate cause of the displacement is the high turbulent flow and negative intrapharyngeal pressure generated during exercise.\textsuperscript{10}

Displacement of the soft palate during strenuous exercise places the soft palate dorsal to the epiglottis, a position in which it impedes flow of air during expiration. Peak expiratory airflow, minute ventilation, tidal volume, and rate of oxygen consumption are all decreased in horses with dorsal displacement of the soft palate, whereas inspiratory flow and breathing rate are not affected.\textsuperscript{3}

Clinical Signs
The clinical signs include exercise intolerance and intermittent production of a gurgling noise during strenuous exercise. \textbf{Endoscopic examination} of resting horses usually demonstrates a normal pharynx and larynx. Brief nasal occlusion (30–60 s) that induces displacement of the soft palate (Fig. 12-18), in combination with a history of respiratory noise during exercise, increases the likelihood of the disorder.

Endoscopic examination of affected horses during exercise is the gold standard for diagnosis and reveals signs of palatal instability or dorsal displacement of the soft palate and related abnormalities.

Detection of palatal instability and associated abnormalities is described as follows:\textsuperscript{3}

\textit{Axial deviation of the aryepiglottic folds:}
Graded as none, mild, moderate or severe.
1. \textbf{Mild} ADAF, defined as axial collapse of the aryepiglottic folds with the folds remaining abaxial to the vocal cords.
2. \textbf{Moderate} ADAF, defined as axial deviation of the aryepiglottic folds less than halfway between the vocal cord and the midline.
3. \textbf{Severe} ADAF, defined as collapse of the aryepiglottic folds more than halfway between the vocal cord and the midline.

\textit{Epiglottic conformation:}
Epiglottic conformation is categorized into three groups.
1. Convex epiglottic appearance when the epiglottis maintained a convex shape during exercise; typically only the tip of the epiglottis is in contact with the soft palate.
2. Flattened epiglottis where the epiglottis loses its convex shape and appears to lie flat or slightly concave on the surface of the soft palate, but the tip of the epiglottis remains ventral to the base.
3. A tipped up appearance when the epiglottis has a flattened or concave appearance and during inspiration the tip of the epiglottis is at the same level as or higher than the base of the epiglottis.

\textit{Obstruction of the rima glottidis by the soft palate (soft palate stability):}
The stability of the soft palate is graded according to whether the \textit{rima glottidis} is obscured by the billowing soft palate.
1. The soft palate is considered stable when there is no movement or lifting of the soft palate was observed (Fig. 12-19).
2. Palatal instability with no \textit{rima glottidis} obstruction when the soft palate lifts up to the level of the base of epiglottis but the \textit{rima glottidis} is not obscured (Fig. 12-20).
3. Palatal instability with \textit{rima glottidis} obstruction when the soft palate lifts so that the \textit{rima glottidis} becomes obscured (Fig. 12-21).

\textit{Soft palate conformation:}
The soft palate of horses with palatal instability is either flaccid, billowing dorsally in front of the epiglottis or billowing dorsally either side of the epiglottis. The presence or absence of a sling appearance to the ventrolateral pharyngeal walls at the level of the gulletal pouch ostia should be noted. The caudal soft palate should be assessed as to whether a concave appearance was present and if so should be graded as absent, small, or large during each of inspiration and expiration.

Radiographic examination of the pharynx reveals a shortened epiglottis (<7 cm) in some affected horses.

\hline
\textbf{Differential Diagnosis} & \\
\hline
Differential diagnoses for exercise intolerance and respiratory noise include \textit{laryngeal hemiplegia}, subepiglottic cysts, \textit{arytenoid chondritis}, and \textit{aryepiglottic fold entrapment}. The important differentiating factor is that the noise occurs predominantly during expiration, and it has a more gurgling sound to it than does the noise produced by horses with \textit{laryngeal hemiplegia}. & \\
\hline
\end{tabular}
\end{table}
Treatment
There is no definitive treatment and no evidence that any one treatment is superior.4,15 Usual methods of surgical intervention include augmentation of the epiglottis by injection of polytetrafluoroethylene (Teflon) paste, resection of the caudal edge of the soft palate or sternothyrohyoid myectomy, and palatal sclerotherapy,17 although some of these interventions may have deleterious effects on upper airway airflow. A newer surgical technique involves the "laryngeal tie-forward" procedure.13,14 Reports of success of surgical treatment of the disease are not definitive, in part because horses with the disorder that went untreated are not examined. It is plausible that the response to surgical treatment could be the result of enforced rest rather than the manipulation. Treatment of retropharyngeal lymphadenopathy may be beneficial. Nonsurgical treatment includes the use of antiinflammatory drugs, tongue-ties,15 a variety of bits, and a laryngohyoid support apparatus.

Persistent Dorsal Displacement of the Soft Palate
Persistent dorsal displacement of the soft palate is usually the result of damage to the innervation of the pharyngeal and palatal muscles as a result of the following:
- Guttural pouch mycosis
- Guttural pouch empyema
- Retropharyngeal lymph node abscessation
- Equine protozoal myeloencephalitis
- Otitis media
- Myositis or muscle disease, such as white-muscle disease
- Botulism
- Idiopathic in young foals.

Blockade of the pharyngeal branch of the vagus nerve by injection of local anesthetic causes persistent dorsal displacement of the soft palate, whereas blockade of the hypoglossal and glossohyoid nerves does not.

Clinical Signs
Persistent dorsal displacement of the soft palate causes dysphagia and stertorous respiration. Food material discharges from the nares and there is frequent coughing, probably secondary to the aspiration of feed material. Affected horses may develop aspiration pneumonia. If the condition persists, there is dehydration and weight loss. Endoscopic examination of the upper airways reveals dorsal displacement of the soft palate and may reveal other abnormalities, such as guttural pouch mycosis, that provide a cause for the disease.

Treatment
Treatment should be directed toward resolution of the underlying disease and provision of food and water. It is often necessary to feed affected horses through a nasogastric tube.

DISEASES OF THE GUTTURAL POUCHES (AUDITORY TUBE DIVERTICULUM, EUSTACHIAN TUBE DIVERTICULUM)

The guttural pouches are diverticula of the auditory (or eustachian) tubes found in equids and a limited number of other species. The function of the guttural pouch is unclear, although it is usually viscid, but over time it becomes inspissated and is kneaded into ovoid masses called chondroids (Fig. 12-22).

Chondroids occur in approximately 20% of horses with guttural pouch empyema. The condition is most commonly associated with S. equi var. equi until proven otherwise. The empyema can be associated with other conditions of the guttural pouches, especially if there is impaired drainage of the pouch through the pharyngeal opening of the eustachian tube.

EPIDEMIOLOGY
The epidemiology, apart from its association with strangles, has not been defined. The disease occurs in all ages of horses, including foals, and all equids, including asses and donkeys. The case-fatality rate is approximately 10%, with one-third of horses having complete resolution of the disease. Guttural pouch empyema occurs in an approximately 7% of horses with strangles. The recovery rate for horses with uncomplicated empyema treated appropriately is generally considered to be good, although the presence of chondroids worsens the prognosis.

PATHOGENESIS
The pathogenesis of guttural pouch empyema is unclear, although when secondary to strangles it is usually attributable to the rupture of abscessed retropharyngeal lymph nodes into the medial compartment. Continued drainage of the abscesses presumably overwhelms the normal drainage and protective mechanisms of the guttural pouch, allowing bacterial colonization, influx of neutrophils, and accumulation of purulent material. Swelling of the mucosa, especially around the opening to the pharynx, impairs drainage and facilitates fluid accumulation in the pouch. The accumulation of material in the pouch causes distension and mechanical interference with swallowing and breathing. Inflammation of the guttural pouch mucosa may involve the nerves that lie beneath it and result in neuritis with subsequent pharyngeal and laryngeal dysfunction and dysphagia.
**CLINICAL FINDINGS**

Clinical findings include the following:
- Purulent nasal discharge
- Swelling of the area caudal to the ramus of the mandible and ventral to the ear
- Lymphadenopathy
- Carriage of the head with the nose elevated above its usual position
- Dysphagia and other cranial nerve dysfunction
- Respiratory stertor

The nasal discharge is usually unilateral, as is the disease, intermittent, and white to yellow. Guttural pouch empyema is not usually associated with hemorrhage, although the discharge may be blood tinged. Bilateral disease, and the resultant neuritis and mechanical interference with swallowing and breathing, may cause discharge of feed material from the nostrils, dysphagia, and respiratory stertor.

**Endoscopic examination** of the pharynx reveals drainage of purulent material from the pharyngeal opening of the eustachian tube of the affected side. The guttural pouch contains a variable quantity of purulent material, although in severe cases the quantity of fluid may be sufficient to prevent adequate examination of the pouch with an endoscope.

**Radiographic examinations** demonstrate the presence of radiodense material in the guttural pouch, sometimes the presence of an air–gas interface (fluid line) within the pouch and distension of the pouch with impingement into the nasopharynx. Chondroids are evident as multiple circular radiodensities. Passage of a catheter into the guttural pouch via the pharyngeal opening permits aspiration of fluid for cytology and bacterial culture.

**CLINICAL PATHOLOGY**

Hematologic examination may reveal evidence of chronic infection, including a mild leukocytosis, hyperproteinemia, and hypofibrinogenemia. Fluid from the affected guttural pouch contains large numbers of degenerate neutrophils and occasional intra- and extracellular bacteria. Bacterial culture yields *S. equi* in approximately 30% of cases and *S. zooepidemicus* in approximately 40% of cases.

**NECROPSY FINDINGS**

Lesions of guttural pouch empyema include the presence of purulent material in the guttural pouch and inflammation of the mucosa of the affected guttural pouch.

**DIAGNOSTIC CONFIRMATION**

Diagnostic confirmation in a horse with clinical signs of guttural pouch disease is achieved by demonstration of purulent material in the guttural pouch by endoscopic or radiographic examination and examination of the fluid.

**DIFFERENTIAL DIAGNOSIS**

Differential diagnosis of guttural pouch empyema includes the following conditions:
- Abscessation of retropharyngeal lymph nodes
- Guttural pouch typany
- Guttural pouch mycosis

Guttural pouch empyema should also be differentiated from other causes of nasal discharge in horses, including the following:
- Sinusitis
- Recurrent airway obstruction (heaves)
- Pneumonia
- Esophageal obstruction
- Dysphagia of other cause

Infection by *Mycobacterium avium* complex organisms causes nasal discharge and granulomatous lesions in the guttural pouch.

**TREATMENT**

The principles of treatment are removal of the purulent material, eradication of infection, reduction of inflammation, relief of respiratory distress, and provision of nutritional support in severely affected horses.

**Removal of purulent material** can be difficult but can be achieved by repeated flushing of the affected guttural pouch. The guttural pouch can be flushed through a catheter (10–20 French, 3.3- to 7-mm male dog urinary catheter) inserted as needed via the nares, or a catheter (polyethylene 240 tubing) with a coiled end inserted via the nares and retained in the pouch for several days. The pouch can also be flushed through the biopsy port of an endoscope inserted into the guttural pouch.

The choice of fluid with which to flush the guttural pouch is arbitrary, but frequently used fluids include normal (isotonic) saline, lactated Ringer’s solution, or 1% (v/v) povidone–iodine solution. It is important that the fluid infused into the guttural pouch be non-irritating because introduction of fluids such as hydrogen peroxide or strong solutions of iodine (e.g., 10% v/v povidone iodine) will exacerbate the inflammation of the mucosa and underlying nerves and can actually prolong the course of the disease. The frequency of flushing is initially daily, with reduced frequency as the empyema resolves.

**Infusion of antibiotics** into the guttural pouches is probably without merit although this is debated. Because of the viscid nature of the empyema fluid, it is necessary to infuse large volumes of lavage solution (1–2 L) on consecutive days. It may be necessary to treat for 7 to 10 days. The infusion of acetylcysteine (60 mL of a 20% solution) into the pouch after lavage with 1 to 2 L of saline has been reported to be effective in aiding the removal of purulent material. Removal of chondroids usually requires surgery, although dissection and removal of chondroids through the pharyngeal opening has been described. A stone remover inserted through the biopsy channel of the endoscope can be useful for removal of small numbers of chondroids, but is tedious if there are large numbers of them. A rule of thumb is that if the chondroids occupy more than one-third of the volume of the guttural pouch, then removal should be carried out surgically.

**Systemic antimicrobial administration** is recommended for all cases of guttural pouch empyema because of the frequent association of the disease with bacterial infection and especially *S. equi* and *S. zooepidemicus* infection of the retropharyngeal lymph nodes. The antibiotic of choice is *penicillin G* (procaine penicillin G, 20,000 IU/kg intramuscularly every 12 hours for 5–7 days), although a combination of sulfonamide and trimethoprim (15–30 mg/kg orally every 12 hours for 5–7 days) is often used. **Topical application of antimicrobials** into the guttural pouch is probably ineffective because they do not penetrate the infected soft tissues of the pouch and retropharyngeal area.

**NSAIDs** such as flunixin meglumine (1 mg/kg intravenously or orally every 12 hours) or phenylbutazone (2.2 mg/kg intravenously or orally every 12 hours) are used to reduce inflammation and pain. Severely affected horses may require relief of respiratory distress by tracheotomy. Dysphagic horses may need nutritional support, including administration of fluids.

**Chronic cases refractory to treatment** might require fistulation of the guttural pouch into the pharynx.

**CONTROL**

Prevention of guttural pouch empyema is based on a reduction in the frequency and severity of *S. equi* infection in horses (see “Strangles”).

**REFERENCES**

**GUTTURAL POUCH MYCOSIS**

**ETIOLOGY**

Mycosis of the guttural pouch is caused by infection of the dorsal wall of the medial compartment of the pouch, caudal and medial to the articulation of the stylohyoid bone and the petrous temporal bone. The most common fungal isolates from the lesions are *Aspergillus (Emericella) nidulans*, *Aspergillus fumigatus*, and, rarely, *Penicillium spp.* and *Mucor spp.*, although spores of these fungi are present in the guttural pouches of normal horses. Other fungal species isolated include *Fusarium*, *Trichosporon*, *Acremonium*, and *Rhodotorula*.

**PENICILLIN G** (procaine penicillin G, 20,000 IU/kg intramuscularly every 12 hours for 5–7 days), although a combination of sulfonamide and trimethoprim (15–30 mg/kg orally every 12 hours for 5–7 days) is often used. **Topical application of antimicrobials** into the guttural pouch is probably ineffective because they do not penetrate the infected soft tissues of the pouch and retropharyngeal area.

**NSAIDs** such as flunixin meglumine (1 mg/kg intravenously or orally every 12 hours) or phenylbutazone (2.2 mg/kg intravenously or orally every 12 hours) are used to reduce inflammation and pain. Severely affected horses may require relief of respiratory distress by tracheotomy. Dysphagic horses may need nutritional support, including administration of fluids.

**Chronic cases refractory to treatment** might require fistulation of the guttural pouch into the pharynx.

**CONTROL**

Prevention of guttural pouch empyema is based on a reduction in the frequency and severity of *S. equi* infection in horses (see “Strangles”).
EPIDEMIOLOGY
The disease occurs in horses of both sexes and all breeds. Horses are affected at all ages, with the youngest recorded case being a 6-month-old foal. The overall prevalence is low, although precise figures are lacking. Among horses left untreated the case-fatality rate is ~50% to 60%, whereas in those treated medically it is ~45%, and in horses treated surgically the case-fatality rate is 33%.1,2

PATHOGENESIS
The pathogenesis of the disease is unclear, although it is likely that fungal spores gain access to the guttural pouch through the pharyngeal opening. The spores then germinate and proliferate in the mucosa of the dorsal, medial aspect of the medial compartment of the guttural pouch. The location of the lesion is consistent, but the reason for the disease occurring in this particular position is unclear. Factors that predispose to the development of mycotic lesions have not been determined, although it appears unlikely that fungal infection is the initial insult to the mucosa. Invasion of guttural pouch mucosa is followed by invasion of the nerves, arteries, and soft tissues adjacent to it. Invasion of the nerves causes glossopharyngeal, hypoglossal, facial, sympathetic, or vagal dysfunction. Invasion of the internal carotid artery, and occasionally the maxillary or external carotid, causes weakening of the arterial wall and aneurysmal dilatation of the artery, with subsequent rupture and hemorrhage. Death is caused by hemorrhagic shock or, in horses with dysphagia, aspiration pneumonia or starvation.

Guttural pouch mycosis is usually unilateral, although in approximately 8% of cases there is erosion of the medial septum and spread of infection into the other pouch. There is no predisposition for either the left or right pouch. Guttural pouch mycosis presents as either epistaxis that is not associated with exercise or as cranial nerve disease.

CLINICAL FINDINGS
The clinical signs of guttural pouch mycosis include epistaxis (75% of cases), dysphagia (15%), and purulent nasal discharge (10%).1,3 Epistaxis is usually severe and frequently life-threatening. There is profuse bleeding of bright red blood from both nostrils during an episode, and between episodes there may be a slight, serosanguineous nasal discharge. There are usually several episodes of epistaxis over a period of weeks before the horse dies. Most horses that die of guttural pouch mycosis do so because of hemorrhagic shock.

Signs of cranial nerve dysfunction are common in horses with guttural pouch mycosis and can precede or accompany epistaxis.

- Dysphagia is the most common sign of cranial nerve disease and is attributable to lesions of the glossopharyngeal and cranial laryngeal (vagus) nerves. Dysphagic horses may attempt to eat or drink but are unable to move the food bolus from the oral cavity to the esophagus.
- Affected horses frequently have nasal discharge that contains feed material and often develop aspiration pneumonia.
- Lesions of the recurrent laryngeal nerve cause laryngeal hemiplegia.
- Horner’s syndrome (ptosis of the upper eyelid, miosis, enopthalmos, and prolapse of the nictitating membrane) is seen when the lesion involves the cranial cervical ganglion or sympathetic nerve trunk.
- Facial nerve dysfunction, evident as drooping of the ear on the affected side, lack of facial expression, inability to close the eyelids, corneal ulceration, and deviation of the muzzle away from the affected side, also occurs.

Signs of cranial nerve and sympathetic trunk dysfunction may resolve with eradication of the infection, but they are frequently permanent.

Guttural pouch mycosis is also associated with pain on palpation of the parotid region, head shyness and abnormal head position. The infection may spread to the atlanto-occipital joint, causing pain on movement of the head, or to the brain, causing encephalitis.4

Endoscopic examination of the guttural pouch reveals a plaque of dark yellow to black necrotic material in the dorsal aspect of the medial compartment. A sample of the material can be collected through a biopsy port of the endoscope and submitted for culture. The mycotic plaque cannot be easily dislodged by manipulation with biopsy instruments or the end of the endoscope. In cases with ongoing or recent hemorrhage, the presence of large quantities of blood might prevent identification of the mycotic plaque. Both pouches should always be examined because of the occasional occurrence of bilateral disease or extension of the disease through the medial septum. Caution should be exercised in performing endoscopic examination of the guttural pouch of horses with acute or ongoing hemorrhage because of the risk of exacerbating the hemorrhage. These horses are usually referred for urgent surgical intervention.

Radiographic examination of the guttural pouches may reveal the presence of a lesion in the appropriate position, but it is frequently unrewarding.

CLINICAL PATHOLOGY
There are no characteristic findings on the hemogram, nor are there serum biochemical abnormalities. Horses with repeated hemorrhage are often anemic. Immunoblot may identify the presence of serum antibodies specific for A. fumigatus in infected horses, although the diagnostic usefulness has not been determined. Culture of a sample of the necrotic tissue will frequently yield one of the causative fungi.

Necropsy Findings
Lesions of guttural pouch mycosis include the presence of a clearly demarcated, yellowish-brown to black, dry plaque of necrotic tissue in the dorsal aspect of the medial compartment of the guttural pouch. The plaque of tissue is firmly adherent to underlying tissues and may perforate the medial septum and invade the other pouch. The infection may involve the adjacent nerves and blood vessels and spread to soft tissues and bone. Histologic examination reveals the presence of inflammatory cells in nerves and tissues surrounding the gross lesion. There is chromatolysis and degeneration of neurones in affected nerves. The internal carotid artery may have an aneurysmal dilatation, or there may be rupture of the arterial wall without dilatation. There is usually partial thrombosis of the arterial wall.

Differential Diagnosis

**Differential diagnoses for epistaxis not associated with exercise include ethmoidal hematoma or guttural pouch empyema, neoplasia, rupture of the longus capitis muscle, and penetration by a foreign body.**

TREATMENT
Treatment of guttural pouch mycosis involves prevention of death from hemorrhage and administration of antifungal agents.

Prevention of hemorrhage from the internal carotid or maxillary artery is achieved by surgical ligation, transarterial coil embolization, or occlusion with intra-arterial balloons of one or more of the external carotid, internal carotid, or maxillary artery.14 Because of the high rate of death from hemorrhage in horses with guttural pouch mycosis, some authorities recommend that all horses with the disease have the internal artery ligated or occluded. Medical treatment of horses with hemorrhage secondary to guttural pouch mycosis is rarely successful.

Administration of antifungal agents by instillation into the guttural pouch through a catheter or endoscope has been reported, although there is disagreement about the need for such treatment in horses that have had the problematic arteries ligated or occluded. Oral administration of antifungal agents is generally ineffective or prohibitively expensive, although itraconazole (5 mg/kg orally once daily) might be useful. Agents reported to be usefuly given by topical administration include enilconazole (60 mL of 33 mg/mL solution once daily for 3
weeks), miconazole (60 mL of 1 mg/mL solution), natamycin, and nystatin. Topical therapy is laborious because it must be continued for weeks and involves placement and maintenance of a catheter in the guttural pouch or instillation of medication by daily endoscopy.

Horses with signs of cranial nerve or sympathetic trunk damage may not recover completely even if cured of the fungal infection because of irreparable damage to the affected nerves. Provision of supportive care, including fluid and nutrient administration to dysphagic horses and administration of antibiotics to prevent or treat aspiration pneumonia, may be indicated.

CONTROL
There are no recognized effective measures to control or prevent the disease.

GUTTURAL POUCH TYPANY
ETIOLOGY AND EPIDEMIOLOGY
Guttural pouch tympany refers to the gaseous distension of one, rarely both, guttural pouches of young horses. Tympany develops in foals up to 1 year of age but is usually apparent within the first several months of life. Fillies are more commonly affected than colts by a ratio of 2 to 4:1, and the disease has a heritability of 0.8. The cause is not known, although a polygenic cause has been proposed for Arabians, and genome-wide association studies have identified linked regions in Arabian and Warmblood horses.

The presence of a quantitative trait loci on ECA2 in fillies and ECA15 in colts supports the reported sex distribution of the disease.

CLINICAL FINDINGS
Clinical findings include marked swelling of the parotid region of the affected side, with lesser swelling of the contralateral side. The swelling of the affected side is not painful on palpation and is elastic and compressible. The disease is usually unilateral but can be bilateral. There are stertorous breath sounds in most affected foals as a result of impingement of the distended pouch on the nasopharynx. Respiratory distress can develop. Severely affected foals are dysphagic and develop aspiration pneumonia.

Endoscopic examination of the pharynx reveals narrowing of the nasopharynx by the distended guttural pouch. The guttural pouch openings are usually normal. There are usually no detectable abnormalities of the guttural pouches apart from distension.

Radiographic examination demonstrates air-filled pouches, and dorsoventral images permit documentation of which side is affected. There are no characteristic changes in the hemogram or serum biochemical profile.

There are no characteristic lesions, and necropsy examination usually does not demonstrate a cause for the disease.

TREATMENT
Treatment consists of surgical fenestration of the medial septum allowing drainage of air from the affected pouch into the unaffected side. The usual approach is through Viborg’s triangle. Creation of salpingopharyngeal fistulas using transendoscopic laser fenestration is reported in a foal with bilateral disease. The prognosis for long-term resolution after surgery is approximately 60%.

A nonsurgical option for treatment involves placement of Foley catheters (22 or 24 French) into the guttural pouches. Placement is achieved by endoscopic guidance via the ipsilateral nostril and resulted in resolution of the tympany in 5 of 8 foals over a period of weeks to months. The catheters are sutured in position and remain in place for weeks.

OTHER GUTTURAL POUCH DISEASES
Rupture of the longus capitis muscle or avulsion of its insertion on the basisphenoid bone causes epistaxis and is usually associated with trauma to the head, such as is caused by rearing and falling over backward. Endoscopic examination reveals the following:

- Compression of the nasopharynx that is asymmetric
- Blood in the guttural pouch
- Submucosal hemorrhage and swelling of the medial aspect of the medial compartment of the guttural pouch

Radiographic examination reveals ventral deviation of the dorsal pharynx and loss of the usual radiolucency associated with the guttural pouch (Fig. 12-23). Treatment is conservative and consists of supportive care, monitoring the hematocrit, and administration of broad-spectrum antibiotics if there is concern of the development of secondary infection. The prognosis for complete recovery is guarded.

Traumatic injury to the guttural pouch can occur during attempts to pass a nasogastric tube. Clinical signs include swelling of the throatlatch area, pain on palpation, crepitation, and pain on swallowing. Endoscopic and radiographic examination is diagnostic. Treatment is supportive, including administration of antimicrobials and analgesics and ensuring maintenance of hydration and nutrition.

Fig. 12-23 Lateral radiograph of the head of a horse with rupture of the longus capitis muscle after rearing and falling over backward. There is loss of radiolucency of the guttural pouches and evidence of an avulsion fracture of the basisphenoid bone (white arrow).
Various neoplasms have been recorded as involving the guttural pouches. The presenting signs are swelling of the parotid region, epistaxis, dysphagia, or signs of cranial nerve disease. Neoplasms include melanoma, lymphosarcoma, hemangiosarcoma, squamous-cell carcinoma, and sarcoma. Diagnosis is made by physical, endoscopic, and radiographic examination and biopsy. The prognosis is very poor to hopeless.

REFERENCE

DISEASES OF THE EPIGLOTTIS AND ARYTENOIDS

Aryepiglottic Fold Entrapment (Epiglottic Entrapment)
Entrapment of the epiglottis in the fold of tissue that extends from the arytenoid cartilage to the ventrolateral aspect of the epiglottis causes exercise intolerance and respiratory noise during exercise in racehorses. The disorder occurs in both young and mature racehorses, and it is found in approximately 1% of Thoroughbred racehorses. The entrapment is often detected during rhinolaryngoscopic examination of racehorses, although it might not be the cause of poor performance. The condition occurs in nonracehorses (13 cases in 23 adult horses with epiglottis disease).

The presence of aryepiglottic fold entrapment causes a predominantly inspiratory obstruction to airflow across the larynx during exercise. The interference with airflow, if any, does not appreciably impair performance in all horses.

Clinical Signs
Clinical signs are of exercise intolerance and respiratory noise during exercise. Acute cases can be associated with epiglottitis, whereas chronic cases are usually an incidental finding during endoscopic examination of the upper airway.

Endoscopic examination of the upper airway reveals the border of the epiglottis to be obscured by the aryepiglottic folds (Fig. 12-24). Normally, the serrated margin of the epiglottis and dorsal blood vessels extending to the lateral margins of the epiglottis are readily apparent, but when the epiglottis is entrapped, these features are no longer visible. Because of the frequently intermittent nature of the entrapment, the horse should be examined on several occasions and preferably immediately after strenuous exercise. Radiography of the pharynx reveals the entrapped epiglottis.

Treatment
Treatment consists of surgical revision of the aryepiglottic fold. Surgery is reported to have both a high success rate and, in some reports, a complication rate for surgical correction of 60%, indicating that careful consideration should be given to not attempting surgical repair, especially in animals performing to expectation. Entrapment associated with acute epiglottitis should include administration of antimicrobials and antiinflammatory agents to resolve the epiglottitis.

Epiglottic Retroversion During Exercise
Retroversion of the epiglottis occurs during exercise in horses. The condition is rare and is associated with poor performance and an inspiratory “grunt” during exercise. Endoscopic examination at rest might reveal that the tip of the epiglottis is pointed more dorsally than normal, but this finding is not conclusive evidence of the disorder. Endoscopy during high-speed exercise demonstrates that the tip of the epiglottis is pointed dorsally or, in severe cases, points caudally through the rima glottidis. Retroversion occurs only during inspiration. Poll flexion during exercise exacerbates the condition. Frequency of retroversion increases as the intensity of exercise increases. There is no definitive treatment, and the prognosis for successful return to athletic performance is poor.

Epiglottitis
Epiglottitis is usually a disease of racehorses, although animals of any age can be affected. The clinical signs are exercise intolerance, respiratory noise, and coughing. The disease can readily be mistaken for epiglottic entrapment. The epiglottis is thickened and ulcerated, and these changes are apparent on endoscopic examination. Treatment includes topical application of a mixture of nitrofurazone, dimethyl sulfoxide, glycerin, and prednisolone, and systemic administration of antiinflammatory drugs. The prognosis for recovery is excellent.

Subepiglottic Cysts
Fluid-filled cysts in the subepiglottic, dorsal pharyngeal, or soft palate tissues cause exercise intolerance and abnormal respiratory noise in exercising adult horses and mild dysphagia, chronic cough, and nasal discharge in foals. Most cysts are asymptomatic. The cysts are usually embryonic remnants, although cysts may be acquired in adult horses by obstruction or inflammation of mucous glands. Endoscopic examination of the upper airway reveals the presence of smooth-walled cysts. Subepiglottic cysts may only be apparent on careful examination of the epiglottis, although most will cause the epiglottis to assume a more upright posture than is normal. Treatment is surgical removal or intralesion injection with formalin.

Arytenoid Chondritis
Arytenoid chondritis is a progressive disease of the arytenoid cartilages in which there is distortion of the cartilage with consequent partial occlusion of the lumen of the larynx. The cause of the disease is not known, but it is most common in racehorses in heavy work. Distortion and swelling of the cartilage, combined with restricted abduction, increase resistance to airflow through the larynx and cause respiratory noise during exercise and exercise intolerance. In severe cases respiratory noise and increased respiratory effort are apparent at rest. The disease can occur as a progression of idiopathic mucosal ulceration of the axial aspect of the arytenoid cartilages.

Endoscopic examination reveals the cartilage to be enlarged and distorted, and there may be luminal projections of cartilage and granulation tissue. In less severe cases there is mild swelling of the cartilage and ulceration of the mucosa covering the cartilage. Bilateral disease is uncommon. Ultrasonographic examination is useful in determining the extent of the lesion. Affect cartilages are increased in size and echogenicity and have an abnormal contour. The cartilage contains areas of necrosis, dystrophic mineralization, and granulation tissue.

Treatment
Treatment requires surgical removal of the affected cartilage, although progression of the disease can be achieved in horses with mild lesions by administration of antimicrobials and antiinflammatory drugs.

The disease also occurs in calves, in which it can be treated by partial arytenoidectomy.

Mucosal Lesions of the Arytenoid Cartilages
Lesions of the mucosa of the axial aspect of the arytenoid cartilages are observed in Thoroughbred racehorses. The condition occurs in approximately 2.5% of Thoroughbred racehorses and 0.6% of Thoroughbred yearlings. The pathogenesis is unknown. The disorder is recognized during endoscopic examination of the horses for other reasons...
and infection by pharynx, brachial cysts remnants, 16 neoplasia is also caused by trauma to the horse barns. Retropharyngeal lymphadenopathy is an important source of new infections in horses.14,15 The disorder can only be detected in horses by endoscopic examination of the larynx while the horse is performing strenuous exercise. Collapse of the axial portion of the aryepiglottic folds causes obstruction of the laryngeal airway during inspiration. Treatment is symptomatic.

**Retropharyngeal Lymphadenopathy**

Lymphadenopathy of the retropharyngeal lymph nodes is usually associated with *S. equi* var. *equi* infection and is often a sequela to strangles (see “Strangles” in this chapter).15 Shedding of *S. equi* from clinically inapparent retropharyngeal lymph node abscesses is an important source of new infections in horse barns. Retropharyngeal lymphadenopathy is also caused by trauma to the pharynx, brachial cysts remnants,16 neoplasia (predominantly lymphosarcoma), and infection by *Actinomyces* spp.17 Enlargement of the retropharyngeal lymph nodes compresses the nasopharynx, increases resistance to airflow, and may impair swallowing (Fig. 12-25).

**Clinical Signs**

Clinical signs are swelling of the parotid region, although this may be slight even in horses with marked respiratory distress, pain on palpation of the parotid region, stertorous respiratory noise, respiratory distress, and dysphagia evident as food material discharging from the nostrils. Affected horses are frequently depressed, inappetent, and pyrexic.

**Endoscopic examination** of the upper airway will reveal ventral displacement of the dorsal wall to the pharynx and narrowing of the nasopharynx. There may be deviation of the larynx to the side away from the mass. Guttural pouch empyema often coexists with retropharyngeal lymph node infection, and the guttural pouches should be examined. Radiography will reveal the presence of a soft tissue density in the retropharyngeal region with compression of the guttural pouches and pharynx. Hematologic examination often demonstrates a mature neutrophilia and hyperfibrinogenemia.

**Treatment**

Treatment consists of administration of penicillin (procaine penicillin 20,000 IU/kg, intramuscularly every 12 hours) until signs of the disease resolve, followed by administration of a combination of sulfadiazine and trimethoprim (15–30 mg/kg orally every 12 hours for 7–14 days). Administration of anti-inflammatory drugs such as **phenylbutazone** (2.2 mg/kg intravenously or orally every 12 hours) is important in reducing inflammation and swelling and thereby allowing the horse to eat and drink. Horses that have severe respiratory distress may require a tracheotomy. Dysphagic horses might require fluid and nutritional support. Surgical drainage of the abscess is difficult and should be reserved for cases with large, cavitating lesions evident on radiographic or ultrasonographic examination.

Control consists of preventing infection of horses by *S. equi* var. *equi* and adequate treatment of horses with strangles.

**References**

**Recurrent laryngeal neuropathy (ROARERS)**

Neuropathy of the recurrent laryngeal nerve (usually the left one) causes paresis or paralysis of the cricoarytenoid muscle and failure of abduction of the arytenoid cartilages. This is apparent during exercise as obstruction of the upper airway and abnormal respiratory noise during heavy exercise. The idiopathic disease is referred to as recurrent laryngeal neuropathy, thereby describing the lesion, whereas other causes of laryngeal hemiplegia are referred to more specifically.

**ETIOLOGY**

The cause of laryngeal hemiplegia is degeneration of the recurrent laryngeal nerve with subsequent neurogenic atrophy of the cricoarytenoid dorsalis and other intrinsic muscles of the larynx. The etiology of **neuronal degeneration** is unknown, but the pathologic changes are typical of a distal axonopathy. There is evidence of a genetic component to recurrent laryngeal neuropathy, with a genome-wide association study in Thoroughbreds demonstrating a major quantitative trait locus near a known locus for body height and explaining 60% of the recurrent laryngeal neuropathy phenotype.1 This study follows on from two others that in total identified three significant loci (EC10, 21, and 31) in Warmblood horses.23 To date,
Endoscopic examination of the upper airway provides the definitive diagnosis in most cases. Examination of the larynx is performed with the horse at rest and the position and movement of the arytenoid cartilages assessed. Laryngeal function can also be observed during swallowing, brief (30–60 s) bilateral nasal occlusion, and during and after exercise. The severity of the disease is graded I through IV with five subgrades; there are therefore seven grades of abnormality:

- **Grade I** is normal, there being synchronous, full abduction and adduction of both arytenoid cartilages.
- **Grade II** presents as weakness of the adductors evident as asynchronous movement and fluttering of the arytenoid cartilage during inspiration and expiration but with full abduction during swallowing or nasal occlusion.
  - Subgrade 1: Transient asynchrony, flutter, or delayed movements.
  - Subgrade: Asymmetry of the rima glottidis as a result of reduced mobility of the affected arytenoid cartilage and vocal fold but with full symmetric abduction achieved and maintained after swallowing or nasal occlusion.
- **Grade III** has asynchronous movement of the arytenoid cartilage during inspiration or expiration; full abduction is not achieved during swallowing or nasal occlusion.
  - Subgrade 1: Asymmetry of the rima glottidis as a result of reduced mobility of the affected arytenoid cartilage and vocal fold but with full symmetric abduction achieved but not maintained after swallowing or nasal occlusion.
  - Subgrade 2: Obvious arytenoid abductor deficit and arytenoid asymmetry. Full abduction is never achieved.
  - Subgrade 3: Marked but not total arytenoid deficit and asymmetry with little arytenoid movement. Full abduction is never achieved.
- **Grade IV** implies marked asymmetry of the larynx at rest and no substantial movement of the arytenoid cartilage during respiration. Intraobserver agreement (two observers, 80 recordings) of the same recording of an endoscopic examination on standing draft horses was 76% when the recording was graded twice, and it is thus regarded as excellent. Two observers assigned the same grade and subtype for 63% of recordings differed by one grade for 32% of recordings and by two grades in 5% of recordings, which is assessed as good agreement. Repeatability of examination in the same horse was low when the same horse was examined twice, 24 to 48 hours apart. Forty-two percent of horses had the same grade assigned on both examinations, 42% differed by one grade, 17% received an improved grade (ie, less severe) and 26% a worse grade, and 13% of horses differed by two grades. One horse improved by four grades.

Endoscopic examination during strenuous exercise on a treadmill or over ground can be beneficial in determining the severity of the disease or detecting disease of lesser severity. Horses with early or mild degeneration of the recurrent laryngeal nerve and associated laryngeal musculature can have normal laryngeal function at rest. However, the loss of muscle function becomes apparent during exercise, when the laryngeal muscles of affected animals fatigue more rapidly than do those of normal animals, with the result that laryngeal dysfunction can become apparent during or immediately after exercise. Endoscopic examination during exercise is useful in differentiating the disease from axial deviation of the aryepiglottic folds.

Ultrasoundographic examination of the larynx and musculature is both sensitive (–90%) and specific (–98%) for detection of atrophy of the cricoarytenoid muscle or abnormal laryngeal function.

There are no characteristic changes in the hemogram or in serum biochemical variables in resting horses. During exercise there is a marked exacerbation of the normal exercise-induced hypoxemia and the development of hypercapnia in affected horses.

**Differential Diagnosis**

Differential diagnoses of exercise intolerance and exercise-induced respiratory noise include the following:

- Dorsal displacement of the soft palate
- Subepiglottic cysts
- Arytenoid chondritis
- Aryepiglottic fold entrapment
- Axial deviation of the aryepiglottic folds

**Treatment**

Treatment requires a prostatic laryngoplasty with or without ventriculectomy. An alternative to prostatic laryngoplasty is implantation of a nerve-pedicle graft into the
larynx. Effectiveness of the procedure is assessed by the return of the horse to its previous level of athletic activity. The disease is not life-threatening, and horses that are not required to work strenuously or in which respiratory noise associated with mild exercise is not bothersome to the rider may not require surgery. A complication of surgical repair that includes prosthetic laryngoplasty is that horses can no longer close the glottis and therefore do not have an effective cough. This could be the cause of tracheal inflammation and accumulation of debris in the trachea of these horses.

EQUINE PLEUROPNEUMONIA (PLEURITIS, PLEURISY)

ETIOLOGY

Pleuropneumonia of horses is almost always associated with bacterial infection of the lungs, pleura, and pleural fluid. The most common bacterial isolates from tracheal aspirates or pleural fluid of horses with pleuropneumonia are as follows:

- **Aerobes or facultative anaerobes.**
  - Including *S. equi* var. zoopneumoniae, *Pasteurella* spp., *Actinobacillus* spp., Enterobacteriaceae (particularly *E. coli*, *Klebsiella* spp., and *Enterobacter* spp.), *Pseudomonas* spp., *Staphylococcus* spp., and *Bordetella* spp. *S. zoopneumoniae* is isolated from over 60%, Enterobacteriaceae from approximately 40% of cases, and *Pasteurella/Actinobacillus* spp. from approximately one-third of cases. *Corynebacterium pseudotuberculosis* can cause septic pericarditis and pleuritis, although this is an uncommon disease. *Mycoplasma felis* is an unusual cause of pleuritis in horses. *R. equi* usually causes a unique pleuropneumonia in immunocompetent adult horses.

- **Obligate anaerobes,** including *Bacteroides* spp. (including *B. fragilis* and *B. tectum*), *Prevotella* spp., *Clostridium* spp., *Eubacterium*, *Prevotella* spp., *Peptostreptococcus* spp., *Fusobacterium* spp., and *Bacteroides* spp. are isolated from approximately 20%, *Clostridium* sp. from 10%, and *Eubacterium* sp. from 6% of horses with pleuropneumonia. Obligate anaerobes are cultured from approximately 70% of horses with severe pneumonia.

SYNOPSIS

Etiology Most infections are polymicrobial combinations of *S. equi* var. *zoopneumoniae*, *Actinobacillus* spp., *Pasteurella* spp., Enterobacteriaceae, and anaerobic bacteria, including *Bacillus fragilis*. Disease attributable to infection by a single bacterial species occurs. Other causes are *Mycoplasma felis*, penetrating chest wounds and esophageal perforation.

Epidemiology Recent prolonged transport, racing, viral respiratory disease and anesthesia increase the likelihood of a horse developing pleuropneumonia. Aspiration of feed material secondary to esophageal obstruction or dysphagia also causes the disease.

Pathogenesis Overwhelming challenge of oropharyngeal bacteria or reduced pulmonary defense mechanisms allow proliferation of bacteria in small airways, alveoli, and lung parenchyma. Subsequent inflammation and further spread of infection involve the visceral pleura. Impaired drainage of pleural fluid and increased permeability of pleural capillaries cause the accumulation of excessive pleural fluid, which then becomes infected. Fibrin deposition and necrosis of lung causes formation of intrathoracic abscesses. Death is attributable to sepsis and respiratory failure.

Clinical signs Fever, depression, anorexia, respiratory distress, cough, nasal discharge, exercise intolerance, reduced breath sounds on thoracic auscultation, and presence of pleural fluid and pneumonia on thoracic radiology and ultrasonography. Chronic disease is characterized by weight loss, increased respiratory rate, nasal discharge, and exercise intolerance.

Diagnosis confirmation Clinical signs, examination of pleural fluid.

Treatment Systemic administration of broad-spectrum antimicrobials for weeks to months, chronic effective drainage of the pleural space, infusion of recombinant tissue plasminogen activator (tenecteplase) into pleural space, and nursing care.

Prevention Reduce exposure of horses to risk factors including prolonged transportation and viral respiratory disease.

Equine pleuropneumonia is associated with polymicrobial infections of the lungs and pleura in 50% to 80% of cases, although disease associated with infection with a single bacterial species occurs. Infections with a single bacterial species are usually by *S. zoopneumoniae*, *Pasteurella/Actinobacillus* sp. or one of the Enterobacteriaceae, whereas almost all infections by anaerobes are polymicrobial. Infection by obligate anaerobic bacteria is associated with disease of more than 5 to 7 days’ duration.

Pleuritis is also caused by penetrating chest wounds, perforated esophagus, and tracheobronchial foreign bodies. *Cryptococcus* spp can cause the disease in horses and other species. Other diseases, such as congestive heart failure or neoplasia, can cause pleural effusion without inflammation.

EPIDEMIOLOGY

Pleuropneumonia occurs worldwide in horses of all ages and both sexes, although most cases occur in horses more than 1 and less than 5 years of age. Estimates of the incidence or prevalence of the disease are not available. The case-fatality rate varies between 5% and 65%, with the higher rate reported in earlier studies.

Risk Factors

The risk of a horse developing pleuropneumonia is increased factorially in the following cases:

- By a factor of 4 if the horse is a Thoroughbred racehorse
- By a factor of 14 if the horse was transported more than 500 miles in the previous week
- By a factor of 10 if the horse has a recent (< 2 week) history of viral respiratory tract disease or exposure to a horse with such disease
- By a factor of 4 if the horse has raced within the previous 48 hours

Other suggested risk factors include general anesthesia, surgery, disorders of the upper airway, exercise-induced pulmonary hemorrhage, esophageal obstruction, and dysphagia.

PATHOGENESIS

Bacterial pleuropneumonia develops following bacterial colonization of the lungs with subsequent extension of infection to the visceral pleura and pleural space. Organisms initially colonizing the pulmonary
parenchyma and pleural space are those normally present in the upper airway, oral cavity, and pharynx, with subsequent infection by Enterobacteriaceae and obligate anaerobic bacteria.

Bacterial colonization and infection of the lower airway is attributable to either massive challenge or a reduction in the efficacy of normal pulmonary defense mechanisms or a combination of these factors. Confinement with the head elevated for 12 to 24 hours, such as occurs during transport of horses, decreases mucociliary transport and increases the number of bacteria and inflammatory cells in the lower respiratory tract and probably contributes to the development of lower respiratory tract disease. Transport alters the composition of pulmonary surfactant, which can impair the activity of pulmonary defense mechanisms, allowing otherwise innocuous bacterial contamination to cause disease.

Overwhelming bacterial challenge can occur in dysphagic horses, horses with esophageal obstruction, and racehorses that inhale large quantities of track debris while racing. A single bout of exercise on a treadmill markedly increases bacterial contamination of the lower airways. Viral respiratory disease can decrease the efficacy of normal lung defense mechanisms.

Bacterial multiplication in pulmonary parenchyma is associated with the influx of inflammatory cells, principally neutrophils, tissue destruction, and accumulation of cell debris in alveoli and airways. Infection spreads both through tissue and via airways. Extension of inflammation, and later infection, to the visceral pleura and subsequently pleural space causes accumulation of excess fluid within the pleural space. Pleural fluid accumulates because of a combination of excessive production of fluid by damaged pleural capillaries (exudation) and impaired reabsorption of pleural fluid by thoracic lymphatics.

Accumulation of parapneumonic pleural effusions has been arbitrarily divided into three stages: exudative, fibrinopurulent, and organizational:

1. The exudative stage is characterized by the accumulation of sterile, protein-rich fluid in the pleural space as a result of increased pleural capillary permeability.
2. Bacterial invasion and proliferation, further accumulation of fluid, and deposition of fibrin in pleural fluid and on pleural surfaces occur if the disease does not resolve rapidly and is referred to as the fibrinopurulent stage.
3. The organizational stage is associated with continued fibrin deposition, restriction of lung expansion, and persistence of bacteria. The pleural fluid contains much cellular debris and bronchopleural fistulas may develop.

These categorizations are useful diagnostically and therapeutically.

**CLINICAL SIGNS OF ACUTE DISEASE**

The acute disease is characterized by the sudden onset of a combination of fever, depression, inappetence, cough, exercise intolerance, respiratory distress, and nasal discharge. The respiratory rate is usually elevated, as is the heart rate.

**Nasal discharge** ranges from serosanguineous to mucopurulent, is usually present in both nares and is exacerbated when the horse lowers its head. The **breath may be malodorous**, although this is a more common finding in horses with subacute to chronic disease. Horses with pleuritis are often reluctant to cough, and if they do, the cough is usually soft and gentle. Ventral edema occurs in approximately 50% of horses with pleuropneumonia.

The horse may appear **reistant to move** or may exhibit signs of chest pain, including reluctance to move, pawing, and anxious expression, which may be mistaken for colic, laminitis, or rhabdomyolysis. Affected horses often stand with the elbows abducted.

**Auscultation** of the thorax reveals attenuation of normal breath sounds in the ventral thorax in horses with significant accumulation of pleural fluid. However, the attenuation of normal breath sounds may be mild and difficult to detect, especially in large or fat horses or in horses in which there is only slight accumulation of pleural fluid. Auscultation of the thorax with the horse’s respiratory rate and tidal volume increased by exercise and an indication of infection with anaerobic bacteria and a poor prognosis, strands of fibrin, or echogenic material consistent with cellular debris. Sterile pleural effusion, such as may be present during the earliest stages of the disease, is clear and homogeneous without fibrin strands. With increasing chronicity the amount of fibrin increases, the parietal and visceral pleura become thickened, and the pleural fluid becomes echogenic consistent with the presence of cellular debris.

- **Regions of consolidated or atelectatic lung** adjacent to the visceral pleura may be evident on ultrasonographic examination, but lung consolidation deeper in the lung is not evident.
- Accumulation of fibrin is associated with a worse prognosis than is accumulation of parapneumonic fluid that does not include fibrin deposits.
- Ultrasonography is more sensitive than radiographic examination in detection of small quantities of pleural fluid.

Radiographic examination of horses with excessive pleural fluid reveals ventral opacity that obscures the ventral diaphragmatic and cardiac silhouettes. Radiographic examination might not reveal the presence of small amounts of excessive pleural fluid. It is not possible on radiographic examination to differentiate accumulation of pleural fluid from consolidation of the ventral lung lobes. Radiographic examination may be useful in demonstrating lesions, such as pulmonary abscesses or consolidation, that are not confluent with the visceral pleura and therefore not able to be detected by ultrasonographic examination.

**Collection of pleural fluid by thoracentesis** of both hemithoraces and of a
**Clinical Signs in Chronic Disease**

The chronic disease is characterized by intermittent fever, weight loss, cough, increased respiratory rate, nasal discharge, malodorous breath, exercise intolerance, and depression. Severely affected horses may display signs of respiratory distress. Signs of thoracic pain are less than in the acute disease.

**Findings on auscultation** of the chest are similar to those of the acute disease, inasmuch as there is attenuation of normal breath sounds ventrally and the presence of crackles and wheezes dorsally. There is frequently ventral edema of the thorax.

**Ultrasonographic examination** reveals the presence of excessive pleural fluid that is very echogenic, consistent with it containing cellular debris, and contains large amounts of fibrin. The visceral and parietal pleura are thickened, and there may be evidence of lung atelectasis, consolidation, or abscessation. Septation of the pleural space by fibrin and fibrous tissue results in localized accumulation of purulent pleural fluid. Air in the pleural space may indicate the presence of one or more bronchopleural fistulae.

**Radiographic examination** reveals a combination of ventral opacity, pulmonary consolidation, pneumothorax, and abscessation.

**Complications**

Complications of pleuritis include the following:  
- Development of jugular thrombophlebitis (~25% of cases)  
- Pulmonary, mediastinal, or pleural abscesses (~10%–20% of cases)  
- Cranial thoracic mass (5%–10% of cases)  
- Bronchopleural fistula (5%)  
- Pericarditis (2%)  
- Laminitis (1%–14%)  
- Appropriate secondary erythrocytosis

**Development of intrathoracic abscesses** is evident as chronic disease, weight loss, cough, and fever, readily detected by a combination of ultrasonographic and radiographic examination.

**Cranial thoracic masses** are evident as an elevation in heart rate, prominent jugular pulse, spontaneous jugular thrombosis, and forelimb pointing. The signs are referable to a mass in the cranial thorax displacing the heart caudally and to the left and impairing venous return to the heart in the cranial vena cava. Ultrasonographic and radiographic examination reveals the presence of the mass.

**Bronchopleural fistulae** develop when a section of pulmonary parenchyma sloughs, leaving an open bronchiole that communicates with the pleural space. Mild pneumothorax develops. The bronchopleural fistula can be diagnosed by infusion of fluorescein dye into the pleural space and detecting its presence at the nares or by pleuroscopic examination.

**Prognosis**

The prognosis for life for horses able to be treated aggressively is very good (60%-95%), and the prognosis for return to previous function if the horse survives is reasonable (60%). The prognosis for return to previous function for horses that develop chronic disease and complications is poor (31%). Prognosis for horses with fibrinous pleural effusion is worse than for horses with pleural effusions that do not include ultrasonographically identifiable accumulations of fibrin (100% of 11 cases vs. 62% of 63 cases, respectively).

**Clinical Pathology**

Acute pleuritis is characterized by leukocytosis with a mature neutrophilia, mild to moderate anemia, hyperfibrinogenemia, and hypoalbuminemia. There are similar findings in horses with chronic disease, and hyperglobulinemia is also evident as chronic disease, weight loss, and laminitis. Development of intrathoracic abscesses is evident and severe in chronic disease, weight loss, cough, and fever, readily detected by a combination of ultrasonographic and radiographic examination. The pneumonia involves all areas of the lungs but is most severe in the cranial and ventral regions. The pleura are thickened and have adherent fibrin tags, and there is excessive pleural fluid. The pleural fluid contains strands of fibrin and is usually cloudy and serosanguineous to yellow. Histologically, there is a purulent, fibrinonecrotic pneumonia and pleuritis.

**TREATMENT**

Given early recognition of the disease and prompt institution of appropriate therapy, the prognosis for horses with pleuritis is favorable. However, the long course of the disease and the associated expense often limit therapeutic options and make the outcome a decision based on economic rather than medical grounds.

The **principles of treatment** are prompt broad-spectrum antimicrobial therapy; removal of infected pleural fluid and cellular debris, including necrotic lung; relief of pain; correction of fluid and electrolyte abnormalities; relief of respiratory distress; treatment of complications; and prevention of laminitis.

**Antimicrobial Treatment**

The prompt institution of **systemic, broad-spectrum antimicrobial therapy** is the single most important component of...
treatment of horses with pleuropneumonia. Antimicrobial therapy is almost always started before the results of bacterial culture of pleural fluid or tracheal aspirate are received and the antimicrobial sensitivity of isolated bacteria are determined. Use of antibiotics or combinations of antibiotics with a broad spectrum of antimicrobial activity is important because of the polymicrobial nature of most infections and because the wide range of gram-positive and gram-negative bacteria that may be associated with the disease makes prediction of the susceptibility of the causative organisms difficult. Furthermore, superinfection with bacteria, especially Enterobacteriaceae and obligate anaerobes, commonly occurs in horses with disease initially associated with a single bacterial species. Administration of drugs that are effective in the treatment of penicillin-resistant obligate anaerobes is also important.

**Recommended doses for antimicrobials** used in the treatment of pleuropneumonia are provided in Table 12-11. Antimicrobial therapy should be broad spectrum to include coverage of the likely bacteria involved in the disease. It should therefore provide coverage against *Streptococcus* spp., *Actinobacillus Pasteurella* spp., Enterobacteriaceae, and anaerobes, including *Bacteroides* spp. A combination of *penicillin G*, an *aminoglycoside*, and *metronidazole* provides broad-spectrum coverage and is a frequently used empirical therapy until the results of bacterial culture are known. Results of bacterial culture and subsequent antimicrobial susceptibility testing may aid selection of further antimicrobials. However, superinfection with gram-negative and anaerobic bacteria is common, and there is a sound rationale for continued use of a combination of antimicrobials providing broad-spectrum coverage throughout treatment of the disease.

**Antimicrobial therapy will be prolonged** in most cases, usually being required for at least 1 month and often several months. As the disease resolves it may be possible to change from parenteral antibiotics to orally administered antibiotics such as a combination of trimethoprim–sulfonamide, although the clinical response to this combination is sometimes disappointing, or doxycycline or enrofloxacin.

### Table 12-11 Antimicrobial agents and recommended doses for treatment of pleuropneumonia in horses

<table>
<thead>
<tr>
<th>Drug</th>
<th>Dose, route, and interval</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Procaine penicillin G</td>
<td>22,000–44,000 IU/kg IM q12h</td>
<td>Effective against <em>Streptococcus</em> sp. and most anaerobes, with the exception of <em>Bacteroides fragilis</em>. Achieves low plasma concentrations but has prolonged duration of action. Cheap. Synergistic with aminoglycosides. Should not be used as sole treatment.</td>
</tr>
<tr>
<td>Sodium or potassium penicillin G</td>
<td>22,000–44,000 IU/kg IV q6h</td>
<td>Effective against gram-positive organisms (except penicillinase-producing bacteria such as <em>Staphylococcus</em> spp.) and most anaerobes. Achieves high plasma concentrations. Synergistic with aminoglycosides. Expensive.</td>
</tr>
<tr>
<td>Ampicillin sodium</td>
<td>11–22 mg/kg IV or IM q6h</td>
<td>Wider spectrum than penicillin G. Achieves high plasma concentrations.</td>
</tr>
<tr>
<td>Ampicillin trihydrate</td>
<td>20 mg/kg IM q12–24h</td>
<td>Synergistic with aminoglycosides. Low blood concentrations. Muscle soreness. Not recommended.</td>
</tr>
<tr>
<td>Ceftriaxone sodium</td>
<td>2.2–4.4 mg/kg IM or IV q12h</td>
<td>Wide spectrum of action against gram-positive and gram-negative organisms and most anaerobes. Can be used as sole treatment, though not recommended. Clinical results sometimes disappointing</td>
</tr>
<tr>
<td>Cefotaxime</td>
<td>40 mg/kg IV q6h</td>
<td>Wide spectrum of action against gram-positive and gram-negative organisms and most anaerobes. Can be used as sole treatment, though not recommended.</td>
</tr>
<tr>
<td>Cefepime</td>
<td>2.2 mg/kg IV or IM q8h</td>
<td>Wide spectrum of action against gram-positive and gram-negative organisms and most anaerobes. Can be used as sole treatment, although not recommended.</td>
</tr>
<tr>
<td>Chloramphenicol</td>
<td>50 mg/kg, PO q6h</td>
<td>Good spectrum of action, including anaerobic bacteria. Poor oral bioavailability and disappointing clinical efficacy. Use prohibited in some countries. Potential human health hazard. Risk of diarrhea</td>
</tr>
<tr>
<td>Gentamicin sulfate</td>
<td>7 mg/kg, IV or IM q24h</td>
<td>Active against <em>Staphylococcus</em> spp. and many gram-negative organisms. Inactive against anaerobes. Poor activity against <em>Streptococcus</em> spp. Synergistic with penicillin</td>
</tr>
<tr>
<td>Enrofloxacin</td>
<td>7 mg/kg IV or PO q24h</td>
<td>Active against some gram-positive and gram-negative bacteria. Not good or reliable activity against streptococci. Contraindicated in young animals because of risk of cartilage damage.</td>
</tr>
<tr>
<td>Amikacin sulfate</td>
<td>10 mg/kg IV or IM q24h</td>
<td>Wider spectrum of gram-negative activity than gentamicin. Expensive</td>
</tr>
<tr>
<td>Trimethoprim–sulfonamides</td>
<td>15–30 mg/kg PO q12h</td>
<td>Theoretical wide spectrum of action. Disappointing clinical efficacy.</td>
</tr>
<tr>
<td>Rifampin</td>
<td>5–10 mg/kg PO q12h</td>
<td>Penetrates abscesses well. Active against gram-positive and some gram-negative bacteria. Must be used in conjunction with another antibiotic (not an aminoglycoside).</td>
</tr>
<tr>
<td>Doxycycline</td>
<td>10 mg/kg PO q12h</td>
<td>Broad spectrum of activity, but resistance unpredictable. Only moderate blood concentrations. Suitable for prolonged therapy but not treatment of the acute disease.</td>
</tr>
<tr>
<td>Ticarcillin–clavulanic acid</td>
<td>50 mg/kg IV q6h</td>
<td>Broader spectrum of gram-negative activity than penicillin G. Expensive.</td>
</tr>
<tr>
<td>Metronidazole</td>
<td>15–25 mg/kg PO q6–8h</td>
<td>Active against anaerobes only. Used in conjunction with other antimicrobials (especially penicillin and aminoglycosides). Neurotoxicity rare.</td>
</tr>
</tbody>
</table>

IM, intramuscularly; IV, intravenously; PO, orally; q, dose administered every “h” hours.
The decision to discontinue antimicrobial therapy should be based on lack of fever, nasal discharge, and respiratory distress or cough; lack of evidence of intrathoracic abscesses on ultrasonographic and radiographic examination of the thorax; and resolution of neutrophilia and hyperfibrinogenemia. There should be no appreciable pleural fluid on ultrasonographic examination.

**Thoracic Drainage**

Chronic, effective drainage of the pleural cavity and intrathoracic abscesses is critical for successful treatment of horses with pleuropneumonia. Horses with sterile pleural fluid may require only a single drainage of pleural fluid. More severely affected horses may require intermittent drainage on each of several days, and most cases will require insertion of a tube into the pleural space to provide continuous drainage for several days to several weeks. Horses with chronic disease may benefit from a thoracotomy that provides continuous drainage and the ability to lavage the chest. Ultrasonographic examination of the chest is very useful in identifying the presence of pleural fluid, the optimal sites for drainage, and the efficacy of drainage.

**Intermittent thoracic drainage** can be achieved by inserting a bovine teat cannula or similar blunt cannula into the pleural space. This should be done aseptically and under local anesthesia. If ultrasonographic examination is not available, the cannula should be placed in the sixth to eighth intercostal space on the right side or the seventh to ninth on the left side just above the level of the olecranon. Pleural fluid that does not contain large fibrin clots (which clog the cannula) can be drained and the cannula removed. However, the process is slow if large quantities of fluid must be removed. Intermittent drainage is indicated when the quantities of pleural fluid are small (< 5 L), relatively cell-free, or localized. This situation is most likely to occur in horses with acute disease.

**Insertion of large plastic chest tubes** (20–30 French, 6- to 10-mm outside diameter) facilitates rapid fluid removal, allows drainage of viscid fluid, and provides continuous drainage. The chest tube should be inserted in an aseptic fashion under local anesthesia at sites indicated by ultrasonographic examination or as described previously. A one-way valve should be attached to the external end of the tube to prevent aspiration of air and development of a pneumothorax. A balloon or condom with the end removed is an effective one-way valve. The chest tube is secured to the chest wall with a purse-string suture. The tube may be retained for several days to a week, but it should be monitored frequently (every few hours) and cleared of fibrin clots as needed.

**Complications of drainage** of pleural fluid include collapse of the animal if the fluid is removed too rapidly, pneumothorax, sudden death as a result of cardiac puncture or laceration of a coronary vessel, and perforation of abdominal viscera. Collapse can be prevented by administering fluids intravenously during pleural fluid drainage and by removing the fluid gradually (over a period of 30 minutes). Some horses develop celluli- tis around the chest tube, which requires that the tube be removed.

**Thoracotomy** may be required in recurrent or chronic cases to provide drainage of intrathoracic abscesses or chronic pleural effusion that is refractory to treatment with antimicrobials. Thoracotomy is an effective intervention in many horses, with 14 of 16 horses treated by thoracotomy surviving and 6 returning to athletic activity. Thoracotomy should not be considered an emergency or heroic procedure in such cases.

**Pleural Lavage**

Infusion and subsequent removal of 5 to 10 L of warm saline or balance polyionic electrolyte solution into the affected pleural space may be beneficial in the treatment of cases with viscid fluid or fluid containing large amounts of fibrin and cell debris. The fluid can be infused through the chest tube that is used to drain the pleural space. Care should be taken not to introduce bacteria with the infusion.

**Fibrinolytic Therapy**

Tissue plasminogen activators have been administered to horses in an attempt to increase activity of plasmin and hence the rate of lysis of fibrin in the pleural cavity. Earlier attempts at fibrinolytic therapy used streptokinase or urokinase and were not beneficial. Use of modified compounds, such as alteplase and tenecteplase, is effective in hastening fibrinolysis, enhancing resolution of accumulated pleural fluid, and improving survival. There does not appear to be an increased risk of prolonged hemostasis. The procedure in one case involved intrapleural infusion of 12 mg of tenecteplase in 500 mL of isotonic saline after drainage of excessive pleural fluid. The treatment was repeated on three occasions over 10 days. Pharmacokinetics of alteplase in horses are described.

A recommended protocol is infusion of tenecteplase (2–10 mg in 1–2 L of isotonic polyionic fluid) q12 to 24h for 3 days, with a dwell time of 4 hours.

**Supportive Therapy**

Acutely or severely ill horses may be dehydrated and azotemic, and they may have acid-base disturbance. These horses should be treated with appropriate fluids administered intravenously.

Pleuropneumonia is a painful disease, and every attempt should be made to relieve the horse’s chest pain. NSAIDS, including flunixin meglumine (1 mg/kg, orally, intramuscularly, or intravenously, every 8 hours) or phenylbutazone (2.2 mg/kg, orally or intravenously, every 12 hours), often provide effective analgesia and presumably reduce inflammation in the pleural space.

Horses should be provided with good nursing care, including a comfortable stall, free access to palatable water, and a good diet. Affected horses will often not eat adequately and should be tempted with fresh and nutritious fodder.

Attention should be paid to the horse’s feet to detect early signs of laminitis and allow appropriate measures to be taken.

**CONTROL**

Prevention of pleuropneumonia involves reduction of risk factors associated with the disease. The main risk factors are other infectious respiratory diseases and transportation. Every effort should be made to prevent and treat respiratory disease in athletic horses, including institution of effective vaccination programs. Horses with infectious respiratory disease should not be vigorously exercised until signs of disease have resolved.

Transportation of athletic horses is common and essential for their participation in competitive events. It cannot, therefore, be eliminated. Every effort should be made to minimize the adverse effects of transportation on airway health. Recommendations for transport of horses first made in 1917 are still relevant. Updated, these recommendations include the following:

- Not transporting a horse unless it is healthy. Horses with fever should not be transported.
- Knowledgeable staff familiar with the horse should accompany it.
- Suitable periods of rest and acclimation should be provided before recently transported or raced horses are transported.
- The time during which horses are confined for transportation should be kept to a minimum. Horses should be loaded last and unloaded first in flights with mixed cargo.
- The route taken should be the most direct and briefest available.
- Horses should be permitted adequate time to rest at scheduled breaks. If possible, on long journeys horses should be unloaded and allowed exercise (walking) and access to hay and water.
- Horses should have frequent, preferably continuous, access to feed and water during transportation.
- Horses should not be exercised after arrival until they are free of fever, cough, or nasal discharge.
- Horses should not be restrained during transportation such that they are unable or unwilling to lower their heads.
• Air quality should be optimal in the vehicle used to transport the horse.

ACUTE BRONCHO-INTERSTITIAL PNEUMONIA IN FOALS

Acute broncho-interstitial pneumonia is a disease of foals less than 7 months of age, and usually less than 2 months of age, characterized by a rapid onset of respiratory distress. The condition is clinically similar to acute lung injury identified in other species. The etiology is unclear in many cases, but causes or agents associated with the disease include equine influenza virus infection, R. equi, equine herpesvirus-2, equine arteritis virus, or Pneumocystis carinii. The disease is likely a result of severe pulmonary injury by any of a number of infectious or toxic agents. The respiratory distress results from loss of pulmonary function because of necrosis of the epithelium of alveoli and terminal bronchioles.

Affected foals typically present with an acute onset (<4 days) of respiratory distress, pyrexia, and tachycardia. Foals are depressed and reluctant to eat. There is a pronounced respiratory effort with a marked abdominal component in most affected foals. Crackles, wheezes, and increased bronchial breath sounds are auscultable in most foals. Radiographic examination reveals a broncho-interstitial pattern that is always diffuse, although in some foals there is also a focal interstitial pattern. The prognosis is guarded, with approximately 50% of affected foals dying of the disease.

There is a neutrophilic leukocytosis and hyperfibrinogenemia in most cases. Arterial hypoxemia is present in severely affected foals. Tracheal aspirate demonstrates neutrophilic inflammation. Culture of the tracheal aspirate yields Rhodococcus equi, S. zooepidemicus, and Actinobacillus sp., in addition to other organisms that are of questionable significance. Serology might demonstrate evidence of infection by equine influenza virus or equine herpesvirus-2. Viral isolation can identify equine influenza virus.

NECROPSY FINDINGS

Necropsy examination reveals the presence of diffusely reddened, wet, and firm lungs that fail to collapse. The predominant histologic lesion is necrosis of the epithelium of terminal bronchioles and alveoli.

TREATMENT

Principles of treatment are correction of hypoxemia, reduction of inflammation, and removal of inciting causes. Severely affected foals might require nasal insufflation of oxygen to ameliorate or correct hypoxemia. Administration of corticosteroids has been associated with improved survival. Broad-spectrum antibiotics are administered to treat concurrent bacterial infections and prevent secondary infection.

CONTROL

There are no specific control measures, but reduction of exposure of foals to infectious respiratory disease would be prudent.

REFERENCES

CHRONIC INTERSTITIAL PNEUMONIA IN FOALS

Chronic interstitial pneumonia is a sporadic disease of foals less than 10 months of age characterized by respiratory distress of several weeks’ duration. The etiology is unknown, but the disease likely represents a common final response to injury caused by any one of a number of infectious or toxic agents (see “Intestinal Pneumonia of Horses” and “Acute Broncho-interstitial Pneumonia of Foals”).

Affected foals are bright and alert and have markedly increased respiratory effort. The respiratory rate is elevated, and there is a prominent abdominal component to respiratory effort. Fever is low grade and intermittent. Thoracic auscultation reveals increased intensity of normal breath sounds and the presence of wheezes and crackles in most affected foals. Ultrasonographic examination of the thorax reveals extensive “comet tail” signs in most cases. Radiography demonstrates the presence of moderate to severe interstitial pneumonia that in some cases can include focal opacities suggestive of alveolar disease. The prognosis with appropriate treatment is excellent.

Affected foals have neutrophilic leukocytosis and hyperfibrinogenemia. Serologic examination for antibodies to common respiratory viruses is unrewarding. Culture of tracheal aspirates does not consistently yield growth of known pathogens, although Nocicellata senolina is associated with similar clinical signs and presentation. Lung biopsy is not warranted because the characteristic changes on radiographic examination, combined with the clinical signs, are diagnostic for the disease. The risk of adverse events associated with lung biopsy outweighs any diagnostic utility given the good prognosis for complete recovery from the disease.

TREATMENT

Treatment consists of administration of corticosteroids such as dexamethasone phosphate at an initial dosage of 0.1 to 0.25 mg/kg intravenously every 24 hours for 3 to 5 days followed by a declining dose administered orally over 2 to 3 weeks. Prednisolone can be substituted for dexamethasone. Broad-spectrum antibiotics (combination of penicillin and aminoglycoside, trimethoprim-sulfonamide, or doxycycline) should be administered for 1 to 2 weeks.

There are no recognized control measures, although control of infectious respiratory disease in the herd is prudent.

INTERSTITIAL PNEUMONIA IN ADULT HORSES

Interstitial pneumonia can be associated with other systemic disease, such as infection by influenza virus, equine infectious anemia virus, or intoxication by various plants or minerals (silica), or it can be a primary disease. Equine multinodular pulmonary fibrosis (EMPF) was previously included in this topic but is now discussed separately later in this section on diseases of the equine respiratory tract.

ETIOLOGY

Interstitial pneumonia is a common finding in horses associated with various infectious agents (Hendra virus, equine influenza virus, equine infectious anemia virus), and Rhodococcus equi, Aspergillus sp., Cryptococcus sp. and Histoplasma sp., Pneumocystis carinii, Parascaris equorum, and Dictyocaulus arnfieldi). Intoxication with perilla ketone, derived from Perilla frutescens, causes acute restrictive lung disease of horses. Similarly, ingestion of Euquotarium sp. in Australia and Hawaii causes interstitial pneumonia in horses. Ingestion of Crotalaria spp. causes interstitial pneumonia in donkeys. Inhalation or ingestion of agricultural chemicals or environmental toxins (e.g., paraquat) has the potential to cause interstitial pneumonia in other species, but this has not been demonstrated in horses. Silicosis causes interstitial pneumonia in horses in California. Lipid pneumonia has an interstitial component.

Chronic pleuropulmonary fibrosis and elastosis occurs in aged donkeys in the United Kingdom. The disease was present in 32% of over 1100 postmortem examinations of donkeys. The etiology of the disease is unknown.

Hypersensitivity reactions may cause severe respiratory disease in horses. Incriminating allergens include fungi (unspecified)
and chicken dust. Interstitial pneumonia has also been reported subsequent to administration of an immunostimulant containing mycobacterial cell-wall extract.

Chronic eosinophilic pneumonia of adult horses is idiopathic.10

**EPIDEMIOLOGY**

The disease occurs in adult horses, without apparent breed, sex, or age predisposition. In cases in which the cause is infectious, the epidemiology of the disease is characteristic of that of the causal organism.

**PATHOGENESIS**

The initial insult causes injury to parenchymal cells and an acute alveolitis. Alveolitis results from damage to epithelial and endothelial cells by toxic, metabolic (free radicals), or infectious agents. This is followed by a phase of cellular proliferation of type 2 pneumocytes and fibroblasts with connective tissue deposition. At this time there is an influx of inflammatory cells, the exact type depending to some extent on the cause of the disease. Infiltration of neutrophils, lymphocytes, and macrophages is common. Continued injury to the lung results in development of severe interstitial fibrosis and destruction of gas exchange units.

Interstitial pneumonia results in altered pulmonary function including reduced compliance, impaired pulmonary gas exchange, and a reduction in total and vital lung capacity. The work of breathing is increased.

**CLINICAL SIGNS**

Horses with interstitial pneumonia have various combinations of: weight loss, recurrent cough, depression, anorexia, fever, or respiratory distress. Signs of respiratory distress are variable between cases and depend on the severity of the disease. The usual history of is a gradual onset of increased respiratory effort. Heart and respiratory rates are usually elevated. Pyrexia is not a constant finding. There may be a nasal discharge. Thoracic auscultation may reveal only increased intensity of normal breath sounds or the presence of occasional crackles and wheezes.

Thoracic radiography reveals pulmonary disease, usually apparent as severe, diffuse interstitial disease. Ultrasonographic examination may reveal the presence of multiple “comet tail” signs in the lung parenchyma confluent with the pleural surface. There is no excess pleural fluid.

Intradermal skin testing may be useful to identify the inciting allergen in cases of allergic interstitial pneumonia.

**CLINICAL PATHOLOGY**

Hematologic and serum biochemical abnormalities vary with the inciting cause of the disease. Bronchoalveolar lavage, which is preferred over collection of tracheal aspirates, demonstrates changes consistent with the underlying disease, which is usually inflammatory.

**NECROPSY FINDINGS**

The lungs do not deflate as anticipated, and there may be indentations from the ribs on the surface of the lungs. The histologic changes depend on the etiology of the disease.

**TREATMENT**

Treatment should be directed toward any cause of the disease that is identified, such as administration of anthelmintics to horses with parasitic disease. Bronchodilating drugs, such as clenbuterol, can be considered, but bronchoconstriction is not a prominent component of the disease.

**CONTROL**

Prevention of exposure to potential infectious, toxic, or environmental causes is prudent.

**FURTHER READING**

**REFERENCES**

**ETIOLOGY**

Exercise-induced pulmonary hemorrhage of horses (EIPH) is a disease that occurs in horses during strenuous exercise.1 There is evidence of a genetic component to epistaxis in Thoroughbred racehorses (F2 = 0.27–0.55), but there are no reports of heritability or genetic factors contributing to EIPH.

**EPIDEMIOLOGY**

EIPH is primarily a disease of horses, although it occurs in racing camels and Greyhounds.2 EIPH occurs in horses worldwide, and there does not appear to be any geographic distribution. It is a disorder of horses that run at high speed, such as Thoroughbred or Standardbred racehorses. The disorder is uncommon in endurance horses and is rare in draft breeds, although it does occur in horses used for these activities.2 There is increasing recognition of its importance in sport horses (3-day event, show jumping, but not in dressage).3 The prevalence of EIPH varies with the method used to detect it and the frequency with which horses are examined, as discussed later in this section. Epistaxis associated with exercise is almost always attributable to pulmonary hemorrhage and occurs only in a small proportion of racehorses. Epistaxis occurs in only 3% of horses that have blood detected in the trachea by endoscopic examination performed within 2 hours of racing. The prevalence of epistaxis...
in racehorses varies between 0.1% and 9.0%, with the frequency depending on the breed, age and sex of horses selected for study, the type of racing, and the training and frequency of observation of horses after racing. Epistaxis is more common in older horses. There are conflicting reports of a sex predisposition, although epistaxis may be more common in female Thoroughbreds. Epistaxis is more common after races of less than 1600 m than in longer races, although not all sources agree on this point. However, horses in steeplechase races, which are typically longer than 2000 m, are at greater risk of epistaxis than are horses in flat races. Incidence of epistaxis in steeplechase horses in the United Kingdom is 5.3 per 1000 starts and 3.6 per 1000 starts in hurdle racing. Risk factors for horses in jumps races (steeplechase) include previous epistaxis (odds ratio [OR] 6.1 [4.4–8.3]), racing in a claiming race (OR 5.9 [1.4–25]), greater than 9 starts in previous 4 to 6 months (OR 10 [2–47]), and racing on firmer ground. Epistaxis is relatively uncommon, and most horses with EIPH do not have epistaxis.

There are a variety of other methods of detecting EIPH, including endoscopic examination of the airways and microscopic examination of tracheal aspirates or bronchoalveolar lavage fluid. Almost all Thoroughbred racehorses in active training have hemosiderophages in bronchoalveolar lavage fluid, indicating that all have some degree of EIPH. The prevalence of EIPH decreases when diagnosis is based on endoscopic examination of horses after exercise or racing.

EIPH is very common in Thoroughbred racehorses, with estimates of prevalence, based on a single endoscopic examination of the trachea and bronchi, of 43% to 75%. The prevalence increases with the frequency of examination, with over 80% of horses having evidence of EIPH on at least one occasion after examination after each of three consecutive races. There can be considerable variability in severity of EIPH within an individual horse on repeated examination over a racing season. The prevalence of EIPH in Standardbred racehorses is assumed to be lower, with 26% to 34% of horses reported to have blood in the trachea after racing. However, these studies were based on a single examination and one only reported as positive those horses with blood covering more than one half the tracheobronchial tree. When examined after each of three races, 87% of Standardbred racehorses have evidence of EIPH on at least one occasion, suggesting that EIPH is as common in Standardbred racehorses as it is in Thoroughbred racehorses. Exercise-induced pulmonary hemorrhage occurs in approximately 62% of racing Quarter Horses and has been observed in Quarter Horses used for barrel racing. The disorder occurs in racing Appaloosa horses. Approximately 11% of polo ponies are affected with EIPH. The disease occurs in draft horses but is not well documented. Age is considered a risk factor for EIPH, with the prevalence of the disorder being higher in older horses, but the risk factor is the amount of racing that a horse has completed, not its age. There is no consistent association of sex with prevalence of EIPH. Among Thoroughbred racehorses there is an unclear relationship between the speed of racing and the risk of EIPH. Lesions of EIPH are not detected in young Thoroughbred racehorses that have trained at speeds of less than 7 m/s.

The risk of EIPH increases with racing at lower ambient temperatures and with the wearing of bar shoes during racing. There is no association between risk of EIPH and track hardness.

### PATHOGENESIS

The cause of EIPH is rupture of alveolar capillary membranes with subsequent extravasation of blood into interstitial and alveolar spaces. The source of blood in such instances is the pulmonary circulation. Bleeding from bronchial circulation during exercise has been suggested, based on histologic evidence of bronchial angiogenesis in horses that have experienced previous episodes of EIPH, but contribution of the bronchial circulation to EIPH has not been demonstrated. Regardless of the contribution of bronchial circulation to blood in the airways, the likely initial lesion is in capillaries associated with the pulmonary circulation. There is increasing evidence that the primary lesion is arteriovenous remodeling of pulmonary veins. Remodeling of pulmonary veins results in loss of distensibility and partial occlusion to blood flow with subsequent presumed increases in pulmonary alveolar capillary pressure. Hemorrhage into the interstitial space and alveoli, with subsequent rostral movement of blood in the airways, results in blood in the trachea and bronchi.

Rupture of alveolar capillaries occurs secondary to an exercise-induced increase in transmural pressure (pressure difference between the inside of the capillary and the alveolar lumen). If the transmural stress exceeds the tensile strength of the capillary wall, the capillary ruptures. The proximate cause of alveolar capillary rupture is the high transmural pressure generated by positive intracapillary pressures, which are largely attributable to capillary blood pressure, and the lower intraalveolar pressure generated by the negative pleural pressures associated with inspiration.

During exercise, the absolute magnitudes of both pulmonary capillary pressure and alveolar pressure increase, with a consequent increase in transmural pressure. Strenuous exercise is associated with marked increases in pulmonary artery pressure in horses. Values for mean pulmonary arterial pressure at rest of 20 to 25 mm Hg increase to more than 90 mm Hg during intense exercise because of the large cardiac output achieved by exercising horses. The increases in pulmonary artery pressure, combined with an increase in left atrial pressure during exercise, probably result in an increase in pulmonary capillary pressure. Combined with the increase in pulmonary capillary pressure is a marked decrease (more negative) in pleural, and therefore alveolar, pressure during exercise. The pleural pressure of normal horses during inspiration decreases from approximately –0.7 kPa (–5.3 mm Hg) at rest to as low as –8.5 kPa (64 mm Hg) during strenuous exercise. Together, the increase in pulmonary capillary pressure and decrease (more negative) in intrapleural (alveolar) pressure contribute to a marked increase in stress in the alveolar wall. Although the alveolar wall and pulmonary capillaries of horses are stronger than those of other species, rupture may occur because the wall stress in the alveolus exceeds the mechanical strength of the capillary.

Other theories of the pathogenesis of EIPH include: small-airway disease, upper airway obstruction, hemostatic abnormalities, changes in blood viscosity and erythrocyte shape, intrathoracic shear forces associated with gait, and bronchial artery angiogenesis. It is likely that the pathogenesis of EIPH involves several processes, including pulmonary hypertension, lower alveolar pressure, and changes in lung structure, that summate to induce stress failure of pulmonary capillaries.

Obstruction of either the upper or lower airways has been proposed as a cause of EIPH. Inspiratory airway obstruction results in more negative intrapleural, and therefore alveolar, pressures. This effect is exacerbated by exercise, with the result that alveolar transmural pressure is greater in horses with airway obstruction. The higher transmural pressure in such horses may increase the severity of EIPH, although this has not been demonstrated. Moreover, although inspiratory airway obstruction may predispose to EIPH, the prevalence of this condition is much less than that of EIPH, indicating that it is not the sole factor inducing EIPH in most horses.

Horses with moderate to severe EIPH have histologic evidence of inflammation of the small airways, and there is a clear association between the presence of EIPH and inflammatory changes in bronchoalveolar or tracheal aspirate fluid. However, instillation of autologous blood into the airways does not induce a marked inflammatory response in normal horses, and it is therefore unclear whether inflammation alone induces or predisposes to EIPH. Theoretically, small-airway inflammation and bronchoconstriction have the potential to produce intrathoracic airway obstruction.
and, therefore, a more negative alveolar pressure. Given that small-airway disease is common in horses, there is the potential for an important effect of factors such as viral infections, air pollution, and allergic airway disease to contribute to the initiation or propagation of EIPH.

The characteristic location of lesions of EIPH in the caudodorsal lung fields has led to the proposal that hemorrhage is a result of tissue damage occurring when waves of stress, generated by forelimb foot strike, are focused and amplified into the narrowing cross-sectional area of the caudal lung lobes. According to the theory, the locomotor impact of the forelimbs results in transmission of forces through the scapula to the body wall, from where they pass into the lungs and caudally and dorsally. As the wave of pressure passes into the narrower caudodorsal regions of the lungs it generates progressively greater shearing forces that disrupt tissue and cause EIPH. However, studies of intrapleural pressures have not demonstrated the presence of a systemic pressure wave passing through the lung and do not provide support for this hypothesis.

Horses with EIPH have been suspected of having defects in either hemostasis or fibrinolysis. However, although exercise induces substantial changes in blood coagulation and fibrinolysis, there is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis.

Regardless of the cause, rupture of pulmonary capillaries and subsequent hemorrhage into airways and interstitium causes inflammation of both airways and interstitium with subsequent development of fibrosis and alteration of tissue compliance. Heterogeneity of compliance within the lungs, and particularly at the junction of normal and diseased tissue, results in the development of abnormal shear stress with subsequent tissue damage. These changes are exacerbated by inflammation and obstruction of small airways, with resulting uneven inflation of the lungs. The structural abnormalities, combined with pulmonary hypertension and the large intrathoracic forces associated with respiration during strenuous exercise, cause repetitive damage at the boundary of normal and diseased tissue with further hemorrhage and inflammation. The process, once started, is lifelong and continuous for as long as the horse continues to perform strenuous exercise.

**CLINICAL FINDINGS**

Poor athletic performance or epistaxis are the most common presenting complaints for horses with EIPH. Although poor performance may be attributable to any of a large number of causes, epistaxis associated with exercise is almost always secondary to EIPH.

Epistaxis as a result of EIPH occurs during or shortly after exercise and is usually first noticed at the end of a race, particularly when the horse is returned to the paddock or winner’s circle and is allowed to lower its head. It is usually bilateral and resolves within hours of the end of the race. Epistaxis may occur on more than one occasion, especially when horses are raced or exercised at high speed soon after an initial episode.

**Exercise-Induced Pulmonary Hemorrhage and Performance**

Failure of racehorses to perform to the expected standard (poor performance) is often, accurately or not, attributed to EIPH. Many horses with poor performance have cytologic evidence of EIPH on microscopic examination of tracheobronchial aspirates or bronchoalveolar lavage fluid or have blood evident on endoscopic examination of the tracheobronchial tree performed 30 to 90 minutes after strenuous exercise or racing. However, it is important to recognize that EIPH is very common in racehorses, and it should be considered the cause of poor performance only after other causes have been eliminated. Severe EIPH undoubtedly results in poor performance and, on rare occasions, death of Thoroughbred racehorses. Thorougbred horses with EIPH have impaired performance compared with unaffected horses. Affected horses have a lower likelihood of finishing in the first three places, are less likely to be elite money earners, and finish further behind the winner than do unaffected horses.

Results of studies in Standardbred racehorses indicate either a lack of effect of EIPH on performance or an association between EIPH and superior performance. There was no relationship between presence of EIPH and finishing position in 29 Standardbred racehorses with intermittent EIPH examined on at least two occasions, nor in 92 Standardbred racehorses examined on one occasion. However, of 965 Standardbred racehorses examined after racing, those finishing first or second were 1.4 times more likely (95% confidence interval 0.9-2.2) to have evidence of EIPH on tracheobronchoscopic examination than were horses that finished in seventh or eighth position.

**Physical Examination**

Apart from epistaxis in a small proportion of affected horses (Fig. 12-26), there are few abnormalities detectable on routine physical examination of horses with EIPH. Rectal temperature and heart and breathing rates may be elevated as a consequence of exercise in horses examined soon after exercise, but values of these variables in horses with EIPH at rest are not noticeably different from those of horses with no evidence of EIPH. Affected horses may swallow more frequently during recovery from exercise than do unaffected horses, probably as a result of blood in the larynx and pharynx. Coughing is common in horses recovering from strenuous exercise and after recovery from exercise; horses with EIPH are no more likely to cough than are unaffected horses. Other clinical signs related to respiratory abnormalities are uncommon in horses with EIPH. Respiratory distress is rare in horses with EIPH and, when present, indicates severe hemorrhage or other serious lung disease such as pneumonia, pneumothorax or rupture of a pulmonary abscess. Lung sounds are abnormal in a small number of EIPH-affected horses and, when present, are characterized by increased intensity of normal breath sounds during rebreathing examination. Tracheal rales may be present in horses with EIPH but are also heard in unaffected horses.

**Tracheobronchoscopy**

Observation of blood in the trachea or large bronchi of horses 30 to 120 minutes after racing or strenuous exercise provides a definitive diagnosis of EIPH. The amount of blood in the large airways varies from a few small specks on the airway walls to a stream of blood occupying the ventral one-third of the trachea. Blood may also be present in the larynx and nasopharynx. If there is a strong suspicion of EIPH and blood is not present on a single examination conducted soon after exercise, the examination should be repeated in 60 to 90 minutes. Some horses with EIPH do not have blood present in the rostral airways immediately after exercise, but do so when examined 1 to 2 hours later. Blood is detectable by tracheobronchoscopic examination for 1 to 3 days in most horses, with some horses having blood detectable for up to 7 days.

Bronchoscopic examination can be used to estimate the severity of EIPH through the use of a grading system. The interobserver repeatability of tracheobronchoscopic assessment of severity of EIPH using a grading scale of 0 to 4 is excellent, and this scoring system has been widely adopted for use (Fig. 12-27).

- **Grade 0**: No blood detected in the pharynx, larynx, trachea, or mainstem bronchi.
- **Grade 1**: Presence of one or more flecks of blood or two or more short...
Thoracic radiography is of limited use in establishing the actual amount of hemorrhage has not been established. The repeatability of this scoring system has been more severe hemorrhage, but although the relationship between the amount of blood in the large airways and the presence of another disease process, such as a pulmonary abscess, contributing to the horse’s pulmonary hemorrhage or poor athletic performance.

**Prognosis**
Horses that have experienced one episode of epistaxis are more likely to have a second episode. For this reason most racing jurisdictions do not permit horses with epistaxis to race for a period of weeks to months after the initial instance, with more prolonged enforced rest after a subsequent episode of epistaxis and retirement from racing after a third bout. The recurrence rate after one episode of epistaxis in Thoroughbred horses is approximately 13.5% despite affected horses not being permitted to race for 1 month after the initial episode. This high rate of recurrence suggests that the inciting pulmonary lesions have not healed.

Long-term examination of performance of horses with EIPH indicates the horses with grade 4 EIPH have shorter racing careers, but it is not clear if this is a function of the biology of the disease or a management decision by owners and trainers. There is no association between measures of long-term performance measured over 10 years and grades 1, 2, or 3 of EIPH in Thoroughbred racehorses.

**Clinical Pathology**
**Examination of Airway Secretions or Lavage Fluid**
The presence of red cells or macrophages containing either effete red cells or the breakdown products of hemoglobin (hemosiderophages) in tracheal or bronchoalveolar lavage fluid provides evidence of EIPH. Detection of red cells or hemosiderophages in tracheal aspirates or bronchoalveolar lavage fluid is believed to be both sensitive and specific in the diagnosis of EIPH. Examination of airway fluids indicates the presence of EIPH in a greater proportion of horses than does tracheobronchoscopic examination after strenuous exercise or racing. The greater sensitivity of examination of airway fluid is probably attributable to the ability of this examination to detect the presence of small amounts of blood or its residual products and the longevity of these products in the airways. Although endoscopic examination may detect blood in occasional horses up to 7 days after an episode of EIPH, cellular evidence of pulmonary hemorrhage persists for weeks after a single episode. Red blood cells and macrophages containing red cells are present in bronchoalveolar lavage fluid or tracheal aspirates for at least 1 week after strenuous exercise or instillation of autologous blood into airways, and hemosiderophages are present for at least 21 days and possibly longer.

Recent studies have reported on the use of red cell numbers in bronchoalveolar lavage fluid as a quantitative indicator of EIPH. However, this indicator of EIPH severity has not been validated nor demonstrated to be more reliable or repeatable than tracheobronchoscopic examination and visual scoring. Furthermore, considerable concern exists over the suitability of red cell counts in bronchoalveolar lavage fluid for assessment of severity of EIPH given that an unknown area, although presumably small, of the lung is examined by lavage and that there is a risk that this area of lung may not be representative of the lung as a whole, similar to the situation of examination of bronchoalveolar lavage fluid of horses with pneumonia. Bronchoalveolar lavage of sections of both lungs, achieved using an endoscope, may obviate some of these concerns.

Tracheal aspirates may be obtained any time after exercise by aspiration either during tracheobronchoscopic examination or through a percutaneous intratracheal needle. Aspirates obtained through an endoscope may not be sterile, depending on the collection technique. Bronchoalveolar lavage fluid can demonstrate the presence of densities in the caudodorsal lung fields of some horses, but many affected horses have minimal to undetectable radiographic abnormalities. Examination of thoracic radiographs of horses with EIPH can be useful in ruling out the presence of another disease process, such as a pulmonary abscess, contributing to the horse’s pulmonary hemorrhage or poor athletic performance.
can be obtained through either an endoscope wedged in the distal airway or a cuffed tube inserted blindly into a distal airway. Collection of fluid through an endoscope has the advantage of permitting examination of the distal airways and selection of the area of lung to be lavaged. However, it does require the use of an endoscope that is longer (2 m) than those readily available in most equine practices. Use of a commercial bronchoalveolar lavage catheter does not require use of an endoscope, and this procedure can be readily performed in field situations.

**DIFFERENTIAL DIAGNOSIS**

Epistaxis and hemorrhage into airways can occur as a result of a number of diseases (Table 12-12).

### Table 12-12 Causes of epistaxis in horses

</table>
that administration of furosemide before racing reduces the frequency and severity of EIPH in Thoroughbred racehorses.1,2 There was either weak evidence or no evidence of efficacy of other interventions. There is a recommendation for use of furosemide, but because of the regulatory issues related to its use, this is only a weak recommendation.1

Therapy of EIPH is usually a combination of attempts to reduce the severity of subsequent hemorrhage and efforts to minimize the effect of recent hemorrhage. Treatment of EIPH is problematic for a number of reasons. First, the pathogenesis of EIPH has not been determined although the available evidence supports a role for stress failure of pulmonary capillaries secondary to exercise-induced pulmonary hypertension. Second, there is a lack of information using large numbers of horses under field conditions that demonstrates an effect of any medication or management practice (with the exception of bedding) on EIPH. There are numerous studies of small numbers of horses (< 40) under experimental conditions but these studies often lacked the statistical power to detect treatment effects and, furthermore, the relevance of studies conducted on a treadmill to horses racing competitively is questionable.1 Treatments for EIPH are usually intended to address a specific aspect of the pathogenesis of the disease and will be discussed in that context but should be considered in the context of the amount and strength of evidence, which for most treatments is scant and weak.

Prevention of Stress Failure of the Pulmonary Capillaries

There is interest in reducing the pressure difference across the pulmonary capillary membrane in an effort to reduce EIPH. Theoretically, this can be achieved by reducing the pressure within the capillary or increasing (making less negative) the pressure within the intrathoracic airways and alveoli.

Reducing Pulmonary Capillary Pressure

Furosemide administration as prophylaxis of EIPH is permitted in a number of racing jurisdictions worldwide, most notably Canada, the United States, Mexico, and most of the South American countries. Within the United States and Canada, almost all Thoroughbred, Standardbred, and Quarter Horse racing jurisdictions permit administration of furosemide before racing.

The efficacy of furosemide in treatment of EIPH is now well documented.3,4 The mechanism by which furosemide reduces the severity of EIPH is unknown, although it is speculated that furosemide, by attenuating the exercise-induced increase in pulmonary artery and pulmonary capillary pressure of horses, reduces the frequency or severity of pulmonary capillary rupture.

Furosemide is associated with superior performance in both Thoroughbred and Standardbred racehorses, which further complicates assessment of its efficacy in treating EIPH. An increase in pulmonary capillary pressure secondary to altered rheostatic properties of blood during exercise has been suggested as a possible contributing factor for EIPH.

Increasing Alveolar Inspiratory Pressure

Airway obstruction, either intrathoracic or extrathoracic, increases airway resistance and results in a more negative intrathoracic (pleural) pressure during inspiration to maintain tidal volume and alveolar ventilation. Causes of extrathoracic airway obstruction include laryngeal hemiplegia and other abnormalities of the upper airway, whereas intrathoracic obstruction is usually a result of bronchoconstriction and inflammatory airway disease. Horses with partial extrathoracic inspiratory obstruction or bronchoconstriction and airway inflammation associated with recurrent airway obstructive disease (heaves) have pleural (and hence alveolar) pressures that are lower (more negative) than those in unaffected horses or in horses after effective treatment. Hypothetical relationships between the horse’s bit, airway obstruction and EIPH are not supported by empirical evidence.1,2

Partial inspiratory obstruction, such as produced by laryngeal hemiplegia, exacerbates the exercise-induced decrease in intrapleural pressures with a consequent increase in transmural capillary pressures. These changes may exacerbate the severity of EIPH, although an association between upper airway obstructive disease and EIPH has not been demonstrated. Surgical correction of airway obstruction is expected to resolve the more negative intrapleural pressure, but its effect on EIPH is unknown.

Recently the role of the nares in contributing to upper airway resistance, and hence lowering inspiratory intrapleural pressure during intense exercise, has attracted the attention of some investigators. Application of nasal dilator bands (Flair strips) reduces nasal resistance by dilating the nasal valve and reduces red cell count of bronchoalveolar lavage fluid collected from horses after intense exercise on a treadmill. Furthermore, application of the nasal dilator strips to horses in simulated races reduces red cell count in bronchoalveolar lavage fluid of some, but not all, horses.

The role of small-airway inflammation and bronchoconstriction in the pathogenesis of EIPH is unclear. However, horses with EIPH are often treated with drugs intended to decrease lower airway inflammation and relieve bronchoconstriction. Beta-adrenergic bronchodilatory drugs such as clenbuterol and albuterol (salbutamol) are effective in inducing bronchodilation in horses with bronchoconstriction, but their efficacy in preventing EIPH is either unknown or, in very small studies, is not evident. Corticosteroids, including dexamethasone, fluticasone, and beclomethasone, administered by inhalation, parenterally, or enteraly, reduce airway inflammation and obstruction but have no demonstrated efficacy in preventing EIPH. Cromolyn sodium (sodium cromoglicate) has no efficacy in preventing EIPH.

Water vapor treatment (inhalation of water-saturated air) has been proposed as a treatment for EIPH because of its putative effect on small-airway disease. However, water vapor treatment has no effect on EIPH. The use of bedding of low allergenic potential (shredded paper) to prevent EIPH has no apparent effect on prevalence of the condition. Although it is suggested that preventing or minimizing small-airway disease may reduce the severity of EIPH, studies to demonstrate such an effect have not been reported. However, optimizing the air quality in barns and stables and preventing infectious respiratory disease appear to be sensible precautions.

Interstitial Inflammation and Bronchial Angiogenesis

Hemorrhage into interstitial tissues induces inflammation with subsequent development of fibrosis and bronchial artery angiogenesis. The role of these changes in perpetuating EIPH in horses is unclear but is probably of some importance. Treatments to reduce inflammation and promote healing with minimal fibrosis have been proposed. Rest is an obvious recommendation, and many racing jurisdictions have rules regarding enforced rest for horses with epistaxis. Although the recommendation for rest is intuitive, there is no information that rest reduces the severity or incidence of EIPH in horses with prior evidence of this disorder.

Similarly, corticosteroids are often administered, either by inhalation, enterally or parenterally, in an attempt to reduce pulmonary inflammation and minimize fibrosis. Again, the efficacy of this intervention in preventing or minimizing the severity of EIPH has not been documented.

Excessive Bleeding

Coagulopathy and Fibrinolysis

Exercise induces substantial changes in blood coagulation and fibrinolysis. However, there is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis. Regardless, aminocaproic acid, a potent inhibitor of fibrin degradation, has been administered to horses to prevent EIPH. The efficacy of aminocaproic acid in preventing EIPH has not been demonstrated.1 Similarly, estrogens are given to horses with the expectation of improving hemostasis, although the effect of estrogens on coagulation in any species is unclear.
There is no evidence that estrogens prevent EIPH in horses.

Vitamin K is administered to horses with EIPH, presumably in the expectation that it will decrease coagulation times. However, because EIPH is not associated with prolonged bleeding times, it is unlikely that this intervention will affect the prevalence or severity of EIPH.

**Platelet Function**

Aspirin inhibits platelet aggregation in horses and increases bleeding time. Seemingly paradoxically, aspirin is sometimes administered to horses with EIPH because of concerns that increased platelet aggregation contributes to EIPH. There is no evidence that aspirin either exacerbates or prevents EIPH.

**Capillary Integrity**

Capillary fragility increases the risk of hemorrhage in many species. Various bioflavonoids have been suggested to increase capillary integrity and prevent bleeding. However, hesperidin and citrus bioflavonoids have no efficacy in prevention of EIPH in horses. Similarly, vitamin C is administered to horses with EIPH because of concerns that increased platelet aggregation contributes to EIPH.

**Summary of Treatment Options**

Selection of therapy for horses with EIPH is problematic. Given that most horses have some degree of pulmonary hemorrhage during most bouts of intense exercise, the decision must be made not only as to the type of treatment and its timing but also which horses to treat. Moreover, the apparently progressive nature of the disease with continued work highlights the importance of early and effective prophylaxis and emphasizes the need for studies of factors such as air quality and respiratory infections in inciting the disorder.

The currently favored treatment for EIPH is administration of furosemide before intense exercise. Its use is permitted in racehorses in a number of countries but is contentious in many. A frequent practice is to administer furosemide before high-speed training, and not on the day of racing, in jurisdictions that do not permit race day administration of medications. There is increasing interest in the effect of furosemide administered 24 hours before racing; its efficacy in this situation remains to be determined. The association between furosemide administration and superior performance in Standardbred and Thoroughbred racehorses should be borne in mind when recommending use of this drug.

**Prevention and Control**

There are no documented preventive strategies. Rest is an obvious recommendation for horses with EIPH, but the hemorrhage is likely to recur when the horse is next strenuously exercised. The duration of rest and the optimal exercise program to return horses to racing after EIPH is unknown, although some jurisdictions require exercise no more intense than trotting for 2 months. Firm recommendations cannot be made on duration of rest because of a lack of objective information.

Although a role for lower airway disease (either infectious or allergic) in the genesis of EIPH has not been demonstrated, control of infectious diseases, and minimization of noninfectious lower airway inflammation appears prudent.

Concern about the role of impact waves in the genesis of EIPH has led to discussion of “low-stress” training protocols, but these have not been adequately evaluated.

**FURTHER READING**

**REFERENCES**

**SYNOPSIS**

**Etiology** Combined genetic predisposition with environmental challenge of inhaled barn and feed dust containing inciting agents that can include particles of moulds, endotoxin, mites, plant debris, and inorganic material.

**Epidemiology** Predominantly a disease of horses stabled in poorly ventilated barns and fed quality hay. Occurs worldwide but more commonly in the northern hemisphere. Increased prevalence in older horses. No breed or sex predilection.

**Clinical signs** Range of severity of clinical signs. Chronic cough, mucopurulent nasal discharge, poor athletic performance, increased respiratory rate, increased expiratory effort, wheezes on thoracic auscultation, and abundant mucopurulent material in the trachea on endoscopic examination.

**Clinical pathology** Neutrophilia in tracheal aspirate and bronchoalveolar lavage fluid.

**Lesions** Bronchiolitis with mononuclear cell infiltration, epithelial, and goblet cell hyperplasia, neutrophil accumulation in airway lumens, and alveolar hyperinflation.

**Diagnostic confirmation** Clinical signs, examination of bronchoalveolar lavage fluid, and the response to treatment.

**Treatment** Remove the inciting cause by providing a dust-free environment, and administer corticosteroids. Bronchodilators are useful for treatment of acute bronchoconstriction.

**Control** Prevent exposure to inciting cause. Ensure optimal air quality in stables or maintain horses at pasture.

**RECURRENT AIRWAY OBSTRUCTION (HEAVES)**

Recurrent airway obstruction (RAO; heaves) is a recurrent disease of stabled adult horses characterized by neutrophilic airway inflammation and airway obstruction manifest clinically by the presence of coughing, excess mucus accumulation in airways, neutrophilic bronchoalveolar lavage fluid or tracheal aspirate, bronchospasm, tachypnea, and increased respiratory effort, and exercise intolerance. Clinical severity ranges from mild coughing with minimal exercise intolerance during infrequent recurrences of the disease through to severe and persistent coughing, airway obstruction, and markedly increased work of breathing and abnormal breathing pattern. Removal of exposure to hay and straw and keeping the horse at pasture results in remission of the disease.

The disease should be differentiated from the usually transient inflammatory airway disease of young adult horses in which there is no clinically significant impairment of pulmonary function. The disease is classically considered to have an allergic component.

**ETIOLOGY**

**Genetics** There is a genetic component to the disease, although the precise pattern of inheritance and gene association is yet to be determined.¹ There is a familial pattern to the disease in some breeds, and for Warmbloods and Lipizzan, affected parents increase the likelihood of off-spring developing recurrent airway obstruction (RAO) by fivefold.² Segregation analysis indicates a mixed mode of
inheritance in Warmbloods.\textsuperscript{3} It appears likely that multiple genes are involved in the predisposition to RAO and the genes involved might differ with breed of horse or other animal or environmental factors. Evidence for a multigenic cause for predisposition to RAO includes the finding of quantitative trait loci (QTL) located on two different chromosomes (ECA 13 and ECA 15) in different families of affected Warmbloods\textsuperscript{4,5} and failure to identify a monogenetic predisposition to RAO. Further studies in half-sibling horses and from unrelated horses indicates that at least one causative variant is a QTL region located on ECA 13 that is not associated with any coding variants, suggesting that the cause is a regulatory mutation.\textsuperscript{6} The cause does not appear to be abnormalities in the gene encoding DNAH5 (dynein—a component of cilia), although it is located in this QTL and has 53 polymorphisms including 7 nonsynonymous variants.\textsuperscript{7} Similarly, mutations in the integrin alpha X gene, which is related to allergy in humans and is located in the region of the QTL in ECA 13, are not associated with RAO.\textsuperscript{8,9} However, expression of interleukin 4 receptor gene, which is also located in the region of the QTL, is greater in bronchoalveolar lavage fluid of RAO-affected half-siblings than in unaffected animals, suggesting a role for this cytokine, or a mutation in its gene, in RAO.\textsuperscript{10}

Environmental Factors

RAO is caused by inhalation by susceptible horses of dust particles found in barns, bedding, and feed materials such as dusty hay. The inhaled particles include endotoxin, mites, plant debris, inorganic materials, and conidia and fragments of molds. \textit{Faenia recrivirgula} (formerly known as \textit{Micropolyspora faeni}), \textit{Aspergillus fumigatus}, and \textit{Thermoactinomyces vulgaris} are molds commonly associated with respiratory disease in susceptible horses, as evidenced by experimental studies involving inhalation of mold or mold fragments by horses. Molds contain a number of inflammatory substances, including various allergens, glucans, mycotoxins, and proteases, and it is not clear which of these agents are the inciting cause of RAO. Furthermore, dust containing mold also contains endotoxin. Inhalation of fungal spores, endotoxin and silica microspheres causes RAO in susceptible horses but not in healthy horses.\textsuperscript{10} There was neutrophilic inflammation in both healthy and RAO horses but bronchospasm in only RAO horses.\textsuperscript{11} Endotoxin contamination of molds contributes to the airway response to inhalation of preparations of molds used in experimental studies and inhalation of endotoxin alone produces airway inflammation and impaired respiratory function in horses in a dose-dependent manner, with RAO-susceptible horses having an exaggerated response at lower doses. Endotoxin concentrations in the breathing zone of horses are eight times higher in stables than at pasture.\textsuperscript{12} However, the response to endotoxin is less than that of susceptible horses exposed to hay dust containing endotoxin, indicating that endotoxin alone is not sufficient to cause the clinical signs of RAO. Other compounds in hay dust are integral to the development of RAO.

It is emphasized that there is not one causative agent acting alone but rather a range of agents that, when inhaled in sufficient concentration by susceptible horses, induce airway disease. It is likely that RAO is associated with the potentiating interactions among several agents present in barn or hay dust and is not simply a response to one agent. The mechanisms underlying development of airway inflammation and respiratory dysfunction are provided under “Pathogenesis.” Viral infections and 3-methylindoole intoxication are not considered important causes of RAO.

**Epidemiology**

**Occurrence**

Although RAO is one of the more common diseases of horses and is a major cause of loss of performance and wastage in European horses, there are few reports of its epidemiologic characteristics. The disease is common in Europe and North America but is rare in Australia. The prevalence of RAO in the Great Britain, based on a random survey of owners who use veterinary surgeons, is 14% (95% confidence interval of 10.7%–17.4%).\textsuperscript{13} The 7-day incidence (ie, new occurrence of the disease in an animal) of RAO in horses and ponies in Great Britain is 0.4% (0%–0.8%), and the prevalence of RAO was 5.8% (95% CI 4.2%–7.5%), as reported by owners.\textsuperscript{13} In Germany, 83% of horses believed to be healthy at an auction were found to have clinical evidence of chronic pulmonary disease. Inflammatory airway disease is very common in horses, with 96% of racehorses in Hong Kong examined at necropsy and 27% of healthy racehorses in training having an increased proportion (>20%) of neutrophils in tracheal aspirate, indicating inflammatory airway disease. Among stabilized pleasure horses in Michigan, \~17% had cytologic or endoscopic evidence of airway inflammation,\textsuperscript{14} and 12% of horses examined in an abattoir in the northern United States had histologic evidence of bronchitis. However, although airway inflammation is a component of RAO, the airway inflammation common in young athletic horses and stabilized horses is not generally considered to be RAO or necessarily a prodrum of RAO.

The **case-fatality rate** for moderately to severely affected horses is approximately 20% over a 2- to 4-year period. Among horses greater than 15 years of age, presence of RAO is not significantly associated with death ($P = 0.73$, hazard ratio $1.19$, 95% CI $0.4–3.2$).\textsuperscript{15} Most mildly to moderately affected horses respond well to treatment and continue to perform at a satisfactory level.

**Risk Factors**

**Animal Risk Factors**

The disease occurs in adult horses and ponies. A survey of horse and pony owners in Great Britain found that the median age of horses and ponies with the disease is 18.2 years versus 12.7 for unaffected animals.\textsuperscript{16} Another owner survey found the median age of RAO affected horses as 13 years (interquartile range [IQR] of 9.5–20 years), whereas that of unaffected horses was 10 years (IQR 7–14.4 years).\textsuperscript{17} The odds of a horse having RAO (as reported by the owner) increases with greater age (odds ratio of 5.1, 8.1, 11.4, 9.5, and 18.3 for horses 5–7, 7–9, 9–11, 11–15, and greater than15 years of age compared with horses <5 years).\textsuperscript{16} Examination of a convenience sample of horses identified 3000 horses of 1e to 40 years of age in the Netherlands revealed spontaneous coughing during a 10 minute observation period in 1% of horses, nasal discharge in 1.9%, and abnormal respiratory effort in 1%.\textsuperscript{18} Of 200 horses and ponies greater than 15 years of age in the United Kingdom randomly chosen for examination by a veterinarian, 13.6% had marked abnormalities (expiratory wheeze, cough and/or increased abdominal effort) during rebreathing examination that are consistent with RAO.\textsuperscript{19} A further 17.8% had moderately severe abnormalities. Those horses and ponies with abnormalities identified during rebreathing examination were significantly older (median 21.2 years) than were animals without abnormalities (18.0 years).\textsuperscript{20} Similarly, 15% of horses greater than 30 years of age have marked clinical signs consistent with RAO, and a further 19% have moderate abnormalities.\textsuperscript{21}

There is no apparent breed, sex, or height predisposition,\textsuperscript{22} with the exception that Thoroughbreds are 3 times more likely to be examined for the disease than are ponies, although this could represent a sampling bias in that owners of Thoroughbreds might be more likely to seek veterinary attention than owners of ponies. The finding of increased likelihood of Thoroughbred horses having the disease is not consistent among studies. A survey of donkey owners in the United Kingdom did not elicit any reports of signs consistent with RAO in any of the \~1700 animals.\textsuperscript{12} This might represent underreporting of the condition in donkeys or a low prevalence of the disease in donkeys.

There are horses that develop the disease and other horses, maintained in an identical situation, that do not.\textsuperscript{23} Development of disease is dependent on the horse being susceptible to the inflammatory effect of inhaled dust but the reasons for this individual susceptibility are poorly understood. As noted earlier (“Etiology—Genes”), familial predisposition has been suggested based on the observation that Lipizaners and German and
Swiss Warmbloed are 3.2 times more likely to have RAO if one parent was affected and 4.6 times as likely if both parents had RAO. There is no association between major histocompatibility markers (equine leukocyte antigens) and occurrence of RAO.

Exposure to inciting agents is associated with a variety of environmental factors, including potentially outdoor concentrations of aeroallergens and climatic factors but most importantly housing and feeding practices.

Environmental Risk Factors

Season

Horses are approximately 2 times more likely to be examined by a veterinarian because of the disease in winter or spring compared with summer, suggesting a seasonality to the occurrence of the disease perhaps as a result of increased stabling during winter. Signs of respiratory disease in horses with RAO are ~2 times more likely to occur in winter months, with peak values of 45% to 50% of RAO-affected horses having clinical signs of the disease in January and February in Great Britain (Fig. 12-28).

Housing and Hay Feeding

There is a clear association between housing, feeding of hay, and development of the disease. Typically, susceptible horses are clinically normal when at pasture and feeding processed feedstuffs, results in resolution of the disease process.22 There is currently no clear consensus on the immune mechanisms underlying these responses to inhalation of dust are not well defined but can be considered in the contexts of immune and inflammatory responses, mucus secretion, and pulmonary dysfunction.

Inflammatory and Immune Responses

The precise immunologic abnormalities and mechanisms causing airway and peribronchial inflammation in affected horses is unclear.21 Inflammation is associated with excessive mucus production, airway swelling, and abnormal lung function. The inflammatory response in horses with RAO is neutrophilic, with lesser numbers of mast cells and rarely eosinophils.20 The mechanisms underlying this inflammatory response have not been fully elucidated, but differing responses in RAO and healthy horses, and differing responses among families of RAO sensitive horses, to antigenic challenge supports an acquired immune-mediated process.23 Furthermore, upregulated expression of IL1β, IL8, TLR4, TNFα, TGFβ1, and NFκβ transcripts in RAO-affected compared with healthy horses and the strong correlation with clinical variables indicative of disease severity provide support for an immune-mediated disease process.23 There is currently no clear consensus on the immune mechanisms involved in development or perpetuation of RAO despite numerous studies examining cell types,20,24-28 cytokines,23,29,34 gene expression,23,29,35 and antibody isotypes.36

The presence of allergen-specific IgE antibodies in bronchoalveolar lavage fluid is supportive of a hypersensitivity reaction (type 1
Diseases

agents in susceptible horses25 and this results than that of hay dust. Regardless of the nature of the inhaled material) with responses magnitude of the inflammatory response predominated Th1- or Th2-like responses. The leukins 4, 5, and 13 and no evidence of a and CD8 lymphocytes in blood and bron - preparations. A study examining just CD4 varying proportions of types of cells in these However, all the studies cited previously interleukins 8 and 17 (potent attractors of affected horses of interferon- involved in lymphocyte development and driving a Th2 response, in bronchoalveolar lavage fluid (BALF) and peribronchial cells of horses with RAO is evidence of a contribu - tion of a Th2 mechanism to RAO.52 One proposed explanation is that RAO-susceptible horses exhibit a Th2-like immune response to inhalation of hay or barn dust characterized by increased expression of interleukins 4 and 5 and decreased expres - sion of interferon-α in cells obtained by bron - choalveolar lavage. Others have not detected a pure Th2-like cytokine profile, finding instead a mixed inflammatory response including increases in expression (mRNA) in cells obtained from bronchoalveolar lavage fluid of affected horses of interferon-γ, tumor necrosis factor-α, interleukins 1β and 4, and interleukins 8 and 17 (potent attractors of neutrophils) but not interleukins 2, 5, and 10. However, all the studies cited previously were performed on crude preparations of cells obtained by bronchoalveolar lavage, and the results could have been influenced by the varying proportions of types of cells in these preparations. A study examining just CD4 and CD8 lymphocytes in blood and bron - choalveolar lavage fluid of RAO-affected horses demonstrated a general down-regula - tion in expression of interferon-γ, and interleukins 4, 5, and 13 and no evidence of a cytokine profile consistent with either sole or predominance Th1- or Th2-like responses. The magnitude of the inflammatory response varies depending on the challenge (i.e., nature of the inhaled material) with responses to endotoxin characteristically being less than that of hay dust. Regardless of the underlying mechanism, it is clear that T cells are involved in mediating and likely modu - lating the response to exposure to inciting agents in susceptible horses45 and this results in airway inflammation and interference with normal respiratory function. The role of the observed increased rate of T-cell apoptosis in resolution of clinical signs after removal of the inciting agents in RAO-affected horses is uncertain.51 Following inhalation of inciting agents there is recruitment of neutrophils, but not eosinophils or platelets, into the lungs in most horses that develop changes in lung function. Histologically, there is perbronch - chiorial accumulation of lymphocytes and luminal accumulations of neutrophils in affected horses. The neutrophilic response is airways is mediated at least in part by IL-8 and IL-17 and by MAPK and PI3K pathways in horses with heaves.30 The entry of neutro - phils into the airways is associated with activation of neutrophils and platelets. Neutro - phil activation occurs in horses with RAO 10 and 24 hours after antigen challenge and is mediated by increased expression of CD13 on circulating neutrophils of susceptible horses exposed to inciting dust.27 However, there is not increased expression of mRNA for TNF-alpha, IL-beta, IL-8, and MIP-2 in horses with RAO, suggesting that release of these cytokines is not necessary for the neu - trophic response characteristic of the disease.59 The neutrophils of horses during episodes of RAO, but not when the horses are asymptomatic, have increased adherence in vitro to protein coated plastic suggesting a mechanism for the increased migration of neutrophils into airways of affected horses. However, neutrophils of asymptomatic RAO-affected horses (ie, those horses in remission of the disease) have an exaggerated serum concentration of TNF and mRNA expression after lipopolysaccharide exposure compared with cells of healthy horses.26 A greater proportion of neutrophils in BALF of RAO-affected horses are viable and have a slower rate of apoptosis compared with those of unaffected horses, suggesting a role for increased neutrophil survival in airways in horses with RAO.58

Inhibition of neutrophil phosphodiesterase-4 activity does not alleviate clinical signs of RAO or decrease neutrophil numbers in bronchoalveolar lavage fluid in affected horses, suggesting that neutrophils are not primarily involved in the genesis of airway obstruction. The extent to which neutrophils in the airways are activated has not been determined, and their role in the development of respiratory dysfunction is unclear given that glucocorticoid administration attenuates the respiratory dysfunction but not airway neutrophilia in horses with RAO (see under “Treatment”). Airway inflammation is associated with increases in concentration of inflammatory mediators including leukotriene B4, prostanooids including thromboxane, and prote - ases. Activity of matrix metalloproteinase-9 is higher in horses with RAO than in unaf - fected horses and is induced in a dose - dependent manner by inhalation of inciting substances including hay dust and endo - toxin. MMP-9 is likely important in the inflammatory process associated with RAO through excessive gelatinolytic proteolysis that can contribute to lung injury and through a role in lung remodeling. Inflam - mation is also associated with increased oxid - ative stress in lungs of horses with RAO as indicated by elevated concentrations of epi - PGF2α and redox ratio of glutathione in pulmo - nary lavage fluid.

RAO is associated with platelet activation and increases in mean platelet volume, indic - ating consumption of platelets and bone marrow release of younger thrombocytes.40,57 Platelets are consumed in part by formation of neutrophil-platelet aggregates.59

Mucus Accumulation of excessive quantities of mucus in the large airways is characteristic of horses affected by RAO and can contribute to nonbronchospastic airway obstruction. Accumulation of mucus is attributable to decreased clearance and increased produc - tion. The mucus in horses with RAO differs in both composition and viscoelasticity from that of clinically normal horses and this might contribute to its decreased clearance. The viscosity of mucus can increase threefold in RAO susceptible horses stabled and exposed to hay dust. Increased production of mucus is associated with up-regulation of the equine MUC5AC gene, which is responsible for production of mucin, but not with IL-13 or epithelial gene (CLCA1, EGFR, Bcl-2 and MUC5C) expression,39 in the small airways of horses with RAO.

Airway Function and Gas Exchange Inhalation of inciting agents causes changes in lung function characterized by an increase in pulmonary resistance, lower dynamic compliance, altered distribution of ventilation, impaired gas exchange, increased functional residual capacity, and an altered breathing strategy. Airway obstruction is a result of bronchospasm, inflammatory thick - ening of airways, and accumulation of mucus and cells in the airways. Bronchospasm is largely relieved by administration of bron - chodilator drugs or removal of the inciting cause, but residual effects on lung function remain and are attributable to inflammation and fibrosis and bronchoconstriction of small airways. Bronchoconstriction in both normal and affected horses is caused by parasympathetic activity and release of acetyl - choline that reacts with muscarinic receptors on airway smooth muscle. However, the response is exaggerated in horses with RAO. Stimulation of airway sensory receptors results in an exaggerated bronchoconstric - tive response, possibly because of the action of inflammatory mediators and/or byprod - ucts. The exaggerated bronchoconstrictive response is not specific for allergens, and any substance that activates airway sensory receptors may incite bronchoconstriction once the sensitivity of the receptors is enhanced by inhalation of the inciting aller - gens. Exaggerated airway responsiveness to inhaled irritants persists for up to 3 days after a single exposure to the inciting agent and is likely important in the development of clinical signs of the disease. Bronchoconstriction increases work of breathing, but hypoventilation probably contributes little to the hypox - emia of affected horses, given that PaCO2 is rarely increased.

Hypoxemia, which can be severe (<60 mm Hg, 8 kPa), is attributable to venti - lation-perfusion mismatches and increased
dead-space ventilation. The increased minute ventilation of affected horses, a result of maintained tidal volume and increased respiratory rate, mainly supplies dead space and regions with high V/Q ratios. Pulmonary hypertension in affected horses is probably attributable to hypoxia and perhaps inflammatory mediators with vasoconstrictor activity.

The elevated functional residual capacity and characteristic breathing strategy of affected horses is attributable to airway obstruction. Airway obstruction causes trapping of air in alveoli and a higher end-inspiratory volume. The high end-inspiratory volume maximizes airway diameter and facilitates the high expiratory and inspiratory flow rates necessary for affected horses to maintain a normal tidal volume while increasing their respiratory rate.

Bronchiectasis (irreversible dilation and deformation of bronchi or bronchioles) occurs in some horses affected with RAO for a prolonged duration. Neutrophilic inflammation is essential for the development of bronchiectasis.

Surfactant of horses with RAO has a lower phospholipid concentration and lower percentage of phosphatidylglycerol that is not a result of leakage of plasma into BALF. The clinical importance of this abnormality is unclear.

RAO causes pulmonary artery hypertension with consequent abnormal cardiac septal motion, decreased left ventricular diameter and stroke volume, and increased pulmonary artery diameter.

**Clinical Findings**

The degree to which horses are affected varies considerably and is quantifiable by consideration of a combination of clinical signs.

Minimally affected horses have airway inflammation evident on endoscopic or cytologic examination of the airways, but few other signs on physical examination, whereas severely affected horses have very obvious clinical signs. Owner-reported scoring systems are useful in staging the disease and predicting onset of clinical signs.

The usual history is that of chronic cough in a stabled horse, and owner-reported rates of coughing correlate well with the clinical condition and bronchial sensitivity to histamine challenge of horse. Typically, the disease is precipitated by exposure to hay and stabilizing, and disease remission occurs in most horses when pastured and removed from hay. There may be a history of reduced exercise tolerance.

Affected horses are usually bright and alert and have a normal appetite and rectal temperature. Severely affected horses appear anxious and have a greatly increased respiratory effort.

Coughing is common in horses with RAO, although it is neither particularly specific nor sensitive as an indicator of the disease. Coughing may consist of a single cough every few seconds to minutes, or there may be a paroxysm of coughing. The cough can also be elicited by digital massage of the larynx and proximal part of the trachea because horses with airway inflammation have increased sensitivity of the cough reflex. Stimulation of the larynx or proximal trachea by digital massage does not elicit coughing in normal horses. The cough becomes more pronounced and wheezing with exercise. It also occurs more frequently when the horse is exposed to cold air, physical activity, or excitement; when placed in a dusty environment; or if dusty feed is offered. The amount of coughing, which must be counted over at least 15 minutes and preferably 1 hour for accurate determination of its severity, correlates closely with the amount of mucus in airways, maximal change in pleural pressure (a measure of bronchoconstriction), and neutrophil count in bronchoalveolar lavage fluid. Coughing is more frequent in horses with RAO, and affected horses often have paroxysmal coughing, especially after barn cleaning and feeding.

An intermittent, bilateral, mucopurulent to serous nasal discharge is a common sign in affected horses.

The resting respiratory rate is increased from a normal of 12/min up to 24 to 36/min. There is a pronounced effort during expiration, and markedly affected horses have an obvious abdominal component to respiration. Normal horses have a biphasic pattern of airflow during inspiration and expiration, whereas affected horses lack the second phase of respiration—evident as lower thoracoabdominal asynchrony.

Longstanding cases develop a “heave line” in the flank as a result of hypertrophy of the abdominal oblique musculature. It is evident as a trough or furrow along the costal arch. In advanced cases the nostrils may be visibly dilated during inspiration, and the force of the expiratory effort causes the anus to protrude.

Heart rate is commonly within the normal range or only slightly increased. In horses with RAO, the heart rate is significantly higher during exercise than in healthy horses.

Abnormal lung sounds are one of the most frequent abnormalities detected on clinical examination and the sensitivity of this finding can be increased from 70% to almost 90% by auscultating the thorax while the horse breathes for 60 to 120 seconds with an airtight plastic bag over its nostrils. The bag should be large enough to enable the horse to breathe unhindered (10-15 L) and should not leak. Accumulation of carbon dioxide in the bag increases the horse’s respiratory rate and tidal volume and accentuates lung sounds. Auscultation of the lungs in the early stages of the disease may reveal only a slight increase in the amplitude of normal breath sounds. Abnormal lung sounds become audible as the disease progresses.

Wheezing and crackling sounds occur at the end of inspiration and the end of expiration. These abnormal sounds are audible over most of the lung but are usually easiest to detect over the upper one-half of both lung fields. Auscultation of the trachea usually reveals moist sounds characteristic of fluid in the trachea. Some affected horses have quieter than expected lung sounds.

Percussion of the thorax may reveal an increase in the area of resonance by as much as one to two intercostal spaces caudally. However, the area of resonance delineated by percussion is too labile and ill-defined to be of diagnostic value.

Endoscopic examination of the upper airways, trachea, and bronchi reveals an abundance of mucopurulent material in the trachea, which, in severe cases, is also present in the nasopharynx. Detection of signs of inflammation in the upper airway does not reflect the presence or severity of inflammation in the lower airway. The amount of mucus can be graded on a scale from 0 to 5 (Fig. 12-29).

- **Grade 0**—no visible mucus.
- **Grade 1**—small blobs of mucus that are not confluent.
- **Grade 2**—multiple blobs of mucus, some of which are confluent.
- **Grade 3**—mucus confluent in a stream in the ventral aspect of the trachea or multiple large blobs around the circumference of the lumen.
- **Grade 4**—large pool of mucus in the ventral aspect of the trachea.
- **Grade 5**—Profuse amounts of mucus occupying more than 25% of the tracheal lumen.

Observation of tracheal mucus of grade 4 or 5 has a high specificity (92%) but low sensitivity (52%) for detection of RAO. Assessment of tracheal septum thickness is not useful in determining the severity of RAO.

Radiographic examination of the thorax usually reveals evidence of bronchial disease with some evidence of interstitial disease. Radiography is more useful in ruling out other diseases, such as granulomatous or interstitial pneumonia, than in confirming RAO.

Sophisticated techniques for measuring pulmonary function, such as determination of tidal flow–volume loops, nitrogen washout, or forced expiratory flow–volume loops, may identify mildly or subclinically affected animals but have limited day-to-day clinical utility.

Measurement of pleural pressure changes by insertion of an esophageal balloon is relatively simple and may be useful in monitoring response to treatment. Affected horses have pleural pressure changes during respiration greater than 6 cm H2O. Administration of atropine (0.02 mg/kg, IM or IV), isoproterenol (isoprenaline), or a β2-adrenergic agonist such as terbutaline.
Fig. 12-29 Endoscopic grading of tracheal mucus in horses. (Modified from Gerber V, Straub R, Marti E et al. Endoscopic scoring of mucus quantity and quality: observer and horse variance and relationship to inflammation, mucus viscoelasticity and volume, Equine Vet J 2004;36: 576–582 with permission from the Equine Veterinary Journal.)

(0.002–0.005 mg/kg, IV) reduces the maximal change in pleural pressure of horses with RAO.

Abnormalities in left and right ventricular function are detectable in horses with RAO. These include reduced early diastolic filling velocities, elevated late diastolic filling velocities, thereby decreased E/A quotient, prolonged electromechanical coupling periods between electrocardiograph Q-wave and maximal velocities, and compensatory elevated systolic strain in the right heart and abnormal cardiac septal motion, decreased left ventricular diameter and stroke volume, and increase pulmonary artery diameter.41,51

The course of the disease is dependent on the removal or continual presence of the precipitating cause. If the cause is removed in the early stages, complete recovery can occur. In the continual presence of the precipitating cause relapses occur commonly or the disease becomes progressive and affected horses become severely incapacitated. Bronchiectasis, evident on radiographic examination of the thorax, develops in horses with RAO of prolonged duration. With conscientious management and adequate housing, breeding animals and hunters or show jumpers with RAO can remain useful for many years.

Lung biopsy of horses with RAO is described,52,53 but it is not a clinically relevant diagnostic test because of the risk of adverse events and clinicians’ ability to detect and stage the disease based on less invasive clinical and clinicopathologic information.52,43,45

CLINICAL PATHOLOGY AND SPECIAL EXAMINATIONS

There are no significant changes in the hemogram or serum biochemistry of affected horses. The \( P_{\text{ao}_2} \) is below normal in moderately to severely affected horses and the \( P_{\text{aco}_2} \) is usually normal, although it may be increased in severely affected horses. Blood oxygen tension measurements should be corrected for the temperature of the animal and the altitude. At approximately sea level, \( P_{\text{ao}_2} \) values of normal horses are usually greater than 90 mm Hg (12 kPa), whereas affected horses have \( P_{\text{ao}_2} \) less than 82 mm Hg (10.9 kPa). With increases in altitude the values in both normal and affected horses decrease. The normal hypoxemia that occurs in horses during intense exercise is exacerbated by RAO.

Bronchoalveolar lavage fluid from affected horses during symptomatic episodes has a relative neutrophil count greater than 5% to 10%, and usually over 50%, of the absolute nucleated cell count. It is recommended that horses not be considered to have airway inflammation unless greater than 15% of cells in bronchoalveolar lavage fluid are neutrophils. During periods of remission, the bronchoalveolar lavage fluid of previously affected horses is not different from that of normal horses. Absolute nucleated cell counts in bronchoalveolar lavage fluid of affected horses are reported, but the values depend on the collection technique used. The relative proportions of macrophages and lymphocytes in bronchoalveolar lavage fluid of affected horses are lower than those of normal horses. Eosinophil numbers in bronchoalveolar or tracheal aspirate fluid of affected horses may be mildly elevated (up

severity of bronchiolar neutrophil and mast cell lumen exudate and neutrophils. The lar lymphoplasmacytic inflammation, goblet cell metaplasia, peribronchiolar fibrosis, and cellular infiltration by lymphocytes, plasma cells, mast cells, and sometimes eosinophils. Plugs of mucus with entrapped neutrophils often occlude broncholar lumina. Changes in airway collagen and elastic fiber content correlate with lung function in horses with RAO.

Samples for Postmortem Confirmation of Diagnosis
- Formalin-fixed lung for light microscopic examination

DIAGNOSTIC CONFIRMATION
Confirmation of the disease is based on the presence of a history and clinical signs consistent with the disease, in particular the response to stabilizing and pasturing, and demonstration of reversible airway obstruction. Objective confirmation can be achieved by measuring the response of maximal changes in pleural pressure in response to bronchodilator drug (atropine or glycopyrrolate) administration.

DIFFERENTIAL DIAGNOSIS
Horses with respiratory distress may have the following conditions:
- Interstitial pneumonia
- Heart failure
- Bacterial pneumonia
- Pleuritis
- Pulmonary or mediastinal neoplasia, including leiomyosarcoma
- Parasitic pneumonia (D. arnfieldi)
- Nasal discharge may be caused by the following:
  - Guttural pouch diseases including empyema
  - Dysphagia of any cause
  - Esophageal obstruction
  - Sinusitis
  - Pneumonia

TREATMENT

The principles of treatment are as follows:
- Removal of the inciting cause
- Reduction of airway inflammation
- Bronchodilation
- Correction of hypoxemia

RAO is an inflammatory disease caused by inhalation exposure to inciting agents. Bronchoconstriction is secondary to inflammation. Control of the disease is based upon preventing inhalation of inciting agents and suppression of inflammation by administration of corticosteroids, practices supported by substantial evidence. Relief of bronchoconstriction should be necessary only during acute exacerbations of the disease, and administration of bronchodilatory drugs for more than several days is not optimal treatment in most horses. Drugs used in the treatment of RAO are summarized in Table 12-13.

It is essential that the horse is not exposed to the inciting agents and irritant substances that could provoke or worsen the disease. Even relatively brief exposure of susceptible horses to the inciting agents, such as can occur if a horse is brought into a poorly ventilated barn to be fed, can result in airway hypersensitivity and the development or maintenance of clinical signs. Affected horses should be moved to a clean environment, ideally pasture, in which the concentration of airborne allergens is reduced to an absolute minimum. If the horse cannot be kept at pasture, then it should be housed in a well-ventilated barn (see "Control" for details), bedded with clean wood shavings or shredded paper and fed a complete pelleted ration. If affected horses are fed hay, it should be thoroughly wetted to minimize the release of spores. Remission of clinical signs can be expected in 4 to 21 days if the environmental changes are adequate. This may be all that is necessary to control the disease in many horses.

Antiinflammatory Drugs

The disease is essentially one of inflammation of the airways, and therefore one of the mainstays of treatment is administration of antiinflammatory drugs. Nonsteroidal anti-inflammatory drugs such as phenylbutazone and flunixin meglumine are not effective. Corticosteroids including dexamethasone, prednisolone, triamcinolone, and betamethasone are effective in controlling the disease. Dexamethasone (0.04-0.1 mg/kg, intravenously, intramuscularly or orally every 24-48 hours) can be given to control the acute signs of the disease, and then the dose reduced and eventually discontinued as environmental alterations have their effect. Similarly, prednisolone (1-2 mg/kg, orally once daily), but not prednisone (which is not absorbed after oral administration to horses), can be given initially, then the dose reduced by approximately one half every 5 to 10 days as the disease is controlled. Both prednisolone (2 mg/kg per day) and dexamethasone (0.05 mg/kg day) improve clinical signs of the disease in the face of continued exposure to inciting causes, and prednisolone improves lung function. Often prednisolone or dexamethasone sodium phosphate is effective when administered every second day when the disease has been controlled. Dexamethasone-21-isonicotinate (0.04 mg/kg, intramuscularly) is effective when administered every 3 days, but not when administered only once. Isoflupredone (0.03 mg/kg, intramuscularly once

Necropsy Findings

The major findings are restricted to the lungs, which are pale and voluminous and do not collapse when the chest cavity is opened. The tissue damage is primarily centered on airways which are less than 2 mm in diameter. Microscopically, a variable degree of alveolar emphysema is accompanied by a chronic bronchiolitis featuring diffuse epithelial hyperplasia, goblet cell metaplasia, peribronchiolar fibrosis, and cellular infiltration by lymphocytes, plasma cells, mast cells, and sometimes eosinophils. Plugs of mucus with entrapped neutrophils often occlude bronchiolar lumina. Changes in airway collagen and elastic fiber content correlate with lung function in horses with RAO.

Intradermal testing using putative allergens has been investigated as a means of identifying horses with RAO or of identifying antigens with which to hyposensitize affected horses with variable or undetermined efficacy. Retrospective examination of records of horses with a history of RAO suggests that they are more likely to react, and react to a larger number, of intradermally injected allergens than horses without a history of RAO. However, reactions to individual allergens cannot be used to determine hypersensitivity to particular allergens, although it is suggested that overall patterns of reactivity, with a history of exposure of the horse to these allergens, might be useful in guiding management of affected horses. Contrary to these results, a prospective study demonstrated that horses with RAO did not have a greater rate of reaction to intradermal skin tests than did horses not affected by RAO. Intradermal testing did not distinguish clinically relevant reactions from those that were not clinically relevant. Horses with RAO have greater sensitivity to intradermal injection of histamine, which is commonly used as a positive control, than horses without RAO. Overall, intradermal skin testing is neither useful in detecting horses with RAO nor in determining hypersensitivity to particular allergens in individual horses. Results of such testing might be useful in management of horses, but this has not been demonstrated. The usefulness of intradermal skin testing and subsequent administration of preparations of antigens selected on the basis of intradermal testing, in an effort to hyposensitize horses with RAO, has not been determined. The apparent lack of efficacy of intradermal testing might be because the extent of reactivity to intradermal injection of mold preparations does not correlate with the severity of pulmonary dysfunction after inhalation of the same preparation in horses with RAO.

Lung biopsy demonstrates peribronchiolar lymphoplasmacytic inflammation, goblet cell metaplasia, alveolar fibrosis, and bronchial lumen exudate and neutrophils. The severity of bronchiolar neutrophil and mast cell infiltration correlates well with the severity of the clinical signs.

DIAGNOSTIC CONFIRMATION

Confirmation of the disease is based on the presence of a history and clinical signs consistent with the disease, in particular the response to stabilizing and pasturing, and demonstration of reversible airway obstruction. Objective confirmation can be achieved by measuring the response of maximal changes in pleural pressure in response to bronchodilator drug (atropine or glycopyrrolate) administration.

DIFFERENTIAL DIAGNOSIS

Horses with respiratory distress may have the following conditions:
- Interstitial pneumonia
- Heart failure
- Bacterial pneumonia
- Pleuritis
- Pulmonary or mediastinal neoplasia, including leiomyosarcoma

</table>

daily) is as effective as dexamethasone in alcohol in control of exacerbations of RAO, although it does cause hypokalemia. Triamcinolone (0.09 mg/kg, intramuscularly) administered once provides long-term (weeks) relief of signs in some horses. **Inhaled corticosteroids**, such as beta-methasone, beclomethasone, or fluticasone, are useful in controlling the disease. Both inhaled and parenterally administered corticosteroids suppress adrenal function of horses but 500 µg of beclomethasone propionate inhaled twice daily effectively alleviated signs of RAO and causes less adrenal suppression than doses of 1000 µg or 1500 µg. Inhaled administration of fluticasone suppressed serum cortisol concentrations of horses for 8 to 24 hours after administration, and this effect persists with continued administration over 1 year. The clinical importance of this long-term suppression is unclear, although it does not impair innate or acquired immunity, and adverse clinical signs are not detected. It is important to reiterate that the use of glucocorticoids should only be as an adjunct to control of the horse’s environment and reduction in the inhaled particle burden. **Clenbuterol** decreases the production of inflammatory cytokines by cells obtained from bronchoalveolar lavage fluid of horses with RAO, suggesting that clenbuterol can have antiinflammatory effects in such horses. The clinical applicability of this finding remains to be determined.

In summary, a number of different corticosteroid preparations are useful in the control of RAO. Drugs administered by inhalation appear to have a reduced
potential for adverse effects including adrenal suppression, but they are more difficult to administer and require more frequent administration than drugs administered orally, intravenously, or intramuscularly. Improvements in respiratory effort and clinical signs are evident in approximately 3 days and persist for the duration of treatment. Cell counts and the neutrophilia in bronchoalveolar lavage fluid are not reliably reduced by administration of corticosteroids. Affected horses, after institution of appropriate measures to control inhalation of hay and barn dust, should be treated with the lowest dose that controls the disease and only for as long as necessary. The dose of corticosteroid can be reduced gradually and the frequency of administration decreased from once daily to once every second or third day (or greater, depending on the preparation) to achieve this end. Administration of the lowest effective dose is important because of the effects of corticosteroids in suppressing immune and adrenal function. It is suggested that dexamethasone and triamcinolone increase the likelihood of horses developing laminitis, but this relationship has not been conclusively demonstrated.

Bronchodilator Drugs

Bronchodilator drugs might be needed to provide acute relief of airway obstruction but should not be used as maintenance therapy. **Atropine** (0.02–0.04 mg/kg, intramuscularly) can be used to provide short-term relief of bronchoconstriction, but its use is associated with gastrointestinal side effects, including colic, that preclude its long-term use. Use of **butylscopolammonium bromide** causes fewer adverse effects than does atropine. **Glycopyrrlate** (0.005 mg/kg intramuscularly every 8–12 hours) is a potent bronchodilator with minimal gastrointestinal effects. **Ipratropium bromide**, a parasympatholytic drug with minimal extra-pulmonary effects when given by inhalation, is very effective in relieving airway obstruction in severely affected horses. Similarly, **revatropine** (1 mg, inhaled), a selective M-1 and M-3 muscarinic antagonist, is as effective as ipratropium (0.3 mg) in relieving clinical signs and improving lung function in horses with RAO.

**β₂-adrenergic agonists** are potent bronchodilators frequently used in the management of horses with RAO. They can be administered orally or by inhalation, with the latter being preferred. **Clenbuterol hydrochloride** is used as maintenance therapy at a dose of 0.8 to 3.2 μg/kg, orally every 12 hours, and is effective in controlling signs in 75% of affected horses. The lower dose should be used initially and then increased in 0.8-μg/kg increments until the desired effect is achieved or side effects of tachycardia, muscle fasciculation, and sweating are apparent. Gradual, incremental increases in dose lessen the frequency and severity of side effects. **Terbutaline** is not absorbed after oral administration to horses. Terbutaline and clenbuterol can also be given intravenously, at a dose one-tenth of that given orally, to severely affected horses in which the need for bronchodilation is urgent. Adverse effects of **β₂-agonist administration** include tachycardia, sweating, and apprehension. Prolonged administration of clenbuterol is associated with potentially adverse effects on cardiac structure, alterations in body composition, and an impaired response to training. Delayed par-turition may occur in mares treated in late pregnancy. **β₂-Adrenergic agonists** may transiently exacerbate hypoxemia in severely affected horses. Intraotracheal administration does not produce detectable bronchodilation.

Bronchodilators administered by inhalation to horses include the **β₂-agonists albuterol, salbutamol, and salmeterol**, and the parasympatholytic ipratropium. The efficacy and duration of action of each of these drugs varies somewhat, but all are effective in producing bronchodilation in affected horses. Salmeterol produces bronchodilation in horses with RAO that persists for up to 6 hours, although onset of action requires 30 to 60 minutes. Similarly, ipratropium reduces pleural pressure changes and attenuates clinical signs of airway obstruction in horses with RAO. Efficacy of drugs is influenced by the mode of delivery, with handheld devices available for the delivery of some compounds.

**Theophylline** (aminophylline) is a non-adrenergic bronchodilator given at a dose of 5–10 mg/kg PO every 8–12 hours. Signs of toxicity include tachycardia, excitement, and convulsions. Theophylline is not a drug of first choice for the treatment of RAO and is now used infrequently because of the availability of efficacious antiinflammatory drugs and other bronchodilators.

**Other Drugs**

**Sodium cromoglicate** is useful for the prophylaxis of RAO, but it has no direct bronchodi-latory activity. Its mechanism of action is unclear, but it may act to prevent the degranulation of mast cells. It can be given at a dose of 80 to 200 mg per 425-kg horse by inhalation once daily for 4 days and then repeated in 1 to 2 weeks.

**Pentoxifylline** at high doses improves respiratory function, but not bronchoalveolar lavage fluid cytology, of horses with RAO. However, bioavailability after oral administration is quite variable, contributing to variations in the responses of horses to the drug.

Drugs that reduce leukotriene production or activity do not appear to be useful in the treatment of RAO. An experimental leukotriene D4 receptor antagonist was not effective in relieving signs of RAO. Similarly, montelukast did not improve respiratory function in 3 horses with RAO.

**Mucolytics** are often used but their efficacy is not established and is doubtful. **Cough suppressants** should not be used because they may impair clearance of muco-purulent material from the airways.

**Antibiotics** are often given to affected horses but are probably not necessary in the vast majority of cases.

**Acupuncture** is not effective in the treatment of RAO.

Administration of large quantities of **isotonic electrolyte solution** intravenously is associated with a decrement in respiratory function in both normal and heavy horses and is not recommended as a treatment for RAO.

An acoustic device ("sound therapy") did not improve clinical signs or lung function in horses with RAO.

**Integrated Therapy**

Initial treatment of affected horses usually involves changes to the horse’s environment and feed in combination with administration of corticosteroids. Corticosteroids and β₂-adrenergic agonists can be given as combined therapy to severely affected horses until the disease is controlled, at which time therapy should consist of environmental control and, if needed, administration of the lowest effective dose of corticosteroids. Bronchodilators are sometimes used as sole therapy, but their use without correction of the housing and feeding factors, and attempts to control inflammation, is not rational. Long-term administration of bronchodilators is not optimal therapy and, given the documented adverse effects, is not recommended. Long-term control of RAO is achieved by environmental management and administration of corticosteroids.

**CONTROL**

Control of RAO centers upon minimizing the exposure of horses to inciting agents. These agents are present in air of stables and barns and, when present in sufficient concentration or combination, induce the disease in susceptible horses. There is considerable evidence supporting the practice of minimizing inhalation by horses of poor-quality air in the control of RAO.

Housing horses in stalls with good air quality is essential in reducing the occurrence of the disease. **Adequate ventilation** is critical in maintaining good air quality in stalls. Few horse housing units have adequate ventilation although a well-designed individual box stall can meet the needs of the horse both for air hygiene and thermal comfort. Many horse barns have inadequate open space for ventilation in still air conditions when the doors are closed at both ends of the building. When the release rate of spores is low, ventilation rates of 4 air changes per hour are satisfactory.
However, suggested minima are 8 to 10 air changes per hour, airspace of 44 m head, and floor space of 9.2 m head. In practical terms, if the upper half of the stable door is open, and faces open air and not into a barn, the natural ventilation should exceed the minimum specifications. Hay and dusty feed materials should not be stored above stalls or in the same airspace as horses. Bedding should be changed frequently, preferably daily. Use of cardboard as bedding material is effective as part of an overall regimen to improve air quality.

A portable slit sampler is an accurate, quick, and simple semiquantitative method of assessing the mold contamination of source materials such as hay, straw, and other feeds and bedding collected from stables. Newer technology, such as real-time continuous particle monitors, is useful in evaluating the effects of interventions to reduce airborne dust concentrations in the breathing zone of horses.  

Real-time continuous monitoring also provides information on peak particle counts, which might be more closely related to disease severity than average counts.

The greatest contributor to airborne dust concentrations in stables is hay with straw bedding being an important other source.

Dust and presence of molds in hay can be reduced by use of agricultural practices during hay making including early harvest, adequate drying (and lack of rain), and preparation as haylage. The health hazard posed by any moldy source material depends on the types of organisms present and their abundance. The size of the respirable challenge from heated hays and straw arises from the proliferation of the species involved and their small spore size. The highest respirable challenges are from the presence of thermotolerant and thermophilic mold species. The most critical factors in determining the microbial development in plant-based materials are water content and thermal environment. Hay baled at 15% to 20% moisture heats to temperatures of up to 35° to 45° (95 to 113°F). At these temperatures, hazardous contamination may develop with the appearance of thermotolerant fungi and actinomycetes. The heaviest contamination of hay and straw occurs with baling at 35% to 50% moisture, when spontaneous heating up to 50° to 60°C (122 to 140°F) may occur. Microscopically, these hays show large numbers of fungal spores in the 2- to 5-μm size range.

Dust particle concentrations in the breathing zone can be reduced by feeding of soaked hay.

**PASTURE-ASSOCIATED HEAVES (PASTURE-ASSOCIATED RECURRENT AIRWAY OBSTRUCTION OF HORSES)**

Summer pasture-associated heaves occurs in horses in the southeastern region of the United States and in Great Britain. It appears to be a disease of adult horses that are on pasture most of the time in the summer. It occurs most commonly in the warm, humid summer months of June to September. A affected horses gradually recover during the cooler months of winter and early spring, and the disease can recur in the same horse each successive summer. Most severe signs occurred during late spring and early summer during times of high airborne pollen counts. Allergy to pollens and fungal spores appears to be a factor and is associated with conditions conducive to production of fungal spores and grass pollens. Affected horses have increased expression of interleukin-4 and interferon-γ in cells of bronchoalveolar lavage fluid and peripheral blood mononuclear cells but not increased concentrations of IgE in bronchoalveolar lavage fluid. Endothelin concentrations are higher in the BALF and serum of affected than unaffected horses.

Affected horses have clinical findings typical of heaves including nasal discharge, coughing, tachypnea, labored expiratory effort, and crackles and wheezes on auscultation. There is moderate-to-severe accumulation of mucus in the large airways evident on endoscopic examination. Lung function testing is consistent with bronchoconstriction. Bronchoalveolar lavage fluid contains large numbers of nondegenerate neutrophils and lesser numbers of lymphocytes and mast cells. Necropsy reveals overinflated lungs that do not collapse when the chest is opened and that retain the impressions made by the ribs. The predominant histologic finding is accumulation of mucus in small airways. Inflammation is not severe and most inflammatory cells present are neutrophils and lymphocytes in peribronchial tissues. Treatment includes stabilizing and administration of corticosteroids and bronchodilators, as discussed for recurrent airway obstruction (see Table 12-13).

Synchronous diaphragmatic flutter in horses (thumps)

Synchronous diaphragmatic flutter in horses is caused by an abrupt and powerful contraction of the diaphragm synchronous with the heartbeat. Contraction of the diaphragm occurs because of stimulation of the phrenic nerve as it passes over the atria of the heart. Thumps is often associated with electrolyte or acid-base abnormalities in horses. The disease occurs commonly in horses used for strenuous exercise, and in particular horses used for endurance racing, in which approximately 10% of horses eliminated from competition have thumps.1 The disease occurs in Standardbred and Thoroughbred racehorses, and individual animals can be affected repeatedly. This disease also occurs sporadically in adult horses and ponies that have not exercised, and peripartum mares (as part of lactation tetany).

The syndrome is characterized by a violent hiccup occurring synchronously with every heartbeat. The lateral aspect of the thorax and cranial abdomen appear to jump or “thump” regularly in affected horses. It is often unilateral, with the contraction being felt very much more strongly on one side than the other. The horse is distressed because the hiccough interferes with eating, and to an extent with respiration. In some cases, there are additional signs suggestive of hypocalcemia. These include muscular rigidity and fasciculation, and a high-stepping gait. There is often hypocalcemia, hemococoncentration, alkalosis or mixed acid-base abnormalities, and hypokalemia, hypochloremia, and elevation of creatinine phosphokinase levels in affected horses. Hypocalcemia can be profound. The disease is reported as a consequence of hypocalcemia secondary to primary hypoparathyroidism in two Thoroughbred horses.

The principles of treatment are correction of abnormalities in blood electrolyte concentration, acid-base status, and hydration. Treatment with calcium borogluconate administered slowly intravenously rapidly resolves the condition in some horses that do not have severe abnormalities of electrolyte concentration or acid-base status. Horses might require administration of balanced isotonic polyionic electrolyte solutions intravenously (e.g., Ringer’s solution or 0.9% sodium chloride), and consideration should be given to supplementing these fluids with calcium (e.g., 50 mL of 23% calcium borogluconate per liter of fluid).

The pathogenesis is thought to be related to hyperirritability of the phrenic nerve caused by metabolic disturbances, including hypocalcemia, and the phrenic nerve being stimulated by each atrial depolarization to fire with each heartbeat. The stimulation occurs because of the close physical proximity of the heart to the nerve in the horse. Dietary supplementation with calcium and other electrolytes during a ride is recommended, but excessive calcium feeding beforehand may reduce the activity of calcium homeostatic mechanisms and is to be avoided.

Regular veterinary inspection of all horses at the mandatory stops of endurance rides will reveal those animals with “thumps,” and these horses should not be allowed to proceed in the event.

Rhodococcus equi pneumonia of foals

Sporadic disease of 1- to 5-month-old foals that is endemic on some farms. Foals are infected likely by inhalation during first weeks of life.

Clinical signs Pneumonia, fever, respiratory distress, cough, lack of nasal discharge, failure to thrive, multiple distended joints and uveitis. Occasionally diarrhoea or septic osteoartemias.

Clinical pathology Leukocytosis, hyperfibrinogenaemia, inflammatory cells in tracheal aspirate.

Necropsy lesions Pulmonary consolidation and abscessation. Nonseptic polyarthritis.

Diagnostic confirmation Culture or polymerase chain reaction (PCR) detection of R. equi from tracheal aspirate.

Treatment Administration of a macrolide in combination with rifampin, for example, azithromycin (10 mg/kg PO q24 h) and rifampin (5 mg/kg PO q12h or 10 mg/kg PO q24h).

Control Ensure adequate transfer of passive immunity. Decrease stocking density. Decrease environmental contamination by virulent strains of R. equi. Do not use mass medication of foals with subclinical disease.

Disease in foals caused by Rhodococcus equi is important because of its high incidence in valuable livestock, widespread distribution, insidious onset, high case-fatality rate in the more severely affected foals, cost of treatment, lack of a protective vaccine, and cost of implementation of control measures.

Etiology Rhodococcus equi (Rhodococcus hoagii/Prescottella equi) is a gram-positive, pleomorphic rod that is a soil-dwelling actinomycete.12 The most important manifestation of R. equi infection is pneumonia in foals. It also causes pleuropneumonia, pneumonia, osteomyelitis, and abortion in immunocompromised and normal adult horses; abscesses that must be differentiated from tuberculosis in pigs and ruminants; pneumonia in immunosuppressed humans; and lymph node infection in wild boar (Sus scrofa), red deer (Cervus elaphus), and roe deer (Capreolus capreolus).23 There is species tropism for ruminants, pigs, and horses, determined by host-adapted plasmids, whereas infection in humans appears to be zoonotic.2 The organism is a natural inhabitant of soil, grows well at temperatures ranging from 10° to 40°C, and is readily isolated from the feces of herbivores and their environment. However, isolates of R. equi vary in virulence, with many isolates obtained from feces or soil not being pathogenic. There are a large number of virulent strains of R. equi, based on pulsed-field gel electrophoresis of chromosomal DNA, and foals can be infected with multiple strains at the same time, with identical strains located in multiple sites in the body.4 Although there is evidence of clustering of strains on farms and on most farms one or two strains predominate, there is little evidence of marked regional variations in prevalence of strains of virulent R. equi. Only rarely will it be possible to link infections to a given site or region on the basis of analysis of chromosomal DNA.

Virulence of R. equi is dependent on the ability of the organism to enter, survive in, and replicate in macrophages. It is a facultative intracellular parasite of macrophages, in which it survives by virtue of virulence factors that act to prevent phagosome-lysosome fusion and bacterial death.2 Virulence is associated in part with the presence of highly immunogenic virulence associated proteins (Vap, coded by plasmid gene pVAP), of which pVAPA is apparently the most important, although the precise role of the other Vap proteins has not been determined. The presence of VapA is necessary but not sufficient for pathogenicity, which requires the presence of other virulence factors, including a number of microbial enzymes.2 Virulence plasmids can be lost by R. equi strains and reacquired by conjugation with virulent strains.5 Genomic analysis has identified additional virulence factors that are chromosomal rather than plasmid based.7 Vap A is a surface-expressed, lipid-modified protein that elicits an intense humoral response by foals. Expression of Vap A, C, D, and E is upregulated by incubation at 37°C (98.6°F), consistent with their role as virulence factors. Other genes probably involved in virulence are also upregulated by conditions that mimic those in vivo. The presence of the virulence proteins is associated with enhanced ability of virulent R. equi to survive and replicate within macrophages,
EPIDEMIOLOGY

Occurrence

*R. equi* pneumonia in foals has a worldwide distribution. Clinical disease is often sporadic but on farms where the disease is endemic, annual subclinical morbidity can be high (up to 92%) and can vary widely from year to year. The median percentage of foals that developed clinical disease caused by *R. equi* at farms on which the disease was endemic was 6.6%, with 38% of farms having more than 10% of foals affected. Increased use of ultrasonographic examination of the thorax of all foals on a farm demonstrates the subclinical disease can affect many, if not the vast majority, of foals on farms in which the disease is endemic. For example, of 444 foals born on one stud farm during a breeding season, 426 (92%) had lesions consistent with *R. equi* infection. Eighteen of the foals had lung lesions less than 1 cm (considered unaffected), 128 had lesion scores greater than 1 cm and less than 10 cm, and 280 had lesions greater than 10 cm. The detection of *R. equi* pneumonia in one foal on a farm should prompt an examination of all other foals on that farm.

Case-fatality rates for foals on farms, as opposed to those treated at veterinary teaching hospitals, are 29% to 42% (for 113 and 19 affected foals, respectively). The median case-fatality rate for 32 farms in Texas was 25%, and the case-fatality rate was more than 50% for 22% of farms. The case-fatality rate among foals treated at veterinary teaching hospitals is approximately 28%.

Current evidence supports the hypothesis that foals are exposed and infected within the first 2 weeks of life. The age at onset of clinical signs of disease associated with *R. equi* varies between 2 weeks and 6 months, but the peak prevalence for pneumonia disease is between 1 and 3 months. The disease is rare in adult horses. Risk factors in foals for development of *R. equi* pneumonia have not been determined, although a large number of factors have been examined. The month in which the foal was born, gestational age, dam’s parity, antimicrobial administration during the first week of life, exposure to pasture at less than 2 weeks of age, need for treatment to correct inadequate transfer of passive immunity, and size of mare/foal groups were not associated with risk of disease on farms in Texas.

The prevalence of virulent *R. equi* in isolates from the environment does not appear to be greater on farms where the disease is endemic. Morbidity varies widely among geographic areas and individual farms, probably because of environmental factors that affect the number of virulent *R. equi* and the ease of infection. Because aerosol infection by virulent *R. equi* in dust is thought to be the most important route of infection of foals, factors that favor the accumulation and persistence of *R. equi* in soil and its ability to become aerosolized most probably increase the risk of infection. Such factors might include the following:

- Hot and dry weather, favoring formation of dust
- Soil pH and moisture
- Crowding of pastures with young horses
- Poor pasture hygiene, allowing accumulation of feces
- Dusty pastures

However, empirical demonstration of the importance of these risk factors has not been reported, with several exceptions. Soil pH, salinity, and concentrations of various elements including iron, zinc, and copper are not associated with the risk of foals developing *R. equi* pneumonia on farms in Texas. These soil-associated risk factors were examined because *R. equi* is a normal inhabitant of the soil and of the intestine of ruminants, horses, and pigs. It is not highly resistant, but it has been found to survive in moist soil for periods of longer than 12 months. The infection is considered to be soil associated and to be maintained through a soil–horse cycle. The number of organisms in the soil and stable areas on horse farms increases with the time that the farms have housed horses, although there is not a strong correlation between *R. equi* concentration in soil and prevalence of pneumonia in foals.

Farms of larger size, with more resident mares, greater numbers of foals (≥15), and greater foal density per acre, and the presence of mares brought on to the farm for breeding, are all associated with greater risk of foals developing *R. equi* pneumonia. *R. equi* pneumonia does not appear to be associated with poor farm management or lack of preventative health practices such as vaccination, deworming, or administration of hyperimmune plasma. The practice of testing for failure of transfer of passive immunity is associated with an increased likelihood of the disease on a farm. However, this association probably reflects the facts that the disease is more likely on larger farms, which are more likely to perform this test, and that farms that have had the disease are more likely to institute preventive care procedures.

Transmission

Most foals are exposed to infection, as demonstrated by seroconversion or ultrasonographic examination of the thorax, but only a few develop severe disease, although many have subclinical infection and lesions. The organism colonizes the intestine of the normal foal during the first 2 months of life and has been detected in the feces as early as 5 days. Inhalation of the organism in dust is probably the most important route of transmission for pulmonary disease. Intestinal disease, which may be clinically apparent, usually occurs with pulmonary disease, but the source of the infection is unclear, although it may be ingestion of contaminated material or swallowing of infected respiratory secretions. Foals over 5 weeks of age have generally been resistant to experimental challenge.

Zoonotic Implications

*R. equi* is an occasional pathogen of humans. Infection is more common in immunocompromised people but is only infrequently associated with strains of *R. equi* that are virulent in foals.

PATHOGENESIS

Exposure of foals to *R. equi* is common, based on rate of seroconversion, yet the development of clinical disease is much less common, although subclinical disease on farms with endemic disease can be as high as 95% (426 of 444 foals born on one farm in one breeding season). The reason for this is not fully understood, although the development of the disease probably depends on exposure to an infectious dose of organism and the susceptibility of the foal. Foals subject to experimental challenge exposure are much more susceptible to infection, and by lower doses, during the first week of life. Higher doses are required to induce disease in 3-week and 6-week-old foals. Lower challenge doses are associated with milder and more slowly progressive disease and spontaneous resolution of infection. For spontaneous disease, exposure presumably occurs within the first few days of life, before waning of maternally derived passive immunity. Infection results in increases in serum concentration of VapA-specific IgG(T) in foals.

In adult horses, in which the disease is rare, protective immunity is associated with both cellular and humoral immune responses characterized by enhanced immunoproliferative responses of CD4 and CD8 cells and presence of IgGa and IgGb antibodies to Vap A. Opsonizing antibody to *R. equi* is an important defense mechanism in experimentally infected foals and administration of *R. equi* hyperimmune plasma or plasma rich in anti-Vap A and C antibodies protects experimentally infected foals from developing pneumonia. Overall, these results suggest that foals that develop *R. equi* pneumonia have a T-helper-cell (Th2)-like response to infection, rather than a Th1-like response. Th1-like responses, which are associated with enhanced CD4 and CD8 responses, are believed to be important in resistance to the disease. Whether the switch to a Th2-like response to infection is a function of virulent *R. equi* or an attribute of susceptible foals has not been determined.

Experimental and clinical studies indicate that the foal is infected several weeks or
months before clinical signs are observed. Virulent strains of *R. equi* are facultative intracellular parasites of macrophages, which they ultimately destroy. Neutrophils are bactericidal for *R. equi* but the organism can survive by inclusion in macrophages. Opsonization of *R. equi* by specific antibodies results in enhanced lysosome–phagosome fusion and greater killing of *R. equi* by equine macrophages and monocytes, whereas entry of *R. equi* into macrophages by nonimmune phagocytosis is not associated with enhanced killing. Its survival in the macrophage is associated with absence of phagosome–lysosome fusion. Nonvirulent strains do not proliferate in macrophages and monocytes. The combined action of humoral and cellular immune systems is important in preventing development of the disease after inhalation of bacteria. Without opsonization, the capacity of the pulmonary macrophage of foals to kill *R. equi* is impaired and the organism can persist in the pulmonary macrophage of infected foals. The inability of the pulmonary macrophages to destroy *R. equi* leads to persistent infection in the lung and a chronic bronchopneumonia with extensive abscessation and an associated suppurrative lymphadenitis.

**Intestinal infection** is common in foals with *R. equi* pneumonia, although clinical manifestations of the intestinal infection, such as diarrhea, are uncommon. Gastrointestinal tract infection is characterized by ulcerative lesions of the mucosa of the large intestine and cecum. In rare cases bacteremia and subsequent suppurrative foci may develop in many organs, including bones and joints, liver, kidneys, and subcutis.

**CLINICAL FINDINGS**

The most common manifestation of the disease is subclinical infection and pulmonary abscessation detected by ultrasonographic examination of the thorax of apparently healthy foals.6,12

**R. equi** pneumonia

*R. equi* pneumonia of foals presents as an acute onset of inappetence, fever, depression, and tachypnea or as a more chronic disease characterized by cough and failure to thrive. Apparent acute onset of the clinical disease is preceded by a long incubation period during which clinical signs are minimal. Severe clinical disease is evident as respiratory distress, and the foal is reluctant to move and to suckle. Cyanosis can be present in severe cases. Auscultation of the chest can reveal crackles and wheezes, but abnormal lung sounds are often much less apparent than the severity of the respiratory disease suggests they should be. Foals with *R. equi* abscesses often do not have abnormal lung sounds, and there is usually minimal nasal discharge. It must be emphasized that the classical severe disease represents one end of the spectrum of consequences of infection of foals by *R. equi*, and much more common is subclinical disease that resolves spontaneously and without treatment. However, clinical disease is important because it is these foals that are at risk of death and that require prolonged treatment.

**Ultrasonographic examination** of the chest reveals the presence of pulmonary consolidation before clinical signs are apparent and is a useful means of detecting subclinical disease and triaging foals for treatment. **Radiographic examination** of affected animals shows evidence of consolidation of lung tissue, lymphadenopathy, and cavitating lesions in the lungs. Odds of survival are inversely related to severity of alveolar pattern and presence and number of cavitated lesions evident on thoracic radiographs.13 Ultrasonographic examination of foals is more sensitive for detection of lesions than is radiographic examination, with radiography enabling detection of lesions in 20 of 42 affected foals in which disease was confirmed by ultrasonographic examination.14

**Extrapulmonary manifestations of R. equi infection**

Extrapulmonary manifestations of *R. equi* pneumonia are common in foals, and many are associated with an increased chance of death (Table 12-14).15 Of 150 foals with *R. equi* pneumonia examined at a referral hospital, 111 (74%) had at least one extrapulmonary manifestation of the disease detected ante or postmortem. Of foals examined postmortem, 76% had an extrapulmonary manifestation of the disease that was not detected, or detectable, antemortem. Common abnormalities include diarrhea (50% of foals), immune-mediated polyosynovitis (37%), ulcerative enterophtlolicitis (31%), intraabdominal abscesses (25%), and abdominal lymphadenitis (25%).15 *R. equi* infection of other structures includes septic synovitis, periortnis, bacteremia, subcutaneous abscesses, osteomyelitis of the axial skeleton, and vertebral body osteomyelitis, in addition to other sites. Noninfectious abnormalities include immune-mediated hemolytic anemia, uveitis, and hyperthermia.

**Intraabdominal** abscesses are associated with ill-thrift, weight loss, variable abdominal distension, fever, depression, and, in some cases, colic. Ultrasonographic examination can reveal the abscess.17

**PROGNOSIS**

The morbidity and case-fatality rates are provided under “Epidemiology.” Presence of an

</table>

One (1/150 [0.7%]) foal each had an antemortem diagnosis of the following: sinusitis, immune-mediated thrombocytopenia, hyperlipemia, telogen effluvium, granulomatous dermatitis, myositis, lymphoid hyperplasia, onophrosis, bone marrow erythroid hypoplasia, seizures, and right ventricular double apex secondary to pulmonary hypertension. One (1/150 [0.7%]) foal each had a postmortem diagnosis of the following: pyometra, pyogranulomatous stonatitis, pyogranulomatous splenitis, pneumothorax, valvular endocarditis, and myelophthisis.
extrapulmonary manifestation of *R. equi* infection is associated with a case-fatality rate of 57% compared with 18% in foals with only *R. equi* pneumonia. A larger number of extrapulmonary manifestation was associated with an increased chance of death. Presence of uveitis, septic synovitis (but not immune-mediated polysynovitis), abdominal lymphadenitis and intraabdominal abscessation, pleural effusion, *R. equi* bacteremia and pyogranulomatous hepatitis were all independently associated with increased risk of death.

*R. equi* infection in Thoroughbred and Standardbred foals is associated with a reduced chance of racing as an adult compared with the overall population of foals, but affected foals that survive have a similar racing performance as adults to horses that did not have *R. equi* pneumonia.

**CLINICAL PATHOLOGY**

Hematologic evaluation usually reveals leukocytosis with neutrophilia and monocytosis, and elevation in the concentrations of acute-phase proteins, including plasma fibrinogen and serum amyloid A—changes characteristic, but not diagnostic, of *R. equi* infection. Monitoring of blood white cell concentration and plasma fibrinogen concentration is useful in foals from farms on which the disease is endemic. **White blood cell concentrations** above 13.0 × 10/L (13,000 cells/µL) have a sensitivity and specificity of 95% and 61%, respectively, for *R. equi* pneumonia. The high sensitivity means that few foals with the disease will be missed, whereas the moderate specificity means that a number of foals will be incorrectly suspected as having the disease. Because a high white cell count can be caused by a number of diseases other than *R. equi* pneumonia, foals with high white cell counts from farms on which the disease is endemic should be further examined for evidence of disease, including detailed clinical examination possibly including ultrasonographic examination, culture or PCR of tracheal aspirates, or thoracic radiography. Measurement of **plasma fibrinogen concentration** is less useful for detecting foals with *R. equi* pneumonia. Plasma fibrinogen concentrations of 400 mg/dL (0.4 g/L) have sensitivity and specificity of 91% and 51%, respectively, whereas concentrations of 600 mg/dL (0.6 g/L) have sensitivity and specificity of 38% and 96%, respectively. The positive and negative predictive values of the tests depend on the prevalence of the disease among the group of foals examined, being low for farms on which the disease is rare and increasing as the prevalence of the disease increases.

Serial measurement of **serum amyloid A** concentrations is not useful for detecting foals with clinically inapparent *R. equi* pneumonia, nor do foals with pneumonia reliably have higher serum amyloid A concentrations than normal foals.

Differentiation of pneumonia caused by *R. equi* from that caused by other infectious causes in foals can be challenging. Using microbiological culture as the "gold standard," identification of gram-positive coccobacilli in tracheal aspirates was highly specific (91%) but poorly sensitive (35%) for *R. equi* infection. White cell counts greater than 20,000 cells/µL (86% specificity), fibrinogen concentrations greater than 700 mg/dL (92% specificity), radiologic evidence of thoracic abscessation (85% specificity), and the presence of gram-positive coccobacilli in tracheal aspirates (91% specificity) in monomorphic pneumonia foals are highly suggestive of *R. equi* infection.

**Transtracheal aspirates** from affected foals reveal a neutrophilic leukocytosis. Intracellular, gram-positive pleomorphic rods characteristic of *R. equi* may be present in tracheal aspirates, but the sensitivity of this observation has not been determined, and all transtracheal aspirates should be cultured.

Although numerous **serologic tests** have been developed, including agar gel immunodiffusion, synergistic hemolysis inhibition, radial immunodiffusion, and various ELISAs, none has demonstrated value in the diagnosis of the disease in individual animals. Currently available serologic tests, either as single or paired samples, are not reliable in confirming or excluding the presence of *R. equi* pneumonia in foals.

Culture of tracheal aspirates is the gold standard for antemortem diagnosis of the disease, although sensitivity of culture is less than that of PCR examination of tracheal aspirates. Culture of tracheal aspirates has a sensitivity of approximately 86%, based on diagnosis of *R. equi* pneumonia at necropsy. A PCR test for the rapid detection of *R. equi* in tracheal aspirates has a sensitivity of 100% and a specificity of 91% in foals with a clinical diagnosis of *R. equi* pneumonia. PCR examination of nasal swabs for presence of *R. equi* has a sensitivity of 15%, which is too low to be clinically useful. More recent quantitative real-time PCR assays permit the rapid detection and quantification of virulent (VapA-gene-positive) strains of *R. equi* in tracheobronchial aspirates. This assay detects *R. equi* at concentrations as low as 20 cfu/mL of tracheobronchial fluid, providing a specific and highly sensitive test for the presence of this organism. A **multiplex PCR test** simultaneously detects *R. equi* and the presence of virulence factors, thereby permitting rapid differentiation of pathogenic from nonpathogenic strains of *R. equi* in biological samples.

Collection and culturing of breath from foals is not useful in diagnosing *R. equi* pneumonia or in predicting onset of the disease.

**Necropsy Findings**

The predominant lesions are a pyogranulomatous pneumonia plus lymphadenitis of the bronchial lymph nodes. Grossly, the firm, raised lung nodules may reach several centimeters in diameter and can be located anywhere in the lung field, especially in the cranioventral quadrant. If several nodules coalesce, the lesion may be misinterpreted as a suppurative bronchopneumonia. Histologically, organisms are easily demonstrated within the macrophages and giant cells comprising these lesions. Many cases also have ulcerative enterocolitis, with abscessation of mesenteric or cecocolic lymph nodes. Although necropsy may reveal widespread infection, many cases are subclinical.

**Samples for Postmortem Confirmation of Diagnosis**

- **Bacteriology**—chilled lung, affected lymph nodes, and swabs from atypical sites (CULT)
- **Histology**—formalin-fixed lung, lymph node, and colonic lesions

**DIAGNOSTIC CONFIRMATION**

Antemortem diagnosis is by culture of *R. equi* from aspirates of tracheal fluid. Currently available serologic tests do not provide confirmation of disease in individual animals.

**Differential Diagnosis**

The pneumonic form of the disease may be confused with other causes of pneumonia in foals (Table 12-15). Other causes of diarrhea in this age group include parasitism as a result of cyathostomes, infection by *Salmonella* sp., and antibiotic-induced diarrhea.

The aseptic synovitis and joint effusion that frequently accompanies *R. equi* pneumonia should be differentiated from septic arthritis as a result of *S. zooepidemicus*, *Salmonella* spp., *R. equi*, or other bacteria.

**Treatment**

The principles of treatment are cure of *R. equi* infection, relief of respiratory distress, and correction of associated immune-mediated diseases.

Elimination of infection requires the administration of antimicrobial agents that are both effective against the organism and able to penetrate infected macrophages to gain access to the organism. Customary **in vitro antibiotic sensitivity testing**, using Kirby-Bauer or dilution methodology, has not been demonstrated to be useful in predicting the clinical efficacy of treatment, and **ex vivo** testing of antimicrobial efficacy using macrophage culture systems more closely predicts in vivo efficacy. *R. equi* isolates from ill foals are frequently sensitive in vitro to a variety of antibiotics, including the aminoglycosides gentamicin and neomycin, tetracycline, sulfonamides, and chloramphenicol, whereas most are resistant to cephalosporins and penicillin. However,
treatment with antibiotics other than a macrolide (erythromycin, azithromycin, clarithromycin, gamithromycin) and rifampin is associated with a lower recovery rate. Treatment with penicillin, with or without gentamicin, chloramphenicol, or tetracycline, is not effective. Trimethoprim–sulfadiazine combinations might be effective in some foals but are not the preferred treatment. Neomycin has been recommended for treatment of R. equi pneumonia, but the risk of nephrotoxicosis, need for parenteral administration, and lack of demonstration of clinical efficacy do not support its use at this time.

The treatment of R. equi pneumonia in foals is achieved by administration of macrolide antibiotics in combination with rifampin. Conventional treatment is administration of the combination of an acid-stable erythromycin (preferably estolate) at a dose of 25 mg/kg orally every 12 hours and rifampin at a dose of either 5 mg/kg every 12 hours or 10 mg/kg every 24 hours. Other esters or preparations of erythromycin are less well absorbed or have shorter elimination half-lives than the estolate ester and must be administered more frequently. Erythromycin ethylsuccinate does not require administration of analgesics in 45% of foals with lesions detected by ultrasonographic examination in 95% of foals with R. equi pneumonia. Treatment of foals with a combination of clarithromycin (7.5 mg/kg orally every 12 hours) and rifampin results in improved survival over foals treated with azithromycin (10 mg/kg orally q24h) and rifampin or erythromycin and rifampin in a veterinary teaching hospital. Azithromycin is typically administered with rifampin at a dose rate of 10 mg/kg q24h for every 24 hours for 5 to 7 days and then once every 48 hours. Gamithromycin (6 mg/kg intramuscularly [IM] or intravenously [IV] once every 7 days, with or without administration of rifampin) is currently not recommended for routine use pending results of studies demonstrating its equivalence to or superiority over other treatments. Administration of gamithromycin (6 mg/kg IM or IV once every 7 days, with foals administered IV gamithromycin also administered rifampin) was associated with resolution of lesions detected by ultrasonographic examination in 95% of foals with R. equi pneumonia. IM was associated with marked lameness in 35% of foals and colic that required administration of analgesics in 45% of foals. Tulathromycin was not as effective as the combination of azithromycin–rifampin in treatment of R. equi abscesses in foals in a large prospective field study. Tilimicosin is poorly active against R. equi.

Ultrasoundography examination of the thorax of foals may permit identification of
foals with clinically inapparent pulmonary abscesses, providing the opportunity for early intervention in the disease. However, many (~90%) lesions less than 10 cm in diameter will resolve without treatment, and treatment with antimicrobials confers no clear benefit over watchful waiting (Fig. 12-30). Another study demonstrated resolution of lesions in 44% of foals with lesions greater than 1.0 cm administered a placebo—a resolution rate not statistically different from that in foals administered tetracycline (IM), azithromycin alone, or azithromycin and rifampin.

It is unclear if there is an advantage to combined therapy of rifampin and a macrolide compared with treatment with a macrolide alone. The current recommendation is to use the combination of drugs.

Gallium maltolate has been investigated for treatment of foals with R. equi pneumonia. The pharmacokinetics in foals have been determined, and it appears to be safe for administration to foals and was not inferior to administration of clarithromycin and rifampin in treatment of foals with pulmonary lesions consistent with R. equi infection. However, the study did not include an untreated or placebo treated group, and given the high rate of spontaneous resolution of lesions without treatment in such foals, it cannot be concluded that either treatment was superior to no treatment.

Therapy should be continued until the foal is clinically normal and has a normal plasma fibrinogen concentration and white blood cell count, which can require treatment for at least 1 month and often longer. Radiographic or ultrasonographic demonstration of resolution of the pulmonary consolidation and abscessation is useful in the decision to stop therapy. The case-fatality rate is approximately 30% (see “Epidemiology”) even with appropriate treatment.

Adverse effects of macrolide–rifampin therapy include the development of diarrhea in some foals and their dams. Administration of erythromycin to foals is associated with an eightfold increase in the risk of diarrhea. Antibiotic therapy should be temporarily discontinued in foals that develop diarrhea.

During hot weather, some foals treated with erythromycin become hyperthermic (40–41°C [104–105.5°F]) and tachypneic, and occasional deaths result from this syndrome. The basis for this hyperthermic event, which may occur in healthy foals administered erythromycin, is unknown. Affected foals should be treated urgently with antipyretics, cold water bathing, and housing in a cooler environment.

The emergence of R. equi isolates resistant to rifampin and one or more macrolides has been documented and underscores the need for monitoring of R. equi sensitivity to these antimicrobials. Case-fatality rate is higher (75%) in foals with R. equi resistant to one or more of rifampin and a macrolide compared with that in foals infected with susceptible bacteria (30%). The development of resistance during monotherapy with rifampin is a recognized contraindication to the use of this drug alone.

Ancillary therapy with NSAIDs, bronchodilators, and mucolytics might be of value. Foals in severe respiratory distress require intranasal or intratracheal administration of oxygen.

CONTROL

Control measures are designed to maximize the resistance of the foal to infection and to reduce the infection pressure on the foal by decreasing contamination of the foal’s environment with virulent R. equi. Ensuring adequate transfer of colostral immunoglobulins in all foals through routine monitoring of serum immunoglobulin concentrations in 1-day-old foals is an essential part of any control program. To decrease environmental contamination with virulent R. equi, efforts should be made to reduce fecal contamination of pastures and to reduce or eliminate dusty or sandy areas. These efforts should include grazing or paving of bare areas, removal and composting of fecal material on a regular basis, reduction of stocking density, and reduction in the size of mare/foal bands.

On farms with endemic disease, regular physical examination, including ultrasonographic examination of the thorax of foals and once-daily monitoring of rectal temperature, can permit early identification of affected foals. These foals can then be monitored for resolution or progression of the disease, with animals in the latter group administered antimicrobials. Comments noted earlier about the effectiveness of mass medication of all foals with lung lesions should be noted. Measurement of blood white cell count, as detailed previously, can be useful in early identification of affected foals. Identification of one foal affected with R. equi pneumonia on a farm should prompt an examination of all other foals on the farm.

The administration to foals of a hyperimmune serum, obtained from mares vaccinated with an autogenous vaccine, limits the severity of disease produced by experimental challenge but has not been consistently useful in preventing or decreasing the prevalence of naturally occurring disease. This unpredictable efficacy could be attributable to variable concentrations of R. equi Vap-A IgG in batches of plasma.

There are no vaccines effective in prevention of R. equi pneumonia in foals.

FURTHER READING

REFERENCES

S. zooepidemicus is frequently isolated from horses with pleuropneumonia, endomtritis, neonatal septicemia, abortion, and mastitis, suggesting a role for this organism in the pathogenesis of these diseases. S. zooepidemicus is likely important in the development of respiratory disease in foals and adult horses. S. zooepidemicus was isolated from 88% of foals with clinical evidence of lower respiratory tract disease, and isolation of the organism was associated with an increased proportion of neutrophils in bronchoalveolar lavage fluid, suggesting a causal role for this organism. Similarly, the number of S. zooepidemicus isolated from tracheal aspirates of adult horses is directly proportional to the number of neutrophils in the aspirate and the probability that they have a cough. The association of S. zooepidemicus and inflammatory airway disease in racehorses is independent of previous viral infection, suggesting a role for S. zooepidemicus as a primary pathogen. Presence and number of colony forming units (cfu) of S. zooepidemicus in tracheal aspirates of horses is significantly associated with the risk of the horse having inflammatory airway disease. Adult horses dying of pneumonia associated with transportation often yield S. zooepidemicus on culture of lung lesions, and the disease can be reproduced experimentally. S. zooepidemicus with Chlamyphila caviae causes conjunctivitis and rhinitis in adult horses. These results clearly demonstrate a role for S. zooepidemicus in the pathogenesis of respiratory disease of horses. However, it is unclear whether S. zooepidemicus is a primary cause of disease, a secondary contaminant, or an invader of airways compromised by viral infection or other agents.

Clinical signs of S. zooepidemicus infection of the lower respiratory tract of foals and horses include coughing, mild fever, mucopurulent nasal discharge, and increased respiratory rate. Endoscopic examination of the trachea and bronchi reveals erythema and presence of mucopurulent exudate. Tracheal aspirates or bronchoalveolar lavage fluid of affected horses or foals have an increased (>10%) proportion of neutrophils. S. zooepidemicus is a frequent isolate from the cornea of horses with ulcerative keratitis.

Treatment consists of the administration of antimicrobials, including penicillin (procaine penicillin, 20,000 IU/kg IM every 12 hours) or the combination of a sulfonamide and trimethoprim (15-30 mg/kg orally every 12 hours). S. zooepidemicus isolates from horses in southern England demonstrate increasing resistance to tetracycline but not the combination of trimethoprim and sulfanamides (TMS). Most S. zooepidemicus isolates (70%) are resistant to gentamicin, whereas 95% are sensitive to penicillin and 55% sensitive to TMS. Forty-five percent of isolates are resistant to enrofloxacin—a recent phenomenon. Different sensitivity patterns are reported for S. zooepidemicus isolates from Western Canada, although the high proportion of isolates sensitive to penicillin (95%) and cefotiofur (99%) is consistent with that in England. A higher proportion of Canadian isolates are sensitive to gentamicin (85%) or enrofloxacin (91%).

Control consists of isolation to prevent spread of infectious respiratory disease and vaccination to prevent viral respiratory disease.

ETIOLOGY

Streptococcus equi subsp. equi (S. equi) is a gram-positive coccobacillus that produces a beta-hemolysin, evident as a zone of clear hemolysis surrounding colonies growing on blood agar. There is evidence that S. equi is a biovar or genovar of S. zooepidemicus. S. equi is highly host-adapted to Equidae. Genetic analysis, particularly of the variable region of the SeM gene, demonstrates the existence of clones that vary geographically.4,5 For instance, 21 SeM alleles were detected among 145 S. equi strains isolated in the United Kingdom,4 and two SeM alleles detected in horses in New Zealand had distinct geographic distributions.5 Similar analysis reveals the presence of two major S. equi clades in Ireland, with both being also common in the United Kingdom.4 Individual outbreaks can be caused by S. equi of the same SeM type and be restricted geographically or by use of horse.6 Analysis of SeM mutations in real time allows differentiation or linkage of strangles outbreaks and enables risk assessment of equestrian events where there is incursion of the disease. It is unclear whether changes in the SeM protein associated with these strains are associated with differing pathogenicity.7 There is variation in virulence related to the amount of M protein and hyaluronic capsule produced. An atypical milder form of the disease is associated with a capsule-deficient variant of S. equi, and an intranasal vaccine is based on a live, attenuated, nonencapsulated SeM-2 strain, although this strain can cause disease.7

EPIDEMIOLOGY

Occurrence

Strangles occurs in horses, ponies, donkeys, and mules worldwide, with the exception of Iceland. Outbreaks are seen relatively frequently on breeding farms and in polo and racing stables, when the infection is introduced by new arrivals that are often asymptomatically infected, and in horses taken to fairs and riding schools. An incidence of 35% over a 3-year period is reported for horse studs in Australia, and there were approximately 600 recorded outbreaks in the United Kingdom in 2010.7

Strangles can affect horses of any age, although the morbidity rate is generally lower in younger horses such as foals and weanlings. Age-specific attack rates of strangles of 18% for brood mares, 48% for 1-year-old horses, and 38% for foals during an outbreak on a breeding farm are reported, although higher morbidity rates (100%) can occur, especially in young horses. The risk of occurrence of an outbreak of strangles increases with the size of the group of horses; farms with 100 or more horses have a 26 times greater risk of experiencing an outbreak than farms with fewer than 15 horses.

The case-fatality rate without treatment is about 9%, but with adequate early treatment it may be as low as 1% to 2%. Deaths are usually attributable to pneumonia.

Source of Infection and Transmission

S. equi is an obligate parasite of horses and all infections are attributable to transmission from infected horses, either directly or by fomites. Nasal and abscess discharge from infected animals that contaminates pasture, tack, stalls, feed and water troughs, grooming equipment, and hands and clothes of grooms and veterinarians is often the source of infection for susceptible horses. S. equi survives in the environment for less than 3 days, and although fomite transfer is important in transmission of infection, prolonged quarantine of facilities is not warranted.8 Direct transmission from infected animals to susceptible animals occurs through contact. Approximately 10% to 40% of horses that recover from the clinical disease have persistent infection of S. equi in the pharynx and guttural pouches for many months and are an important source of infection. Horses with clinically inapparent disease, such as some cases of guttural pouch empyema, can shed the organism for over 3 years. The period of infectivity is important in terms of the length of quarantine that needs to be imposed on horses that have apparently recovered from the disease. Because nasal shedding of S. equi can be intermittent, repeated culture of nasopharyngeal swabs or use of PCR examination of guttural pouch washings is necessary to document the carrier status of individual horses.

The clinically inapparent nature of the infection makes detection of carriers problematic, especially when considering introduction of horses into a previously closed herd in which strangles is not endemic. Endoscopic or radiographic examination of clinically inapparent shedders can demonstrate lesions in the guttural pouches, parasanal sinuses, or pharynx, but because some persistent carriers of S. equi do not have detectable abnormalities of the nasopharynx, the most reliable approach to detecting carriers is PCR examination of nasal swabs or guttural pouch lavage fluid (see "Control").7

Animal Risk Factors

Strangles is more common in young or naive horses, although the disease can occur in horses of any age. Animals that have previously had the disease are less likely than naive animals to develop the disease on subsequent exposure. A proportion (approximately 25%) of horses that recover from the disease do not develop a protective immune response and are susceptible to reinfection and a second bout of strangles. Resistance to the disease is associated with the production of serum and mucosal IgG antibodies to the streptococcal M protein. The presence in the nasopharynx of antibodies to streptococcal M protein is thought to be important in conferring resistance to the disease. Serum IgG antibodies specific for SeM protein, which is important in the anti-phagocytic activities of S. equi, are produced by most but not all horses during convalescence. Similarly, IgA and IgGb against SeM protein are detectable on nasal and pharyngeal mucosa after S. equi infection but not after intramuscular administration of vaccines containing M protein. Serum bactericidal activity alone is not considered to be a good indicator of resistance to the disease, especially if it is induced by administration of a vaccine. Antibodies similar to those found in the nasopharynx after infection with S. equi are present in colostrum and milk of mares that have recovered from the disease, are passed to foals via thecolostrum, and are secreted into the foals’ nasopharyngeal mucosa. These acquired antibodies are important in mediating the resistance of young foals to the disease.

Although strong immunity occurs after an attack, this immunity wanes.

Importance

Strangles is one of the most important diseases of horses in developed countries, accounting for up to 30% of reported infectious disease episodes. The disease is important not only because of the deaths that it causes but more importantly because of the disruption of the management of commercial horse establishments, the time necessary to treat affected horses, and the esthetic unpleasantness of the running noses and draining abscesses.

PATHOGENESIS

Virulence of S. equi is attributable to the presence of M proteins on the surface of the bacteria, a hyaluronic acid capsule and the production of a leukocidinal toxin. M proteins are associated with S. equi adhesion to oral, nasal, and pharyngeal tissues; invasion of pharyngeal tonsils and associated lymphoid structures; and evasion of the innate host immune response. S. equi produces two M proteins—SeM and SzPse. SeM is unique to S. equi and plays a dominant role in resistance of the organism to phagocytosis. Variations in structure of M protein are associated with decreased virulence. The M proteins interfere with the deposition of complement component 3b on the surface of the bacteria and bind fibrinogen, both of which reduce the susceptibility of the bacteria to phagocytosis by neutrophils. The antiphagocytic activity of S. equi reduces the efficacy of neutrophils in engulfing and destroying the bacteria.

The capsule of S. equi is associated with resistance to nonimmune phagocytosis and pathogenicity. Strains of S. equi that do not produce a capsule do not induce disease, although they are able to inject guttural
pouches and cause seroconversion in experimental studies. Following exposure of the oral and nasopharyngeal mucosal surfaces to \textit{S. equi}, bacteria lodge in the \textit{pharyngeal and tonsillar lymphoid tissues}, where they multiply rapidly. There is no evidence of colonization of mucosal surfaces and streptococci can be detected in pharyngeal tonsils within hours of exposure. The binding of \textit{S. equi} to pharyngeal cells is caused by fibrinogen binding proteins associated with M protein. The resistance of \textit{S. equi} to nonimmune phagocytosis occurs as a result of rupture of abscesses into a body cavity. Rare deaths also occur by metastatic infection. Other deaths include perforation of the heart valves, metastatic infection of the lungs, mesenteric lymph nodes, liver, spleen, kidneys, and brain. Clinical signs depend on the organ affected and the severity of the infection, but intermittent fever, chronic weight loss, and sudden death as a result of rupture of abscesses into a body cavity are common manifestations of metastatic infection. Rectal examination or percutaneous ultrasonographic examination can reveal intra-abdominal abscesses in some horses with metastatic abscesses in the abdomen. Peritoneal fluid from these horses is often abnormal. Metastatic infections can occur in the \textit{central nervous system}. Extension of infection to the meninges results in suppurative meningitis characterized clinically by excitation, hyperesthesia, rigidity of the neck, and terminal paralysis. Abscesses in the brain cause a variety of clinical signs, depending on location of the abscess, including severe depression, head pressing, abnormal gait, circling, and seizures. Metastatic infections of the ocular and extraocular structures, heart valves and myocardium, joints, bones, tendon sheaths, and veins may occur. Purpura hemorrhagica can occur as a sequel to \textit{S. equi} infection. Two myopathic syndromes occur with \textit{S. equi} infection in horses. Muscle infarction, occurs in only about one-half of the affected horses.

**Strangles in burros** is a slowly developing debilitating disease. At postmortem examination the characteristic lesions consist of caseation and calcification of abdominal lymph nodes.

**Complications**

Complications occur in about 20% of cases. The most common fatal complication is the development of \textit{suppurative necrotic bronchopneumonia}, which probably occurs secondary to the aspiration of pus from ruptured abscesses in the upper airway, or metastatic infection of the lungs. Extension of the infection into the \textit{guttural pouches}, usually as a result of rupture of retropharyngeal lymph nodes into the medial compartment, causes empyema, which can lead to the formation of accretions of inspissated pus (chondroids). Involvement of the guttural pouches is evident clinically as distension and, after resolution of other signs, unilateral or bilateral nasal discharge. Guttural pouches of affected horses should be examined endoscopically for evidence of retropharyngeal abscessation or guttural pouch empyema or chondroid formation.

Retropharyngeal lymphadenopathy can impair the function of the \textit{recurrent laryngeal nerves}, with subsequent unilateral or bilateral laryngeal paresis and consequent respiratory distress.

**Metastatic infection** ("bastard strangles") results in the formation of abscesses in any organ or body site but most commonly in the lungs, mesenteric lymph nodes, liver, spleen, kidneys, and brain. Clinical signs depend on the organ affected and the severity of the infection, but intermittent fever, chronic weight loss, and sudden death as a result of rupture of abscesses into a body cavity are common manifestations of metastatic infection. Rectal examination or percutaneous ultrasonographic examination can reveal intra-abdominal abscesses in some horses with metastatic abscesses in the abdomen. Peritoneal fluid from these horses is often abnormal. Metastatic infections can occur in the \textit{central nervous system}. Extension of infection to the meninges results in suppurative meningitis characterized clinically by excitation, hyperesthesia, rigidity of the neck, and terminal paralysis. Abscesses in the brain cause a variety of clinical signs, depending on location of the abscess, including severe depression, head pressing, abnormal gait, circling, and seizures. Metastatic infections of the ocular and extraocular structures, heart valves and myocardium, joints, bones, tendon sheaths, and veins may occur. Purpura hemorrhagica can occur as a sequel to \textit{S. equi} infection. Two myopathic syndromes occur with \textit{S. equi} infection in horses. Muscle infarction,
which may be extensive, is assumed to result from immune-mediated vasculitis associated with purpura hemorrhagica. Often the muscle lesions in these horses are associated with other lesions consistent with severe purpura hemorrhagica, including infarctions in the gastrointestinal tract, skin, and lungs. Rhabdomyolysis and subsequent muscle atrophy result in signs of muscle disease, including stilted gait and elevated serum activity of creatine kinase and other muscle-derived enzymes, and is assumed to be attributable to cross-reactivity of anti-SeM antibodies with myosin.

Myocarditis and glomerulonephritis have been suggested as sequelae to S. equi infection but have not been conclusively demonstrated to occur.

**CLINICAL PATHOLOGY**

Hematologic abnormalities during the acute phase of the disease include leukocytosis, with a neutrophilia reaching a peak as the lymph nodes abscess. Hyperfibrinogenemia is characteristic of both the acute and chronic disease. Hematologic and biochemical abnormalities associated with metastatic infection depend on the site of the infection and its severity. Leukocytosis with a hyperproteinemia attributable to a polyclonal agammaglobulinemia is characteristic of metastatic and chronic abscessation. Hypoalbuminemia may be present. Serum biochemical profile can reveal evidence of specific organ dysfunction. There can be an anemia, which is likely attributable to the hemolytic effect of streptolysin O, immune-mediated hemolysis, or anemia of chronic disease.

A number of serologic tests to measure antibodies to SeM have been developed. An early commercial test that measured the serum IgG antibody titer to SeM was used to determine response to vaccination, suitability for vaccination and presence of metastatic infection. This ELISA has a sensitivity and specificity of 90% and 77%, respectively.

The test is not useful in diagnosis of the acute disease. Serum antibody titers to SeM are very high (>1:12800) in horses with metastatic infection or purpura hemorrhagica. Further tests have been developed with the aim of detecting horses that have been exposed to S. equi, with the intent of enabling quarantine and control measures.

ELISA assays for antibodies to SeM that combined analysis of two antigens restricted to S. equi provides sensitivity and specificity of 93% and 99%, respectively. Use of this assay allows detection of horses that have been exposed to S. equi and therefore might be carriers of the organism. These horses can then be examined using PCR of nasopharyngeal swabs (3 over 3 weeks) or guttural pouch lavage fluid (once). The high sensitivity of the test means that horses that test negative are unlikely to have been exposed or to be carriers.

PCR testing is useful to detect shedding of S. equi DNA and has a greater sensitivity than routine culture. PCR testing of nasopharyngeal swabs or guttural pouch lavage fluid has a sensitivity of 90% to 95% and specificity of 86% to 97% with turnaround time of approximately 2 hours.

The test is reported to be more specific than culture for detection of S. equi shedding. The PCR does not differentiate between live and dead S. equi, and false-negative results occur in the presence of large numbers of S. equi.

Culture of nasal, pharyngeal, guttural pouch, or abscess discharge will usually yield S. equi in 30% to 40% of horses with active disease or in carriers. Abscesses can rapidly become contaminated with S. zooepidemicus, which can impede isolation of S. equi, although the two can be differentiated by culture or PCR analysis.

**NECROPSY FINDINGS**

In the rare fatalities that occur, necropsy examination usually reveals suppuration in internal organs, especially the liver, spleen, lungs, pleura, and peritoneum. When the last is involved, it is usually as a result of extension from abscesses in the mesenteric lymph nodes. The microscopic changes of abscessation and suppurative lymphadenitis are uncomplicated. The widespread ecchymotic hemorrhages of purpura hemorrhagica are not specific to this infection, but S. equi should always be investigated as a potential cause of such lesions.

**Samples for Confirmation of Diagnosis**

- Bacteriology—swab of abscess wall, enlarged lymph node (CULT), or PCR

**DIAGNOSTIC CONFIRMATION**

Confirmation of strangles depends on the detection of S. equi from nasopharyngeal swabs, discharges from abscesses, or guttural pouch lavage by PCR or culture. As discussed previously, PCR has greater utility at detecting presence of the organism. Shedding of S. equi in nasal discharges begins 1 to 4 days after the onset of fever, and ruptured abscesses often become contaminated with Streptococcus zooepidemicus and S. equisimilis.

History and clinical findings are usually highly suggestive of the disease, and classical cases of the strangles do not represent a diagnostic challenge. However, outbreaks of milder form of the disease are more challenging to diagnose, and confirmation is based on identification of the organism or demonstration of seroconversion. In acute disease, nasopharyngeal swabs or pus aspirates from abscesses can confirm S. equi infection. Because false negative culture results occur in 30% to 40% of cases, and qPCR has a sensitivity 94% and specificity 96%, and combining qPCR with culture will detect more than 90% of infected horses.

Carriers are defined as horses shedding bacteria more than 6 weeks after clinical recovery. These horses will have serologic evidence of infection and can be detected by a series of at least 3 nasopharyngeal swabs at weekly intervals, or a single guttural pouch lavage ideally combined with a single nasopharyngeal swab, submitted for qPCR combined with culture. This will detect greater than 90% of carriers.

Infection by Actinomyces denticolens caused submandibular abscessation in horses that can appear clinically similar to strangles. Diagnosis is based on bacterial culture.

**TREATMENT**

The specific treatment of choice for S. equi infection of horses is penicillin, either as procaine penicillin G (22,000 IU/kg intramuscularly every 12 hours) or potassium or sodium penicillin G (22,000 IU/kg intravenously every 6 hours). Tetracycline (6.6 mg/kg intravenously every 12-24 hours) and sulfonamide–trimethoprim combinations (15-30 mg/kg orally or intravenously every 12 hours) can be efficacious but should only be used if penicillin cannot be administered. Aminoglycosides, such as gentamicin or amikacin, and the fluoroquinolones are not effective. Proportions of a small number (10) S. equi isolates from horses in southern England during 2007 to 2012 resistant to various antimicrobials were as follows: enrofloxacin 40%, gentamicin 80%, penicillin or cefotiofur 0%, trimethoprim–sulfonamide combination 20%, doxycycline 10%, oxytetracycline 0%, and resistant to three or more antimicrobials 20%. Similar sensitivities are reported for 22 isolates from Western Canada, with all isolates sensitive to ampicillin, cefotiofur, cephalothin, penicillin, erythromycin, amoxicillin-clavulanic acid, and no isolates sensitive to amikacin or neomycin. Approximately 80% of isolates were sensitive to TMS or tetracycline. Use of ceftiofur, a third-generation cephalosporin, in horses is discouraged on public health grounds.

**DIFFERENTIAL DIAGNOSIS**

See Table 12-16 for a list of differential diagnoses of infectious upper respiratory tract disease of horses. Pneumonia should be differentiated from pleuropneumonia associated with transport or other stress. Chronic weight loss as a result of metastatic infection should be differentiated from equine infectious anemia, parasitism, inadequate nutrition and neoplasia, especially gastric squamous-cell carcinoma, alimentary lymphosarcoma, and granulomatous enteritis.
There is considerable debate about the treatment of horses with strangles. Folklore and anecdotal reports suggest that antibiotic treatment of horses with strangles is contraindicated because it promotes the development of metastatic infection. There is no experimental or empirical evidence to support this contention, and horses with strangles should be treated with therapeutic doses of an appropriate antibiotic, such as procaine penicillin, for a period of time sufficient to effect a cure, as appropriate.

Treatment for *S. equi* infection depends on the stage of the disease, as follows:

- **Horses with early clinical signs** including fever, anorexia, depression, and purulent nasal discharge should be isolated and treated with therapeutic doses of penicillin for at least 5 days. The purpose of treatment is to prevent further development of the disease in the affected animal and to minimize environmental contamination with *S. equi* and transmission to other horses. Treatment should start as soon as clinical signs are observed, and the full course of treatment should be completed to minimize the chances of recrudescence of the infection. Treatment at this stage causes rapid resolution of fever, anorexia, nasal discharge, and lymphadenopathy in individual horses and may abort an incipient outbreak of the disease in a stable or yard. However, treated horses may not develop a protective immune response and consequently may be at risk of reinfection if exposed to *S. equi* after completion of the course of treatment, leading one authority to

*ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.*
recommend that only severely affected animals be treated.
• Horses with submandibular lymph node abscessation but without other clinical abnormalities probably do not require antibiotic treatment. Such horses should be isolated and efforts made to aid maturation and rupture of affected lymph nodes.
• Systemic antibiotic therapy with penicillin is indicated in horses with advanced signs of strangles, including prolonged fever, depression, anorexia, or dyspnea resulting from retropharyngeal lymphadenopathy. Retropharyngeal abscessation frequently responds to antimicrobial therapy, although surgical drainage may be required in some instances.
• Horses with metastatic infection require systemic penicillin therapy in combination with specific therapy for the complication. Pulmonary and mesenteric abscesses are problematic because they are usually not amenable to surgical drainage, and prolonged antimicrobial therapy is required to attempt to effect a cure.
• Guttural pouch empyema requires either surgical drainage or repeated flushing of the affected pouch through the pharyngeal openings. Removal of pus and inspissated material in the guttural pouches can be achieved under endoscopic guidance. Alternatively, rigid or flexible indwelling catheters can be inserted for repeated flushing of the pouches with sterile isotonic electrolyte solutions (such as 0.9% NaCl) and topical medications. Substances and solutions that are irritating or injurious to mucous membranes, such as iodine,23 hydrogen peroxide, and similar irritant compounds, should not be infused into the guttural pouches. Combined topical and systemic administration of potassium benzyl penicillin may be beneficial. Chondroids can often be removed using wire snares. Horses with metastatic or guttural pouch infections are likely infectious and should be isolated.
• Treatment of purpura hemorrhagica is dealt with elsewhere.
• Management of horses that have been exposed to horses with strangles is controversial. Some authorities recommend treatment of such in-contact horses with penicillin until affected horses are isolated and no longer are a source of infection. However, close examination of exposed animals, including monitoring rectal temperature, and treatment of horses at the first sign of illness is probably a more reasonable approach.
Ancillary treatment consists of administration of nonsteroidal antiinflammatory drugs (NSAIDs) to reduce swelling and provide pain relief, application of hot poultices to encourage rupture of abscesses, provision of intravenous hydration in animals unable to drink, and wound care, including cleaning of ruptured abscesses and application of petroleum ointment to surrounding skin to prevent scalding. Horses with severe upper airway obstruction may require placement of a short-term tracheotomy.

CONTROL
All establishments that house multiple horses, and at which horses both enter and leave, should have biosecurity plans detailing the measures to be taken before new horses enter the facility. The principles of control measures include the prevention of transmission of S. equi from infected horses (cases or carriers) to susceptible animals and enhancement of resistance to infection and disease.

There are two basic approaches to strangles prevention: eradication or control.24 The eradication approach aims to create and maintain a guaranteed disease-free state within the group and is most suited for closed herds. The control approach aims to reduce the frequency and severity of outbreaks but accepts that disease will occur from time to time. In many facilities with large numbers or frequent turnover of horses, such as large training yards or stud farms, a control approach may be more achievable than eradication.24

The approach to managing horses entering a facility in which S. equi infection is not present involves serologic testing of all horses before entry using an ELISA of known high sensitivity and specificity. Horses that are seropositive on arrival have prima facie evidence of exposure and are considered to be potential carriers of S. equi until demonstrated by PCR and culture to be negative for the organism. These horses are then screened for S equi carriage by guttural pouch lavage combined with a nasopharyngeal swab tested by qPCR and culture.11 Horses with negative or equivocal serology on arrival should not be admitted to the facility and should be retested 10 to 14 days later to establish serologic status and then either admitted to the facility if they are seronegative or screened for S equi carriage if they are seropositive.24 Any horses testing positive for carriage need to be treated (see previous discussion) and cured of infection before entry into the yard.

Vaccination provides a useful adjunct to management changes, especially in groups of horses with open management systems, and may be more appropriate for yards aiming for control rather than eradication.24 However, vaccination complicates interpretation of serologic screening of new arrivals because it is not possible at this time to differentiate between serologic responses to vaccination and infection.

Prevention of Transmission
Methods to control transmission of S. equi on affected premises are detailed in Table 12-17 and are as follows:
• Infected animals should be isolated immediately.
• All potential sources of fomites—including pails, brooms, grooming brushes, and blankets—should be thoroughly cleaned and disinfected and the bedding burned. Disinfection with phenolic compounds is preferred because they retain their activity in the presence of some organic matter, whereas bleach and quaternary ammonium compounds are inactivated by organic material.
• Emergency prophylactic treatment, using injections of benzathine penicillin every 48 hours in foals and yearlings that are most susceptible, has been used but most treated animals develop strangles when the treatment is discontinued. This method of prophylaxis is not recommended.
• People who care for affected horses should, ideally, avoid contact with susceptible animals. If this is not practical, then strict isolation protocols, including the wearing of protective boots and clothes that are changed between affected and normal horses, should be implemented.
• Horses with elevated temperatures should have nasopharyngeal or guttural pouch swabs cultured.
• As detailed previously, horses should be examined by nasopharyngeal swab or guttural pouch lavage to detect carriers. Carriers should be treated and demonstrated to be no longer carriers before being allowed access to potentially susceptible horses.

Enhanced Resistance
The majority of horses develop solid immunity to strangles after recovery from the spontaneous disease. This immunity lasts for up to 5 years in approximatelty three-quarters of recovered horses. Maximum resistance to disease probably requires both systemic and mucosal factors including, but not limited to, M protein. As noted previously, vaccination will result in positive results of serologic testing for exposure to S. equi. It is not possible at this time to differentiate between responses
Aims

Streptococcus equi

Prevent spread of S. equi infection to horses on other premises and to new arrivals on the affected premises. Establish whether clinically recovered horses are carriers. Investigate apparently healthy horses from which S. equi is recovered. Eliminate S. equi from guttural pouches. Prevent infection of uninfected horses by S. equi from infected horses.

Measure

Stop all movement of horses on and off affected premises immediately and until the outbreak is controlled. Horses with strangles and their contacts should be maintained in well-demarcated quarantine areas. Clustering of cases in groups allows parts of the premises to be allocated as contaminated or clean. At least three nasopharyngeal swabs or washings taken at weekly intervals from all recovered cases and their contacts and examined by culture and PCR. Horses that are consistently negative are returned to the clean area. Serology to determine exposure, with positive horses subject to nasopharyngeal swabbing (three times) or guttural pouch lavage and PCR and culture. Serologically negative horses should be retested in 10–14 days. Treatment of guttural pouches, as detailed under “Treatment.” Personnel should have dedicated protective clothing when dealing with infected horses. Personnel should not deal with infected and uninfected horses. If this is not possible, then infected horses should be dealt with after uninfected horses. Strict hygiene should be implemented, including provision of disinfection facilities for personnel and diligent and thorough cleaning of stables and barns. If practicable, equipment should be destroyed after use with infected horses. Organic material should be removed from stables and then appropriate phenolic disinfectants or steam should be applied. This cleaning should be repeated. Feces and waste from infected animals should be composted in an isolated location. Uninfected horses should not be introduced to pastures used to house infected horses for 4 weeks. Water troughs should be disinfected daily. Horse vans should be thoroughly cleaned and disinfected after each use.

PCR, polymerase chain reaction.

Administration of a live, attenuated submucosal vaccine to mares appears to be safe.26 This result suggests that, in the face of an outbreak, vaccination might reduce the number of horses that develop strangles but will not prevent strangles in all vaccinated horses. A common vaccination protocol involves the administration of an M protein vaccine intramuscularly for an initial course of three injections at 2-week intervals, with further administration of the vaccine every 6 months in animals at increased risk of contracting the disease. On breeding farms, vaccination of mares during the last 4 to 6 weeks of gestation and of the foals at 2 to 3 months of age might reduce the incidence of the disease.

The vaccines are administered by the intramuscular route and frequently cause swelling and pain at the injection site. Injection site reactions are usually less severe with the M protein vaccines. Injection into the cervical muscles may cause the horse to be unable to lower its head to eat or drink for several days—reversion into the pectoral muscles is preferred for this reason. There are reports of purpura hemorrhagica, the onset of which was temporally associated with administration of a S. equi vaccine. Owners should be clearly warned of the limited efficacy and potential adverse effects of vaccination. The effect of vaccination in confounding interpretation of results of serologic testing used in control of the disease should be considered before horses are vaccinated.

Foals that receive adequate high-quality colostrum from exposed or vaccinated mares have serum and nasopharyngeal mucosal immunoglobulins (IgGb) that provide them with resistance to S. equi infection. This passive immunity wanes at approximately 4 months of age. Vaccination of brood mares 1 month before foaling increases colostral IgG antibodies to M protein, and presumably serum and mucosal immunoglobulin concentrations in their foals, but the efficacy of this approach in preventing strangles in foals is not reported.

An intranasal vaccine of an avirulent live strain of S. equi has recently been developed and appears useful. Use of the intranasal modified live vaccine can result in strangles caused by the vaccine strain.7 The vaccine is composed of a live variant (strain 707-27) that does not possess a capsule and is therefore avirulent when administered intranasally. Anecdotal reports suggest that recent manipulation of the genome by deletion of genes HasA and HasB, associated with formation of the capsule, has increased the genetic stability of the vaccine strain. The live attenuated vaccine should only be administered intranasally to healthy horses. The efficacy of the vaccine in field situations, safety in the face of an outbreak and in pregnant mares, incidence of adverse effects, and risk of reversion to virulence have not been reported. It should not be used in potentially exposed horses during an outbreak of the disease. Intramuscular injection of the vaccine results in the formation of abscesses. The vaccine should not be administered to horses concurrently with intramuscular administration of other vaccines because of the risk of contamination of needles and syringes with S. equi vaccine strain and subsequent development of abscesses at injection sites.

An experimental modified live vaccine administered intramuscularly to ponies conferred protection to experimental challenge.27 Owners should be advised to use submucosal injection of a modified live vaccine is reported to provide short-lived (90-day) immunity to disease. The commercial form of the vaccine is administered into the submucosal tissues of the upper lip and is recommended for use in horses at moderate to high risk of developing strangles. At present there is no evidence of reversion of the vaccinal strain to virulence, and horses developing strangles subsequent to vaccination have all been infected with virulent strains of S. equi, apparently before.
development of immunity as a result of vaccination. The vaccine appears to be safe for use in pregnant mares.4,5

GLANDERS

SYNOPSIS

Etiology Burkholderia mallei

Epidemiology Contagious disease of solipeds (equids) and possibly camels. Important potential zoonosis.

Clinical findings Acute or chronic form, and characterized by pneumonia and nodules or ulcers in the respiratory tract and on the skin. The disease is highly fatal.

Clinical pathology Complement fixation test, mallein test, isolation of organism

Necropsy findings Extensive bronchopneumonia in acute cases. Miliary nodules in internal organs and ulcerated nodules in skin and respiratory tract.

Treatment and control Control is by slaughter of clinically affected and carrier animals detected by serologic or mallein tests. Rarely are affected animals treated, and if so it is by prolonged administration of antimicrobials.

ETIOLOGY

Burkholderia mallei, a gram-negative bacterium, is the causative organism of glanders.

It has close genetic and antigenic relatedness to Burkholderia pseudomallei. Isolates of B. mallei recovered from three continents over a period of 30 years have identical allelic profiles, but phylogenetic determination of strains can be achieved using molecular diagnostic techniques (for example, next-generation whole-genome sequencing and multiple-locus variable-number tandem repeats). Determination of phylogenetic relationships is a powerful tool for determining the source, and epidemiologic characteristics, of outbreaks of the disease.

Once inhaled or ingested, B. mallei enters the body through the respiratory tract or gastrointestinal tract, and is then transported to lymphatic tissue to cause infection. The organism is considered a category B bioterrorism threat (biologic warfare agent) by the Centers for Disease Control in the United States.

EPIDEMIOLOGY

Geographic Occurrence

Glanders is restricted geographically to South America, eastern Europe, Asia Minor, Asia, and North Africa. Recent cases in Western Europe (Germany) are reported in horses imported from Brazil, where the disease is present, and in another horse, some years later, that was born in Germany. These cases highlight the need for vigilance in detection of glanders. Occurrence of outbreaks of the disease since 1986 is cataloged and available.

The disease has reemerged, or at least been detected, recently in India and Pakistan. An outbreak in Bahrain was attributed to multiple introductions of infection, rather than simply one source. The disease was more widespread but has been eradicated from most countries. Glanders was an important disease when there were large concentrations of horses in cities and armies, but now has sporadic occurrence, or occurs in localized outbreaks, even in infected areas.

Host Occurrence

Horses, mules, and donkeys are the species usually affected. The disease can occur naturally in camels, although the number of reported cases is low, suggesting that camels are not particularly susceptible to infection.

Humans are susceptible and the infection is often fatal. Carnivores, including lions can be infected by eating infected meat and infections have been observed in sheep and goats.

Source of Infection and Transmission

B. mallei is an obligate parasite and is readily destroyed by light, heat, and the usual disinfectants and is unlikely to survive in a contaminated environment for more than 6 weeks.

Infected animals or carriers that have made an apparent recovery from the disease are the important sources of infection. Carriers can be clinically normal and shed the organism for years. Chronic nodular lung lesions, which have ruptured into the bronchi, infect upper airway passages and nasal or oral secretions. Spread to other animals occurs mostly by ingestion, the infection spreading on fodder and utensils, particularly communal watering troughs, contaminated by nasal discharge or sputum. Rarely the cutaneous form appears to arise through contamination of skin abrasions by direct contact or from harness or grooming tools. Spread by inhalation can also occur, but this mode of infection is probably rare under natural conditions.

Experimental Reproduction

An experimental model for disease has been reproduced by intratracheal inoculation of horses with cultures of B. mallei. Horses showed fever within 24 to 48 hours of challenge followed by the progressive development of signs of respiratory distress with epistaxis and purulent nasal and ocular discharge. On postmortem there was lymphadenopathy, ulcerative lesions in the nasal septa, and pneumonia.

Host and Pathogen Risk Factors

Horses tend to develop the chronic form, mules and donkeys the acute form, but all types of equid and all ages are susceptible. The disease is more likely when animals are in a stressed state from heavy work, and animals that are poorly fed and kept in a poor environment are more susceptible.

The stress associated with movement of a large number of horses can precipitate an outbreak with high mortality rates. In the few animals that recover, there is a long convalescence with the frequent development of the “carrier” state. Animals rarely make a complete recovery.

Economic Importance

The disease has little current economic importance, although the threat of horse movement reintroducing glanders into countries that have eradicated it is a concern.

Zoonotic Implications

Although humans are not highly susceptible, the infection can gain access through skin abrasions to produce granulomatous disease and pyemia. Infection can also occur from inhalation of infectious material. The case fatality is high. Horse handlers in general are at risk, and veterinarians conducting postmortem examinations without proper precautions are at particular risk. The organism is identified as a possible agent of bioterrorism.
PATHOGENESIS
Invasion occurs mostly through the intestinal wall and a septicemia (acute form) or bacteremia (chronic form) is set up. Localization always occurs in the lungs but the skin and nasal mucosa are also common sites. Other viscera can become the site of the typical nodules. Terminal signs are in the main those of bronchopneumonia or, in acute disease, chronic wasting.

CLINICAL FINDINGS

Acute Disease
Acute disease presents with high fever, cough, and nasal discharge, with rapidly spreading ulcers appearing on the nasal mucosa and nodules appearing on the skin of the lower limbs or abdomen. Death as a result of septicemia occurs in a few days.

Chronic Disease
The disease is evident as fever, inappetence, weight loss, enlargement of submandibular lymph nodes, and exercise intolerance in almost all affected horses. Cough, dyspnea, and nasal discharge occur in approximately two-thirds of cases, and greater than 70% of cases have ulcers on the nasal septum or nodules in the skin, usually of the legs.12

Three major manifestations are described, although one or more of all three can occur in the same animal:
1. Pulmonary
2. Skin
3. Nasal, although the chronic nasal and skin forms commonly occur together.

Pulmonary Form of Disease
The pulmonary form manifests as a chronic pneumonia with cough, frequent epistaxis, and labored respiration.

Nasal Form of Disease
In the nasal form, lesions appear on the lower parts of the turbinates and the cartilaginous nasal septum. They commence as nodules (1 cm in diameter), which ulcerate and may become confluent. In the early stages there is a serous nasal discharge that may be unilateral and that later becomes purulent and blood stained. Enlargement of the submaxillary lymph nodes is a common accompaniment. On healing, the ulcers are replaced by a characteristic stellate scar.

Skin Form of Disease (“Farcy”)
The skin form is characterized by the appearance of subcutaneous nodules (1-2 cm in diameter), which soon ulcerate and discharge pus of the color and consistency of dark honey. In some cases the lesions are more deeply situated and discharge through fistulous tracts. Thickenened fibrous lymph vessels radiate from the lesions and connect one to the other. Lymph nodes draining the area become involved and may discharge to the exterior. The predilection site for cutaneous lesions is the medial aspect of the hock, but they can occur on any part of the body.

Animals affected with the chronic form are usually ill for several months, frequently showing improvement but eventually either dying or making an apparent recovery to persist as occult cases.

CLINICAL PATHOLOGY
Chronic disease caused anemia and a moderate leukocytosis and neutrophilia.12

The principal tests used in the diagnosis of glands are demonstration of presence of the organism by culture or detection of specific DNA (such as by PCR testing),13 the mallein test, or one of various serologic tests—complement fixation test, ELISA,24 dot-ELISA,24 C-ELISA,24 immunoblot,24 Rose Bengal test, indirect hemagglutination, agar-gel immunodiffusion, indirect fluorescent antibody testing, counterimmune electrophoresis, and dot-ELISA.24 Details of test procedures are available in the OIE Manual on diagnostic tests and vaccines.17

All serologic tests are dependent on the host mounting an immune response to infection. Detectable immune responses might require a period of up to 2 weeks after infection to develop to the stage where they are detectable. The precise time depends on host factors and the characteristics of the particular serologic test.

The intent of testing affects the test chosen for use. Tests intended to screen horses for international travel must have a high sensitivity, to avoid false negative results, but also high specificity, to ensure that there are few false-positive results. From the point of international movement of horses, tests should first have a high sensitivity to ensure that there are few false-negative results—with the potential for consequent transportation of infected animals—whereas detection of diseased animals in populations of horses in which the disease is rare demands tests with high specificity. The solution is often to first screen with tests of high sensitivity, such as the complement fixation test, followed by a test with much higher specificity (but often lower sensitivity), such as immunoblotting.16 The outcome of such serial testing is a high sensitivity and specificity. The diagnostic performance of various tests has improved with use of refined reagents (including use of recombinant or purified bacterial proteins or lipopolysaccharide,17 or antibodies) and optimized tests conditions,13 such as the temperature at which complement fixation tests are incubated.15 All serologic tests can be inaccurate for periods up to 6 weeks following performance of the mallein test.

Molecular diagnostic techniques must discriminate between B. mallei and the closely related B. pseudomallei. Whereas older molecular diagnostic tests did not do so because of the close genetic relationship between these organisms, more modern tests do discriminate at a level that is clinically useful.13,14

Discussion of all the currently available tests is beyond the scope of this text, and readers are referred to recent publications.1,4

Mallein Test
The test is not generally recommended because of animal welfare concerns; however, it can be useful in remote endemic areas where sample transport or proper cooling of samples is not possible.16 The mallein test involves the intradermal injection of mallein, a purified or semipurified protein of B. mallei,14 into the subcutaneous tissues of the eyelid or lateral side of the neck. Mallein (0.1 mL of a 1.0 mg/mL concentration of mallein) is injected intradermally with a tuberculin syringe. Ideally, the thickness of the skin is measured using calipers before injection of mallein and 48 hours following injection. Some infected animals exhibit a general hypersensitivity reaction after inoculation. The mallein test can be negative in recently infected animals, in those with acute disease, and in advanced cases in horses.17

The mallein test has poorer sensitivity (~75%) than does serologic testing (Rose Bengal—90%, complement fixation—97%, and others).21

NECROPSY FINDINGS
In the acute form there are multiple petechial hemorrhages throughout the body and a severe catarrhal bronchopneumonia with enlargement of the bronchial lymph nodes.

In the more common chronic form, the lesions in the lungs take the form of miliary nodules, similar to those of miliary tuberculosis, scattered throughout the lung tissue. Ulcers are present on the mucosa of the upper respiratory tract, especially the nasal mucosa and to a lesser extent that of the larynx, trachea, and bronchi. Nodules and ulcers may be present in the skin and subcutis of the limbs, which may be greatly enlarged. Local lymph nodes receiving drainage from affected parts usually contain focus of pus and the lymphatic vessels have similar lesions. Necrotic foci may also be present in other internal organs. B. mallei, and sometimes Arcanobacterium pyogenes, are isolated from infected tissues, and this is the main means of confirmation of diagnosis at necropsy.

DIAGNOSTIC CONFIRMATION
In live animals that could be carriers, the complement fixation test is used as the official test in most countries. The mallein test is used in those horses whose sera is anticomplementary.
DISEASES

Diseases

• Rhodococcus equi
• Strangles
• Sporotrichosis
• Epizootic
• Other ulcerative

DIFFERENTIAL DIAGNOSIS

• Epizootic lymphangitis
• Ulcerative lymphangitis
• Sporotrichosis
• Melioidosis
• Strangles
• Rhodococcus equi infection
• Equine pleuropneumonia
• Other causes of pneumonia

TREATMENT

There is little information on treatment because control of the disease requires death of affected equids to prevent further spread of infection, and the granulomatous nature of the disease likely requires prolonged administration of antimicrobials capable of penetrating abscesses. Antimicrobial sensitivity of B. mallei isolates is reported.

However, in instances in which high-value animals are treated, a treatment protocol of enrofloxacin (8 mg/kg IV q24 h) and trimethoprim–sulfadiazine (32 mg/kg IV q24h) for 7 days, followed by enrofloxacin (4 mg/kg IV q24h) and trimethoprim–sulfadiazine (16 mg/kg IV q24h) for 2 weeks, and then 6 mg/kg doxycycline PO q12h for 9 weeks has been used. Treated horses responded within 1 week to treatment, with reduction of pyrexia and improved appetite. Nodules on the legs had resolved by week 3 and did not have evidence of disease recurrence or a carrier status 1 year after the cessation of treatment.

CONTROL

Control of glanders involves measures to reduce spread of the disease among equids in areas where the disease is endemic and eradication of the disease when desired or when the disease occurs as an emergency disease outbreak in areas where the disease is not endemic.

Control of glanders is based on identification of infected animals by either serologic testing, intradermal mallein testing, or detection of the organism (culture or PCR) (see previous discussion). The mallein test and complement fixation test are the OIE-approved tests for glanders for the purposes of international movement of horses—note the comments given previously about the characteristics of these tests. When attempting to identify infected animals, the delay in seroconversion or development of a positive mallein test after infection should be considered. Mallein testing can influence the sensitivity of subsequent serologic testing.

If glanders is detected, or suspected, in an area free of the disease, then the affected horse and contact animals should be promptly quarantined until their disease status has been established. Eradication of the disease involves identification of infected animals with subsequent euthanasia and controlled disposal of these equids. Equids that could have been infected but that are negative on serologic or bacteriologic testing should have serologic tests repeated in 2 to 3 weeks. During this time, they should be quarantined.

Complete quarantine of affected premises is necessary. A vigorous disinfection program for food and water troughs and premises generally should be instituted to prevent spread while eradication is being carried out. Carcasses of infected animals and contaminated or potentially contaminated bedding, feed, and tack that cannot be disinfectant should be burned or deeply buried, consistent with local culture and laws. B. mallei is susceptible to most common disinfectants, including benzalkonium chloride, 1% sodium hypochlorite, 70% alcohol, and others. B. mallei does not persist in soil and is destroyed by exposure to sunlight or heating (>55°C, >131°F for at least 10 minutes).

B. mallei is a potential zoonosis that can cause severe illness and death in people. Barrier precautions, including the wearing of surgical masks, face shields, gloves, and gowns, are strongly recommended for people dealing with infected or suspect equids.

There is currently no vaccine for glanders in animals or people.

VIRTUAL INFECTIONS OF THE RESPIRATORY TRACT OF HORSES

Viral respiratory tract disease is considered by veterinarians in the United States to be second only to colic among medical diseases in importance to the health and welfare of horses. The situation is likely similar in most developed countries and especially those in which equine influenza is endemic. Episodes of upper respiratory tract disease characterized by fever, nasal discharge, and cough are common in horses, especially young animals and horses housed in groups in stables and barns. An estimated 17% of equine operations in the United States have one or more horses affected by upper respiratory disease each year, and 1.5% of horses develop the disease every 3 months. Upper respiratory disease is most common in spring and least common in winter. Strangles was an uncommon cause of disease, occurring in only three horses per 1000 per 3 months. Viral respiratory disease is approximately three times more common in horses less than 5 years of age.

With the exception of Streptococcus equi and possibly Mycoplasma spp, all the other known or suspected causes of nonparasitic infectious upper respiratory disease of horses are viral and include the following: equine herpesvirus types 1, 2, 3 (rarely), and 4; equine influenza virus; arguably, equine rhinitis virus types A-1 and B-1, 2, and 3; equine adenovirus; equine viral arteritis; and, historically, equine parainfluenza type 3 virus. Equine Hendra virus and African horse sickness cause signs of severe respiratory disease. There is minimal evidence that equine coronavirus causes respiratory disease in horses, and there is evidence that the Middle Eastern respiratory syndrome (MERS) coronavirus, a disease of humans and camels, does not cause disease in horses. Both s. equi and equine arteritis virus infection can be mild and lack outstanding clinical signs, thus closely resembling disease associated with some viral causes of upper respiratory tract disease. Therefore differentiation among diseases associated with these agents based on clinical signs and epidemiologic characteristics is difficult, and definitive diagnosis is only achieved through serologic or microbiological examination of blood or nasal discharge.

Isolation and identification of a causative organism from nasopharyngeal swabs or airway washings of acutely affected horses provides a definitive diagnosis, although on occasion more than one potential pathogen may be isolated. Demonstration of seroconversion or a three- to fourfold increase in titer from serum samples collected during the acute and convalescent (usually 3 weeks after onset of clinical signs) phases of disease is persuasive evidence of infection. Immunofluorescence,
enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction (PCR) tests may provide rapid diagnosis through detection of viral particles in nasal swabs and tissue specimens. The ability to determine the cause of an outbreak of upper respiratory disease in horses is enhanced by the use of multiple diagnostic tests and obtaining samples from more than one horse in an outbreak. However, definitive diagnosis of the cause of nasal discharge, cough, and fever is often not achieved.

All the agents known to cause upper respiratory disease in horses are relatively sensitive to environmental influences, and spread of the agent is dependent on transmission from infected horses, either directly or on fomites. Introduction of an infected horse into a susceptible population of horses may result in an explosive outbreak of upper respiratory tract disease. Such events are common on stud farms and in racing stables, where relatively closed bands of horses are maintained for much of the year. The movement of horses over long distances may facilitate the introduction of pathogens to which the local population of horses is naive.

The opposite situation occurs when young horses are introduced into larger bands of mixed aged animals, such as happens in racing stables or barns of pleasure horses. The younger, possibly naive, horse is then exposed to endemic pathogens to which the resident horses have developed resistance.

Young horses are at particular risk of developing infectious disease of the upper respiratory tract. The diseases are usually a problem only in yearlings and 2-year-olds; young foals acquire a passive immunity from the dam and adults have acquired a permanent immunity through exposure or vaccination. In a horse population it is the average age and the mix of ages that largely determine its herd resistance, and when 30% to 40% of that population has not previously been exposed to infection then major outbreaks are likely. All of the diseases are transmitted by droplet infection, and over long distances, so that limitation of their spread is possible only by rigid isolation and intensive sanitary precautions, and even the best protected studs are likely to be infected from time to time.

Parainfluenza-3 Virus
Upper respiratory tract disease associated with equine parainfluenza-3 (PI-3) is characterized by a mild self-limiting disease that is not clinically distinguishable from the others in the group. The epidemiology and economic importance of disease associated with this agent is unknown.

Equine Adenovirus Infection
Two antigenic types of equine adenovirus, EAdV-1 and EAdV-2, are recognized that have been associated with respiratory disease in foals and adult horses and diarrhea in foals, respectively. The virus causes fatal pneumonia in Arabian foals, and likely fell pony foals, with severe combined immunodeficiency and has been isolated from otherwise apparently healthy foals with severe pneumonia, but its importance in clinical respiratory disease of immunocompetent foals is uncertain. EAdV-1 can be isolated or detected by PCR from healthy adult horses, although at a very low rate, and from 1% to 3% horses with signs of upper respiratory disease. Genomic analysis of EAdV-2 indicates markedly different lineage to that of EAdV-1. The virus is readily isolated from, or detected by PCR, in nasal swabs of approximately 50% of sick or healthy foals.

Postparturient mares can shed the virus. Infection with EAdV-1 and EAdV-2 is worldwide. Serologic surveys differ in the proportion of seropositive horses, likely at least partially a result of the testing methodology, with serum neutralization tests yielding higher seropositive rates than ELISA tests. Approximately 80% of horses in New South Wales, Australia are positive by serum neutralization assay for either or both of EAvV-1 or EAdV-2. EAdV is considered to cause a mild respiratory disease with fever, coughing, nasal discharge, and conjunctivitis. Foals are assumed to acquire the infection from their dams, which secrete the environmentally stable virus in nasal discharge, urine, and feces. The virus is not associated with inflammatory airway disease in racehorses in England, but it has been associated with small outbreak of upper respiratory tract disease.

Diagnosis can be made on cell smears taken from conjunctiva or nasal mucosa that reveal characteristic adenoviral intranuclear inclusion bodies. Serologic methods include serum neutralization, hemagglutination inhibition, complement fixation, ELISA, or precipitating antibody tests. The serum neutralization test is most accurate, but the hemagglutination inhibition test is most suitable for a screening test. Virus genetic material can be detected by specific PCR testing. No specific control measures are indicated for normal foals.

Reovirus
A reovirus, or a series of serotypes, cause mild upper respiratory tract disease of horses. Infection with these agents appears to be of little clinical or economic importance.

References

Equine Influenza

Etiology
Influenza virus H3N8 (previously A equine 2) of two lineages (Eurasian and American) and numerous, evolving, strains. Currently circulating viruses are of the American lineage, Florida clades 1 and 2. H7N7 has not been identified as a cause of disease for decades.

Epidemiology
Short incubation period and highly contagious nature of the virus result in explosive outbreaks of disease. Viral shedding by subclinically affected horses is important for introduction of infection to populations. Prolonged carrier state is not recognized.

Clinical signs
Upper respiratory disease complicated by pneumonia. Abortion is not a feature of the disease.

Clinical pathology
None characteristic.

Lesions
Rhinitis, pneumonitis. Rarely causes death.

Diagnostic confirmation
Demonstration of virus in nasopharyngeal swab either by culture, enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR), or membrane-bound immunosassay.

Treatment
Supportive care. There is no specific treatment.

Control
Quarantine to prevent introduction of the virus. Hygiene and disinfection to prevent fomite spread. Vaccination in enzootic areas with vaccine containing strains or antigens protective against currently circulating strains (Florida clade 1 and clade 2), to prevent clinical disease.

Etiology
Equine influenza is associated with infection by influenza A virus—including equine influenza A/H7N7 or equine influenza A/H3N8 virus, members of the influenza virus A genus of the family Orthomyxoviridae. Equine A viruses are typed according to the surface proteins—hemagglutinin (HA) and neuraminidase (NA) of which there are 18 subtypes (H1–H18) and 11 NA subtypes (N1–N11). Influenza virus is an RNA virus that has eight segments to its genome that encode 10 proteins. The hemagglutinin and neuraminidase proteins are used for antigenic characterization of virus strains. Mutations in these genes or poor-fidelity RNA copying results in changes in amino acid composition of viral proteins that can be detected by serologic tests (see “Clinical Pathology”) and that have important consequences for infectivity and pathogenicity of the virus.
of the two serologically distinct subtypes of equine influenza virus, all reported outbreaks in the past three decades have been associated with strains of EIV-A/H3N8. There are no reports of disease associated with EIV-A/H7N7 in the past 35 years, and reports of seroconversion might be related to use of vaccines containing EIV-A/H7N7 antigen. There are no reports of other influenza viruses, such as the H1N1 avian virus, causing disease in horses, although the avian-like influenza A/H1N1 (H3N8) caused severe disease and high mortality among horses in China in 1989 and there is a single report of avian H5N1 being isolated from sick horses, which also had serologic evidence of exposure to the virus, in Egypt during an outbreak of the disease in birds.5

Equine influenza H3N8 virus can infect dogs and cause serious disease and death.3 Canine influenza virus infection, which originated in horses, is now endemic in dogs populations in much of the world.3 Dogs are also susceptible to infection with equine influenza virus (Florida clade 1) when in close contact with horses infected with, and clinically ill from, the virus.6 Equine influenza virus H3N8 was isolated from one of ~400 healthy Bactrian camels sampled in Mongolia.6 The H3N8 virus can infect pigs but is not associated with disease; seals, in which it can cause a fatal respiratory disease; and birds.7 Experimental infection of cats with equine H3N8 virus causes respiratory disease, and the infection can spread to in-contact cats.8

Canine influenza, H3N8, which is of equine origin, does not appear to pose a zoonotic risk.10 At this time, equine H3N8 virus does not appear to be an important zoonotic threat.4 Equine influenza H3N8 virus was first detected as a cause of respiratory disease in horses in 1963 in the United States. It subsequently became widely distributed, appearing in the United Kingdom in 1965, and evolved into multiple lineages and sublineages. There are two major lineages of EIV-H3N8 that circulate in horse populations—a Eurasian lineage and an American lineage (the names of which do not reflect the current geographic distribution of the viruses). This divergence in the virus occurred in the early 1980s, and there has been subsequent evolution of the American lineage into Kentucky, Argentinian, and Florida sublineages, with the Florida sublineage composed of two clades—clade 1 and clade 2 (Fig. 12-31).11 For purposes of vaccine production, clade 1 is represented by A/eq/South Africa/04/2003-like or A/eq/Ohio/2003-like viruses, and clade 2 is represented by A/eq/Richmond/1/2007-like viruses.12 13

The predominating virus lineage or strain varies from year to year and from region to region. Both of Florida clades currently cocirculate and coevolve worldwide. Viruses of the Eurasian lineage have not been detected since 2005 (2015 OIE data).12 14 The important point is that there is continual change in the viral lineage or strain in some populations of horses and that constant monitoring of viral strains is vital for appropriate composition of vaccines and for molecular epidemiology. For instance, the majority of viruses from Europe (France, Italy and the United Kingdom) and North America characterized antigenically and/or genetically between January 2003 and April 2004 were of the American lineage. This continues to be the case with American lineage, Florida sublineage, clade 2 being the virus detected in Europe,7 Northern Africa,8 Asia (India, China, Mongolia),12 13 Ireland (before 2009), and the United Kingdom.12 13 Within clade 2, there are at least two identified virus subpopulations with amino acid substitutions in HA1 at either position 144 or position 179. The majority of 2014 viruses characterized had a valine at position 144 and an isoleucine at position 179.13 Equine influenza viruses detected in recent outbreaks in the United States of America have been Florida sublineage clade 1.12 although clade 2 was isolated from a horse in California that had been imported from Europe.20 Although clade 1 viruses predominate in America and clade 2 in Europe, clade 1 viruses have caused outbreaks in Europe (France),12 21 Australia, Africa, and Asia, and the virus circulating in Ireland in 2014/15 is from clade 1 (although different from the virus that caused outbreaks in Australia and Japan in 2007).22

Viral Evolution
Identification of the lineage and sublineage of the virus is based on nucleotide sequencing of the hemagglutinin gene to detect mutations in the gene resulting in amino acid substitutions in the HA1 domain. These amino acid substitutions alter the charge, acquisition of glycosylation sites, and/or receptor binding avidity of the virus and hence its biologic activity including infectivity, immunogenicity, and virulence.11 Hemagglutination inhibition assay (HI) has been used to type viruses, but this is now being complemented by genetic testing and determination of amino acid composition of major antigens (HA and NA). For instance, the amino acid composition of clade 1 and clade 2 viruses differs by at least seven amino acids in the HA1 domain of hemagglutinin.20 Information about EIV strains changes constantly and is available at the equiflunet or OIE websites.12 13

The existence of lineages and strains of virus is important in the epidemiology of the disease because the antigenic differences among strains can be sufficient to prevent cross-protection provided by natural infection or vaccination. Cross-protection refers to the ability of one antigen (virus strain) to produce immunity in the horse against infection with another type of antigen (virus strain). Infection or challenge with the same type of antigen is referred to as homologous challenge, whereas that with a different antigenic type is referred to as heterologous challenge. Strains of influenza virus circulate between and among populations of horses, with more than one strain of virus circulating at any one time in some horse populations, although individual disease outbreaks are associated with a single viral strain. Many, but not all, of these virus strains are constantly evolving, and evolution of the viruses is necessary for perpetuation of cycles of infection through the emergence, or reemergence by cycling, of heterologous strains. Evolutionary stasis, the continued circulation of older strains of virus, occurs and has importance for vaccine composition for many diseases, but not, apparently, for equine influenza virus (EIV), where emergence of new strains is common and of great importance for control of the disease. Evolution of strains of equine H3N8 virus occurs through antigenic drift. Antigenic drift, the accumulation of point mutations in the gene coding for the major surface protein hemagglutinin, occurs continuously in virus circulating in horse populations. Antigenic drift occurs most rapidly in hemagglutinin protein but also occurs in M and NS genes. Antigenic drift, by producing heterologous viral strains, contributes to the continuing susceptibility of horses to infection and the reduced efficacy of some vaccines.1 For example, the 2007 outbreak of equine influenza in Japan in a population of vaccinated horses, was associated with the Florida clade 1 virus, whereas the vaccines in use at that time included viruses of Eurasian and American (Argentinian) strains.7 8

Antigenic shift is an event in which there is a dramatic alteration in the viral genome occurring by reassortment of viral genes during coinfection of a cell by two different types of virus (for example infection of a pig by both avian and human influenza viruses). Antigenic shift, which has not been documented for influenza viruses infecting horses, has the potential to produce new viruses with markedly different host infectivity and pathogenicity to either parent virus. RNA viruses, such as equine influenza virus, are genetically labile, and during an outbreak there is considerable genetic variation of the viruses infecting a single animal, with dominant and one or more less dominant variants of a strain proliferating in the horse and being transmitted to other horses.23 24 Furthermore, the dominant form of the virus within a horse can change over the course of the infection. This pattern of multiple variants infecting one horse and being transmitted to other horses results in a relatively large number of variants of the virus in a group of horses during an outbreak, constituting a loose bottleneck to viral evolution.25 26
Fig. 12-31 Phylogenetic tree illustrating evolving nature of equine influenza virus N3H8 from the virus originally detected in 1963. Note that there are two lineages (Eurasian and American) that diverged in the early 1980s; that the American lineage further evolved into Kentucky, Argentinian, and Florida sublineages (clades 1 and 2); and that these continue to evolve. Strains causing substantial outbreaks are highlighted in green, dates of large outbreaks are identified in the boxes, and vaccine strains are identified in yellow. (Reproduced with permission.)
Diseases

Epidemiology

Occurrence

Worldwide, the only large horse populations in which influenza virus infection does not occur are in Australia and New Zealand, although Australia experienced its first outbreak of equine influenza in 2007 and subsequently was declared free of the virus.\(^{28,29}\) Widespread use of aircraft to move horses between countries in short periods has increased the spread of equine influenza viruses, as exemplified by the 2007 outbreak in Australia allegedly associated with importation of horses and failure to contain the infection in the quarantine facility;\(^{30}\) the 2003 outbreak in South Africa associated with a virus from North America; and an earlier outbreak in Hong Kong. In all cases virus was introduced by imported horses.\(^{31}\) Outbreaks associated with the introduction of virus into a population of susceptible horses. Virus may be introduced by clinically affected horses or, more commonly, by horses that are not noted to be clinically ill. Vaccinated horses can become infected and shed influenza virus while not becoming ill,\(^{32}\) especially if vaccinated with heterologous strains, and this is likely a common method of introduction of virus into susceptible populations.

Outbreaks of influenza virus infection can cause clinical disease in nearly all (98%) horses in a susceptible population, although in populations of horses of mixed age and with varying serum titers to equine influenza the morbidity rate can be much lower (16%-28%). The incidence of disease in one race track population was approximately 130 cases per 1000 horses at risk per month, although this rate likely varies widely among outbreaks. The mortality rate is usually very low (<1%) with most deaths associated with secondary bacterial infections. However, an outbreak of disease in China associated with a novel H3N8 (Jilin virus) strain was associated with a morbidity rate of 80% and mortality rate of 20% to 35%.

The disease in populations of vaccinated or previously exposed horses is associated with a lower morbidity and mortality and slower spread, as a result of the milder disease induced by influenza virus infection of immune or partially immune horses. In an outbreak among vaccinated racehorses in Hong Kong, 75% of horses had serologic evidence of infection, 37% had clinical signs of infection, and 0.2% died. Horses imported from Australia and New Zealand, where the disease does not occur, had a morbidity rate of 52%, whereas horses from the northern hemisphere had a morbidity rate of 20%, likely reflecting the effect of previous exposure to influenza virus or repeated vaccination. The attack rate of infection (proportion of at risk horses infected by the virus) during an outbreak in a large population of naïve horses in Australia was ~98% (mean) varying from 10% to 100%, with farms with lower numbers of horses generally having a higher attack rate.\(^{33}\) The mortality rate attributable to equine influenza was 0.6% and case-fatality rate 6%, based on a questionnaire of more than 1200 horse owners in Australia during the influenza outbreak (46% return rate) that involved self-reporting and was therefore at risk of sampling bias.\(^{34}\) The mortality rate appeared to be highest among foals (68% of reported deaths).\(^{35}\)

The profile of an epidemic can vary from explosive with a large proportion of a small group of susceptible horses housed in close proximity, such as a small band, developing clinical disease within 24 to 48 hours, to much more prolonged outbreaks lasting several weeks in larger groups of horses of varying susceptibility housed in multiple barns. During larger outbreaks among horses of varying susceptibility there is a characteristic three phase pattern. The first stage is associated with the first cases of disease and slow spread over the first 10 to 14 days. This stage is followed by one of rapid spread of the disease to horses clustered in stalls around horses affected during the first phase of the outbreak. The third phase is characterized by declining numbers of cases.

Origin of Infection and Transmission

Equine influenza virus is relatively susceptible to environmental conditions, and during an outbreak infection must originate from an infected horse, although the proximate source of virus can be contaminated equipment or other fomites, including people. Transmission of equine influenza virus occurs by direct contact, inhalation of aerosols of infected material, and on fomites. Survival of the virus on clothing and surfaces, including vehicles used to transport horses shedding the virus, can result in transmission of infection in the absence of horse to horse contact. Fomite transfer on veterinary clothing, equipment, or vehicles was likely responsible for the spread of infection from quarantined horses in both South African outbreaks. However, in most instances, horses are infected by other horses that are in close proximity or that have physical contact, for instance, exercise ponies (horses or ponies used to accompany racehorses from the stable to the track in preparation for racing or training gallops) or stable mates. Aerosol spread occurs over distances of 35 m, possibly further (see “Meteorologic factors” on this page), and is enhanced by the frequent coughing characteristic of the disease. Equine influenza virus in aerosols survives longer (24–36 hours) than human or porcine strains (15 hours).

Clinically affected horses excrete more virus than do horses in which the infection is inapparent. The duration of infectivity of clinically affected horses is 3 to 8 days and with the short incubation period of 2 to 3 days combined to produce the potential for a very rapid new infection rate and a characteristic explosive outbreak.

Risk Factors

Animal Factors

All age groups of horses, including newborn foals, are susceptible. The greatest risk appears to be between the ages of 2 and 6 months, serum levels of passively acquired antibodies being lost by foals at 2 months of age. A recent survey of more than 8000 horses in the United States revealed that only 20.2% of horses aged 6 to 17 months had a detectable influenza antibody titer (HI), compared with 89.0% of horses aged 20 years or more. The percentage of horses that had a high equine influenza antibody titer increased as the horse’s age increased such that 45% to 51% of horses older than 5 years had high titers. This observation is consistent
with most cases of the disease occurring in 2-year-old or younger horses, probably because older horses are immune through either natural exposure or vaccination. Thoroughbred racehorses 2 years of age or older were 5 to 8 times more likely to develop influenza than were horses 5 years of age in a well-characterized series of outbreaks. Seronegativity to a H3N8 virus (Saskatoon/90) was associated with a 13- to 38-fold increase in likelihood of developing influenza, independent of the effect of age. It is probable that outbreaks occur as a result of a natural accumulation of young animals that have not been previously exposed, the concomitant of these susceptible animals with older infected ones at race and show meetings, and the significant level of antigenic "drift." This capacity of the virus to change slightly and continuously in antigenic composition leads to the frequent appearance of new strains that are likely to breach existing natural and induced immunologic barriers.

Outbreaks can occur at any time of year, and their timing probably depends on husbandry and management practices, such as yearling sales, transport of horses for racing and sale, and movement of show and breeding animals. These events often provide the combination of a population of susceptible animals housed in crowded, poorly ventilated barns that facilitate transmission of the virus.

Immunity depends on the means of exposure (vaccination or natural infection), the strain of the virus, and the time since exposure. After infection, protective immunity to homologous strains of the virus is present and persists for 1 year, possibly up to 2 years. Field studies of disease outbreaks indicated that the concentration of antibodies in serum that provide some resistance to disease might be less than that suggested from experimental studies. Protective immunity induced by natural infection is characterized by production of IgA in nasal secretion and IgGa and IgGb in serum, whereas administration of an inactivated, alum-adjuvanted commercial vaccine induces only a serum IgG(T) response that is not protective against challenge. Immunity after vaccination lasts for a much shorter period of time, 3 to 4 months, and is specific for the subtype, and their strains, of virus included in the vaccine. Immunity following infection or vaccination is less protective against infection by a heterologous strain. Similarly, vaccination exposure to a heterologous virus may induce only a poor anamnestic immune response. These observations are consistent with the concurrent circulation of multiple viral strains influenza virus in horse populations and the cycling of virus strains causing disease in consecutive years.

Management Factors
Housing of large numbers of horses in close contact, or in enclosed environments such as large barns or stables, provides optimum conditions for facilitating contact and aerosol spread of the virus. Shed barns, which characterize have poorer ventilation and greater stocking density than pole barns, are associated with a fourfold increase in risk of influenza.

Presence of small numbers of horses with access to large numbers of at risk horses might affect the course of an epidemic. Track ponies, which have close contact with large numbers of horses on a daily basis, are important in spread of influenza in racing barns.

Meteorologic Factors
The influence of weather and wind on spread of equine influenza has not been extensively investigated. During the outbreak in Australia, the hazard of equine influenza infection was higher when relative humidity was less than 60% and lowest on days when daily maximum air temperature was 20° to 25°C (68 to 77°F).36 The increased risk of spread at lower relative humidity is mediated by both virion and aerosol droplet nuclei stability.36 In cool, dry conditions, droplets are desiccated and remain small, which may stabilize influenza aerosols and facilitate longer range transmission, whereas at high relative humidity, the droplets absorb water and settle, thereby decreasing the time aloft available for dispersion by wind.36

There was a relationship between the direction of prevailing winds and spread of equine influenza infection during the 2007 outbreak in Australia. There was a clear trend for appearance of newly infected premises to occur to the west of previously infected premises, consistent with predominant wind patterns.36 It is likely that wind carriage of the virus facilitated dispersal of infection. In a cluster of 437 infected premises, 81% were not contiguous to a previously infected premise and the mean distance from newly infected premises to the closest previous infected premises was 0.85 +/- 1.50 km, with a range of 0.01 to 12.94 km.37 Wind speeds greater than 30 km per hour from the direction of nearby infected premises were associated with increased hazard of infection.36 At wind speeds of greater than 30 km per hour, an aerosol of influenza droplet nuclei would only need to be stable for minutes to be able to infect horses on nearby premises.36 This is consistent with spread of equine influenza virus over 1 to 2 km, or possibly up to 13 km, via wind-borne aerosol.36,37

Economic Importance
Influenza causes minimal loss through death of horses, but it causes much inconvenience in racing stables because it occurs in explosive outbreaks and affected horses have to break training. Such outbreaks have the capacity to close down the racing industry in a country for a period of months. An additional cost is incurred because of restrictions on international movement of horses and associated quarantine periods.

Zoonotic Potential
There is evidence that humans can be infected by equine influenza virus H3N8, especially among individuals working with horses, although such seroconversion appears to be uncommon.39-41

AUSTRALIAN OUTBREAK (2007)
Australia experienced its first ever outbreak of equine influenza in 2007 as a result of equine influenza in horses in a quarantine station and a breach in the quarantine of these infected imported horses.42,43 Equine influenza virus H3N8, American subtype, Florida clade 1 lineage, with an HA sequence identical to that of a virus isolated from a contemporaneous outbreak in Japan,44 was introduced into a population of horses that were naive to the infection and unvaccinated for the disease. Over the course of 4 months, nearly 70,000 horses were infected on over 9,000 premises in New South Wales and Queensland, with a mean attack rate of 98%.44 In the first 10 days of the equine influenza outbreak in Australia, horses on 197 premises were infected.44 Timely and complete implementation of a horse movement ban ("standstill") is widely credited as the most effective of the control measures that facilitated the rapid eradication of this disease from the Australian horse population. The effectiveness of this ban was impressive: of 1052 horse movements in a contact-tracing data set, 978 occurred during the first 10 days of the epidemic.45 Vaccination was introduced in an attempt to control spread of the disease, but this began 6 weeks into the outbreak, well after the peak of reported daily infections.45 Modeling indicates that vaccination could have contributed to abbreviating the duration and reducing the geographic size of the outbreak by 8% to 9%.46

A comprehensive series of articles describing aspects of this epizootic is available.5,28-30,34,35,37,38,43-94

PATHOGENESIS
The disease is principally one of inflammation of the upper respiratory tract, although pulmonary lesions are common in adult horses, and the disease can cause severe, fatal pneumonia in foals. The virus is inhaled and attaches to respiratory epithelial cells with its hemagglutinin spikes, fuses with the cell, and is released into the cytoplasm, where it replicates. New virions are released from the cell surface and infect other cells or are expelled into the environment. Initial viral infection and replication occurs mainly in the nasopharyngeal mucosa, but by 3 to 7 days after infection, virus can be recovered from cells throughout the respiratory tract. Infection of the respiratory mucosa results in death of epithelial cells, inflammation, edema, and loss of the protective mucociliary clearance.
Death of cells is a result of influenza virus-induced apoptosis of respiratory epithelial cells and local and systemic increases in interferon and interleukin-6. Proliferation by opportunistic bacteria, commonly Streptococcus zooepidemicus, occurs because of the disruption of normal clearance mechanisms and can exacerbate the inflammation and cause bronchopneumonia. Viremia, if it occurs, is mild and brief, although it may be related to some of the systemic signs of the disease. Some speculate that myocarditis, myositis, and encephalitis occur occasionally in response to influenza virus infection, but definitive proof is lacking and was not evident in horses in the Australian epizootic or in ponies experimentally infected with equine influenza virus. Influenza virus has not been isolated from tissues other than those of the respiratory tract. Enteritis was reported in horses in the 1989 Chinese outbreak (Jilin/89), but is not reported for disease associated with conventional virus strains.

**CLINICAL FINDINGS**

Outbreaks of equine influenza are characterized by a sudden onset and rapid spread of disease. Typically, in a large group of susceptible horses the incidence of the disease peaks about 1 week after the first case is noticed, and new cases do not develop after 21 to 28 days. The disease may have an attenuated clinical course in a population of vaccinated or previously exposed horses, and there is evidence that disease severity varies widely among even naive horses, with some horses having severe signs of disease and others having no clinical evidence of infection.

The mild disease in immune animals may be clinically indistinguishable from upper respiratory diseases associated with other common agents such as EHV-4, equine rhinitis virus, and arteritis virus.

Clinically, the disease starts with a fever (38.5–41°C [101–106°F]) after an incubation period of 24 to 72 hours. Horses may be depressed, refuse feed, and be reluctant to move. The dominant sign is cough, which is dry and hacking in the beginning and moist later, and that commences soon after the temperature rise and lasts for 1 to 3 weeks. It is easily stimulated by manual compression of the upper trachea. During the early stages of the disease, nasal discharge is not a prominent sign and, if it occurs, is watery. There is no marked swelling of the submaxillary lymph nodes but they may be painful on palpation in the early stages of the disease, especially in younger horses. Limb edema or swelling is unusual in horses with influenza. Abnormal lung sounds, characterized by crackles, wheezes, and increased intensity of normal breath sounds, may be apparent in both uncomplicated disease and in horses with secondary bacterial pneumonia. Ultrasonographic examination of lungs of horses with influenza, even clinically mild disease, reveals pulmonary consolidation, fluid bronchograms, and peripheral irregularities.

Tracheal aspirates are neutrophilic, yield heavy growth of S. zooepidemicus, and are consistent with bronchitis and pneumonia. Horses, unusually, forced to exercise have reduced endurance. Horses that are protected against environmental stress pursue an uncomplicated course, with most horses have complete recovery in 7 to 14 days, although a mild cough can persist for weeks.

The previous paragraphs provide a description of the classical disease. However, in outbreaks there is a range of disease severity. Mucopurulent nasal discharge is observed in 75% to 90% of horses, cough in approximately 60%, fever in 20% to 50%, inappetence in 20% to 30%, and signs of depression in 20% to 40%. Undoubtedly, the proportion of horses showing each of these signs will vary from outbreak to outbreak depending on the age and susceptibility of horses in the population, among other factors.

Late term mares and young foals were the groups of horses that appeared to have large numbers or proportion of severely affected individuals during the Australian epizootic. Late term mares appeared to have a greater frequency of severe, paroxysmal coughing and a higher-than-expected incidence of dystocia, although these reports are largely anecdotal. Young foals had the highest case-fatality rate (see below) and death was often attributable to interstitial pneumonia.

Complications and more severe disease occurs in a small number of horses. Horses that are worked, transported, or exposed to adverse climatic conditions can experience a worsening of the cough, and severe bronchitis, pneumonia, and edema of the legs may develop. Complications are usually associated with secondary bacterial infection, usually Streptococcus zooepidemicus, which results in a mucopurulent nasal discharge, persistent fever, and markedly abnormal lung sounds. Icterus, encephalitis signs, incoordinated, and myoglobinuria are reported as rare complications. Electrocardiographic abnormalities have been reported in horses with influenza and were attributed to myocarditis. However, there is no objective evidence of myocarditis secondary to influenza infection of horses. Nor is there a clear association between influenza infection and electrocardiographic abnormalities. A more severe form of the disease, associated with an antigenically distinct strain of equine influenza 2, is reported from China. The mortality rate is 35%, and death is attributable to pneumonia and enteritis.

A severe form of the disease is also reported in young foals. Foals develop fever, severe respiratory distress, and acute interstitial pneumonia that is commonly fatal. The disease is not invariably associated with failure of transfer of passive immunity.

**CLINICAL PATHOLOGY**

There are no characteristic changes on hematology or serum biochemical examination of horses clinically affected by equine influenza virus infection.

**Confirmation of the diagnosis** of infection by equine influenza virus is achieved through virus isolation, indirect demonstration of virus in nasopharyngeal swabs by detection of viral genome (RT-PCR or variations) or proteins (ELISA), and/or serology.

**Serology**

Measurement of antibody concentrations against the viral hemagglutinin antigen is important in determining susceptibility to infection, vaccine efficacy, and exposure—factors important in implementing control measures (see following discussion). Documentation of seroconversion, a three- to fourfold increase in hemagglutination inhibition (HI) antibody titer, or a doubling in antibody titer measured by the single radial hemolysis test, in paired sera collection 14 to 21 days apart provides retrospective confirmation of the diagnosis. The single radial hemolysis test is more reproducible than the hemagglutination inhibition test, is the preferred test for determining concentrations of antibody against the hemagglutinin antigen, and better correlates with susceptibility to infection. For the single radial hemolysis test, the virus is coupled to red blood cells that are then included in agarose. Wells are punched in the agar plate filled with test sera. Influenza antibodies then cause lysis of red cells, with the diameter of the zone of hemolysis proportional to the concentration of the strain-specific antibody in the serum. Antibodies against the nonstructural protein (nucleocapsid protein, NS1) are detectable in horses after natural infection, but not after vaccination with an inactivated virus, thereby permitting differentiation of immunologic responses to infection and vaccination by canary pox-vectorized vaccines, but not by other subunit vaccines.

ELISA tests for detection of antibodies to equine influenza virus are available and have been characterized. A blocking ELISA for influenza A was accurate (area under curve = 0.993+/− 0.003 standard error), informative (z = −32.0; p < 0.0001) and had sensitivity and specificity at cut-point percentage inhibition greater than or equal to 50 of 0.99 (95% CI: 0.98–0.99) and 0.97 (95% CI: 0.96–0.98), respectively, and detected seroconversion as early as day 3 after onset of clinical signs and in 50% of horses by day 5. Other commercially available ELISA tests have similar diagnostic test characteristics.

Rapid Detection of Virus

Rapid identification of the cause of the outbreak is important when instituting control measures. Timely demonstration of virus in
nasopharyngeal swabs can be achieved by use of tests that detect viral antigen (ELISA or similar tests) or viral genome (real-time reverse-transcription polymerase chain reaction (rtRT-PCR or qRT-PCR)) or a reverse-transcription loop-mediated isothermal amplification assay. Such tests can be invaluable in confirming an outbreak or occurrence of disease, in monitoring infection rates, and in achieving control. Detection of viral antigen by ELISA or similar methods and of viral genome by RT-PCR is not necessarily associated with shedding of live (infectious) virus (a false-positive test result). Both methodologies can detect non-viable remnants of viruses, often for long periods of time, and detection of low levels of viral RNA or antigen should be considered in the context of available clinical and epidemiologic data. Viral RNA has been detected in nasal swabs of horses for up to 34 days after natural infection, with RNA detected in all of 36 horses tested for the first 10 days after onset of clinical signs.95

Virus can be detected rapidly in clinical specimens by a reverse-transcription PCR (RT-PCR) test for nucleoprotein gene, hemagglutinin gene of H3N8 viruses and hemagglutinin gene of H7N7 virus. The rtRT-PCR is widely available, is the most sensitive of the currently available tests, and is suited for throughput of large numbers of samples when rapid decision making is required, such as during outbreaks of the disease.74,87-107 The rtRT-PCR can detect virus as early as 1 day after experimental infection of horses, at the same time as virus isolation detected the virus, and before onset of clinical signs.111 RT-PCR is highly sensitive and can result in detection of even very small quantities of viral RNA, such as can occur when nasal swabs are contaminated with inactivated intramuscular vaccine.94

Recent development of field tests (on-site tests) to detect viral genome will further enhance diagnosis and control of the disease. The insulated isothermal RT-PCR (iIRT-PCR) method on the POCKIT™, a field-deployable device, is about 100-fold more sensitive than the rRT-PCR assay targeting the NP gene of EIV subtype H3N8 (Miami 1/63/H3N8). The iIRT-PCR assay identified accurately 15 EIV H3N8 strains and two canine influenza virus (CIV) H3N8 strains, and it did not cross-react with H6N2, H7N7, and H1N1 subtypes or any other equine respiratory viral pathogens. There was 100% agreement between the iIRT-PCR assay and the universal influenza virus type A rRT-PCR assay in detecting the EIV A/equine/Kentucky/7/07 strain in 56 nasal swab samples collected from experimentally inoculated horses.112 The utility of this test in field situations remains to be demonstrated.

The Directigen Flu A test (Becton Dickinson) is a rapid test designed for use with humans that identifies influenza viral nucleoprotein (NP, which is highly conserved among influenza A viruses) by a membrane-bound enzyme immunoassay. It has been validated for use in horses and is effective because of the conserved nature of the target antigen across influenza A strains. Results are available in as little as 15 minutes. The test had sensitivity of 68% to 83% and specificity of 78% to 95%, compared with RT-PCR or virus culture.113 Sensitivity was 54%, but specificity and positive predictive value were 100% compared with serologic diagnosis. The low sensitivity compared with serology was ascribed to inadequate collection of nasopharyngeal swabs, or collection of samples when horses were not excreting virus. The high specificity and positive predictive value of the test mean that a positive result confirms the diagnosis of influenza infection. The relatively low specificity means that samples should be collected from a number of horses in various stages of the disease. Nasopharyngeal swabs should be collected by inserting a cotton gauze swab approximately 30 cm (12 in.) into the nostril or, preferably, nasopharynx of an adult horse and leaving it in place for 60 seconds. The swab should then be transferred to specialized transport media and shipped to the laboratory.

Other rapid diagnostic tests include the Flu OIA (BioStar) assay for influenza A and B viral antigen. The test cross reacts with equine herpesvirus 2 and is therefore not useful for diagnosis of upper respiratory disease of horses. Other ELISA diagnostic assays, including an antigen capture ELISA, are available.116

Use of rapid tests is not a substitute for viral isolation, which is important for typing of the isolate and subsequent epidemiologic studies and vaccinal applications. Isolation of the virus provides a definitive diagnosis and is best achieved when samples are collected during the first 48 hours after onset of clinical signs. Material for viral culture should be inoculated into the transport medium quickly. The transport medium should contain phosphate buffered saline (PBS) containing either 40% glycerol or 2% tryptose phosphate broth with 2% antibiotic solution (penicillin [10,000 units], streptomycin [10,000 units] in sterile distilled water [100 mL]), and 2% fungizone (250 mg/mL stock).117 If the samples are to be inoculated within 1 to 2 days they may be held at 4°C (39°F), but, if kept for longer, they should be stored at −70°C (~94°F) or below. Samples should be kept cool during transport to the laboratory.

**NECROPSY FINDINGS**

Necropsy material is rarely available for adult horses, and the lesions in these fatalities are usually complicated by other pathogens. Histologically, a necrotizing bronchiolitis accompanies widespread pulmonary edema. Foals dying of acute respiratory distress associated with influenza infection have severe diffuse interstitial pneumonia that is characterized histologically by necrotizing bronchiolitis and bronchiolitis multifocal interstitial pneumonia.97

**Samples for Postmortem Confirmation of Diagnosis**

- Nasal swabs in viral transport media, and sections of lung and trachea should be submitted for virus isolation or demonstration by fluorescent antibody or PCR testing.
- Formalin-fixed nasopharynx, trachea, and lung should be submitted for light microscopic examination.

**DIFFERENTIAL DIAGNOSIS**

See Table 12-16.

**TREATMENT**

Currently, there is no specific treatment of influenza virus infection of horses.

**Amantadine** is used in humans for prophylaxis and treatment of influenza infection in high-risk populations, and it has been investigated for use in horses. Amantadine administered intravenously caused transient neurologic abnormalities in experimental horses. **Rimantadine** (30 mg/kg PO q12 hour) administered 12 hours before experimental inoculation of horses with equine influenza KY/91 mitigated signs of disease but did not eliminate viral shedding. Administration of **peramivir** (~8 mg/kg IV once) to horses experimentally infected with equine influenza virus attenuated the severity of clinical signs.118,119 The safety and efficacy of peramivir, amantadine, and rimantadine in horses with naturally occurring disease have not been demonstrated at this time. Until these issues are resolved, and because the infection has such a low case-fatality rate, the use of these drugs in horses cannot be recommended.

**Antibiotic treatment** of uncomplicated cases is probably not warranted, but horses that develop prolonged fever (longer than 5 days), signs of pneumonia, or a profuse mucopurulent nasal discharge should be treated with broad-spectrum antibiotics, such as potentiated sulfonamides (15-30 mg/kg, PO, IM, or IV, every 12 h), cefotiofur (2.2 mg/kg, IM, every 12 hours), or procaine penicillin (20,000 IU per kg, IM, every 12 hours) with or without gentamicin (6.6 mg/kg, IM, every 24 hours). The usual cause of secondary bacterial infection is **S. zooepidemicus**, which is susceptible to penicillin.

**Supportive treatment** includes rest, provision of a dust-free environment and, on occasion, administration of nonsteroidal antiinflammatory drugs (NSAIDs). However, NSAIDs should be used judiciously, as their analgesic properties may mask signs of...
complications, such as pleuritis. Corticosteroids are contraindicated in the treatment of this disease. Cough suppressants are also contraindicated because coughing is a normal protective mechanism that aids in the clearance of material from the airway. Mucolytics can be administered but their efficacy is unknown. Clenbuterol administration does not alter the course of the disease and is not recommended.

CONTROL

The fundamental aims of a control program are the following:

- Increase the immunity of both individual animals and the population to infection.
- Reduce the opportunities for spread of infection between horses.
- Prevent the introduction of infection or of novel strains of the virus into a population.

These aims are achieved by vaccination, hygiene, and quarantine. It is important to note that effective quarantine that includes isolation of horses for 4 weeks before introduction into a new population of horses prevents introduction of the disease. 103

Immunity and Vaccination

The aim of vaccination in enzootic areas is to prevent clinical disease caused by infection with equine influenza virus. This aim includes two components—induction of herd immunity by widespread vaccination of almost all horses in a population and induction of protective immunity in individual horses. 102,118

The first aim is actually more difficult to achieve because of the perception by horse owners in enzootic areas that influenza is not an important disease or that their horse(s) are not at risk and the inability of regulators to mandate vaccination on a country-wide scale. 118 The result is that an insufficient proportion of horses in a population are vaccinated to confer herd immunity on the population as a whole, with consequential localized outbreaks or epizootics of the disease. 102,118

Induction of protective immunity in individual horses through vaccination is achievable with certain limitations. Immunity induced by vaccination, especially vaccination using inactivated virus, is not as durable as that conferred by natural infection, nor does it induce the same type of immune response, although this might not apply for modified live vaccines. 102 Furthermore, many factors influence the onset, duration, spectrum, and efficacy of vaccination programs, including the product administered, frequency of administration, frequency with which different equine influenza vaccines are administered to horses, age, and sex. 102-128

That said, the responses of most horses to vaccination are predictable, and with increasing knowledge of the immune responses to vaccination, vaccination programs can be expected to confer immunity to clinical disease when properly applied. 103,104,110,112,122-124 Reports of vaccine failure might in actuality be failures of vaccination programs. 118

Vaccination does not induce sterile immunity to equine influenza virus, and this is important in understanding of the epidemiology and control of the clinical disease. 27,30,151 The extent of cross-protection against infection and/or disease by each of two influenza virus strains depends on the antigenic distance between the strains (see Fig. 12-31). Infection by equine influenza virus or vaccination using an effective vaccine can induce immunity and resistance to infection and development of disease as a result of a homologous virus. For example, vaccination with an inactivated Florida clade 2 virus, or vaccine containing the relevant HA antigen, confers considerable resistance to infection by a Florida clade 2 strain of the virus, but limited immunity, or immunity only at peak antibody titers, to infection by an Eurasian lineage virus or a Florida clade 1 virus. 102 Therefore, the level of protection provided by vaccines is often critically dependent on how closely the vaccine strain matches the virus encountered by the horse. This phenomenon is the basis for the recommendation that contemporary vaccines contain both Florida clade 1 (A/equi2/South Africa/4/03 or Ohio/03) and a clade 2 (Richmond/3/07) virus strains or HA antigens. 12,13,118

A large number of vaccines to prevent disease as a result of infection by equine influenza virus and recommendations for vaccination programs are available. 12,13,18,19,118,130,131 These include vaccines that include whole virus sub-units (e.g., HA protein) either as the purified protein or in a live vector (canary pox), 122,123,129 and vaccines containing various adjuvants and immune stimulating complexes, 132 or live attenuated virus for intranasal administration. 129,133 There are numerous reports of the efficacy of one or more of these vaccines. 12,13,19,110,119,122,129,132-134 A comparison of each vaccine is beyond the scope of this text, but several principles should be considered when selecting a vaccine: the vaccine should induce a measurable immune response and demonstrable protection against disease (natural or experimental), it should contain pertinent viral strains, it should be safe, and it should be practical (i.e., readily administered). Ideally, it should be possible to differentiate naturally infected horses from those that are seropositive as a result of vaccination.

Immunity to influenza through administration of inactivated vaccines can be assessed by measurement of serum antibody concentrations associated with heterologous virus. Furthermore, the immune responses induced by administration of inactivated virus or subunit vaccines, which are primarily an increase in serum IgG(T) antibody titer, differ markedly from the immune responses to natural infection, which are production of IgA in nasal secretions and IgGa and IgGb in serum.

Multiple factors are important in determining the efficacy of a vaccine in protecting against disease. Factors include efficacy of the vaccine in stimulating an immune response, viral strains included in the vaccine and antibody and antigens included, and the adjuvant used is available at the equilunet website. 13 This site should be consulted for up-to-date information on equine influenza vaccines as this is a rapidly developing field. At time of writing, there was only one vaccine that included both Florida clade 1 and Florida clade 2 virus. However, serum antibody concentration is currently used as an indicator of susceptibility of individual horses to infection, and as a guide in the development and application of vaccination protocols, including monitoring of need for vaccination in individual horses. Serum antibody concentrations to hemagglutinin measured by single radial hemolysis are specific for the strain of virus and are strongly predictive for resistance to disease associated with that virus in both experimental and field challenge. Failure of a commercial inactivated virus multivalent vaccine to induce detectable increases in antibody concentration in Thoroughbred racehorses was associated with lack of protection against natural infection by a heterologous influenza virus. It is important to reiterate that resistance to disease after vaccination or natural infection is greatest for homologous virus and less for challenge by heterologous virus. Thus horses with antibody concentrations protective to disease associated with homologous virus can be susceptible to disease associated with heterologous virus.

Vaccination against equine influenza is now in general use in countries where the disease occurs, and use of efficacious vaccines is effective in limiting the severity of clinical illness and morbidity during an outbreak. 12,13 Administration of a subunit, canary pox–vectored vaccine, is partially credited with abbreviating the equine influenza epizootic in Australia and for allowing continued commercial racing. 63,81,98 Vaccine efficacy is limited by the short duration of immunity induced by vaccination, the presence in horse populations of multiple viral strains and of antigenic drift in these strains, and the poor immunity induced by vaccines (and natural infection) to challenge by heterologous virus. Furthermore, the immune responses induced by administration of inactivated virus or subunit vaccines, which are primarily an increase in serum IgG(T) antibody titer, differ markedly from the immune responses to natural infection, which are production of IgA in nasal secretions and IgGa and IgGb in serum. A complete listing of current commercially available vaccines, the viral stains or antigens included, and the adjuvant used is available at the equilunet website. 13 This site should be consulted for up-to-date information on equine influenza vaccines as this is a rapidly developing field. At time of writing, there was only one vaccine that included both Florida clade 1 and Florida clade 2 virus.
antigens (clade 1 is represented by A/eq/ South Africa/04/2003-like, and Clade 2 is represented by A/eq/Richmond/1/2007-like viruses213), consistent with the most recent OIE recommendations.11 The OIE recommends that H7N7 and H3N8 (Eurasian lineage) virus no longer be included in vaccines.

Most vaccines are comprised of inactivated or subunits of virus combined with an adjuvant. Inclusion of an adjuvant is important in maximizing the immune response to vaccination. The important factor in vaccine composition is the inclusion of adequate amounts of antigen of pertinent strains of virus. H7N7 virus is no longer a cause of clinical disease, and it should not be included in contemporary vaccines. Inclusion of antigen from both American and Eurasian lineages of H3N8 virus is essential, and vaccine composition should be regularly updated to reflect those viruses currently circulating in the horse population. The vaccine must include an adequate amount of antigen, measured by the single radial hemolysis assay, preferably, the single radial hemolysis assay, because there is a clear relationship between dose of antigen and magnitude and duration of antibody response. There is increasing concern, and some evidence, that inclusion of multiple antigens in vaccines (for example, tetanus toxoid, equine herpesvirus, encephalomyelitis virus) reduces the efficacy of influenza vaccines. Although this concern has yet to be proved conclusively, it should be borne in mind when formulating vaccine programs for horses at high risk of influenza.

A modified live-virus vaccine is available in North America and has proven to be effective in experimental studies in preventing disease against heterologous virus challenge (both American and Eurasian lineages).222 Furthermore, the duration of protection is at least 6 months after completion of a course of vaccination and there is a strong anamnestic response.212 Vaccinated ponies had significantly lower clinical scores, had smaller increases in rectal temperature, and shed less virus over fewer days than did the unvaccinated controls in response to challenge 6 months after vaccination. After challenge at 12 months, vaccinated horses were rectal temperatures and duration and concentration of virus shed significantly reduced compared with those in unvaccinated animals.

A live recombinant canary pox–vectored vaccine has been used in Europe, America, South Africa, and Australia.211,212 The vaccine uses the viral vector to introduce influenza hemagglutinin genes into host cells. The recombinant virus expresses the hemagglutinin gene of both Florida clade 1 H3N8-Ohio/03 and Florida clade 2 H3N8-Richmond/1/07.17 The canary pox infection of the host cell is abortive, with no virus produced, but influenza viral gene is expressed and presented through MHC class 1 by the host cell, with subsequent induction of an immune response. A form of this vaccine, including both European and American lineages, was used to aid in the control of the 2003 influenza outbreak in South Africa and the 2007 epizootic in Australia.82 An advantage of use of this vaccine is the ability to differentiate vaccinated horses from horses that seroconvert as a result of natural infection. This is achieved by detection of antibodies to both HA and internal viral proteins (NP) in naturally infected horses and only antibodies to HA in vaccinated horses.54,74 There are variations of this testing, based on the same principle of differential induction of antibodies, that can differentiate infected horses from those receiving an inactivated virus vaccine.

Other novel vaccine strategies include use of DNA or vector vaccines.135 Although effective in inducing a protective response, technological issues currently limit the widespread use of DNA vaccines.

**Objective**

The objective of a vaccination program is to ensure that horses have maximal immunity at the times of greatest risk of exposure to influenza virus. Therefore young horses should be adequately vaccinated before being introduced into larger populations of horses. Older horses should receive frequent booster vaccinations before, and during, the racing or show season. Mares should be revaccinated before being shipped to breeding farms. It is important in any control program that all horses in a herd be vaccinated so that the population immunity to infection is maximal.

The objective of vaccination during the epizootic in Australia was to first control and then eliminate infection from the continent.82 As such, the program of vaccination involved prophylactic vaccination, implemented before a disease outbreak, and reactive vaccination, implemented as part of a response to a disease outbreak, in conjunction with quarantine and movement control measures, as set out in the Ausvet Plan.27 Reactive strategies include ring vaccination around identified sources of infection to limit further spread by producing an immune buffer, blanket (mass) vaccination and predictive vaccination whereby selective groups of horses are vaccinated because they are identified as having the potential to contribute most to future spatial transmission of infection. Ring vaccination was implemented through the creation of vaccination buffer zones 10-km wide or wider around foci of infection where lateral spread of infection was occurring. Predictive vaccination was used where there were large accumulations of horses and/or movement of personnel or fomites (vehicles) in contact with horses. Groups of horses suitable for predictive vaccination include racehorses, breeding horses, police horses, and other essential groups.

Blanket vaccination refers to vaccination of all horses in an area, thereby permitting limited movement and use of horses in that area.27,68

**Timing**

**Foals**

Timing of vaccination of foals depends on the immune status of the mare and consequent acquisition of passive immunity by the foal. The presence of even small amounts of maternally derived antibody interferes with the immune response of foals to vaccination. Furthermore, vaccination of foals while they continue to have passive immunity can result in impaired responses to subsequent vaccinations. The practical significance of this latter observation is unknown but because of its potential importance should be considered when developing vaccination protocols for foals. Therefore vaccination of foals born to mares vaccinated more than once yearly should be delayed until the foals are at least 24 weeks of age when the immunity resulting from the vaccination is much better; this might leave some foals unprotected because passively acquired immunity is short lived, and some foals of recently vaccinated dams are seronegative by 4 weeks of age. Foals of unvaccinated mares can be vaccinated at less than 1 month of age. Vaccinations are carried out at 6- to 12-week intervals for at least two injections. Subsequently, booster injections are given at least once a year, although more frequent vaccination confers a greater immunity.

**Racehorses and Show Horses**

Yearlings and young horses are at increased risk of disease, and careful attention to their vaccination status is important in reducing the incidence of disease in this group. Yearlings and 2 year olds in racing stables in Great Britain typically have antibody concentrations against influenza before vaccination on arrival at the stable that are not protective. Vaccination increases antibody titer such that approximately three quarters of yearlings and 2 year olds have protective titers. For yearlings entering training the important predictors of antibody titer before vaccination on arrival at the stable were the time since a previous vaccination, total number of previous vaccinations, and the age at first vaccination. This study demonstrates the need for appropriate vaccination of young horses before they enter larger populations of horses, both to protect the young horse from disease and also to confer herd immunity on the population that they are entering.

Vaccination of racehorses and show horses and other horses at increased risk of exposure should be frequent. Booster vaccines should be timed to maximize immunity at the time of greatest exposure, such as introduction to a new stable or at the beginning of the show season. For maximal protection subsequent booster injections should
be administered at intervals of 6, or even 4, months. Measurement of antibody concentrations by single radial hemolysis can be useful in determining the need for booster vaccination. Previously, vaccination during the racing season was disliked by trainers because of transitory swellings at injection sites and an infrequent mild systemic reaction; however, administration of contemporary vaccines is rarely associated with these adverse effects. In general, vaccination appears to have no adverse effect on performance.

**Schedule**

Various schedules have been proposed for influenza vaccinations of horses, with different regulatory bodies having specific recommendations. The FEI requires all horses competing in FEI competition to provide evidence of sufficient vaccination against equine influenza.136 This involves regular six monthly booster vaccinations following a primary vaccination course. All horses and ponies for which an FEI Passport or a National Passport approved by the FEI has been issued must have the vaccination section completed and endorsed by a veterinarian, stating that it has received two injections for primary vaccination against equine influenza, given between 1 and 3 months apart. In addition, a booster vaccination must be administered within each succeeding 6 months (± 21 days) following the second vaccination of the primary course. None of these injections must have been given within the preceding 7 days, including the day of the competition or of entry into the competition stables.

The British Horse Racing Authority has strict vaccination requirements that must be complied with to enter horses in their competitions or onto its premises.130 The program includes a first equine influenza vaccination to be followed by a second vaccination 21 to 92 days later, with a third vaccination 150 to 215 days from the second vaccination. Thereafter vaccinations should be annually, with the last permissible day being the same date as the previous year’s vaccination.

A schedule proposed for control of influenza in a large area includes the following rules:

- Mandatory vaccination for all horses entering racing premises
- Horses not to race in the 10-day period following vaccination
- Horses coming from international locations must be vaccinated before departure.
- All horse events, including shows, sales, and gymkhanas, should apply the same restrictions.
- The recommended vaccination program using inactivated or subunit vaccine is as follows:
  - Mares should be vaccinated during the final 4 to 6 weeks of gestation to ensure adequate passage of passive immunity to the foal.
  - Vaccination of foals at 6 months of age
  - Two vaccinations initially at 21 days, and not more than 92 days apart
  - A booster vaccination 5 to 7 months later
  - Annual boosters or, in the face of increased infection pressure or when the risk of infection is high, boosters should be at 6-month or even 4-month intervals.
  - When vaccination schedules break down and a horse goes longer than 12 months without a booster, recommence with a two-vaccination schedule.
  - Yearlings and 2-year-olds may require an additional vaccination between the second vaccination of the primary series and the booster at 6 months.

**Control Measures**

Spread of equine influenza virus is by infected horses, fomites, and vehicles, and by dispersion of infected aerosols by wind or, more proximately, by coughing and sneezing. Control is achieved by preventing movement of infected or potentially infected horses and their contact with uninfected horses (i.e., quarantine), disinfection of fomites or personnel or prevention of contact of potentially contaminated fomites or personnel with susceptible horses, and reduction of ambient contamination of the virus.

**Hygienic precautions** can be of value in limiting the spread of the disease, as was documented during the epizootic in Australia. A comprehensive plan for management of incursion of equine influenza into an area free of the infection is provided in Austvet Plan for equine influenza and in the special issue of the *Australian Veterinary Journal* (2011, Volume 89, Supplement) describing responses to the 2007 incursion of equine influenza into Australia and its prompt eradication.7

**Quarantine** is imperative to prevent introduction of virus by animals in the incubation period of the disease or subclinically infected horses. The most common introduction of infection, especially internationally, is through importation of subclinically infected horses. Also, because vaccinated animals can be infected and be shedding virus but not have signs of infection, isolation of introduced animals is an essential precaution, especially when an outbreak is in progress. The period of isolation should be at least 21 days and ideally 28 days.115 The degree of isolation required cannot be specified because of lack of basic information, but it is suggested that droplet infection can occur over a distance of 32 m and wind-borne spread of up to 13 km. There should be maximum biosecurity with regard to clothing, utensils, and personnel because this is effective in preventing spread of infection.60,90

It is important to recognize that abrupt imposition of quarantine and “standstill” of horses during an epizootic of the disease is associated with considerable psychological, emotional, logistic, and economic impact on owners, trainers, and horse-related businesses. 50,52,57,60,66,80,93

**Control measures during an outbreak** are intended to eliminate sources of infection, reduce transmission of virus, enhance the resistance of at-risk horses, and decrease the number of horses at risk. Infected horses (identified by stall-side or rapid laboratory tests), and clinically affected horses should be removed from the group and isolated for 3 to 4 weeks. Ventilation of shed rows and barns should be optimal to minimize aerosol spread of the virus. No horses should be introduced or allowed to leave until the outbreak is over, probably about 4 weeks after the first case is identified. Movement of horses between barns or paddocks should be avoided. Training and racing should be suspended. The opportunity for fomite transfer on clothing, tack, feed utensils, or vehicles should be minimized by strict hygiene. Vaccination of clinically normal horses in the face of an outbreak can enhance the immunity of at-risk horses and is probably safe.

A comprehensive plan for management of incursion of equine influenza into an area free of the infection is provided in Austvet Plan for equine influenza and in the special issue of the *Australian Veterinary Journal* (2011, Volume 89, Supplement) describing responses to the 2007 incursion of equine influenza into Australia and its prompt eradication.7

EQUINE RHINITIS (EQUINE RHINITIS VIRUS)

The equine rhinitis viruses are ubiquitous in populations of horses. Infection has been associated with mild respiratory disease, although their role in the common infectious respiratory diseases of horses is uncertain.

The equine rhinitis viruses are of four types—ERAV-1 and ERBV-1, 2, and 3. Equine rhinitis A virus (formerly equine rhinovirus-1) is a species within the genus Aphthovirus containing a single serotype, equine rhinitis A virus-1 (ERAV-1). There is little genetic variation in this virus. The genus includes foot-and-mouth disease virus and bovine rhinitis virus, of the Picornaviridae. Equine rhinovirus 2 and equine rhinovirus 3 are now classified in the genus Erbovirus as equine rhinitis B virus (ERBV) types 1 and 2, respectively. A third equine rhinitis B virus has been identified—ERBV-3. The viruses are widely distributed in horse populations globally and infect substantial proportions of horses worldwide. For example, antibodies to ERBV were detected in 86% of 50 weanling Thoroughbred from three stud farms in Australia, with 48%, 10%, and 62% of yearlings being seropositive for ERBV-1, ERBV-2, and ERBV-3, respectively. Fifty-six percent of the horses had evidence of infection by two serotypes, and 12% had evidence of infection by all three serotypes. Other finds similar seroprevalence for ERBV-1 and ERBV-2 in Australia. Virus genome is detected by PCR in nasal swabs in a much smaller proportion of horses (0%-1%), suggesting differences in sensitivity of the assay, minimal or intermittent shedding of the virus or differences in the populations of horses sampled. Serologic evidence of infection with ERAV is present in 50% to 100% of horses, although the prevalence of seropositive animals varies from almost zero in yearlings, to 8% in horses newly introduced to a training yard, to 61% in the same horses 7 months later. Twenty-eight percent of 113 horses in
Ontario with signs of respiratory disease were seropositive for ERAV.10 ERAV is present in nasal discharge, feces, and/or urine of experimentally infected clinically normal horses and can be shed in the urine for at least 37 days.11,12 Virus was detected in 23% of 215 urine samples collected from Thoroughbred racehorses as part of postrace drug monitoring.13 These horses were therefore presumed to not have signs of infectious respiratory disease, and this represents a shedding rate in clinically normal horses.14 The importance of urine shedding of the virus in transmission of infection is unclear, although the inhalation of aerosols of infected urine might transmit the virus. The virus has been detected in semen of a stallion.15

The role of ERAV or ERBV in genesis of respiratory disease of horses is unclear. The disease can be reproduced experimentally in seronegative ponies,16,17 and there are a small number of reports of ERAV association with respiratory disease, but clear causal association with common naturally occurring respiratory disease is lacking. High titers to ERAV are detected in horses with disease caused by equine influenza virus in Ontario, and it is suggested that this could be important in the development of respiratory disease, but without conclusive evidence.18

The high prevalence of ERAV infection in horses means that detection of the virus in horses with signs of respiratory disease could occur by chance in a proportion of individuals with ERAV not being causative. None of 52 horses with signs of infectious respiratory disease in New Zealand had ERAV or ERBV virus (by tissue culture) or viral DNA (by PCR) detected in nasal swabs.19 Similarly, ERAV was not detected in nasal swabs of any of 336 horses with respiratory disease (or in any of the 39 healthy controls) in the western United States, and ERBV was detected in 9 of 336 samples.20 Although there is some evidence to indicate a causative role for ERAV and ERBV in common infectious respiratory disease of horses, the importance of the virus remains to be determined.

The disease thought to be associated with ERAV is characterized by an incubation period of 3 to 8 days, fever, pharyngitis, pharyngeal and submandibular lymphadenitis, and a copious nasal discharge that is serous early and becomes mucopurulent later. A cough persists for 2 to 3 weeks. The uncomplicated disease is mild and self-limiting. Among a group of susceptible horses, there is rapid spread of infection and disease. Studies in England have not identified the virus as an important cause of inflammatory airway disease in racehorses.

The virus has been associated with abortion in dromedary camels.15 Virus neutralizing antibody develops within 7 to 14 days of infection and persists for long periods.16 Immunity after natural infection is said to be solid and long-lasting.

Diagnosis is based on serologic testing, detection of viral DNA, or tissue culture of the virus, which is environmentally resistant.

There is no specific treatment, and a commercial vaccine is not available. Planned exposure of young horses to infection has been recommended, but this should be reconsidered in light of current knowledge of the prolonged shedding of the virus in urine and feces. The virus appears to have minimal zoonotic potential.

REFERENCES

ETIOLOGY
Upper respiratory disease of foals and adults is associated with equid herpesvirus-4 (EHV-4) or, less commonly, EHV-1, an alpha-herpesvirus. The DNA sequence of EHV-4 has been determined. There appear to be strains of EHV-4 that vary in virulence, based on severity of clinical disease, but at present it is not possible to differentiate between strains of low and high virulence by laboratory methods.

EPIDEMIOLOGY
Occurrence
Infection with EHV-4 is endemic in horse populations worldwide.1,2 The serologic surveys of prevalence of serologic evidence of infection are of limited value because earlier studies used techniques that were unable to differentiate between antibodies to EHV-1 and EHV-4. Recent serologic surveys using ELISA tests capable of differentiating between antibodies to EHV-1 and EHV-4 demonstrate that almost all horses and foals greater than 60 days of age have evidence of infection by EHV-4. Young foals can be seropositive as a result of transfer of immunoglobulins from seropositive dams, making determination of the time of first infection, and active seroconversion, difficult. Furthermore, serologic tests are also unable to differentiate between responses to natural infection and to vaccination.

EHV-4 can be isolated from both clinically normal foals and those with signs of upper respiratory disease with similar frequency. Shedding of virus is more likely in foals with nasal discharge. There is a marked seasonal distribution to the pattern of shedding, with the most frequent detection of shedding being in early autumn (March).

Upper respiratory tract disease attributable to EHV-4 is very common and probably affects almost all horses during the first 2 years of life. EHV-4 rarely causes abortion in mares, septicemia in newborn foals, or myeloencephalopathy in adult horses. The frequency of respiratory disease attributable to EHV-1 is unclear but is apparently much less common than that for EHV-4.4,5 Seroprevalence of EHV-1 specific antibodies is 9% to 28% in adult Thoroughbred horses, 26% of Thoroughbred brood mares, 11% of Thoroughbred foals, and 46% to 68% of 1- and 2-year-old Thoroughbred racehorses in Australia. Sixty-one percent of 82 normal horses and horses with upper respiratory tract disease had antibodies to EHV-1 in New Zealand. Prevalence of serum antibodies to EHV-4 and EHV-1 were 93% and 1%, respectively, in young Thoroughbreds presented for sale as yearlings in South Africa. EHV-4 DNA was detected in 14% of animals, whereas EHV-1 DNA was not detected in any horses at sale. Similarly, in England, EHV-1 was not associated with clinical respiratory disease in Thoroughbred racehorses.

EQUINE VIRAL RHINOPNEUMONITIS (EQUINE HERPESVIRUS-1 AND -4 INFECTIONS)

SYNOPSIS

Etiology EHV-4, and EHV-1, alpha-herpesvirus.

Epidemiology Transmission between horses and by mediate contagion. Lifelong latency of infection with putative periodic reactivation of virus shedding. Respiratory disease occurs as sporadic disease and as outbreaks. Younger animals more commonly affected by disease. Immunity following vaccination or infection is apparently short lived.

Clinical signs Upper respiratory disease; rarely, abortion or myeloencephalopathy.

Clinical pathology Seroconversion or increase in titer detected by enzyme-linked immunosorbent assay (ELISA) able to differentiate EHV-1 from EHV-4.

Diagnostic confirmation Virus isolation from, or polymerase chain reaction test on, blood, nasopharyngeal swabs, or tissue. Seroconversion or increase in titer detected by ELISA able to differentiate EHV-1 from EHV-4.

Treatment There is no specific treatment.

Control Vaccination (of minimal efficacy). Quarantine. Hygiene.
Method of Transmission

EHV-4 is highly infectious, and transmission probably occurs by the inhalation of infected droplets or by the ingestion of material contaminated by nasal discharge. Foals infected with EHV-4 have prolonged and profuse shedding of virus in nasal secretions. Mediation may occur, the virus surviving for 14 to 45 days outside the animal.

Infections always arise from other horses, both by direct contact and via fomites. Horses and foals are infectious during the active stage of disease and, because horses become latently infected, presumably during subsequent periods of viral reactivation and shedding. The duration of latency is unknown but is assumed to be lifelong. EHV-4 establishes latency in the trigeminal ganglion, which is the origin of the maxillary branch of the trigeminal (5th cranial) nerve that provides sensory innervation to the nasal mucosa. It is assumed that reactivation of the virus and subsequent virus shedding poses a risk to in-contact, susceptible animals, but this has not been definitively demonstrated in field situations. If this were the case, then clinically normal animals harbor latent virus that during periods of reactivation can infect susceptible animals. If true, this feature of the disease has obvious importance in the prevention, control, and management of outbreaks of disease.

Economic Importance

Disease associated with EHV-4 is apparently of considerable economic importance because of the loss of training time and opportunities to perform during convalescence and quarantine. Although the upper respiratory disease is a mild inflammation of the respiratory tract of horses, characterized by coughing and nasal discharge, the importance of the disease is the large numbers of animals affected in an outbreak. Fatalities in uncomplicated cases of rhinopneumonitis are rare.

PATHOGENESIS

The pathogenesis of EHV-4 infection and disease is assumed to be similar to that of EHV-1, with the exception that the virus does not commonly cause abortion, neonatal septicemia, or myeloencephalopathy. The virus is inhaled and binds to epithelium of the upper respiratory tract, enters epithelial cells, and reproduces. The infection then spreads throughout the respiratory tract, including trachea and bronchioles, and to lymphoid tissues associated with the respiratory tract. There is a viremia, although this may be of short duration. There is cell death and development of intranuclear inclusion bodies in the respiratory tract and associated lymphoid tissues. The EHV-4 virus then becomes latent, as evidenced by isolation of virus from lymph nodes associated with the respiratory tract and detection of viral genome in trigeminal ganglia, although this has not been a consistent finding. The factors causing viral recrudescence from these latent sites have not been determined. It should be noted that definitive evidence of viral recrudescence of EHV-4 as a cause of outbreaks of disease is lacking, and experimental induction of recrudescence is achieved only by administration of large doses of corticosteroids.

Diseases of the Equine Respiratory Tract

Infections always arise from other horses, both by direct contact and via fomites. Horses and foals are infectious during the active stage of disease and, because horses become latently infected, presumably during subsequent periods of viral reactivation and shedding. The duration of latency is unknown but is assumed to be lifelong. EHV-4 establishes latency in the trigeminal ganglion, which is the origin of the maxillary branch of the trigeminal (5th cranial) nerve that provides sensory innervation to the nasal mucosa. It is assumed that reactivation of the virus and subsequent virus shedding poses a risk to in-contact, susceptible animals, but this has not been definitively demonstrated in field situations. If this were the case, then clinically normal animals harbor latent virus that during periods of reactivation can infect susceptible animals. If true, this feature of the disease has obvious importance in the prevention, control, and management of outbreaks of disease.
Diseases

Vaccines for protection against rhinopneumonitis by diagnostic virology laboratories handling many routine samples continues to be the traditional methodology of cell culture isolation followed by sero-identification of the isolated viruses. The virus can be isolated in tissue culture, chick embryos, and hamsters, from either nasal washings or aborted fetuses.

Samples of nasopharyngeal exudate for virus isolation are best obtained from horses during the very early, febrile stages of the respiratory disease, and they are collected via the nares by swabbing the nasopharyngeal area with a 5 x 5 cm gauze sponge attached to the end of a 50-cm length of flexible, stainless steel wire encased in latex rubber tubing. A guarded uterine swab device can also be used. After collection, the swab should be removed from the wire and transported promptly to the virology laboratory in 3 mL of cold (not frozen) fluid transport medium (serum-free minimal essential medium [MEM] with antibiotics). Virus infectivity can be prolonged by the addition of bovine serum albumin or gelatine to 0.1% (w/v).

**Diagnosis**

Samples for Confirmation of Diagnosis

- Virus isolation or identification by fluorescent antibody testing or PCR of nasal swabs or blood

**Necropsy Findings**

Fatalities are extremely rare in the respiratory forms of EHV-4 infection or EHV-1 disease restricted to the respiratory tract.

**Samples for Confirmation of Diagnosis**

- Virus isolation or identification by fluorescent antibody testing or PCR of nasal swabs or blood

**Differential Diagnosis**

The upper respiratory diseases of horses are listed in Table 12-16. There is no specific treatment, although antibiotics are often administered to horses with respiratory tract disease to prevent or treat secondary bacterial infection. There is, however, no evidence that antibiotic treatment shortens the duration of the disease or prevents complications.

**Control**

Principles of a control program include the following:

- Enhancing the immunity of individual horses by vaccination
- Minimizing the risk of introducing EHV-4 infection to the farm or stable
- Hygiene to prevent spread of virus on fomites such as clothes and tack
- Rapid isolation of any horse with disease that could be attributable to EHV-4

**Vaccination**

Vaccines for protection against rhinopneumonitis contain both inactivated EHV-1 and EHV-4 virus, presumably because both viruses cause respiratory disease in horses. None of the currently available vaccines consistently prevents infection of vaccinated horses or provide complete protection against disease associated with EHV-4, although a combined EHV-1/EHV-4 inactivated virus vaccine attenuated the clinical signs of disease in experimentally infected foals. The development of modified live-virus vaccines administered intranasally holds promise for effective control of both EHV-1 and EHV-4 in foals and adults.

**Hygiene**

Standard hygienic procedures should be adopted to avoid spread of the disease, with particular attention being given to the isolation of introduced horses.

**Equine Multinodular Pulmonary Fibrosis**

Equine multinodular pulmonary fibrosis (EMPF) is a recently described progressive fibrosing lung disease of adult horses.

**Etiology**

EMPF is strongly associated with infection by equine herpesvirus-5 (EHV-5), a gamma-herpesvirus.1-10 Most cases of EMPF have detectable EHV-5 in the lung lesions or in bronchoalveolar lavage fluid, the virus is most abundant in lesions compared with unaffected areas or lung from unaffected horses, and inoculation of healthy horses with EHV-5 derived from affected horses results in nodular pulmonary fibrosis.11 EHV-5 antigen can be detected in lungs of unaffected horses, and the virus is widely distributed in horses worldwide, with both healthy horses and horses with evidence of non-EMPF respiratory disease having detectable virus in respiratory secretions.12,13,14 The ubiquity of EHV-5 infection in horses raises the possibility that infection with EHV-5 in horses with EMPF is coincidental and not causative or contributory to the disease. However, the almost universal detection of EHV-5 in horses with EMPF and the similarity of distribution of EHV-5 antigen in lungs and lesions of horses inoculated with the virus and naturally occurring cases of EMPF suggests a role for EHV-5 in the genesis of the lesions. It is plausible, but increasingly unlikely, that EHV-5 infects the abnormal tissues of lungs of horses with EMPF after development of the lesions and is not a contributory agent to the disease. Although Koch’s postulates have not been fulfilled for EHV-5 and EMPF, the weight of evidence supports a role for EHV-5 in the initiation, development, or proliferation of nodular pulmonary fibrosis in horses.

Both asinine gammaherpesvirus-5 and equine gammaherpesvirus-5 were isolated from two horses with EMPF.15,17 The importance of this finding is unclear and might just represent the high frequency of infection of horses by asinine gammaherpesvirus-5.

EHV-5 is also associated with skin and ocular disease and lymphoma in horses, and both EMPF and lymphoma can occur in the same animal.16-21

**Epidemiology**

The epidemiology of EMPF is not well established, and current knowledge is based on individual reports of small numbers of cases with the resultant potential for reporting and case-selection bias. The disease has been reported from Australia, New Zealand, Brazil, Europe, the United Kingdom and North America and appears to have a worldwide distribution.12,13,14,15,16,17,18,19,20,21 Horses most commonly reported as affected are middle-aged to older light breeds (Thoroughbreds) and Warmbloods, although the disease is reported in horses as young as 2 years of age.19,20,21 There are no readily apparent risk factors.

The case-fatality rate is high (>50%) in untreated and treated horses. There are no estimates of cause-specific mortality or morbidity rates.

**Pathogenesis**

The molecular pathogenesis of EMPF is unknown, although parallels are drawn between Epstein-Barr virus associated interstitial (fibrosing) pneumonia in people and the disease in horses.6 The lesion in horses progresses through proliferation of type 2 pneumocytes to alveolar fibrosis and focal obliteration of normal lung architecture. There is systemic evidence of inflammation, and the fever, weight loss, lethargy, and exercise intolerance of affected horses demonstrate a systemic response to the disease. Exercise tolerance could be attributable to diminished gas exchange in damaged lungs, the systemic inflammatory effects of the disease, or, more likely, a combination of both.

**Clinical Signs**

Horses with EMPF have various combinations of weight loss, recurrent cough, depression, anorexia, fever, tachycardia, tachypnea, or respiratory distress.3,4,5,16,27 Signs of respiratory disease might not be apparent at
Histopathologic findings are restricted to the lungs and bronchial lymph nodes, and the lesions are similar regardless of the gross pathology. Nodules are sharply demarcated from unaffected lung tissue, and they consist of marked interstitial expansion of alveolar parenchyma by well-organized mature collagen. In most cases, the alveolar architecture is preserved, but in rare cases, fibrosis is arranged in broad interlacing bundles without preserving the alveolar structure. Affected alveoli are lined by cuboidal cells, and the lumen contains inflammatory cells, primarily neutrophils and macrophages, the latter occasionally containing intranuclear inclusion bodies consistent with a herpesvirus infection. Changes in bronchial lymph nodes consist of marked lymphoid hyperplasia, often with nonspecific sinus histiocytosis.

**Diagnostic Confirmation**

Diagnosis is confirmed by demonstration of compatible lesions in lungs at necropsy or on biopsy.

**Treatment**

There are no treatments with established efficacy, and management of the disease is based on first principles and empirical treatment with antiviral drugs, antiinflammatory drugs, and antimicrobials.

Reduction of inflammation and relief of pain is achieved by administration of nonsteroidal antiinflammatory drugs (phenylbutazone, flunixin meglumine, ketoprofen) or corticosteroids (dexamethasone or prednisolone). Antimicrobials are administered to treat secondary bacterial infection and include penicillin, penicillin in combination with an aminoglycoside, or tetracycline or doxycycline.

Antiviral drugs have been administered to horses with EMPF, and some of these treated horses have survived. Acyclovir and valacyclovir (a metabolite of acyclovir) are both active in vitro against gammaherpesviruses. Acyclovir is administered orally (20 mg/kg PO q8h) but has variable absorption compared with valacyclovir, and one cannot be confident that adequate concentrations in the blood are achieved in all horses.

The preferred drug, based on pharmacokinetic properties, is valacyclovir (30–40 mg/kg PO q8h). A 2-week course of treatment with valacyclovir was associated with resolution of the disease in one horse.

**Control**

There are no known control measures.

**References**

Diseases in postal codes where fruit bats roost. 8 Sero-
×
40 increase in risk of disease for horses excreted from bats. 9 This is consistent with contact with virus soon after (hours) it is disease occurs in horses. 6

Transmission

The source of the virus is a wildlife host, the frugivorous pteropid bats (fruitbats and flying foxes, Pteropus spp.). Approximately 25% of pteropid bats, including representa-
tives of all four main species in eastern Australia (the grey-headed flying-fox, Pteropus poliocephalus; the black flying-fox, Pteropus alecto; the little red flying-fox, Pteropus scapulatus; and the spectacled flying-fox, Pteropus conspicillatus), were identified as being seropositive for HeV. The bats are endemic areas to exit from equine practice.14

Transmission

The disease in horses is uncommon, in that the morbidity or mortality rate within the population of at risk horses is low, with approximately two to four outbreaks reported each year involving a small number of horses. Between 1994 and 2013 there were 48 outbreaks of disease in horses, of which approximately 6 involved human disease.2 The case-fatality rate was high in early outbreaks, and because of control measures that involve test and slaughter of infected horses, all horses infected in outbreaks are destroyed.

The disease is important because of the zoonotic nature of the infection and the high case-fatality rate in infected humans.

Zoonotic Potential

The disease has important zoonotic implications; there have been four human deaths (~60% case-fatality rate) as a result of meningoencephalitis or pneumonitis and respira-
tory failure. Deaths all occurred in people who had close contact with infected horses, and the high risk associated with treating infected horses, or performing postmortem examinations on horses that have died of the disease, has prompted some veterinarians in equine practice.14

The reasons are concern about personal safety or legal liability for the safety of coworkers and owners of horses. However, the virus is not easily transmitted to humans, as evidenced by the observation that most people in contact with clinically affected horses do not develop antibodies to the virus.

CLINICAL SIGNS

The incubation period of the spontaneous disease is 8 to 11 days, but it is much shorter in experimentally induced disease. Death usually occurs within 24 to 48 hours of first onset of clinical signs, and affected horses housed in paddocks are often found dead.13

Clinical signs of the disease in horses include lethargy, which is often marked, depression, loss of appetite, fever, ataxia, blindness, head pressing, aimless wandering, tachycardia, tachypnea, and copious frothy nasal discharge. Horses can show aimless pacing and can become entangled in fence— which can be mistaken for an accident rather than a consequence of neurologic disease associated with HeV infection.9 There can also be hemorrhagic nasal discharge and swelling of the head. Some horses have muscle tremor. Death in acutely affected horses is sometimes associated with severe respiratory distress. Clinically apparent infections of horses can occur.

An important understanding is that HeV can cause protean clinical signs, which might be interpreted as evidence of respiratory (dyspnea), neurologic (ataxia, blindness), muscular (muscle fasciculations), hepatic (head pressing) or gastrointestinal (terminal colic) disease.

CLINICAL PATHOLOGY

Characteristic changes in the hemogram or serum biochemical profile are not reported. If infected animals survive more than a few days after the onset of clinical signs, they develop serum-neutralizing antibodies. The recommended range of samples for HeV exclusion from the live horse are 10 mL of clotted, EDTA, and heparin blood; pooled nasal swabs from each nostril; swabs from other mucosal surfaces (e.g., oral cavity, rectum, or conjunctiva); or urine collected in, preferably, phosphate-buffered glycerol saline or isotonic sterile saline. Antibodies are detectable by immunofluorescence microsphere immunoassays, or rapid immune plaque assay.15 Viral genome can be detected by RT-PCR that is highly specific. Viral isolation in Vero cells or imaging using electron microscopy demonstrate presence of the virus. Details of diagnostic tests are available from the OIE.

NECROPSY

Necropsy examination reveals pulmonary edema with hemorrhage and froth in the airways. Histologic examination reveals an interstitial pneumonia characterized by extensive vascular damage and necrosis of alveolar macrophages. Pulmonary vascular changes include edema and hemorrhage within alveoli, plus necrosis and thrombosis of alveolar capillaries and small arterioles. The distinctive histologic feature is the presence of syncytial giant cells within blood vessels of the lungs and other organs. Retrospective diagnosis of the disease can be documented using an immunohistochemi-
cal technique or demonstration of viral nucleic acid in tissue by a test based on the PCR. Postmortem, 10 mL of blood can be collected from the jugular vein in addition to the submandibular lymph node and swabs as per a live horse. Field experience suggests that it is relatively easy to safely collect jugular blood from recently dead horses.6

TREATMENT AND CONTROL

There is no specific treatment for this disease. Ribavirin has been investigated for use in infected or exposed humans but is not used in horses, for which control measures are implemented.9

CLINICAL SIGNS

The incubation period of the spontaneous disease is 8 to 11 days, but it is much shorter in experimentally induced disease. Death usually occurs within 24 to 48 hours of first onset of clinical signs, and affected horses housed in paddocks are often found dead.13

The incubation period of the spontaneous disease is 8 to 11 days, but it is much shorter in experimentally induced disease. Death usually occurs within 24 to 48 hours of first onset of clinical signs, and affected horses housed in paddocks are often found dead.13

Clinical signs of the disease in horses include lethargy, which is often marked, depression, loss of appetite, fever, ataxia, blindness, head pressing, aimless wandering, tachycardia, tachypnea, and copious frothy nasal discharge. Horses can show aimless pacing and can become entangled in fence— which can be mistaken for an accident rather than a consequence of neurologic disease associated with HeV infection.9 There can also be hemorrhagic nasal discharge and swelling of the head. Some horses have muscle tremor. Death in acutely affected horses is sometimes associated with severe respiratory distress. Clinically apparent infections of horses can occur.

An important understanding is that HeV can cause protean clinical signs, which might be interpreted as evidence of respiratory (dyspnea), neurologic (ataxia, blindness), muscular (muscle fasciculations), hepatic (head pressing) or gastrointestinal (terminal colic) disease.

CLINICAL PATHOLOGY

Characteristic changes in the hemogram or serum biochemical profile are not reported. If infected animals survive more than a few days after the onset of clinical signs, they develop serum-neutralizing antibodies. The recommended range of samples for HeV exclusion from the live horse are 10 mL of clotted, EDTA, and heparin blood; pooled nasal swabs from each nostril; swabs from other mucosal surfaces (e.g., oral cavity, rectum, or conjunctiva); or urine collected in, preferably, phosphate-buffered glycerol saline or isotonic sterile saline. Antibodies are detectable by immunofluorescence microsphere immunoassays, or rapid immune plaque assay.15 Viral genome can be detected by RT-PCR that is highly specific. Viral isolation in Vero cells or imaging using electron microscopy demonstrate presence of the virus. Details of diagnostic tests are available from the OIE.

NECROPSY

Necropsy examination reveals pulmonary edema with hemorrhage and froth in the airways. Histologic examination reveals an interstitial pneumonia characterized by extensive vascular damage and necrosis of alveolar macrophages. Pulmonary vascular changes include edema and hemorrhage within alveoli, plus necrosis and thrombosis of alveolar capillaries and small arterioles. The distinctive histologic feature is the presence of syncytial giant cells within blood vessels of the lungs and other organs. Retrospective diagnosis of the disease can be documented using an immunohistochemi-
cal technique or demonstration of viral nucleic acid in tissue by a test based on the PCR. Postmortem, 10 mL of blood can be collected from the jugular vein in addition to the submandibular lymph node and swabs as per a live horse. Field experience suggests that it is relatively easy to safely collect jugular blood from recently dead horses.

TREATMENT AND CONTROL

There is no specific treatment for this disease. Ribavirin has been investigated for use in infected or exposed humans but is not used in horses, for which control measures are implemented.
The control measures in the described outbreaks included slaughter of all infected horses, extensive serologic testing, and control of movement of horses within a defined disease control zone. The disease in index cases is likely attributable to contact of susceptible horses with infected fluids of pteropod bats, and interventions that susceptible horses with infected fluids of index cases is likely attributable to contact of infected horses in areas where the disease is endemic, although this practice is often met with resistance. Because of the protein nature of the disease, all sick horses should be considered as sources of infection. Biosecurity measures should be in place for examination of all horses, and the degree to which personal protective equipment is used can be adjusted based on the risk that the horse being examined is infected. Detailed guidelines for personal biosecurity are available.

PULMONARY AND SYSTEMIC ASPERGILLOSIS (ASPERGILLUS SPP.)

Diseases of horses and cattle associated with infection with Aspergillus spp. are characterized by either localized infections with slow progression or fulminant systemic or pulmonary disease. Localized infections are of the nasal cavities and paranasal sinuses;1-3 eye; reproductive tract, including placenta;1,3 mediastinum; or gullett pouch (see “Gut- tural Pouch Mycosis”). Systemic disease can affect any organ, including the brain, liver, and kidney, but the most common manifestation is as acute pulmonary disease with or without infection of other tissues.3,5-9

ETIOLOGY

The causative organism is Aspergillus spp., usually A. fumigatus but occasionally one of A. flavus, A. deflectus, A. nidulans, A. niger, A. clavulatus, A. nidulans, or A. sydowi. Aspergillus reproduce both sexually and asexually and hence are classified as dimorphic fungi. Asexual reproduction is by production of conidiophores and conidia. The organism is ubiquitous in organic material, and infections are opportunistic and associated with heavy contamination with the organism or decreased host defenses, although obvious risk factors are not always identified. Because its ubiquitous, the organism is often recovered from tracheal aspires performed using contaminated equipment in horses with mild signs suggestive of noninfectious respiratory disease, such as heaves. In this instance recovery of the organism is of no clinical importance.

EPIDEMIOLOGY

Risk factors for development of aspergillosis include heavy environmental contamination with conidia and decreased host resistance, such as in horses with immune suppression associated with myeloproliferative disease (lymphoma), enterocolitis, or administration of immunosuppressive drugs such as corticosteroids. Specific risk factors for gullett pouch mycosis and infections of the nasal cavity or paranasal sinuses have not been identified, with the exception of an association between surgical resection of ethmoidal hemotoma and subsequent nasal aspergillosis. Systemic or pulmonary aspergillosis is commonly associated with rumenitis, third-compartment ulceration in cameldis,1 enterocolitis, or administration of immunosuppressive drugs in adult horses. An outbreak pulmonary aspergillosis causing death of five albino Asinara donkey foals aged 20 to 30 days, but not of nonalbino herdmates, occurred without history of intercurrent disease or drug administration.

CLINICAL FINDINGS

Aspergillus spp. causes both localized and systemic disease in horses, cattle, camels, and likely other species. Localized diseases include gullett pouch mycosis, which is discussed in detail elsewhere in this text. Fungal granulomas in the paranasal sinuses or nasal passages in any species of farm animal are caused by a number of organisms, including Cryptococcus neoformans, Conidiotubus spp., Rhizomucor pusillus, Scedosporium apiospermum, and, rarely, Aspergillus spp.3,5,13,14 The disease is evident as nasal discharge that is usually unilateral, distortion of the contour of the head over the affected sinus, and lesions detectable on endoscopic examination of the nasal passages. Radiography can reveal the presence of a mass in the paranasal sinuses or nasal cavity associated with lysis and proliferation of bone. There is hyperfibrinogenemia and leukocytosis.

Systemic aspergillosis, including aspergillosis pneumonia, is a severe disease usually evident as acute death without localizing signs in animals with other preexisting systemic disease, such as enterocolitis, neonates with inadequate passive immunity, or those receiving immunosuppressive drugs.1,5,3 Horses with aspergillosis pneumonia often have a very brief clinical course once signs of respiratory disease develop. Most commonly, affected horses with pulmonary aspergillosis die without signs of respiratory disease. Signs of pulmonary aspergillosis include fever, tachypnea, crackles and wheezes on thoracic auscultation, epistaxis, and frothy nasal discharge. Radiography reveals diffuse, miliary, nodule interstitial pneumonia (Fig. 12-32). Ultrasonographic examination demonstrates numerous small intrapulmonary masses adjacent to the pleural surface. Affected horses have hyperfibrinogenemia and leukocytosis at the time of development of the disease, but usually they have had neutropenia as a result of the enterocolitis. Aspergillus spp. can be isolated from tracheal aspirates of affected horses. The prognosis is very poor.

Aspergillus fumigatus can cause solitary, cavitated lesions in the lungs of foals.5 Disseminated aspergillosis has a variety of manifestations but is always a severe disease with a brief clinical course. Affected horses often have severe depression and can have signs of brain disease as a result of mycotic vasculitis and encephalitis.7 The prognosis is very poor.

Aspergillus spp. is also associated with development of granulomas in the mediastinum of horses without apparent predisposing factors. Affected horses have progressively worsening respiratory distress, cough, fever, and occasional nasal discharge. Horner’s syndrome can develop if the mass encroaches on the vagosympathetic trunk within the thorax. The mass is evident on radiographic examination of the thorax. Cultures of tracheal aspirates yields Aspergillus spp. Affected horses have neutrophilia, hyperfibrinogenemia, hyperglobulinemia, and mild anemia.

Keratomycosis attributable to Aspergillus spp. infection is infrequent in horses. The disease is characterized by blepharospasm, photophobia, epiphora, and corneal ulceration and opacity. Aspergillus spp. infections of the reproductive tract include mycotic placentitis and abortion and mycotic...
endometritis. Fungal osteomyelitis of the proximal sesamoid occurs in horses that have received intraarticular administration of corticosteroids. 

**CLINICAL PATHOLOGY**

Definitive diagnosis of the disease is based on demonstration of organisms within lesions, either by histologic examination, culture, or use of PCR to demonstrate fungal DNA. Antemortem demonstration of high concentrations of antibodies to *Aspergillus* spp. provides persuasive, but not definitive, evidence of infection. Both agar gel immunodiffusion assays and ELISA assays are available. These assays might not be useful in immunocompromised animals or in those with fulminant disease.

**NECROPSY FINDINGS**

Acute lesions are characterized by purulent, necrotizing inflammation. Chronic lesions are granulomas that contain macrophages, neutrophils, and giant cells. Pulmonary lesions are characterized by an acute necrohemorrhagic alveolitis. Organisms morphologically consistent with *Aspergillus* spp. are detected in the lesions as fungal hyphae, although these must be differentiated from *Pseudallescheria boydii* or *Fusarium* spp. Reagents for immunofluorescent detection of *Aspergillus* spp. in lesions are available and useful in confirming the diagnosis.

**TREATMENT AND CONTROL**

Treatment of systemic or pulmonary disease is usually unrewarding, although surgical resection of a single large cavitating lesion in the lungs of a foal followed by administration of voriconazole (10 mg/kg PO q24h for 2–4 weeks) effected a cure. A dose of voriconazole of 4 mg/kg orally q24h produces concentrations of drug greater than 0.5 μg/mL in body fluids. This concentration is greater than the concentration of voriconazole required to inhibit growth of filamentous fungi.

Localized disease can be treated by surgical resection and administration of antifungal agents. Antifungal agents reported to be effective in treatment of localized disease in horses associated with *Aspergillus* spp. include itraconazole (3 mg/kg q12h, PO for 3–5 months) or enilconazole (0.2%–2.0% solution administered topically via an indwelling intranasal catheter q12h for 2–5 weeks). The lesions were debulked before treatment with enilconazole was started. Seven of eight horses with nasal aspergillosis treated in this way recovered. Topical treatment with enilconazole (10 mg/mL of solution) after surgical resection resulted in resolution of aspergillosis of the frontal sinus of a horse. Topical administration of natamycin (25 mg) was used for varying periods of time to treat mycotic rhinitis in three horses.

Amphotericin is likely effective against *Aspergillus* spp. and is cheaper than the azole class of drugs, but it is potentially nephrotoxic and must be administered intravenously. Fluconazole is not effective against the filamentous fungi, including *Aspergillus* spp.

There are no specific control measures or means of preventing disease associated with *Aspergillus* spp.

**REFERENCES**

**RHINOSPORIDIOSIS**

Rhinosporidiosis is a chronic disease of the nasal mucosa in cattle and nasal mucosa, pharynx, and larynx in horses that causes formation of large polyps or granulomatous lesions (Fig. 12-33). The causative agent, *Rhinosporidium seeberi*, is an aquatic protist that typically causes disease in amphibians. Its exact taxonomy is the subject of debate.

Exposure to the organism is almost universal, based on serologic studies, in buffalo, cats, cattle, dogs, goats, horses, and in some areas with high prevalence of the disease, humans (such as Sri Lanka). The disease is not endemic in western Canada or the United Kingdom, and affected horses in those areas were imported from Argentina. The disease is reported in a Warmblood horse in Belgium that had never left the country. Other cases in horses are reported from the Costa Rica, the southern United States, South Africa, and South America.

The disease is evident as single or multiple, pedunculated or sessile, pink to red masses in the mucous membranes of the...
LUNGWORM IN HORSES

SYNOPSIS

Etiology The nematode parasite *Dictyocaulus arnfieldi*.

Epidemiology Infection is by ingestion of larvae on herbage; donkeys and foals shed most larvae, but adult horses can perpetuate life cycle.

Signs Chronic cough in adult horses.

Clinical pathology Eggs or larvae in feces (but often absent in affected adults); eosinophils in tracheal mucus.

Lesions Discrete areas of hyperinflation in lung tissue.

ETIOLOGY

Lungworm disease in horses is associated with the nematode parasite *Dictyocaulus arnfieldi*.

LIFE CYCLE

The life cycle of *D. arnfieldi* is direct and is almost identical to that of *D. viviparus*, except that the eggs do not hatch until shortly after they are passed in the feces.

EPIDEMIOLOGY

Infestations with *D. arnfieldi* are recorded more commonly in donkeys than in horses, and the former are considered to be the more normal host. Patent infections may persist in donkeys throughout their lives but in horses are generally confined to foals. These animals therefore provide the most important sources of pasture contamination. Nevertheless, a small proportion of infected adult horses shed low numbers of eggs, and this may be sufficient to perpetuate the life cycle even in the absence of donkeys and foals. As with *D. viviparus*, larvae can cross field boundaries by fungal transfer.

PATHOGENESIS

Adult worms are found in the smaller bronchi, which they almost completely block. In adult horses however, few larvae reaching the lungs develop to this stage. Bronchioles in affected areas are surrounded by dense infiltrations of inflammatory cells, the epithelium becomes hyperplastic, and excessive mucus is produced. The consequent interference with airflow leads to patches of hyperinflation in the lung tissue.

CLINICAL FINDINGS

Lungworm disease in horses is characterized by a chronic cough. Experimental infections produce an afebrile condition with coughing, increased respiratory rates, and forced expiration being most intense during weeks 3 to 5 after infection. Thereafter the signs decrease in severity but coughing may persist for several months. Heavy infestations in donkeys do not cause clinical illness. Horse foals may also be symptomatic, although some show clinical signs.

CLINICAL PATHOLOGY

Characteristic eggs may be found in the feces of a small proportion of cases. Eosinophils and sometimes eggs or larvae may be demonstrated in tracheal mucus.

NECROPSY FINDINGS

The most obvious lesions at necropsy are discrete patches of overinflation.

DIAGNOSTIC CONFIRMATION

*D. arnfieldi* eggs in fresh feces are oval, are thin shelled, and contain a larva. Because the eggs may have hatched before arrival at the laboratory, it is usual to harvest larvae with the Baermann technique. The larvae resemble those of *D. viviparus*, but the tail ends in a small spine. Because many clinical cases are nonpatent and because tracheal mucus is difficult to sample, confirmation of diagnosis is often dependent on response to treatment.

DIFFERENTIAL DIAGNOSIS

- Recurrent airway obstruction (heaves)
- Pulmonary abscessation and pneumonia
- Inflammatory airway disease

TREATMENT

- Eprinomectin (0.5 mg/kg, top.) (R2)
- Ivermectin (0.2 mg/kg SQ) (R2)
- Mebendazole (20 mg/kg, q1d for 5 days) (R3)

Eprinomectin, as a pour-on formulation (0.5 mg/kg), has 100% efficacy in eliminating fecal larvae in donkeys within 7 days after treatment. Ivermectin at the standard equine dose is highly effective against immature and mature stages. For donkeys, mebendazole may be used at 15 to 20 mg/kg daily for 5 days, but this should not be attempted within the first 4 months of pregnancy.

CONTROL

Donkeys and horses should not be grazed on the same pasture. If this is impossible, the former should be treated regularly for lungworm. If there is a problem in a closed herd of adult horses, individuals with patent infection can be identified by fecal screening and treated.

REFERENCE

Diseases of the Swine Respiratory Tract

PROGRESSIVE ATROPHIC RHINITIS (CONCHAL ATROPHY OF SWINE)

Atrophic rhinitis is a disease affecting primarily young pigs but causing anatomic lesions that may persist for life. The term nonprogressive atrophic rhinitis is used for the
slight to severe rhinitis and usually transient atrophy of the conchal bones (formerly called the turbinates) in which no toxigenic Pasteurella multocida are found, when there are no clinical signs and no obvious growth retardation. This mild form is probably as a result of infection with Bordetella bronchiseptica (BB) or nontoxigenic Pasteurella multocida (PM).

The term progressive atrophic rhinitis is proposed for the infection with toxigenic Pasteurella multocida (PM) (capsular serotype D and A strains) characterized by shortening or distortion of the snout, sneezing, nasal discharge, and epistaxis. Progressive atrophic rhinitis is often accompanied by reduced growth rates in severe cases.

The organism is a zoonosis, but this is rarely from the pig, although pig farmers often have PM in their nasal cavities.

ETIOLOGY
Infection of the nasal cavities with BB followed by toxigenic strains of PM—primarily capsular type D and occasionally type A—results in progressive turbinate atrophy. PM has four subspecies (multocida, septica, gallicida, and tigris), but multocida is usually isolated from pigs. There are five capsular serotypes (A-F) of PM. PM type A strains were formerly thought to be associated entirely with lung infections but there is increasing evidence that some strains of PM type A are toxin producers and may be involved in atrophic rhinitis. Toxin production appears to be independent of serotype. The strains of PM isolated from the lungs are usually nontoxigenic and of capsular type A but a small proportion are toxigenic and are capsular type D. Serotype B is probably the most common one associated with septicemic pasteurellosis.

The majority of cases of progressive atrophic rhinitis are associated with toxA-containing capsular type D strains.

Somatic antigens reflecting differences in lipopolysaccharides have also been used, in addition to a variety of other techniques. The poultry type of analysis based on multilocus sequence typing will be adapted for use for the pig eventually. There may be a limited genetic heterogeneity in both the healthy pig strains and the PAR strains.

EPIDEMIOLOGY
Occurrence
Atrophic rhinitis occurs worldwide where pigs are reared under intensive conditions. It has, however, become much less important with the onset of vaccination, improvement in resistance by pig breeding companies, and general attention to the environment in the farrowing house.

Some surveys have shown that 50% of finished pigs and sows at slaughter have lesions of atrophic rhinitis. The incidence of clinical disease varies from 5% to 30%, which in part depends on the method of detection of the gross lesions. Abattoir surveys of the snouts of slaughtered pigs indicate that the incidence of gross lesions ranges from 14% to 50%. However, the incidence of gross lesions in abattoir surveys is biased by the source of the pigs; the incidence may be low in pigs from herds that have attempted to control the disease and high in some commercial herds with no control program. In pigs slaughtered from pig testing stations the incidence of lesions may be uniform over a long period. The published data on the incidence of gross lesions are also variable because of the lack of a uniform method of evaluating and quantifying the lesions.

The incidence and severity of the lesions may vary with the season and the type of facility in which pigs are reared. In a slaughter survey of the snouts and lungs of pigs from 21 pig herds over one winter and one summer, the lesions of atrophic rhinitis were more severe among pigs slaughtered in the summer, whereas lesions of pneumonia were more severe among pigs slaughtered in the winter. Lesions of atrophic rhinitis were also more severe in pigs farrowed in central, enclosed farrowing houses and finished in enclosed, mechanically ventilated buildings than in pigs farrowed individually in sow huts and finished on dirt lots. It is possible that the incidence and severity of the lesions at slaughter may be a reflection of the condition of the housing facilities when the animals were piglets several months previously, but many other factors could have been involved.

Prevalence of Infection
B. bronchiseptica readily colonizes the ciliated mucosa of the respiratory tract of pigs and infection of the nasal cavities of pigs is present in almost every pig herd, with the prevalence of infection in pigs in commercial herds varying from 25% to 50%. Serologic surveys of individual herds have found that up to 90% of the pigs are positive, which indicates that there is no reliable correlation between the frequency of isolation of the organism and the percentage of animals with antibody. The prevalence of infection is just as high in specific-pathogen-free herds as in nonspecific-pathogen-free herds.

The prevalence of infection of toxigenic PM type D is higher in herds with clinical disease. The organism can be present in 50 to 80% of weaned pigs in a herd with clinical disease in the finishing pigs. Toxigenic type D PM was first detected in New South Wales, Australia, in 1986; in all herds examined, the introduction of pigs from an infected herd in South Australia was associated with an increased risk of infection. Toxigenic PM type D has been isolated rarely from herds free of atrophic rhinitis.

Whereas BB is eliminated from the respiratory tract of most infected pigs, leaving only a few infected at slaughter, PM often persists.

Method of Transmission
Direct contact and droplet infection are presumed to be the most likely methods of transmission. The reservoir of infection is the infected sow, and litters of piglets become infected at an early age. Colonization of the tonsil by PM in conventionally reared pigs is common. In the Netherlands, it has been recognized that infection is usually by one of four possibilities. These are artificial insemination centers, laborers, neighborhood infection by direct aerosol or indirect local contact, and the presence of carrier animals and birds.

The infection is usually introduced into a herd by the purchase of infected pigs. Spread between piglets is probably enhanced after weaning when mixing of litters occurs, and 70% to 80% of a large weaned group may become infected. Infection persists for up to several weeks and months, followed by a gradual reduction in the intensity and rate of infection. In herds where BB is the initiating agent, up to 90% of pigs 4 to 10 weeks of age will have nasal infection, but this infection rate falls to approximately 15% by 12 months of age, and the proportion of carrier pigs within the breeding herd decreases with increasing age of sow.
prevalence of infection is also much higher during the period from October to March than at other times of the year, and the prevalence of serologically positive animals is highest from July to December. The most probable result of the winter housing conditions, with few air changes per hour, fluctuating temperatures, and high humidity.

The epidemiology of toxigenic strains of PM as a causative agent of atrophic rhinitis is not as well understood. The organism colonizes the tonsils of clinically normal pigs. In contrast to BB, which is ubiquitous in pig herds, the toxigenic isolates of PM appear to be restricted to herds affected with progressive atrophic rhinitis. The organism is invariably present in herds with progressive atrophic rhinitis but may also be present in about 5% of the pigs in a herd with no clinical history of atrophic rhinitis. The main source of toxigenic isolates of PM for young pigs appears to be the pharyngeal tissues of the breeding stock. About 10% to 15% of sows in farrowing houses may be infected with toxigenic isolates, and piglets become infected within a week after birth. In contrast to BB, infection of piglets at 12 to 16 weeks of age with toxigenic PM will still result in varying degrees of severity of lesions.

It is possible for growing pigs to develop lesions of atrophic rhinitis well beyond the age of 3 weeks if they are exposed to pigs affected with disease and infected with PM and BB.

**Risk Factors**

**Animal Risk Factors**

The age at which piglets first become infected with BB has an important effect on the development of lesions. The most severe lesions occur in nonimmune animals infected during the first week of life. Animals infected at 4 weeks of age develop less severe lesions, whereas those infected at 10 weeks do not develop significant lesions.

**Immune Mechanisms**

The level of immunity in the young pigs will influence the level of infection and the incidence of clinical disease. Colostral immunity from sows serologically positive to BB is transferred to piglets and provides protection for 2 to 5 weeks. Clinical disease does not occur in piglets with high levels of passive antibody. Older pigs from 10 to 12 weeks of age may become infected but are less likely to develop severe turbinate atrophy and may develop inapparent infection and become carriers.

Vaccination of the sow before parturition to increase colostral immunity or vaccination of the young pig will increase the rate of clearance of the organism from the nasal cavity and reduce the incidence of clinical disease. In chronically affected herds a level of immunity develops with increasing age of the breeding herd.

**Pathogen Factors**

The virulence characteristics of BB and the toxigenic isolates of PM are important risk factors. Both organisms are required to produce lesions similar to the naturally occurring progressive disease. The virulence of BB is dependent on the ability to produce heavy, persistent colonization in the nasal cavity and the production of a heat-labile toxin. *Bordetella* spp. produce several virulence factors and toxins, which are regulated by a two-component sensory transduction system encoded by the bvg locus. These virulence factors include adhesins such as filamentous agglutinin, pertactin, and fimbriae; the adenylyl cyclase–hemolysin toxin; and the dermonecrotic toxin. In cell cultures the dermonecrotic toxin stimulates DNA and protein synthesis and assembly of actin stress fibers while inhibiting cell division, resulting in polynucleation of cells. It mediates the death of cells through the modification and activation of the small guanosine 5'-triphosphate (GTP)-binding protein Rho.

There are both toxigenic and nontoxigenic strains of BB. Colonization of the nose was greater with the dermonecrotic-toxin-positive strains than with the dermonecrotic-toxin-negative mutant strains. This was maintained for the first, second, and third weeks postinoculation, but by the fourth week the position had changed to the opposite. All dermonecrotic-toxin-positive pigs had pneumonia but the dermonecrotic-toxin-negative animals were able to colonize the lung more freely. There is an outer membrane protein P68 perlaclin (BB perlaclin gene [prn]), an adhesin, that may play a part in the protective immunity and may be extremely variable. The most important experiment is one that shows that PM mutant strains without the capacity to produce PM type D toxin did not cause progressive turbinate atrophy. Only certain porcine phase 1 cultures possess both properties. However, even the most virulent of 10 isolates of BB did not cause progressive turbinate atrophy or significant snout deformation in experimental infections. The severe lesions of atrophic rhinitis cannot be attributed to this organism alone. Experimental inoculation of specific-pathogen-free or gnotobiotic pigs with the organism results in a nonprogressive moderately severe turbinate atrophy 2 to 4 weeks after infection, followed frequently by regeneration of the turbinate. These virulence characteristics of BB are consistent with the observations that in herds where the organism is common it can provoke sneezing and coughing but no evidence of clinical turbinate atrophy. Examination of the turbinites within 2 weeks after the sneezing will reveal some mild lesions, but no lesions will be evident when the pigs are examined at slaughter. It may be that the adhesins left over in the nasal cavity from an infection of BB are subsequently available for the attachment of other bacteria.

Toxigenic isolates of PM colonize the nasal cavities, elaborate several toxins, and produce progressive lesions of the turbinates, nose, and snout. Toxigenic PM can colonize the upper respiratory tract of pigs, and the presence of the capsule is a virulence factor. The presence of BB can enhance the colonization of PM, particularly the toxigenic type D strains isolated from pigs. The cytotoxic of BB is required for optimum growth by toxigenic PM; other products of phase 1 BB growth assist colonization by PM, and the degree of atrophy of the turbinites in these mixed infections is related to the numbers of toxigenic PM in the nasal cavity. Severe turbinate damage and shortening of the snout can be reproduced in specific-pathogen-free and gnotobiotic pigs by combined infection with BB and certain strains of PM. Following experimental infection both organisms may persist in the nasal cavities for up to 64 days. The cell envelope proteins and lipopolysaccharides of PM strains associated with atrophic rhinitis have been characterized and compared. At least three protein patterns and six lipopolysaccharide patterns can be distinguished, which can be used to predict the pathogenic character of some of the strains. This will obviate the need to use the guinea-pig skin test to distinguish those strains that are associated with atrophic rhinitis and those that are not.

The gene for the osteolytic toxin of PM has been cloned and expressed in *E. coli*; the protein expressed has been shown to have the same properties as the native toxin. The toxin is the main colonization factor produced by toxigenic strains of the organism and antitoxin made from the toxin is protective experimentally and cross-protective between toxins from different capsule types. The toxin can produce turbinate atrophy when injected intranasally and also when given intramuscularly, intraperitoneally, intravenously, or intradermally. Fingerprinting techniques have been used to show that outbreaks of atrophic rhinitis since 1985 in Australia have been associated primarily with a single strain of toxigenic type D PM.

**Environmental Factors**

The effects of housing, population density, and adequacy of ventilation on the prevalence of infection of BB and toxigenic isolates of PM and on the incidence and severity of atrophic rhinitis have not been examined in detail. Atmospheric ammonia, dust, and microbial concentrations in the farrowing house and dust in weaner barns have a significant role in the severity of atrophic rhinitis. The mean daily gain of gilts with atrophic rhinitis exposed to ammonia may be smaller than that of those not affected. Undocumented field observations suggest that the disease is more common and severe when pigs are confined, overcrowded, and housed in poorly ventilated unsanitary conditions.
18% higher than in herds where pigs had severe atrophic lesions. In an Australian report there was no correlation between the severity of atrophic rhinitis and growth rate or back-fat thickness.

In one study of three commercial pig herds, the snouts and lungs of individual pigs were examined and scored at slaughter, and the results were correlated with growth indicators for each pig (average daily gain during the growing and finishing phases, and days to reach market). Scores for lung lesions were also correlated to scores for snout lesions. Contrary to findings in many other studies, pigs that reached market weight at the youngest age did not have the lowest score for lung lesions, nor the lowest grade for snout lesions, nor the least extensive or severe lesions. It was concluded that lung lesions and grades for snout lesions in pigs at slaughter are not valid indicators for determining the economic effect of either pneumonia or atrophic rhinitis on growth performance of pigs.

**PATHOGENESIS**

Following infection of the nasal cavity, BB becomes closely associated with the ciliated epithelium of the respiratory tract. It can bind to respiratory tract mucus. The organism produces a heat-labile toxin that results in a nonprogressive, moderately severe turbinate atrophy that is apparent within 2 to 4 weeks after infection, followed frequently by regeneration of the conchae. There is, initially, ciliary loss and ciliary stasis, followed by reduction in mucociliary clearance, followed by hyperplasia and metaplasia of the nasal epithelium, fibrosis in the lamina propria, and resorption and replacement fibrosis of the osseous core. Experimental infection with BB alone does not result in severe persistent conchal atrophy or twisting or shortening of the snout. The strains of BB that produce cytotoxin may predispose to the colonization of PM in the nasal cavities.

The preferred habitat of PM appears to be the tonsillar crypt, but following damage by BB, it can inhabit the epithelium of the URT.

Infection and colonization of the nasal cavities, particularly the mucus, with the toxigenic strains of PM results in the elaboration of a toxin that causes progressive conchal atrophy. The toxin is thermostable and dermonecrotic and is called the dermonecrotic toxin of PM. It interferes with G-protein and Rho-dependent signaling pathways in the cells. It is encoded by the toxA gene. The inoculation of a toxin from a toxigenic strain of type D PM into the nasal cavities of gnotobiotic pigs results in severe bilateral atrophy of the conchae. Atrophy of the ventral conchae can be produced experimentally with pathogenic BB in piglets at 6 weeks of age and with toxigenic PM strains in piglets as old as 16 weeks of age.

The toxin enhances osteoclastic resorption and impairs osteoblastic synthesis of the conchal osseous core; irreversable changes can occur within a few days. The toxin is a one chain toxin of 1285 amino acids, and different domains of the toxin are involved in cell uptake and intracellular activities. The toxin is able to subvert cell cycle progression and cell–cell signaling systems in osteoblasts and osteoclasts. The toxin is the sole agent responsible for the conchal atrophy, and the effect appears to be related to the total exposure to the toxin; that is, it is dose dependent. The toxin PMT activates various heterotrimeric G proteins, which causes the deamidation of the alpha-subunits of the G proteins.

More important, this also appears to have an immunomodulatory effect. There is an inverse relationship between the number of PM and the total concentration of immunoglobulin. This may in part be one of the reasons that local changes in the nose and neutrophilic infiltration occur, and they may be a result of the fact that the PM type D toxin has in fact changed the immune functions and that the PM may have predisposed to many other agents. These authors’ conclusion is that PM significantly suppresses the antigen-specific IgG immune responses of pigs to parenteral antigen challenge. The epithelium and the submucosa undergo secondary atrophy, and the conchae may disappear almost completely within 10 to 14 days. These lesions can persist until the animal is 90 kg in body weight. The conchal atrophy is not accompanied by an inflammatory reaction. The effect of the PM toxin is restricted to the nasal cavity; this is supported by the intriguing observation that the parenteral injection of the toxin into gnotobiotic piglets results in severe lesions and shortening and twisting of the snout. The parenteral injection of the dermonecrotxin of PM capsular type D into specific-pathogen-free adult pigs will result in moderate conchal atrophy. In piglets 7 days of age, the intramuscular injection of the purified dermonecrotxin will result in severe atrophy of the conchae. The culture filtrate of a nonatrophic-rhinitis pathogenic PM will not cause lesions after intramuscular injection. The disappearance of the conchae and the involvement of the bones of the face lead to deformity of the facial bones with the appearance of dishing and bulging of the face and, if the lesion is unilateral, to lateral deviation of the snout.

The effect on growth rate, if any, may be attributable to the chronic irritation and interference with respiration. Experimentally, atrophic rhinitis suppressed the health of pigs, reducing their activity and feed intake. Experimentally, parenteral injections of the toxin decrease physical activity and reduce chondrocyte proliferation in long bones, in addition to conchal atrophy.

Reliable experimental models of atrophic rhinitis in gnotobiotic pigs are now available and are useful for studying the pathogenesis of the disease and testing vaccine strategies.
A sterile sonicate of a toxigenic strain of BB is instilled into the nasal cavities of piglets at 5 days of age followed by intranasal inoculation of toxigenic strains of PM at 7 days of age.

The toxin can also affect the liver and urinary tract and decrease the phyleal area in the long bones.

**CLINICAL FINDINGS**
The clinical findings of atrophic rhinitis depend on the stage of the lesions. In acute cases in piglets 3 to 9 weeks of age, irritation of the nasal mucosa causes sneezing, some coughing, small amounts of serous or mucopurulent nasal discharge, and transient unilateral or bilateral epistaxis. The frequency of sneezing may be a measure of the incidence and severity of the disease. In piglets born from sows vaccinated with BB and PM vaccines before farrowing, followed by two vaccinations within 3 weeks of age, the frequency of sneezing at 3 to 9 weeks of age was much less than in piglets given only BB vaccine. There may be rubbing of the nose against objects or on the ground. A watery ocular discharge usually accompanies this and may result in the appearance of dried streaks of dirt below the medial canthus of the eyes. There may be a decrease in growth rate. In infection with BB these clinical signs will disappear spontaneously in a few weeks, when the pigs will appear normal. In severe cases, respiratory obstruction may increase to the point of dyspnea and cyanosis, and sucking pigs may have great difficulty in nursing. The nasal secretions become thicker and nasal bleeding may also occur.

In the more chronic stages, inspissated material may be expelled during paroxysms of sneezing. During this chronic stage, there is often pronounced deformity of the face as a result of arrested development of the bones, especially the concha, and the accumulation of necrotic material in the nasal cavities. The nasal bones and premaxillae turn upward and interfere with approximation of the incisor and, to a lesser extent, the molar teeth. There are varying degrees of brachygnathia superior and protrusion of the lower incisor teeth. Prehension and mastication become difficult, with a resulting loss of body condition. Facial distortion in the final stages takes the form of severe “dishing” of the face with wrinkling of the overlying skin. If the condition is unilateral, the upper jaw may be twisted to one side. These visible facial deformities develop most commonly in pigs 8 to 10 weeks old within 3 to 4 weeks after infection, but they may occur in younger pigs.

The most serious effects of the advanced disease are depression of growth rate and unthriftiness. The appetite may be unaffected, but much feed is lost by spillage, and feed efficiency may be reduced in some instances.

**CLINICAL PATHOLOGY**

**Culture and Detection of Bacteria**

It is important to be able to detect infected animals in a herd, especially the carrier animal. Nasal swabs are used to detect the bacteria and to determine their drug sensitivity. The collection of the nasal swabs must be done carefully and requires a special transport medium to ensure a high recovery rate. A sampling technique and a special culture medium to facilitate the isolation and recognition of BB are described. The external nares are cleansed with alcohol, and a cotton-tipped flexible wire is pushed into the nasal cavity (of each side in turn) until it reaches a point midway between the nostril and the level of the medial canthus of the eye. On removal, the cotton tip is cut off into 0.5 mL of an ice-cold sterile transport medium comprising phosphate-buffered saline (PBS, pH 7.3) with fetal calf serum (5% v/v). The samples are then placed on special media, preferably within 4 hours. Normally the organism grows well on conventional culture media, especially when younger pigs are sampled. However, in the carrier pig the organism may be sparse, and the selective medium is recommended.

The nasal culturing procedure has been used as an aid in the control of atrophic rhinitis associated with BB. A series of three nasal swabs from each animal is considered to be about 77% efficient in detecting infected animals for possible culling and elimination from the herd. However, in some studies there may be no marked difference in the prevalence of BB or PM in pig herds with or without clinical atrophic rhinitis.

Toxigenic PM grow readily in the laboratory but are difficult to isolate from nasal swabs because they are frequently overgrown by commensal flora. Selective laboratory media containing antimicrobial agents have been developed to promote the isolation of PM from nasal swabs. Inoculation of cotton swabs to selective medium on the same day as the sampling provides the best isolation of toxigenic PM. Immersion of pigs at slaughter in the scalding tank can result in a marked reduction in the isolation of toxigenic PM.

A cell culture assay using embryonic bovine lung cell cultures is available and is sensitive in vitro test for the differentiation of toxigenic from nontoxigenic isolates of PM. This test can replace the lethal tests in mice or the dermonecrotic tests in guinea pigs.

**Antigen Detection**

A PCR method originally described in 1996 for the enhanced detection of toxigenic PM directly from nasal swabs has been described and upgraded. This was shown to be 10 times more sensitive than PM type D toxin (PMT) ELISA and 5 times more sensitive than clinical bacteriology with subsequent use of PMT ELISA. A nested PCR has also been described. Similarly, a PCR method for the detection of BB has been described that produces 78% more positives than culture, particularly with swabs with a high mixed bacterial load. Recently a nested-PCR has been described that was reported to be more specific and sensitive than the other PCR methods previously described. It does not require culture, it is less laborious, and the results can be provided within 24 hours. The authors concluded that this test was suitable for breeding company evaluations and for eradication schemes.

**Radiography**

Some aids to the clinical diagnosis have been examined but are not highly accurate. Radiography of the nose is not reliable in detecting the severity of conchal atrophy.

**NECROPSY FINDINGS**

The typical lesions of atrophic rhinitis are restricted to the nasal cavities, although concurrent diseases, especially virus pneumonia of pigs, may produce lesions elsewhere. In the early stages there is acute inflammation, sometimes with the accumulation of pus, but in the later stages, there is evidence only of atrophy of the mucosa and decalcification and atrophy of the concha and ethmoid bones, which may have completely disappeared in severe cases. The inflammatory and atrophic processes may extend to involve the facial sinuses. There is no evidence of interference with the vascular supply to the affected bones. The changes in the nasal cavities are most readily seen if the head is split in the sagittal plane but for accurate diagnosis the degree of conchal symmetry, volume, and atrophy and medial septum deviation should be assessed by inspection of a vertical cross-section of the skull made at the level of the second premolar tooth.

The clinical diagnosis is confirmed and the severity of the lesions is assessed by the postmortem examination of a cross-section of the snout. The snout must be sectioned at the level of the second premolar tooth because the size of the conchal bone reduces anteriorly and may give a false-positive result if the section is taken too far forward. Quantification of the severity of the lesions has been of value for monitoring the incidence and severity of the disease in a herd. Several systems have been used for grading the severity of lesions of the snout. Most of them have used a subjective visual scoring system in which snouts are grade 0 (complete normalcy) to 5 (complete conchal atrophy).
Reasonable agreement among observers recording morphologic changes of nasal conchae is achievable with some training. The standards for each grade are as follows:

- **Grade 0**: No deviation from absolute normality, with nasal septum straight and conchae symmetric and filling nasal cavities.
- **Grade 1**: Slight irregularity, asymmetry, or distortion of the nasal structures without atrophy.
- **Grade 2**: Marked distortion of nasal structure but without marked atrophy.
- **Grade 3**: Definite atrophy of the conchae with or without distortion.
- **Grade 4**: More severe atrophy with severe atrophy of one or more conchae.
- **Grade 5**: Very severe atrophy in which all conchae have virtually disappeared.

Such a discontinuous grading system does not provide a direct quantitative relationship. Regular examination of the snouts from heads of pigs sent to slaughter can be used to assess the level of conchal atrophy in the herd. Morphometric methods, using either point counting or semiautomated planimetry applied to photographic or impression prints of sections of the snout to measure the extent of conchal atrophy on a continuous scale as a morphometric index, are now available. Cross-sections of the snout are photographed or used to make impression prints, which are then measured. A morphometric index is determined, which is the ratio of free space to total cross-sectional area of the nasal cavity. The system correlates well with the visual grading system of 0 to 5 but is labor-intensive and relatively expensive. The conchal perimeter ratio may be a more reliable morphometric measure of atrophic rhinitis and also provides parametric data suitable for quantitative analysis. A morphometric analysis using conchal area ratio is the best method for quantifying gross morphologic turbinate changes. Descriptions of the methods for making snout impressions are available. Computed tomography has been described.

A major limitation of the grading system is that conchal atrophy occurs as a continuous spectrum, and it is difficult to decide, for example, if a pig with a grade 3 lesion represents the more severe manifestation of BB infection, which may not progress further, or an early manifestation of infection with toxigenic PM, which could develop into a severe herd problem.

Histologically, the lesions vary according to the stage of the disease; initially there is a neutrophilic infiltrate followed by more chronic mononuclear cell infiltration. The conchal bones are eroded by osteoclasts, and new bone formation is reduced with degener- 
dystrophy and reparative processes.

**Samples for Confirmation of Diagnosis**

- **Bacteriology**—nasal swabs are not as good as tonsil swabs but are easier to obtain. The highest isolation rates are achieved with Knight medium or KPMD. Conventional biochemistry can then be used to identify.
- **Histology**—formalin-fixed cross-section of snout at level of second premolar.
- **Antigen detection**—nasal swabs. ELISAs based on the use of PMT-specific monoclonal AB are rapid, sensitive and specific. The kmt1 gene has been used as a target for the loop-mediated isothermal amplification method. Diagnostic tests have been reviewed. Computer tomography can be helpful.

**DIFFERENTIAL DIAGNOSIS**

The occurrence of sneezing in the early stages and of facial deformity in the later stages are characteristic of this disease. Diagnosis depends on clinical signs, pathology, and demonstration of PM and its toxin.

Inclusion-body rhinitis as a result of a cytomegalovirus is a common infection in young piglets in which there is sneezing and conjunctivitis. However, by itself it does not progress to produce turbinate atrophy and facial distortion. Under good hygienic conditions the course of the disease is about 2 weeks, and the economic effects are minimal. In the early acute stages, atrophic rhinitis may be mistaken for swine influenza, which, however, usually occurs as an outbreak affecting older pigs and accompanied by a severe systemic reaction without subsequent involvement of facial bones.

Necrotic rhinitis is manifested by external lesions affecting the face, and virus pneumonia of pigs is characterized by coughing rather than sneezing.

The inherited prognathic jaw of some breeds of pigs has been mistaken for the chronic stage of atrophic rhinitis; protrusion of the lower jaw is quite common in adult intensively housed pigs and has been attributed to behavioral problems of pushing the snout against fixed equipment such as bars and nipple drinkers.

**TREATMENT**

Treatment early in the course of the disease will reduce the severity of its effects, but it is of little value in chronically affected pigs, and these pigs are best culled at an early age because of their persistent poor growth rate and high food conversion.

Tyllosin at 20 mg/kg BW, oxytetracycline at 20 mg/kg BW, or trimethoprim–sulfadoxine (40 mg/200 mg/mL) at 0.1 mL/kg BW may be given parenterally, or the creep feed may be medicated with sulfamethazine and/or tylosin at 200 and 100 mg/kg of feed respectively. Parenteral injections need to be repeated every 3 to 7 days for at least three injections, and feed medication should be given for 3 to 5 weeks. The problem with early creep medication is in obtaining adequate intakes of the antibacterial. This is seldom achieved before 2 weeks of age, and parenteral antibiotics may be required if significant infection occurs before this stage.

The parenteral administration of antimicrobial agents to individual piglets at -to-7-day intervals beginning at 3 days of age for a total of three to five injections per piglet has been recommended for the treatment and control of atrophic rhinitis. However, in a large herd such a treatment regimen would be a major task, and until a cost–benefit analysis indicates a beneficial effect over other methods, we cannot recommend such a practice.

The treatment of experimental BB infection in young pigs has been successful with the use of trimethoprim–sulfadiazine in the drinking water at levels of 13.3 and 77.6 µg/mL respectively, for 3 weeks. This method would remove the necessity to inject pigs repeatedly.

Tilmicosin has proved useful; fed continuously over 6 weeks at concentrations of 200 g per ton of feed, it controlled transmission of atrophic rhinitis, weight gains were positively affected, and fewer nasal swabs were positive for PM at the end of the study period. A resistance to some antibiotics has recently been reported.

**CONTROL**

Effective control depends on developing methods of eliminating or controlling the prevalence of toxigenic isolates of PM, which cause progressive atrophic rhinitis if they become established in the nasal cavity. Previous infection of the nasal cavity with BB may enhance the establishment of toxigenic PM and result in progressive atrophic rhinitis.

Although there is considerable information available on the ecology of BB and the methods by which it might be eliminated or controlled in a herd, there is little documented information available on methods that can be used for control of the toxigenic isolates of PM associated with atrophic rhinitis.

Control of atrophic rhinitis can be attempted in at least four ways:

- Total eradication
- Reduction of infection pressure
- Mass medication with antimicrobials to reduce the severity and adverse effects of infection
- Vaccination

Regardless of the method employed, any effective control program must have a system for monitoring the incidence of clinical disease in the herd and the incidence and severity of conchal lesions of the pigs sent to slaughter. Accurate and reliable methods for monitoring clinical disease are not available,
but the incidence of acute rhinitis and facial deformities could be recorded regularly. At slaughter, snouts can be examined for lesions of conchal atrophy and for assessing a mean snout score for each group of pigs slaughtered.

**Eradication**

Total eradication can only be achieved with confidence by complete depopulation for a 4-week period and repopulation with primary or purchased specific-pathogen-free stock. This approach has the added advantage of also eliminating enzootic pneumonia, which may be a significant contributing factor to the economic importance of this disease. However, this method of control is extremely costly, and the economic importance of the disease would need to be carefully evaluated in relation to this cost before this method was instituted. Other techniques of obtaining pigs free of atrophic rhinitis, such as the isolated farrowing of older and presumed noncarrier sows with subsequent clinical and postmortem examinations of a proportion of the litters, have had a significant failure rate in the field and are not recommended. Eradication by repopulation with cesarean-derived stock may be essential in breeding nucleus herds where a high generation turnover results in a low herd sow age and a low herd level of immunity. The breakdown rate of herds established by this method can be significant, presumably because the initiating organisms are not solely confined to pigs.

A pilot control scheme was initiated in Britain in which a herd had to meet the following conditions:

- It must be inspected by a veterinarian every 6 months over a period of 2 years, over which time there must be no clinical evidence of atrophic rhinitis.
- The herd owner must certify that atrophic rhinitis has not been suspected over the same time period.
- Cross-sections of snouts taken from at least 30% of marketed pigs must be examined regularly by a veterinarian, and over a 2-year probationary period the average six-month snout score must not exceed 0.5.
- There must be no vaccination or treatment for atrophic rhinitis.
- New breeding stock can be introduced only from other qualified herds or herds derived by hysterectomy, artificial insemination, or embryo transfer techniques.

Over a 5-year period 45 herds qualified at some stage, and 34 were still qualified at the end of 5 years. As of 1988, some herds had exceeded the snout score limit of 0.5, with their average scores increasing to 2.24. In these herds, there was no clinical, epidemiologic, or bacteriologic evidence that they were at risk of developing severe atrophic rhinitis. It is suggested that the higher scores were associated with a group of recurrent husbandry factors, especially overstocking and unsatisfactory conditions in the weaner barns. These increased scores suggested the possibility that the upper limit for the snout scores in qualifying herds could be raised and allow bacteriologic testing to be confined to more doubtful herds.

Eradication in the Netherlands was based on the fact that they thought that there were four main possibilities for the spread of toxigenic PM: artificial insemination centers, laborers, neighborhood infection either by aerosol or by local spread, and carrier animals or birds. They assumed that most herds were closed or buying certified stock and that the major source of infection was therefore the boar. In this study they tested boars in herds with less than 50 boars they tested all, and in those with more than 50 they tested 50 as the minimum. They took nasal and tonsil samples, which were placed in cold transport medium and sent to the laboratory within 24 hours under cooled conditions for overnight culture followed by PCR.

**Reduction of Infection**

Reduction of infection pressure can be attempted. Infection of piglets occurs primarily either from carrier sows or from other infected piglets in the immediate environment and severe atrophic rhinitis generally results from infection of piglets under 3 weeks of age. If these factors can be minimized, the incidence and severity of the disease can be reduced. An all-in, all-out pig flow is one of the most effective methods of control of atrophic rhinitis. Changing to an all-in, all-out pig flow from continuous flow management can improve snout scores by 50%, lung scores by 55%, average daily gain by 0.14 lb, and days to market by 13 days.

Because severe lesions depend on infection of the piglet under 3 weeks of age, every attempt should be made to minimize the severity of the challenge to young piglets. It is a common observation that the effects of atrophic rhinitis are minimal under good systems of management and adequate ventilation, nondusty conditions, and good hygiene. The use of continual-throughput farrowing houses and weaner houses allows a buildup of infection with the presence of actively infected pigs that can provide a high infection pressure on piglets born into or introduced into these areas. The use of all-in, all-out systems of management in these areas is recommended, and young piglets should be kept in a separate area from older pigs.

**Mass Medication**

The prophylactic use of antimicrobials is frequently employed to reduce the incidence of the disease within the herd. Antimicrobials are used both within the breeding herd to reduce the prevalence of carriers and in young suckling and weaner pigs to reduce the severity of the infection. The medication is begun about 2 weeks before farrowing, is continued throughout lactation, and incorporated in the creep feed for the suckling pigs and the starter feeds for the weaned pigs. In this way there is continuous medication of the sow and the piglets during the most susceptible period. For the breeding herd, sulfamethazine at levels of 450 to 1000 mg/kg feed, with the higher levels being given to dry sows on restricted feeding, has been recommended. Sulfonamide resistance has proved a problem in some countries but beneficial results may still be achieved with these levels. It is recommended that medication be continued for a 4- to 6-week period. Carbadox at a level of 35 ppm in combination with sulfamethazine at 110 ppm is reported to be effective in clearing experimentally induced BB infection, and when used alone improved growth rate and feed efficiency in pigs with naturally occurring atrophic rhinitis. In the starter period, carbadox fed alone or in combination with sulfamethazine improved average daily gain in piglets from herds with naturally occurring atrophic rhinitis. Use of the medication, however, did not result in a reduction of mean nasal lesion scores as a result of atrophic rhinitis. Sulfamethazine at 110 mg/kg of feed is more effective than sulfathiazole at the same concentration for the control of experimentally induced atrophic rhinitis attributable to BB. Sulfamethazine may also be incorporated in creep rations, and the use of tetracyclines (200 mg/kg), tylosin (50-100 mg/kg), and penicillin (200 mg/kg) has also been suggested.

Medicated early weaning is recommended to obtain pigs free from pathogens, including BB that are endemic in the herd of origin. The sows are fed medicated feed from 5 days before to 5 days after weaning, and the piglets are dosed from birth to 10 days of age.

**Vaccination**

There has been considerable interest in the development of vaccines for the control and prevention of atrophic rhinitis attributable to BB. Inactivated vaccines have been used to vaccinate the pregnant sow 4 to 6 weeks before farrowing; in some cases, this is followed by vaccination of the piglets at 7 and 28 days of age. In general, the use of the vaccine in pregnant sows in herds where the disease has been endemic has reduced the incidence of clinical atrophic rhinitis. However, the results from one study to another have been highly variable. Vaccination of the pregnant sow results in an increase in colostral antibody titer, which does improve the clearance rate of BB in the piglets. However, it has been difficult to evaluate the efficacy of the BB used alone because the conchal atrophy associated with infection of piglets with BB experimentally or naturally heals and regenerates completely

**Diseases of the Swine Respiratory Tract**

1053
when they are reared to about 70 to 90 kg BW in good housing conditions.

Vaccination with both components (BB and PM) in a vaccine reduces lesions considerably compared with a placebo and a group with only PM type D toxin in the vaccine, but neither vaccine eliminated toxigenic PM from the upper respiratory tract.

Experimentally, piglets born from sows vaccinated with PM are protected from a challenge with atrophic rhinitis toxin. This indicates that artificial immunization for atrophic rhinitis should be possible. Vaccination of sows at least three times before farrowing for the first time and during each subsequent pregnancy with a vaccine containing BB and PM was highly successful in reducing the incidence of atrophic rhinitis in the pigs. The incidence in affected herds was reduced from 7.5% to about 2%. Experimentally, the vaccine provides good protection against challenge in piglets from vaccinated sows. A recombinant PM toxin derivative vaccine given to gilts 4 to 5 weeks before farrowing and again 2 to 3 weeks later provided excellent protection in their piglets against experimental challenge with BB and toxigenic PM. This indicates the excellent immunoprotective properties of the nontoxic derivative of the PM toxin. In five field trials, a single-component vaccine containing a nontoxic but highly immunogenic protein, as the antigen, provided much better protection than the control vaccine containing killed PM and killed BB.

Experimental infection and vaccination of pregnant minimum-disease sows with BB resulted in much higher agglutinins in serum of pregnant minimum-disease sows with BB and PM was highly successful in inducing BB and PM toxin resulted in a high degree of protection of their progeny against progressive atrophic rhinitis.

A new vaccine has been described using a truncated PM type D toxin that is immunogenic and nontoxic, a toxoid for BB, and an adjuvant. Sows were vaccinated at 8 to 6 weeks and 4 to 2 weeks before farrowing. The vaccinated animals had fewer organisms.

BORDETELLA RHINITIS
Bordetella bronchiseptica (BB) is capable of causing two major disorders on its own. The first is Bordetella rhinitis, and the second Bordetella bronchitis. It is also capable of infecting man but the contribution of pig strains to human disease is unknown.

ETIOLOGY
It is a small, aerobic, gram-negative bacterium that produces a beta hemolytic to 2-mm gray colony on some nutrient blood agars but is nonhemolytic on some enriched media. On MacConkey media it produces nonlactose fermenting colonies in 48 hours. Nearly all the strains express one of two antigenically distinct O-antigen serotypes (O1/ O2) that are not cross-reactive. Variation in virulence can result from strain variation and may be related to different phylogenetic lineages.

EPIDEMIOLOGY
The bacterium is often isolated from healthy animals. Carrier animals usually introduce it to a herd. Strains from other animals (dogs, rodents, etc.) are not so likely to colonize the pig because only a few strains occur in the pig, and these tend to be different from other species. Spread is by aerosol from sneezing and through direct and indirect contact.

Infection usually occurs early in life and what happens then depends usually on the state of immunity. Maternal antibody usually lasts long enough to cover the establishment of infection and prevents pathology but does not lead to removal of the agent.

Cross-fostering; multiple ages in the same house; multisourcing to a nursery or finishing house; poor ventilation and environmental control and, in particular, lack of an all-in, all-out policy followed by effective cleaning, disinfection, and drying policy are conducive to the spread of the condition.

PATHOGENESIS
Bordetella is a complicated organism with several virulence factors. It exists in four colony phases. Expression of the virulence genes requires cooperation of the BvgAS (virulence genes system).

Phase I colonies contain fully virulent organisms (Bvg +) expressing genes for flagellae (flu), the mannose-resistant filamentous hemagglutinin, and the outer membrane protein pertactin (PN), all of which are involved in adhesion. Other factors include a hemolysin that is adenylate cyclase, a cytotoxin, an osteocytic toxin, and the dermonecrotic toxin (dnt). The adenylate cyclase may modulate cytokine production in dendritic cells and alter immunomodulatory function. The tracheal cytotoxin is likely to act on the cilia and cause ciliostasis. The Bvg + organisms also possess the bfrZ gene for the exogenous ferric siderophore receptor, which
is essential because BB has huge requirements for iron. Phases II and III do not have all these. Reversion to phase I only takes place in vivo.

The organisms also differ between strains in the presence of genes for flagellae and fimbriae. The organisms colonize the cilia of the URT and then proliferate, and then the cilia are lost as the organisms increase further in number. Pertactin may be required for this.9 Toxic substances then diffuse from the BB into the epithelium and below and damage the osteoblasts. Mild turbinate atrophy may then begin but usually resolves by about 70 days postinfection.

In the lung, BB causes a pneumonia similar to *Mycoplasma hyopneumoniae* (EP), and the organism lives in large numbers in the main bronchi (formerly called bronchitis X), where it may cause a mucopurulent tract, notably other organisms to colonize the respiratory tract, notably *P. multocida*, *P. porci*, *P. multocida*, *P. multocida*, and *M. parvula*, formerly known as *APP*.

In early infections BB can be isolated from the whole of the respiratory tract, but in chronic or recovered cases it may only be isolated from the nasal cavity (ethmoturbinals in particular). Nasal swabs using cotton tips can be collected, placed in transport media, and cultured on special media.

Antibody tests (agglutination and ELISAs) can also be used to assess the herd status.

**IMMUNITY**

There is an IgM immunity to the hemagglutinin within 7 days and IgG appears 4 to 5 weeks later. This immunity usually prevents turbinate atrophy and pneumonic damage. It is necessary for a good IgA response to clear the URT of infection,15 but vaccine protection is not as good as natural infection protection.

**TREATMENT**

Parenteral treatment with almost all antibiotics is possible for severe acute case because in vitro sensitivity to most antibiotics is high. Only after this should treatment via water and food should be considered. BB are, however, largely resistant to Ceftiofur, and the organisms are resistant to trimethoprim–sulphonamide combinations. It is necessary for a good IgA response to clear the URT of infection,15 but vaccine protection is not as good as natural infection protection.

**CONTROL**

Medication can be used to control the onset of the problem. Threatened pigs in a single airspace should all be given antibiotics in the feed after weaning (trimethoprim/sulphonamides at 30 mg/kg daily) or tetracyclines.

Strategic medication using the same antibiotics, given parenterally, at 3, 10, and 21 days later. This immunity usually prevents turbinate atrophy and pneumonic damage. It is necessary for a good IgA response to clear the URT of infection,15 but vaccine protection is not as good as natural infection protection.

Control medication can be used to control the onset of the problem. Threatened pigs in a single airspace should all be given antibiotics in the feed after weaning (trimethoprim/sulphonamides at 30 mg/kg daily) or tetracyclines.

Strategic medication using the same antibiotics, given parenterally, at 3, 10, and 21 days of age will also reduce the clinical signs. Medicated early weaning techniques and ELISAs can also be used to assess the herd status.

**PLEUROPNEUMONIA OF PIGS ASSOCIATED WITH ACTINOBACCILLUS PLEUROPNEUMONIAE**

**ETIOLOGY**

Actinobacillus pleuropneumoniae (APP), formerly known as *Haemophilus pleuropneumoniae*, is the causative organism of pleuro pneumonia in pigs. Some strains require V factor (NAD) for growth (biotype I), but some strains do not require this factor (type II). It forms small translucent mucoid beta-hemolytic colonies around staphylococcal streaks on sheep blood agar. It is a small gram-negative, encapsulated rod. The organism causes severe, rapidly fatal fibrohemorrhagic and necrotizing pleuroneumonia. The survivors often have bacteria-laden sequestra in the lungs that are poorly penetrated by antibiotics but do act as sources of the organism for later outbreaks. It does not affect humans and has no public health significance.

Recently a completely nonpathogenic species, *A. porcitonsillarum*, has been identified.

**EPIDEMIOLOGY**

**Occurrence**

It is widely distributed worldwide. The primary reservoir is domesticated pigs, but wild boar are also affected.1

The only natural host is the pig but it has been isolated from cattle, deer, lambs,
some rodents can be infected experimentally. It is probably not carried by birds and rodents. The diversity of strains isolated from healthy pigs could be higher than that of strains recovered from diseased pigs.

It appears that few pigs are infected from their sows, and then the organism spreads after weaning as the maternal antibodies disappear. The disease occurs worldwide in growing pigs from 2 to 6 months of age, with rapid spread both within the initially affected group and subsequently to other older or younger pigs in a herd. There are probably large numbers in the nose of affected animals. Abattoir surveys have found that the lungs of pigs from about 50% of herds monitored for several months may have lesions attributable to APP. This chronic pleurisy is presumably associated with APP. 2 Sero-epidemiologic surveys have found that pigs in 70% of herds may have antibodies to one or more of several recognized serotypes of the organism. The prevalence of infection continues to increase—presumably as a result of confinement rearing, crowding, inadequate ventilation, close contact, and commingling of pigs of various age groups. The incidence of clinical disease is much less than the prevalence of infection. In most countries, the more dense the pig population, the more prevalent the APP is likely to be, and this has been documented in Belgium. In the United States it may not be as important as in Eurasia, and it was not reported to be of major importance at the Iowa clinic. 1 In Europe, it may have become more common in recent years.

Most herds have one or more types but these are usually avirulent. In some countries there may have been a shift from virulent to avirulent serotypes. In Canada, over 75% of the pigs were positive for APP in the upper respiratory tract. 1 There is a relative homogeneity within a particular serotype. 4

A strain may be virulent in one country but not in another depending on the genetic makeup determining the presence of virulence factors.

Morbidity and Case Fatality

The morbidity rate can exceed 50%, and the mortality may vary from 1% to 10%.

Methods of Transmission

Transmission is usually by pig to pig contact or more correctly nose-to-nose contact. Aerosol droplets only carry over short distances before they are precipitated. In Denmark it was suggested that the paramount factor in the spread of APP was the aerosol spread from infected neighbors. 1 In this study, the trading of subclinically infected animals, the frequency of stock purchases, the use of multiple sources, and poor biosecurity were factors associated with the spread of APP in the Danish SPF herds. Most of the herds use AI and bring in pigs in sterile containers. The organism can be spread in the air for a distance of 1 m. Aerosol transmission of APP9 was possible over 2.5 m. An experiment with transferring air from a group of pigs with serotype 2 showed that if 10% of the air was transferred, there was no transmission, but if 70% was transferred, then the APP did spread. Experimental aerosol exposure of pigs to serotype 9 results in infection and induces protection to subsequent challenge from the homologous strain.

Only a few organisms need to be carried in the tonsil and nasopharynx for a pig to become infectious during travel. Pigs may carry the APP in the nose, and the carriage occurs for both low- and high-virulence strains. The carrier state can be activated by stress or other pathogens. The subclinically infected carrier pig is the most common source of infection. It has been suggested that shedding only takes place at the time of active infection, not when the organism is just carried.

Transmission is by the respiratory route, principally via nose-to-nose contact. Overcrowding and inadequate ventilation may facilitate spread. Peak transmission may occur at around 11 weeks. Experimental intranasal challenge has been followed by death in a period as short as 24 hours. The mixing of infected pigs (seeder pigs) with normal susceptible pigs for 48 hours can mimic field infection, with the development of clinical disease, febrile responses, lung lesions, and mortality.

The subclinically infected carrier pig is the most common means by which the infection is transmitted between herds. Severe outbreaks may occur unexpectedly in susceptible breeding herds with no previous history of the disease or in intensive feeder pig operations in which pigs are introduced on a regular basis from a variety of sources. Herds that continuously introduce replacement stock are highly susceptible to an outbreak. Following the initial outbreak, general herd immunity develops, but the infection persists, and sporadic cases may continue to occur. The organism is not readily isolated from normal respiratory tissues, but persists in chronic lesions within the lungs of recovered and apparently clinically healthy pigs. These pigs provide a source of infection, especially in a finishing herd buying from diverse sources. The indirect transmission of infection has been proposed but may be rare. An on-farm study described five cases of being transmitted by aerosol or boots or clothes, but the other three cases could have been any combination of these three or even other indirect sources.

Risk Factors

Pathogen Factors

Biotypes

There are two biotypes. Biotype 1 requires NAD (NAD dependent) (13 serotypes), and biotype 2 does not (NAD independent; 2 serotypes). Biotype 1 should be differentiated from other Actinobacillus species. The isolation of biotype 2 may be increasing. It easily grows on blood agar plates, as does A. suis (see later discussion), which may also under some circumstances produce pleuropneumonia. 5 In addition, atypical biotype II strains belonging to APP serotypes 2, 4, 7, 9, and 11 have also been identified. 6 In Canada, two biotype I APP13 strains have been found (should be biotype II). 7

Serotypes

In 1997, two new serotypes were proposed: APP14 and APP15. Serotypes APP1 to APP12 form biotype 1 together with APP15. Biotype 2 is composed of APP13 and 14. Within these categories there are variations because strains may acquire characteristics of other strains. Some of the serotypes are heterogeneous (they share antigenic determinants with other serotypes). Heterogeneity has been reported for APP3, 6, and 8; APP4 and 7; and APP1, 9, and 11. Restriction endonuclease fingerprinting analysis can be used for comparison of serotypes.

Serotype 5 is subdivided into subtypes A and B. Serotype 1 has also been divided into antigenic subtypes 1A and 1B. The prevalence of serotypes of APP varies considerably according to geographic location. APP1, 5, and 7 are common in North America; APP2 and 9 are common in continental Europe; and APP3 is common in England and Ireland. APP8 is also found in Ireland. In the British Isles, APP2 and 8 were most common, with 3, 6, and 7 also occurring frequently. APP5, 9, 10, and 12 occurred only rarely, APP1 and 4 were not isolated.

In Denmark they routinely find 9 strains of the 15. It is usually APP2 followed by 6, 5, and 12. APP1, 7, 8, and 14 are infrequent, and APP3, 4, 9, 11, 13, and 15 have not yet been found. APP2 is the dominant isolate in Sweden and Switzerland. APP10 is common in France (also Brazil). APP4 is common in Spain as APP7 and many are nontypeable, but APP4 rarely appears elsewhere. 8 And in Spain, biotype II is also quite common.

APP1, 7, and 12 are common in Australian pigs, with APP1 being the most common, and APP15 is also found there and in Japan. 9

In North America, the most common serotypes, in order of frequency, are APP1, 5, and 7. APP1 is most common in eastern Canada, accounting for 66% to 83% of the isolates, and is the second most prevalent isolate in western Canada and the United States. APP2 is of low frequency in Canada. However, serotype 2 has now been reported as causing disease in growing and finishing pigs in the United States. Serotype 3 has a low incidence in Canada and the United States. Serotype 5 isolations are common in Canada and the United States. The most common serotypes isolated in Quebec were 1, 5, 2, and 7 in that order. Serotype 6 has not been reported in North America.
The serotyping of isolated strains is important in the epidemiologic and immunologic study of APP infection. It is also important when comparing or analyzing the effectiveness of different treatments to know the virulence of the strains and sensitivity to antimicrobials. An effective immunization program also depends on consideration of the multiplicity of immunogenic types that occur in a particular area or country.

It is important to realize that some strains share lipopolysaccharide O-chains and may therefore cross-react. The antigenic cross-reactions between APP3, 8, and 15 can also be explained by the presence of structural similarities. In one study it was suggested that the presence of APP9 may go clinically unnoticed as M. hyopneumoniae as this potentiates the APP infection.

### Virulence Factors

APP attaches to tonsillar epithelium. It also adheres to tracheal rings in vitro and alveolar epithelial cells. Genes that are involved in energy metabolism, nutrient uptake, and stress response are essential for the survival of APP in the pig host. These would include enzymes that are produced in vivo to ensure that there is oxygen. A metalloprotease has been found that can degrade porcine IgA and IgG.

Several other virulence attributes and their biological effects have been described. Multiple virulence factors are involved in the development of the disease, and lesions are likely caused by toxic factors associated with the organism.

The capsular components are antiphagocytic and inhibit bactericidal activity of the serum but do not cause any lesions themselves. Discovery of mutants without capsules that were no less able to adhere to respiratory tract tissues suggests that the outer membrane proteins were then unmasked (without the capsule), and these were able to adhere to epithelial cells. It is therefore an LPS independent adherence. The outer membrane proteins (OMPs) (60 kDa) adhere to fibers of type III collagen in the lung. The outer membrane proteins appear to be common to all serotypes. Some of the outer membrane proteins are also involved in iron uptake, which is essential for proliferation.

The lipopolysaccharides (LPS) of APP are serotype specific but will cross-react with one another. LPS of APP is an important adhesin. It also induces inflammation by stimulating TNF-α, IL-1, II-6, and IL-8. However, the construction of antibodies to LPS blocked adherence to tracheal cells, so our understanding is not yet complete. The LPS causes an endotoxemia and reproduces certain typical lesions of the natural disease but not the hemolytic or necrotizing effects. Some LPS also help APP to stick to mucus, tracheal rings, and lung, but they do not seem to be involved in adherence to cultured porcine alveolar epithelial cells.

Porcine hemoglobin also binds to LPS with APP, and this is a property of the APP OMP.

Under iron-deficiency growth conditions, APP expresses 2 transferrin binding proteins. Recently a ferrichrome receptor in APP has been described.

There are adhesins (fimbriae) involved in attachment. They are particularly associated with serotype 1 but also 3 and 5 and are usually a feature of subculture 1 (56% of strains), but only 8% on subculture 2 and none on 3.

#### Apx Toxins

Not all the differences in virulence are explained by capsules, LPS, hemolysins, and Apx toxins. Certainly, all strains need Apx IV and two out of Apx II or III. There is no certain way to differentiate virulent from avirulent strains.

Several exotoxins are produced including hemolysins. The hemolytic activity of this organism is characteristic of this species of bacteria. This range of exotoxins is part of the pore-forming RTX group known as the Apx toxins. The latest is Apx IV A, and the gene is present in all APP strains and is species specific for APP and is thus being used in a PCR to identify APP strains. It is secreted by a type I secretion system.

The Apx toxins are described in the following discussion: I through III can be produced in vitro, but Apx IV A is only produced in vivo and is specific to APP. All 90 strains investigated in one study had Apx IV A genes. Mutants without the capacity to produce Apx toxins do not cause disease. There are basically four different patterns. Both ApxI and II are essential for the production of lesions. Apx III specifically targets leukocytes by binding CD18.

The gene is present in all APP strains.

Major RTX toxins in APP are as follows:
- **ApxI**: 110 kDa is strongly hemolytic and weakly cytotoxic.
- **ApxII**: 102 kDa is weakly hemolytic and moderately cytotoxic.
- **ApxIII**: 120 kDa is not hemolytic but strongly cytotoxic.
- **ApxIV**: 202 kDa has largely unknown actions but is essential for full virulence of APP.

Serotypes 1, 5a, 5b, 9, and 11 produce I and II; serotypes 2, 3, 4, 6, and 8 produce II and III; serotypes 7 and 12 produce II; serotype 10 only produces Apx I.

There are differences in opinion as to what constitutes virulence. Generally, the following is representative, but it does vary considerably from country to country and isolate to isolate (Box 12-2).

These are toxic to alveolar macrophages, neutrophils, and endothelial cells. In small doses they are stimulatory but in large doses lethal. The gene expression is controlled over the growth curve by a novel regulating pathway. Several genes have recently been identified that have helped in survival, including the knowledge that it can produce toxins under anaerobic conditions. The LPS of APP can also stimulate the release of nitric oxide from macrophages by virtue of the enzyme nitric oxide synthase that damages tissues and may disrupt vascular tone, neuronal signaling, and host defense mechanisms. Nitric oxide synthase 2 and cyclooxygenase 2 have been found in swine experimentally infected with APP. Urease activity may also be required for APP to establish infection in the respiratory tract.

The increase in antimicrobial drug resistance that has occurred is an indirect virulence factor and an important disease-promoting mechanism. The ability of the organism to resist complement killing in vitro may reflect a virulence mechanism in vivo that assists bacteria in avoiding the pulmonary defenses of swine and promotes bacterial invasion of the lung.

Differences in pathogenicity exist between serovar 1 and serovars 7, 3, and 2. The differences between serotypes 1, 2, and 7 are low. Serotype 3 seems less virulent than 1. The differences in capsular structure and biochemical composition between virulent and avirulent isolates may contribute to virulence. A smooth-type lipopolysaccharide and a rough-type lipopolysaccharide have been isolated and characterized from serotype 5. The intrabronchial infusion of the preparations into pigs induces lesions typical of those in pigs that die of acute pleuropneumonia.

APP may interact with *P. multocida* to produce a severe pneumonia, whereas *P. multocida* alone is relatively nonpathogenic. Experimentally, a combination of *P. multocida* and the crude toxin of APP resulted in moderate-to-severe pneumonic pasteurellosis.

Of increasing importance and recognition is the formation of biofilms at mucosal...
surfaces. It is part of the extracellular stress response to the presence of APP. Many strains of APP under appropriate growth conditions form biofilms. Serovars 5b and 11 may exhibit biofilm formation, and a histone-like protein H-NS regulates biofilm formation and virulence of APP.

Animal Risk Factors

The major animal risk factors are related to the immune mechanisms and the immune status of pigs of varying ages. A major animal risk factor is that clinically recovered pigs commonly serve as carriers of the organism and never fully recover from the infection. Normally, the APP is detected in mixed bacterial samples from the tonsils and/or nasal samples by PCR from the age of 4 weeks on, but it has been detected as early as 11 days in tonsil samples, so it is possible for the sow to infect the piglet. Isolations become more common from 4 to 12 weeks as maternal antibody wanes. The median length of tonsillar carriage may be 7 to 8 weeks. Colonization of the lungs can develop from around 12 to 16 weeks in some herds to as late as 23 weeks in others.

Factors associated with pleurisy in pigs in a case-control analysis of slaughter pigs in England and Wales showed that risk factors included the following:

- No all-in-all-out policy
- Pigs with more than 1-month age difference in the same shed
- Repeated mixing
- Moving during the rearing phase

Decreased incidence was associated with the following:

- Grow to finish or wean to finish in a house filled with less than 3 sources
- With cleaning and disinfection of grower and finisher groups between groups and extended down time of grower or finisher units

Noninfectious factors in the occurrence of pleurisy have been investigated in France. This study was in 143 farrow to finish herds, where management, husbandry, and housing conditions were recorded. An increased risk for extensive pleuritis occurred where there was a short temperature range for the ventilation control, lack of disinfection in the farrowing room, late surgical procedures on the piglets, a mean temperature below 23°C (75°F) in the finishing room, and a herd size above 200 sows.

Immune Mechanisms

Colostral immunity lasts from 2 weeks (usually 5) to 3 months. After an experimental or natural infection antibodies occur 10 to 14 days postinfection and reach their height at 4 to 6 weeks postinfection. In the animals that are subclinically affected there may be no antibodies produced to the toxins.

In most herds, high antibody levels in 4-week-old piglets can still be detected, and this maternal antibody (AB) continues to decrease until about 12 weeks, and then the AB starts to rise with the acquisition of a pathogenic burden. The presence and decay of acquired colostral antibodies between 2 weeks and 2 months determines the age at which APP infection is most likely to occur. The maternal antibody titers halve every 3 weeks and therefore may remain for 12 to 56 days.

Nasal colonization can occur as early as 4 weeks, and APP can be found in the lungs from 12 weeks; it is usually 12 to 23 weeks before there is any seroconversion to Apx toxins. In other words, nasal colonization does not always produce antibodies.

Active immunity to disease usually follows experimentally induced and naturally occurring infections, and infection with one serotype of APP confers a strong immunity to the same serotype and a partial protection against heterologous strains. Most recovered pigs have a strong humoral immunity but it does not necessarily stop them from becoming carriers and thence possible shredders of APP. Vaccination with killed bacteria produces partial protection against the homologous strain and none against heterologous strains. Second-generation vaccines with Apx toxins produce good protection against clinical disease caused by any serotype but do not prevent animals from becoming carriers through subclinical infections. However, vaccine immunity is serotype specific.

The antibody response to APP infections or vaccination is demonstrated by the complement fixation test or other serologic tests. There is a good correlation between a CF titer and resistance to infection, and the organism usually cannot be isolated from seropositive animals. Susceptibility to APP can be predicted by the absence of neutralizing antibodies to the organism, whereas protection can be predicted by the presence of these antibodies. An aerosol exposure of pigs to viable or inactivated serotype 9 induced antibodies in pulmonary fluids and serum, and protected against homologous challenge. However, the organism may persist in necrotic foci in the lungs or tonsils of pigs considered immune to the infection.

Within 2 to 3 weeks of an acute disease outbreak, the morbidity decreases because of the development of immunity. Clinical disease is unlikely in adult immune animals, and immune sows confer passive immunity to their piglets that provides protection for the first weeks of life. However, acute disease may occur in piglets 3 to 8 weeks of age if colostral immunity is initially low and wanes to below protective levels. Also, severe cases can occur in nonimmune gilts and boars introduced into infected herds.

Pigs infected with hemolytic *Actinobacillus pleuropneumoniae* may become false-positive reactors for APP. Such pigs may also be less susceptible to pleuropneumonia caused by APP.

Environmental and Management Factors

Outbreaks of the disease appear to occur in pigs that lack immunity, are overcrowded, or have been subjected to recent stressors, such as marked changes in ambient temperature or a failure in the ventilation system. The organism survives better when conditions are wet or in mucus and may last days or even weeks. It survives in water for 30 days at 4°C (39°F) but has a very short survival under dry and warm conditions. Outbreaks may occur in breeding herds following transportation to and from livestock shows and sales. Presumably, the infection was contracted by commingling with clinically healthy but infected pigs. The hypothalamic-pituitary–adrenal axis is stimulated in response to a wide variety of stressors, and this may lead to activation of the organism from the tonsils. The highest risk is associated with the introduction of pigs from sales barns and the lowest risk from stock whose health status is known to the purchaser.

Economic Importance

The economic losses associated with the disease are considered to be attributable to peracute deaths, the costs of treatment of individually affected pigs and mass medication of the feed and water, and chronic disease that delays the marketing of finishing pigs. Field observations indicate that 5.64 additional days are required for pigs with subclinical infection to reach market weight of 113.6 kg compared with uninfected herdmates. However, other observations and investigations indicate that average daily gain is not significantly affected by infection with APP. Undoubtedly, there are major economic losses associated with the endemic nature of the disease, which is characterized by peracute deaths that recur sporadically, sometimes punctuated by outbreaks.

PATHOGENESIS

The interactions of APP with host epithelial cells seem to involve complex interactions resulting in the regulation of various bacterial genes, including some coding for putative adhesins.

The natural route of infection is aero- genous. In growing pigs the disease appears to be a respiratory infection without septicaemia, producing a fibrinous necrotizing hemor hagic pleuropneumonia with pleuritis. Early after intranasal inoculation the bacteria were mainly associated with the stratified squamous epithelium and detached epithelial cells in the tonsil. If only a few organisms are inhaled, probably they are trapped in the tonsil and remain there until they are activated. If large numbers are inhaled or if spread from the tonsil reservoir occurs, then a bacteremia probably results. Vacuolation and desquamation of the tonsilar epithelium was observed and there were many migrating neutrophils and these distend the
tonsillar crypts. They do not bind to the tracheal (perhaps in the newborn) or to the bronchial epithelium, but they can stick to the alveolar wall.21 The Apx1 of APP10 induces apoptosis in porcine alveolar epithelial cells.21 The adhesion of bacteria to cells appears to be essential and seems to be mediated by polysaccharides and proteins.22 The role of the fimbriae is not clear. Discharge of vesicles containing proteases and Apx toxins from APP1 has been described. Later the bacteria are associated with the crypt walls and detached cells in the crypts. Experimental aerosol exposure of pigs to APP results in a severe fibrinous hemorrhagic necrotizing pleuropneumonia that simulates the natural disease. The organism expresses a number of factors that help to acquire iron and it can use a variety of compounds, including hemoglobin.23 Normally, the APP are kept out of the alveoli by the mucociliary clearance mechanism but not if there are large numbers of APP or there is preexisting damage to the clearance such as occurs as in M. hyopneumoniae infection.23 It is a very determined battle in the alveolus between the APP virulence factors and the host defense mechanisms. The cytokine production excites the defenses and increases the permeability of the alveolar capillary walls and allows access of antibodies and complement. The macrophages need opsonins to help phagocytosis as APP is resistant to the action of complement. The Apx1 toxin induces apoptosis in the macrophages, which are then killed by leukotoxins, and these then release further amounts of proteases etc. The characteristics of the pathogenesis have been described.23,24 Within a few hours following endobronchial inoculation of various doses of the organism into 12-week-old pigs, clinical evidence of dyspnea and fever are obvious. An aerosol infection with the organism results in pulmonary edema with multifocal petechial hemorrhages and a diffuse neutrophilic bronchiolitis and alveolitis within hours of infection. In the lung, the recruitment of neutrophils is directed toward the viable APP organisms, and possibly 30% of the lung neutrophils respond. This is further enhanced by IL-8 activity. The porcine mononuclear cell phagocytic populations during inflammation produced by APP have been described.25 The lesion is particularly marked in the dorsocaudal regions of the lung. The ability of APP hemolysin to deglutitate pulmonary macrophages may enhance the multiplication of the organism, but experimentally the hemolysin of serovar 2 is not an essential factor for the production of the lesions. In the acute stages there are marked vascular changes in the lungs. The lesions resemble infarcts because of the vasculitis, thrombosis, and hemorrhage. There are many necrotic foci that serve as reservoirs of the organism in pigs that recover. In the experimental disease, the leukogram is typical of acute inflammation; however, hypoxemia and alveolar hypoventilation are not features of the disease. The hematologic and physiologic findings indicate that the peracute disease resembles septic shock. Immediately after infection the levels of IL-1, IL-6, and TNF-α begin to rise. Moderate levels help in defense, but high levels make things worse. At the same time the IL-10 suppresses TNF-α and IL-1 production in macrophages and monocytes, which up-regulates the other inflammatory cytokines. Pretreatment of the pig with IL-10 reduces the severity of the pleuropneumonia. The prolonged survival of APP during the infections may be attributable to the effect the organism has in downgrading the protective responses of the host.

The distribution of porcine monocytes in different lymphoid tissues and the lungs during experimental A. pleuropneumoniae infection and the role of chemokines has been described.25 This study showed that monocyte counts in various organs changed during inflammation. The CD163 + monocyte counts were found in the lungs and TBLN from APP-infected pigs, suggesting that monocytes migrate just to these organs.

**CLINICAL FINDINGS**

The clinical signs vary with the immune status and environmental stress and customarily may be seen between 6 and 20 weeks of age. In all cases there is a reduced growth rate and reduced feed intake, therefore leading to reduced weight gain. There is no relationship between average daily gain and serologic response to APP. The illness may be paracutaneous, acute, subacute, or chronic. In all stages there is very little exercise tolerance, with varying degrees of increase in respiratory rate. The onset is sudden. Several pigs that were not seen ill may be found dead, and others show severe respiratory distress. Affected pigs are disinclined to eat, with elbows abducted to relieve pressure 1 to 2 days. In many cases, the animals “dog sit” with elbows abducted to relieve pressure on the lungs, and they show dyspnea. Chronic cases, which usually appear after the acute phase has disappeared, are febrile and anorexic initially, but respiratory distress is less severe, and a persistent cough may develop. If affected pigs are not treated, there will be a high case-fatality rate. Otitis media in a weaned pig caused by infection of the middle ear with the organism has been described. There may also be lesions in the joints with fluctuating swellings of the hocks and the synovial membranes replaced by granulation tissue.

The course of the disease in a herd may last for several weeks, during which time new acute cases develop and chronic cases become obvious by an unthriftiness appearance and chronic coughing.

Abortions may occur and the disease may cause sudden deaths in adult pigs, particularly those that are kept outdoors during the summer months and exposed to very warm weather.

Computer tomography and radiography have been described as aids to diagnosis.25 Recently a very mild condition very similar to swine influenza, with just a slight increase in respiratory rate, has been described.26

**CLINICAL PATHOLOGY**

Plasma cortisol rises 24 hours postchallenge. Haptoglobin is increased. Within 48 hours of IL-1α, IL-1β, and IL-8 were increased, and there was a 50% reduction in iron and zinc. Plasma IGF-1 concentrations were reduced in response to the APP challenge as they were with endotoxin challenge. The LPS of APP produces rises in inflammatory cytokines (TNF-α, IL-6, and IL-10). Band neutrophils are significantly increased in early infections from 18 to 48 hours, and the early changes have been described.27

**Culture of Organism**

In an outbreak, the diagnosis is preferably made by culture at necropsy. Carrier pigs can be identified by culturing the organism from the upper respiratory tract using nasal swabs from live pigs on the farm and samples from tonsils at slaughter. A selective medium for the culture of the organism from the airways of slaughtered pigs may increase the isolation rate because of the high degree of contamination. The culture of APP has recently been complicated by the identification of the nonpathogenic A. porcinsillarum.

**Serotype of Organism**

Tests to determine the serotype include slide agglutination, immunodiffusion, ring precipitation, indirect hemagglutination, immunofluorescence, coagglutination, and counterimmunoelectrophoresis. The latter is quicker, more sensitive, and more easily performed than direct immunofluorescence and immunodiffusion procedures. The coagglutination test is simple and rapid, the immunodiffusion test is considered to be the most serotype-specific, and there is a good correlation between the rapid slide agglutination test and the indirect fluorescent antibody tests. The rapid slide agglutination test is the method of choice of some workers, but the coagglutination test is serotype-specific, sensitive, simple, rapid, reproducible, and easier to read and interpret than the rapid slide or tube agglutination tests. The International Pig Veterinary Society has recommended that the coagglutination test is currently the method of choice for routine
serotyping of field strains. This technique does not allow separation of the heterogeneous serovar 8 from serovars 3 and 6, the heterogeneous serovar 9 from serovar 1, or the heterogeneous serovar 7 from 4. The results are reported as group 9–1, group 8–3–6, and group 7–4, respectively. The final identification of heterogeneous serovars can only be achieved by the agar gel diffusion test and by indirect hemagglutination. Reference strains and the corresponding antisera are available to bring some uniformity into serotyping.

Detection of Antigen
The polymerase chain reaction (PCR) is a highly sensitive test for the detection of the organism from tissue samples. A PCR for type 4 has been developed. Some detect OMP; others detect Apx genes. Apx IVA based ELISAs can be used for evaluating APP status in commercial herds, but some appear limited by high carriage rates of low-virulence APP. Immunomagnetic separation of APP1 and 2 has been described with greater sensitivity than possible with isolation or even PCR. A PCR-based RFLP analysis of the OM1A gene may also be of value in differentiating APP serotypes. A multiplex PCR has been developed. There is often disparity between immunologic and PCR-based serotyping.

Serology
Serology is the best method for surveillance purposes and is the best way to detect subclinical infections but may give unexplained results. In addition, some of the strains do not produce ApxIV do not produce antibodies. Sometimes diagnostic interpretation is difficult.

Tests for antibodies to toxins and/or capsular antigens have a low specificity and can also be positive for A. suis infection. Most commonly used are antigens using O-chain LPS. They tend to be grouped together: (1, 9, 11), (2, 3, 6), (8, 4, 7), (10 and 12), (3 and 5), (15, 3, 6). For the serologic diagnosis of infection in live animals the complement fixation test is reliable, but an enzyme-linked immunosorbent assay (ELISA) test is highly specific and more sensitive than the complement fixation test.

The complement fixation test has been used routinely in the past in some countries and has a high degree of sensitivity and specificity. It is, however, a cumbersome test, and many laboratories find it difficult to perform, and so it is rarely used nowadays. Pigs being imported into China and Russia still require a CFT negative test.

The ELISA is a rapid and sensitive test and can be adapted to automation. The ELISA for serotypes 1, 2, 5, and 7 distinguishes exposed from unexposed pigs or herds. Because of cross-reactivity with other serotypes and A. suis, the serodiagnosis of serotype infections cannot be made with certainty. A blocking ELISA is available for detection of antibodies against serotype 2 and also 2, 6, 8, and 12, which is the dominating serotype in Danish swine herds, causing approximately 70% of diagnosed outbreaks of pleuropneumonia. A similar test is available for serotype 8. A mixed-antigen ELISA for serodiagnosis of serotypes 1, 5, and 7 has a sensitivity of 96% and specificity of 99.5% and can be used for herd health monitoring programs. The long-chain lipopolysaccharide of serotypes 4, 5, and 7 is a superior antigen to the crude extracts used as antigens in the ELISA for the serodiagnosis of pleuropneumonia.

There are now ELISAs for the detection of antibodies to the Apx toxins, and the one for type II Apx was described as sensitive, inexpensive, and highly discriminatory. A multiplex PCR for all toxins in one test is a reliable typing system. A new ELISA for the Apx IV produced by all 15 serotypes means that you can detect all APP with one test. It has a specificity of 100% and a higher sensitivity than culture (93.8%). This is important because you can find Apx I to III in pigs associated with A. suis and A. rossii, but Apx IV is only produced by APP in vivo. It will detect the toxin from 2 to 3 weeks post-infection.

An inhibition enzyme immunoassay for the serodiagnosis of serotypes 2 and 5 had a sensitivity and specificity of 100% and 98.9%, respectively. The detection of antibodies to APP is an essential feature in the epidemiologic study and control of pleuropneumonia in pigs. Serologic testing can be used to monitor the level of infection in a breeding herd over a period of time and as the piglets become older. A minimum of 30 serum samples from adult pigs is necessary to provide a reliable assessment of the herd’s infection status. None of these serologic tests is completely reliable, and in certain situations a combination of two tests is needed for interpretation of low titers in some pigs. In most instances, serologic diagnosis is type-specific, and protection obtained by vaccination is type-specific and will protect only against the serotype contained in the vaccine. Thus it is important to determine the serotypes that are causing disease in the herd.

An important strategy of control of this disease is to detect infected pigs in a herd or to exclude infected pigs from being imported into a herd. Because there is no reliable method for the detection of every infected pig, the effectiveness of this barrier is reduced whenever pigs, such as breeding stock or weanlings, are allowed into a herd. Because there is no reliable method for the detection of every infected pig, the effectiveness of this barrier is reduced whenever pigs, such as breeding stock or weanlings, are allowed into a herd. There is a need for a highly sensitive and specific test for the identification of infected pigs. Although bacteriologic culture is specific it is not sensitive. The ELISA test may be a useful test for the antemortem diagnosis of infected herds.

Necropsy Findings
Characteristic lesions are confined to the thoracic cavity and consist of hemorrhagic and fibrinous pleuropneumonia with a tendency to sequestration in the chronic form. In peracute cases the lungs are swollen, firm, and dark red. In peracute cases the trachea and bronchi are full of frothy fluid. Fluid and blood ooze from the cut surface, and there may be marked edema of the interlobular septa, reflecting widespread thrombosis and alterations in capillary permeability. There may be hemorrhagic areas of necrosis that are very variable. In acute cases there are layers of fibrin on the pleural surface and pericardium. In pigs that die less acutely, focal black or red raised areas of pneumonia are present. Lesions may occur throughout the lung, including the diaphragmatic lobes. The quantitative morphology of peracute pulmonary lesions induced by the organism has been described. In chronic cases there is fibrosis of the fibrinous pleurisy and adhesions result between the visceral and parietal pleura, and on removal of the lungs from the thorax portions of lung may remain adherent to the thoracic cage. A fibrinous pleuritis overlies the affected lung tissue, and a fibrinous pericarditis may also be present. The organism can be isolated from affected lung tissue, but generally not from other internal organs. Occasionally, otitis, endocarditis, pericarditis, and serous arthritis may follow, particularly when infection involves serotype 3. An osteomyelitis and arthritis caused by APP has been demonstrated using fluorescent in situ hybridization.

Histologically, vasculitis and widespread thrombosis is usually evident, in addition to an abundance of fibrin and neutrophils within alveoli. A fibrinous thrombosis with IHC demonstration of APP has been described. In situ hybridization can be used to detect IL-1, IL-6, and TNF-α in streaming degenerate alveolar leukocytes (oat cells) and the boundary zone of oxidative necrosis. A less intense signal was seen in the dense zone of degenerate cells in granulation tissue surrounding the necrotic areas. IL-1 was also seen in the scattered endothelial cells bordering zones of coagulative necrosis. IL-6 is the cytokine that is most elevated, and serum amyloid and haptoglobin are also elevated.

In a chronically infected herd, fibrous pleural adhesions may be present in a large proportion of the pigs at market as a result of infection several months earlier. Subacute to chronic lung lesions are encapsulated by fibrous tissue, and sequestrum may be present. A high prevalence of fibrous or fibrinous pleuritic lesions on inspection at the abattoir is very suggestive of APP infection.

Diagnosis
The provisional diagnosis of pleuropneumonia associated with APP in the pig is usually based on history, clinical signs, and the post-mortem picture. The acute cases then require
laboratory investigation to confirm, and chronic cases may prove antigen negative (the lesions are usually fibrous or fibrinous) but possibly antibody positive. A variety of samples need to be taken from acute cases and should be from lesions not from inflammatory exudates and particularly not from the lungs.

### Samples for Confirmation of Diagnosis

The evolution of diagnostic tests has been described as follows:39

- **Bacteriology**—lung culture is relatively easy if the carcass is freshly dead. The culture is achieved on 55 sheep blood agar with a cross-streak of *Staphylococcus epidermidis* or *S. aureus*. The plates are incubated overnight with 5% CO₂, and a clear zone of complete hemolysis results. Typing will confirm the identity of APP1-15 and if atypical PCRs can be used. PCRs for 3, 6, and 8 were described;10 1, 7, and 12;41 15 and 7;42 and also 1, 2, and 8. Sometimes serotypes cannot be differentiated. Toxin typing using a PCR can be used to determine which Apx toxin genes are carried by a certain isolate. They can also be isolated from pure and mixed bacterial cultures by immunomagnetic separation.

- **Histology**—formalin-fixed lung (LM). APP can be further identified by IHC, which is particularly useful in chronic cases and ISH.

- **Serology**—used to check the herd status. Coagglutination can be used first, with confirmation by agar gel diffusion and indirect hemagglutination.

### Differential Diagnosis

The rapidity of onset and spread with fever, anorexia, severe dyspnea, and high mortality differentiates APP from the majority of respiratory diseases in pigs.

- **Enzootic pneumonia** is more insidious in its occurrence and has distinctly different epidemiologic, clinical, and pathologic features.

- **Pasteurellosis** is characterized by a necrotizing bronchopneumonia.

- **Swine influenza** is characterized by an explosive outbreak of respiratory disease. However, this is not restricted to growing pigs and the mortality is low. There is a distinct difference in the respiratory lesion on necropsy examination.

- **Glasser’s disease** is characterized by serositis, arthritis, and meningitis, and occurs in younger pigs.

- **Mulberry heart disease** may present with similar clinical findings, but there is no pneumonia on necropsy examination.

### Treatment

#### Antimicrobial Therapy

The results of treatment are often disappointing because of the severity of acute disease and persistence of infection in recovered pigs. It is best to assume that APP cannot be eliminated using antibiotic therapy.40 Although antimicrobials may reduce mortality and improve average daily gain, treated animals often continue to harbor the organism and are a source of infection to other animals. If animals are clinically ill, then injection of antimicrobials is necessary. Affected and in-contact pigs should be treated parenterally with antimicrobials. Tetracycline, spectinomycin, and penicillin have been effective and are recommended unless drug resistance has occurred. Penicillin may have inconsistent results.43 Fluoroquinolones are distributed to bronchial secretions, bronchial mucosa, and alveolar macrophages. The pharmacokinetics of danofloxacin are favorable for APP treatment. In fact, elevated C-reactive protein, IL-6, and haptoglobin (all elevated rapidly after infection) all return to normal, as do the reduced plasma zinc, ascorbic acid, and alpha tocopherol rapidly after treatment. Cefiofur and fluoroquinolones were the most active agents against APP. APP is only eliminated from the respiratory tract in animals medicated with enrofloxacin. Tilmicosin is useful for treating outbreaks.

In a large study in Switzerland of 83 APP and 58 A. porcitonsillarum (PT) strains screened for susceptibility to 20 antimicrobial agents, it was found that there was resistance to sulphamethoxazole, sulphonamide–trimethoprim, tiamulin, tilmicosin, tetracycline, and ampicillin. A few of the PT strains showed increased susceptibility to enrofloxacin.44 Both APP and PT remain susceptible to cephalosporins, fluoroquinolones, and phenicols, which are not be used except in special cases. In the last few years resistance to tetracyclines and trimethoprim–sulphonamide has increased.45 There is no clear association between antimicrobial susceptibility and serotype.44 There have been enrofloxacin-resistant APP isolates found in Taiwan.46

In finishing units, where outbreaks of the disease have been confirmed, the twice-daily intramuscular injection of pigs early in the course of the disease with antimicrobials, based on drug sensitivity tests, daily until clinical recovery occurred, was superior to the mass medication of feed and water. A considerable amount of labor is required, but it is considered to be the most cost-effective method.

In a study of SPF pigs experimentally infected with APP2 and treated with enrofloxacin (E), tetracycline (T), or penicillin (P) at the onset of disease or left untreated, it was found that the animals treated with E and T recovered rapidly. All except the E group developed antibodies. They were later challenged with APP2 again, but here the E group developed serious disease. The implication is that the E was so successful initially in eradicating the APP that it did not allow an antibody response to develop to resist the rechallenge.41

### Antimicrobial Sensitivities

The antimicrobial sensitivities of isolates of APP have been monitored, and there is some variation based on geographic location. The large expansion in the size of swine herds, and the introduction of breeding stock from many different sources, has led to an increase in the incidence of porcine pleuropneumonia and extensive use of parenteral antimicrobials. To ensure an optimal response to therapy, it is necessary to monitor antimicrobial sensitivity on a herd basis.

The antimicrobial sensitivity of the organism was determined in isolates from Europe, Japan, South Africa, and North America between 1989 and 1991. They were highly susceptible to danofloxacin and moderately susceptible to amoxicillin, cefiofur, and trimethoprim–sulphamethoxazole. There was widespread resistance to other currently available antimicrobials. In another study, thiampenicol and metronidazole had good activity, and the cephalosporins and fluoroquinolones were most active. A comparison of the minimum inhibitory concentrations (MICs) of several antimicrobials against several bacterial pathogens of swine, including APP, from the United States, Canada, and Denmark found that cefiofur and enrofloxacin were the most active antimicrobials.

Plasmid-mediated antimicrobial resistance has been found in isolates of the organism that are resistant to certain antimicrobials.

### Antimicrobials in Experimental Disease

In these experimental infections enrofloxacin and cefiofur are particularly effective and also tulathromycin.40

The therapeutic efficiency of some commonly used antimicrobials has been evaluated for the treatment of experimentally induced pleuropneumonia using serotype 1 APP. Florfenicol in the feed at 50 ppm prevented pneumonia when pigs were experimentally inoculated with serotype 1, 2, and 5 strains and thiampenicol-resistant strains of the organism. The combination of trimethoprim and sulphamethoxazole is superior to...
a combination of trimethoprim and sulfadimethoxine. Oxytetracycline in the water at 222 mg/L for 7 days beginning 24 hours before experimental challenge reduced the case-fatality rate, lung lesions, and the isolation of the organism compared with the unmedicated group. Treatment of chronically affected pigs did not improve rate or gain, nor did it eliminate the infection. Enrofloxacin at 150 ppm in the feed provided effective control of the experimental disease.

**Mass Medication of Feed**

In-feed medication with sulfadimethoxine and sulfamethoxazole in combination with trimethoprim has been described. Oxytetracycline in the feed at 1600 mg/kg of feed for 6 days before experimental challenge and for 9 days after challenge, provided 100% protection from clinical disease, but 400, 800, or 1200 mg/kg of feed did not prevent subsequent shedding and transmission to seronegative animals. Tetracycline should be administered through the feed of all in-contact pigs during the outbreak, but the persistence of the organism in chronically affected pigs may result in clinical disease when the medication is withdrawn. Doxycycline in feed at 250 ppm for 8 consecutive days is useful for the control of APP. Tilmicosin fed to pigs at 200 to 400 µg/g is effective in controlling and preventing APP-induced pneumonia, using seeder pigs, when administered in the feed for 21 days. In commercial herds, 400 µg/g of feed for 21 days is no more effective than 200 µg/g of feed for the control of naturally acquired pneumonia caused by APP and P. multocida. Sulfathiazole at the rate of 28 g/3.8 L of drinking water for 12 days has also been successful. Tiamulin in the drinking water at a concentration to deliver 23 µg/kg BW for 5 days after an initial individual treatment of affected pigs has also been recommended.

**CONTROL**

It is impossible to guarantee freedom because the detection of carriers is almost totally impossible. There are no techniques as yet for identifying the animal that may have only a few organisms in the tonsill. You can guarantee freedom from clinical disease at the time of inspection but little else. In a recent study of 980 pigs there was no evidence of an APP clinical or pathologic case until the occurrence of PMWS resulted in the isolation of an APP7 from the series of pigs in a unit that had until that time been considered free.

There are two options for the control and prevention of porcine pleuropneumonia: 1. Control at an economical level using good management combined with the possible use of vaccines 2. Eradication of the infection from the herd

Determining which option to select requires careful consideration of the advantages and disadvantages of each option. With an understanding of the factors that result in clinical disease, it is possible to maintain an infected breeding herd and produce pigs with a small risk of clinical disease.

**Control by Management**

Management and housing improvements can prevent clinical episodes. One of the most important things to do is to make sure that there is vaccination for enzootic pneumonia.

Control is difficult and unreliable because pigs that recover from clinical disease provide a source of future infection for finishing operations that purchase all of their introductions. The all-in, all-out system of purchasing, feeding, and marketing pigs, with a thorough cleaning between groups, animals in a finishing operation, should be adopted. The disease is highly contagious, and control measures must be directed toward identifying infected pigs and eliminating their introduction into uninfected herds. When moving pigs between herds, it is critically important that the herds be matched according to their infection status. Source herds for feeder animals are sero-tested, and then pigs of like immune status are commingled to produce a population that is compatible immunologically. By commingling only animals from seronegative herds, the risk of disease is greatly decreased and growth performance improved. The mixing of animals from herds known to be infected with homologous serotypes is also effective.

Every economical effort must be made to identify and isolate infected pigs and to exclude the importation of clinically normal but infected pigs into herds in which the infection is not present. This is a major challenge that is dependent on the availability of a highly sensitive and specific laboratory test. The acquisition of new breeding stock for herds free of the infection should include a period of quarantine and two serologic tests 3 weeks apart. Only seronegative animals should be introduced into the herds. A seropositive animal should be considered a potential carrier. Field trials have shown that it is not possible to rear seronegative animals within a breeding and rearing herd heavily infected with serotype 2 of the organism. Neither medication of the sows and piglets with trimethoprim-sulfonamides, nor a strictly applied all-in, all-out system reduced the percentage of seropositive animals.

Management practices must emphasize the rearing of weaned pigs in pens separate from older stock that are carriers of the organism. Large breeding herds and finishing units should subordinate the total herd into separate units, which minimizes the spread of infection. Early weaning and segregation of gilts from infected stock have been used to develop a seronegative herd.

Herds can be classified into one of three categories depending on their infection status:

**CATEGORY 1. Serologically positive for APP without a history of clinical disease. A majority of herds are serologically positive but do not have clinically apparent disease. Good management and environmental quality control can minimize the incidence of clinical disease. Good ventilation, the use of all-in, all-out management practices, and appropriate stocking densities are important.**

**CATEGORY 2. Serologically negative and clinically free of APP. These herds can be maintained free of infection with good biosecurity practices.** New breeding stock must be obtained from herds free of infection. Artificial insemination can be used to limit the introduction of live pigs. Pigs sold from these herds to herds with endemic infection are highly susceptible to infection.

**CATEGORY 3. History of clinical disease caused by APP, which has been pathologically and microbiologically confirmed. In these herds, acute disease outbreaks occur most commonly in pigs 9 to 20 weeks of age. Pigs are usually protected by colostral immunity for the first 8 weeks of life. The severity of outbreaks can be reduced by mass medication of the feed, treatment of individual pigs, and good management practices to ensure adequate ventilation.**

**Eradication**

The Danish SPF system was the first to try to eradicate APP. Each month 20 serum samples were tested for APP 2 and 6 and were collected at the monthly clinical inspection. This happened every 3 months also for APP12 and annually for APP 1, 5, 7, and 10. Recurring outbreaks of pleuropneumonia is the most common reason for an eradication strategy. Eradication is done by depopulating the entire herd, followed by repopulation with animals from herds that are clinically and serologically negative. Eradication can be successful but the risk of introducing infections into the herd is high unless biosecurity measures are adopted and strictly implemented.

An alternative to depopulation is medicated early weaning, in which pigs are weaned at 10 to 15 days of age, treated with antimicrobials, and reared in isolation. Transmission of infection between the sow and piglets does not occur before 11 days of age, about half of the piglets are infected at 16 days of age, and if weaned at 21 days of age most of the piglets are infected.
The early weaning program can be expanded to the three-site system of rearing. Adults and nursing piglets are housed in one site. At weaning, piglets are moved to the nursery barn for growth to 25 kg, and then moved to a third site for the final growing period. The adults may be serologically positive for infection, but the nursery pigs, growing pigs, and finishing pigs are negative.

Age segregation, distance that prevents aerosol transmission, and adherence to strict biosecurity practices can reduce the prevalence of infection and the incidence of disease.

**Vaccination**

A wide range of vaccines have been developed over the years. There are two main groups of vaccines. One is killed organisms the bacteria, and these are serotype specific. The second group are subunit toxin-based vaccines. These contain Apx I, II, III with or without OMP and show a high degree of protection against APP1-12 serotypes. The in vivo ApxIV works well but has not yet been commercialized, although ApxIV is not needed for effective vaccination. An Apx I A mutant has potential for a live attenuated APP vaccine. Animals vaccinated with bacterins will produce antibodies that will cross-react with ELISA tests that use polysaccharides as antigens. There is a considerable effect of adjuvants in these vaccines.

Natural or experimental infection with a serotype of APP induces a strong immunity to both homologous and heterologous serotypes. Vaccination has been attempted to prevent pleuropneumonia in pigs. However, the protection obtained by parenteral vaccination is serotype specific, and vaccines must therefore contain the serotype existing in the swine population. The mortality rate is lower in vaccinated animals, but they are still carriers of the organism.

Serotype 8 is closely related to serotypes 3 and 6, and parenteral revaccination using a capsular extract or killed APP serotype 8 provides a high degree of protection against challenge with serotypes 3 or 6. A tetravalent vaccine containing serotypes 1, 2, 5, and 7 stimulated titers to all four serotypes and an anamnestic response was induced by a second vacation. This suggests that the serologic and cross-protective properties of APP serotypes should be identified before they are used as antigen in the complement fixation test and in vaccines. The protein associated with the capsule of APP is responsible for serotype-specific protection against mortality in mice. Further purification and characterization of this protein antigen is needed to determine whether it is the specific antigen responsible for protection against mortality in swine or if it is a necessary carrier for a serotype-specific capsular disaccharide antigen.

The vaccines that have been evaluated are killed vaccines with an adjuvant. In one experimental trial, two and three vaccinations using a bacterin containing serotypes 1 and 5 prevented mortality following an aerosol challenge with the same serotypes as present in the vaccine. However, all vaccinated pigs had severe signs of respiratory disease and the vaccine did not prevent the development of lung lesions. The use of a formalin-inactivated alum-precipitated vaccine containing serotype 1 was effective in decreasing the morbidity and mortality rates from naturally occurring pleuropneumonia. The adjuvanted vaccines have caused considerable tissue reaction, resulting in abscesses and granulomas. The mineral oil adjuvants are highly irritant and cause granulomas, which are present 8 weeks after vaccination but result in high titers. The aluminum hydroxide adjuvants are less irritating but result in lower titers. Vaccines containing a lecithin-base oil at 5% are non-irritating and stimulate high complement fixation titers.

Subunit vaccines containing purified or partially purified antigens provide better protection than whole cell vaccines. Capsular antigens, outer membrane proteins, lipopolysaccharide, can result in the failure of cross-protection within a capsular serotype. This lack of cross-protection within a capsular serotype of APP induces a strong immunity against both mortality and morbidity in homologous challenge. Pigs vaccinated with the cell extract had fewer clinical signs of pleuropneumonia than pigs vaccinated with three other commercial vaccines and challenged with serotype 1. A vaccine containing the LiCi cell extracts and a crude hemolysin provided protection against both mortality and morbidity in vaccinated pigs challenged by intratracheal inoculation. An experimental vaccine using bacterial “ghosts,” which are empty cells produced by bacteriophage lysis appears to be successful. A better cellular response was observed to inactivated bacteria than to ghost vaccines. Bacteria grown in conditions resulting in high in vitro adhesin levels induced better protection than those grown in NAD rich medium. An APP type 2 vaccine has been described with deletions in the Apx IIIA gene, which can then function as a negative marker vaccine, which appears to be capable of protecting pigs without shedding.

Antigenic variation within a capsular serotype, for example in subtypes IA and IB, as a result of antigenic variation within the lipopolysaccharide, can result in the failure of whole cell bacterins to provide protection against the same capsular serotype. This lack of cross-protection within a capsular serotype provides a partial explanation for vaccination failures observed under field conditions.

A polyvalent bacterin containing serotypes 1, 3, 5, and 9 provided satisfactory protection against homologous challenge 14 days after the second vaccination. Mortality was reduced, and lung lesions, pleural adhesions, and isolations of the organism from the tonsils and lungs were reduced.

It is possible in the future that a differentiation from vaccinated animals test may be based on the ApxIVA gene.

Live vaccines using laboratory-obtained nonvirulent mutants have also been developed and shown to protect against homologous and heterologous serotypes.

**REFERENCES**

MYCOPLASMA PNEUMONIA (MYCOPLASMA HYOPNEUMONIAE)

ETYIOLOGY
Mycoplasma hyopneumoniae (once also called Mycoplasma suipneumoniae) is the primary causative agent. M. hyopneumoniae (MH) inhabits the respiratory tract of pigs, appears to be host specific and survives in the environment for only a very short period of time. The disease has been reproduced with pure cultures, and the organism can be demonstrated directly or indirectly in pigs with enzootic pneumonia worldwide. The isolation of MH is complicated by the presence of other mycoplasmas in the upper respiratory tract of pigs including M. hyopharryngeum, M. hyorhinis, M. suapri, and Acholeplasma species. The nonpathogenic M. flocculare also complicates the culture of M. hyopneumoniae. The strains of MH are antigenically and genetically diverse. Multilocus sequence typing has been used to estimate genetic diversity,11 and it showed that specific MH strains are responsible for local outbreaks as they are in geographic contact or operative contact.

A wide variety of genetic diversity was found in U.S. strains using comparative genomic hybridization. Significant variation at the genetic level has also been found; 3 genomic hybridization. Significant variation found in U.S. strains using comparative typing of MH in wild boar samples showed that variability was high, but there was no correlation between the seroconversion.11

EPIDEMIOLOGY
Occurrence and Prevalence of Infection
Enzootic pneumonia occurs in pigs worldwide, and the incidence is high in intensive pig rearing enterprises. Lesions may be present in 40% to 80% of the lungs of pigs at abattoirs. The peak incidence of pneumonia occurs at 16 to 20 weeks of age, which is likely related to the increased stocking density in this period. In northern climates, the incidence of clinical disease and prevalence of lesions at slaughter are higher in the summer months. The prevalence of lung lesions is often highest in pigs slaughtered in the winter months compared with autumn-slaughtered pigs. The amount of bronchopneumonia lesions in individual lungs ranged from 0% to 69%, with an average of 7.8%. A 2002 survey in the United States showed that 82.3% of finishing sites had at least one animal positive on antibody testing and 94.4% of breeding sites. Seroprevalences were higher in the clinically affected herds, and most of the pigs were infected with MH at a younger age. A study in the United Kingdom showed that geographic location of the finishing unit appeared to be a statistically significant risk factor for EP-like lesions and pleurisy.9 In addition, they also found that part-slatted floors were a potential risk factor. In a study of colonization at weaning and the infection at slaughter, average lung lesion scores, percentage of affected lungs, presence of MH on the bronchial epithelium, and seroconversion, it was found that the severity of the disease can be predicted by the prevalence at weaning in segregated systems. Strategies focused on reducing colonization at weaning may help to control MH in segregated production systems.10 Vaccination does not prevent transmission to sentinel pigs in contact with infected animals. Transmission of MH from asymptomatic carriers to unvaccinated and vaccinated sentinel pigs was not different.11

Morbidity and Case Fatality
In infected herds, the morbidity rate is high during the growing period, but the case-fatality rate is low. There is however, an increase in the number of treatments of sick pigs in comparison with herds free from the disease. The morbidity rate falls markedly into a herd that has been previously free of the disease, all ages of pigs are affected, and mortality, even in adults, can occur.

Methods of Transmission
The organism is an inhabitant of the respiratory tract of pigs, and transmission occurs by direct nose-to-nose contact, which is the main form of transmission. Airborne transmission and fomites are less important. Mycoplasma can be transmitted over 1, 75, and 150 m, and recently aerosol has been seen to be transmitted over 9.2 km.3 M. hyopneumoniae was found to travel long distances from an infected experimentally infected group of pigs.7 Airborne transmission was suggested on 80% of farms where acute respiratory disease was present. No airborne organisms were found on farms without acute respiratory disease. There is no other known host for the organism, although infection and breakdown of closed pneumonia-free herds has occurred without any pig introductions. The number of organisms required for infection is very small, and the possibility of wind-borne infection has been suggested. Transmission is by the respiratory route and in infected herds occurs primarily from the sow to the suckling piglets. In a study of shedding of MH in different parities: gilts were 73% positive, parity 2 to 4 sows were 42% positive, parity 6 to 7 sows 50% positive, and parity 8 to 11 sows were 6% positive. Generally, the nursery is considered the area where transmission occurs and infection spreads slowly. Within pen transmission measured by PCR is very slow. Animals can be PCR positive and not infectious for long periods of time and then can become very infectious up to 119 days, as has been recorded.11 There is therefore a nonlinear excretion of MH. It is thought that one infected nursery pig will infect on average one littermate. Boars can also infect sows when they are kept together in service areas, but in these areas the disease spreads slowly. The disease is also transmitted and exacerbated during the grouping and stress of pigs that occurs at weaning. Transmission can occur as early as 1 week of age, but usually it is not observed under 6 weeks of age.11 The highest clinical and pathologic incidence of the disease occurs in the postweaning and growing period, and in most herds this is maintained through the growing period to market age. The start of finishing is the critical point. Direct exposure (nose-to-nose contact) of pigs at 9 to 11 weeks of age to seropositive gilts results in seroconversion to the organism by 21 days and is most frequent by about 11 weeks after exposure. The presence of gross lesions of pneumonia correlated with the seroconversion.

Frequent coughing by infected, intensively reared pigs suggests that repeated aerosol exposure occurs and is an important natural mode of transmission of respiratory pathogens. There is general agreement that management and environmental conditions considerably influence the severity of the disease.

The reinfection of enzootic pneumonia-free herds, recurrences or so-called breakdowns, occurs at a rate of about 3% of herds every 6 months. In a study of swine herds that had participated in the Pig Health Control Association Scheme in the United Kingdom, the close proximity of the uninfected herds to infected herds appeared to be the most important risk factor that could explain the introduction of the infection. The size of the herd, the density of the pig population in the area, the distance to the next road regularly used for transportation of pigs, and differences in topography were risk factors associated with reinfection. There was little evidence to indicate that unexplained breakdowns occurred in association with long-term latent infection in other herds from which animals had been imported. Clinical signs of enzootic pneumonia in these herds commonly did not occur for several months after the introduction of infected pigs.

MH was not transmitted during a 20-week period when personnel weekly contacted susceptible pigs in a naïve herd after they had been in contact with pigs in an infected herd. A comprehensive herd specific
prevention program is necessary to reduce transmission of disease caused by MH.\(^{11}\)

### Risk Factors

The prevalence, incidence, and severity of pneumonia in swine herds are determined by interactions among infectious agents, the host, the environment, and management practices. This being said a large survey of the seroprevalence of MH in 50 finishing herds showed that there were no risk indicators. Each farm is an individual one, with the farm itself exerting a great effect. A recent study in suckling pigs at the age of weaning in the United Kingdom\(^{15}\) has suggested that an increase in the number of live pigs born alive was linked to a lower incidence of MH in suckling pigs at weaning. Grinding the piglets’ teeth also reduced the incidence of MH. A second dose of iron was also associated with a reduced level of MH. A low environmental temperature also produced an increase in the incidence of pneumonia.

In a study of MH in coughing piglets (3-6 weeks of age) from 50 herds with endemic respiratory disease in Germany,\(^{17}\) it was found that MH was detected in the lavage fluid in 12.3% of the suckling piglets and 10.6% of the weaned piglets. The study showed that the detection of MH in young piglets is associated with one or two site production and inappropriate gilt acclimatization. In a study of nasal carriage in farmers using PCR it was found that 15% of farmers carried MH in their nose, but it is not possible to say that they were colonized.\(^{18}\)

### Animal Risk Factors

Several factors such as breed, age, presence of diarrhea, the prevalence of atrophic rhinitis, birth weight, and weaning weight, have been examined as animal risk factors. In some herds, the risk of coughing and pneumonic lesions increased with increasing age of pigs within a herd. In a survey of two different groups of pigs slaughtered at different ages, the age-specific prevalence of pneumonic lesions was 2.7% in pigs less than 16 weeks of age at slaughter, but it increased rapidly when pigs were between 16 and 22 weeks of age at slaughter. Infection at an early age has a greater effect than infection later in life. Pigs coughing by 14 weeks of age were, on average, 6.2 to 6.9 kg lighter than those with onset of disease near market age. The highest seroconversion rate occurs between 3 to 4 months of age. In a recent experimental infection, 77.7% of the infected animals were still positive 185 days later, and 100% of the naturally infected animals were still infected at the same time. There may be selective differences in the colonization rates between litters. There may also be a sex effect on colonization. A longitudinal study of the diversity and dynamics of MH infection has been described.\(^{19}\)

In a study of a large number of sows in northwestern Germany, it was found that the risk of a sow being seropositive was increased in herds with two- or three-site production, when piglets were not vaccinated, when herds had 2-week farrowing intervals, and in herds without AI/AO management of the farrowing units. The lack of an acclimatization period for boars was also associated with the risk of a sow being seropositive.\(^{20}\)

### Immune Mechanisms

Pigs that recover from experimentally induced enzootic pneumonia are resistant to subsequent challenge. The nature of the immunity induced by MH, whether serum or local antibody mediated, T-cell mediated, or a combination of these factors, is not clear. Based on lymphocyte transformation tests of experimentally infected pigs, it is possible that cell-mediated immunity correlates with protective immunity. The median half-life of passively acquired antibodies to MH is 16 days, the persistence of antibodies is related to the initial antibody concentration, and antibodies waned by 30 to 63 days after birth depending on initial concentration. It has been detected as late as 155 days of age. The titer of maternal antibodies is a major concern when pigs are vaccinated. The age of the piglet vaccinated is not the key factor. The level of the sow’s antibodies approximately 4 weeks prepartum are at their highest and similar to the levels in colostrum. Immunity is not conferred through colostral immunoglobulins, and thus piglets born from immune dams are susceptible to infection and clinical disease. No significant correlations have been found between the colostral antibody levels and the colonization status of the sows. The level of immunoglobulins to MH can be used to monitor infection in the herd. Pigs usually seroconvert to APP and then MH.

Pigs raised under unfavorable conditions develop pneumonic lesions more frequently than pigs raised under better conditions, regardless of their immune status. Pigs vaccinated with inactivated MH organisms develop both a cell-mediated and humoral immune response, but they are not protected from challenge exposure by natural infection. Local immunity, particularly secretory IgA, is considered to be important in protection against mycoplasma infection. MH may suppress alveolar macrophage function, which may predispose the lung to secondary infection. The organism is very clever in evading the immune response, probably by changing the nature of the immune response to one that is less effective. To do this it causes the production of cytokines IL-10 and beta, IL-6, and TNF-α by macrophages and monocytes and induces local inflammation. This is essentially moving the immune response from a TH1 type response to a T-helper type 2 response.

In an experimental study it was shown that PRRSV vaccine strain and the natural infection were able to induce T-regs in pigs naturally infected with MH. This suggests that the exacerbation of MH following PRRSV may be attributable to the ability of PRRSV vaccination and viral infection to induce regulatory T cells.\(^{21}\)

### Pathogen Risk Factors

MH adheres to the tracheal and bronchial mucosae and causes an extensive loss of cilia. An evaluation of the virulence factors of MH field isolates has been made.

### Environmental and Management Risk Factors

#### Pathogenesis

MH colonizes the respiratory epithelium for a long time and produces a prolonged inflammatory response and suppresses and modulates the immune reactions. Little is as yet known about the virulence factors of MH. A wide variety of proteins are produced. Mycoplasma have the smallest genomes of organisms capable of separate existence. This genome encodes for several immunogenic proteins including a cytosolic protein p36 (which may have lactic dehydrogenase activity); membrane proteins P46, P65, and P74 (can produce neutralizing antibodies); and an adhesin P97. The P97 adhesin mediates adherence of MH to swine cilia. An adhesin-like protein (P110) composed of a P54 and 2 P28 units has also been found. Attachment is a complex process involving many gene products. A recent study of the total protein profile, glycoprotein profile, and size differences in the amplified PCR product of P97 adhesin genes suggests that there is an intraspecies variation in the MH population in the United States. Combination with the P102 adjacent gene allows the two proteins to contribute to cellular adherence.\(^{5,6}\)

A highly immunogenic MH lipoprotein Mhp366 was identified by peptide–spot array,\(^{22}\) and this may be a useful method for detecting MH infections. The in vivo virulence of MH isolates does not correlate with in vitro adhesion assessed by a microtiter adherence assay.\(^{23}\) These observations suggest that mechanisms other than adherence may be responsible for observed differences in virulence.

The Mycoplasma penetrate the mucus layer and attach to cilia. They appear only to attach to the cilia. They release calcium ions from the endoplasmic reticulum of the ciliated cells. As a result there is a clumping and a loss of cilia and excess production of mucus by goblet cells.\(^{24}\) This results in a dysfunction of mucociliary clearance. The secondary bacteria attach to the damaged epithelium.

In experimental infections of tracheal explants with MH, it was shown that IL-10, IL-6, and IL-8 were produced.\(^{25,26}\) There is also a production of TNF-α and IL-1\(^{27}\) and IL-18, but the production of IFN-γ is inhibited.\(^{28}\) These are possible mechanisms for the down-regulation of cell-mediated immunity.
Diseases

that allows for the enhancement of the duration and severity of pneumonia with PRRSV and a mechanism to modulate the immune response.

Macrophages have an impaired phagocytic activity after MH infection. MH also alters the function of B- and T-cell lymphocytes.

The experimental inoculation of the J strain of MH into piglets causes gross pneumonia lesions that are detectable 7 to 10 days later. Moderately extensive pneumonia is present 6 weeks after inoculation, progressive recovery can be observed after 10 weeks, and residual lung lesions are detectable in a few pigs up to 37 weeks after inoculation. Experimental infections vary in their effects in clinical signs and pathology.

MH causes peribronchial lymphoid hyperplasia and mononuclear accumulation in the lamina propria, which causes obliteration of the bronchial lumina. There is also perivascular lymphoid hyperplasia. The bronchial mucous glands undergo hypertrophy; there are increased numbers of polymorphonuclear cells in the bronchial lumina and macrophages in the alveoli. Lymphocytes, together with plasma cells and macrophages are responsible for the increase in the thickness of the interlobular septa as the disease progresses. The hyperplastic BAL (bronchial and bronchiolar associated lymphoid tissue) in enzootic pneumonia cases consisted of macrophages, dendritic cells, T- and B-lymphocytes, and IgG and IgA+ cells. In these aggregates CD4+ predominated over CD8+ cells. The cells in the BAL released IL-2, IL-4, TNF-α, and, to a lesser extent IL-1α and β. IL-1α and TNF-α were also released in bronchoalveolar lavage fluids, and IL-6 and IL-8 were found in the mononuclear cells of the alveolar septa.

Hyperplasia of type II alveolar epithelial cells is progressive as the disease becomes worse. Affected pigs cough persistently, show labored respiration and reduced exercise tolerance. The lesions are similar to those of chronic bronchitis. After infection, MH multiplies in tracheal and bronchial mucosae, adheres to the ciliated cells, and causes a cytopathic effect and exfoliation of epithelial cells. There is a significant increase in the gland/wall ratio and a decrease in the ratio of respiratory to expiratory resistance.

The effects of this chronic pulmonary lesion have been the subject of considerable investigation. It is thought that the presence of mycoplasmal lesions uncomplicated by secondary bacterial infections has minimal effect on the production of the pig if the environmental conditions are suitable. The lesions will heal, and any loss in production from the initial infection will be regained by compensatory regrowth. Severe lesions or those accompanied by secondary bacterial bronchopneumonia and pleuritis will usually cause a significant decrease in average daily gain and feed efficiency. Secondary infection with Pasteurella spp. results in acute episodes of toxemic bronchopneumonia and pleuritis. Dual infections are usually more severe than single infections. For example, SIV and MH together are more severe.

A longitudinal study was made in four herds until slaughter. The percentage of pigs testing positive increased from 35% at 6 weeks to 96% at slaughter at 26 weeks. Within each herd only one distinct strain was detected and was present in the same animal for at least 12 weeks.

The pulmonary and hematologic changes in experimental MH pneumonia cause no significant changes in heart rate, respiratory rate, and rectal temperature, even though at necropsy well-demarked pulmonary lesions were present. There were several measurable changes in respiratory functions as a result of the atelectasis; partial occlusion of the bronchioles with exudate, localized pulmonary edema, and a reduction in oxygen perfusion to the alveoli leading to a decrease in the partial pressure of oxygen in the arterial blood. There are no remarkable changes in the hematology. The body weight gains are decreased compared with the control animals.

The distribution of lesions is characteristic. They occur in the right middle lobe, the right cranial and left middle lobes, and the left cranial and diaphragmatic lobes, in that order of frequency. The differences in pathogenicity between high- and low-virulence isolates is associated with a faster in vitro growth, a raised capacity to multiply in the lungs, and the induction of a more severe inflammatory process. It has been shown recently that MH- derived lipid-associated proteins induce apoptosis in alveolar macrophages by increasing nitric oxide production, oxidative stress and caspase-3 activation.

In a study to assess the duration of infection with MH 60 pigs were infected and studied until the population became negative on estimation of DNA in bronchial swabs. DNA was detected in 100% of the animals at 94 days postinfection, 615 at 214 days, and 0% at 254 days PI. Experimentally infected pigs transmitted to sentinel at 80 and 200 days post infection.

CLINICAL FINDINGS

The appearance of clinical pneumonia depends on the number of organisms, their virulence, and the involvement of secondary agents. The more pathogenic strains induce more pneumonia. It is also influenced and made more severe by PCV2 and together with PRRSV is also more severe.

A natural incubation period of 10 to 16 days is shortened to 5 to 12 days in experimental transmission. Two forms of the disease are described. In the relatively rare acute form, a severe outbreak may occur in a susceptible herd when the infection is first introduced. In such herds pigs of all ages are susceptible and a morbidity of 100% may be experienced. Suckling piglets as young as 10 days of age have been infected. Acute respiratory distress with or without fever is characteristic and increased mortality may occur. The usual course of this form of the disease within a herd is usually about 3 months, after which it subsides to the more common chronic form.

The chronic form of the disease is much more common and is the pattern seen in endemically infected herds. Young piglets are usually infected when they are 3 to 10 weeks of age, and clinical signs may be seen in suckling piglets. More commonly, the disease shows greatest clinical manifestation after weaning and in the growing period. The onset of clinical abnormality is insidious and coughing is the major manifestation. Initially only a few pigs within the group may show clinical abnormality, but then the incidence generally increases until coughing may be elicited from most pigs. It may disappear in 2 to 3 weeks or persist throughout the growing period. In affected herds, individual pigs may be heard to cough at any time, but coughing is most obvious at initial activity in the morning and at feeding time. Coughing may also be elicited by exercising the pigs around the pen, and it occurs with greater frequency in the period immediately following the exercise. A dry or crackling, hacking cough, which is usually repetitive, is characteristic. Respiratory embarrassment is rare and there is no fever or obvious inappetence. Subsequently there is retardation of growth that varies in severity between individuals so that uneven group size is common. Clinical disease becomes less obvious with increasing age and is rarely detected in the sow herd, although gilts and young sows frequently harbor MH.

CLINICAL PATHOLOGY

Raised haptoglobin levels have been found in pigs with lung conditions resembling Mycoplasma infection but not A. pleuropneumoniae-type lesions.

Serologic Tests

Serologic tests are best used to assess the herd status. All the three assays in use in the United States have excellent specificity, but the sensitivity is low, from 37% to 49%. The tests vary in their efficacy in different experimental infections.

Serologic tests have included the CFT (low sensitivity), indirect hemagglutination test (good for early detection as it detects IgM), and the latex agglutination test. The unsatisfactory sensitivities and specificities of these tests led to the development of ELISA systems, DNA probe technology, and PCR to accurately diagnose enzootic pneumonia. The ELISAs detect all classes of IgG and are very sensitive, but they detect the onset of seroconversion rather than infection. An SLgA-ELISA has been developed for
detecting secretory IgA from nasal swabs, and it is capable of detecting MH infection from MH vaccinated pigs.

An ELISA using a commercially available antigen (Auspharm) is highly sensitive (95.6%) and specific (98.8%) for antibodies against MH when pig sera from commercial herds of known infection status were evaluated. An improved ELISA is also available, and the two ELISAs are able to distinguish populations of gross pathology-negative pigs in endemic herds from pigs in true specific pathogen-free (SPF) herds. Pigs from the former group have significantly higher ELISA activity with both tests and would represent recovered or exposed nondiseased pigs, or pigs with only histologic lesions in endemic herds. The ELISA is ideal for diagnostic laboratories and should obviate much of the need for culture and immunofluorescent histopathology, reducing the cost of diagnosis. The ELISA can also detect antibodies in the colostrum of sows with a high specificity. A recent study comparing three ELISAs has shown that the sensitivities of the tests were lower than previously reported especially for vaccinated animals. Animals within 21 days postinfection were also not easily detected. The blocking ELISA was the most sensitive. All three were highly specific. There is also a blocking ELISA against a p40 protein.

Colostrum has also been used for the certification of freedom from MH but must be achieved during the first 2 hours after parturition. High-parity sows are a better source for the detection of antibodies.

Detection of Organism

For the highest level of accuracy in detecting the organism the use of a number of tests would be best.

The organism can be detected in lung tissues by culture, immunofluorescence, PCR, and antigen-ELISA, and all have high sensitivity in the acute stages of pneumonia. A PCR-based assay can differentiate MH, M. flocculare, and M. hyorhinis and also detect low numbers of organisms. It can also be used on the bronchoalveolar lavage. The identification of the p36 and p46 protein genes has enabled them to be used in a PCR for MH, with a sensitivity of 86.6% and a specificity of 96.7%. Nested PCR is much better. There is a good correlation between the results of nested-PCR and histology. In situ hybridization shows MH on the surface of the epithelial cells, not in the cytoplasm, with an occasional signal in the cytoplasm of the alveolar and interstitial macrophages. A PCR had a diagnostic sensitivity of 97.3% and a specificity of 93.0%.

Herd Certification

The determination of the presence or absence of MH within a herd for certification purposes can be difficult and should be approached with caution. It should not be based on a single examination procedure. It requires a surveillance system that combines regular farm visits and serologic, cultural, and tissue examination of selected pigs and of those sent to slaughter. The herd should be examined clinically for evidence of the disease, and the lungs from several shipments of pigs should be examined at the abattoir and subsequently histologically. There can be seasonal variation in the severity of lung lesions and at certain times market-age pigs may not have visible gross lesions, even though infection may be present in the herd. If doubt exists, the lungs of younger pigs, preferably clinically suspect pigs, or recently weaned pigs, should be examined after elective slaughter. The herd should also be examined for the presence of antibody to MH.

NECROPsy FINDINGS

Except in severe cases, the damage is confined to the cranial and middle lobes, which are clearly demarcated from the normal lung tissue. The lesions are commonly more severe in the right than in the left lung (simply because it is larger, has a larger supply of main-stem bronchi and a greater arterial supply). Plum-colored or grayish areas of lobular consolidation are evident. Enlarged, edematous bronchial lymph nodes are characteristic. In acute cases, there is intense edema and congestion of the lung and frothy exudate in the bronchi. When secondary invasion occurs, pleuritis and pericarditis are common, and there may be severe hepatisation and congestion with a suppurative bronchopneumonia.

Evaluation of the pneumatic lesions at slaughter has been used extensively for herd health monitoring. Scoring of the lesions is typically done on both lungs (the entire pluck). To overcome the logistical problems associated with examining entire plucks during the slaughtering procedure, an alternate system based on scoring the right lung only has been investigated. The overall right lung relative sensitivities for the detection of catarrhal pneumonia or chronic pleuritis were 81% and 72%, respectively. It is suggested that an evaluation of the right lung pathology is a useful alternative when the purpose of the survey is to demonstrate the presence or absence of lesions, or when scoring the severity of the lesion is the objective.

The microscopic changes of enzootic pneumonia include lymphohistiocytic peri-bronchial cuffing with increased numbers of mononuclear leukocytes in the bronchial lamina propria. There is hyperplasia of the bronchiolar epithelium and filling of alveoli with macrophages, protein-rich fluid and small numbers of lymphocytes and plasma cells. Hyperplasia of type II alveolar epithelial cells occurs as the disease progresses.

These histologic changes were most marked from 7 to 28 dpi coinciding with a significant increase in the immunohistochemical demonstration of IL-1α, IL-1β, IL-8, TNF-α and INF-γ, lymphoid markers CD4+ and CD8+, muramidase, and IgG and IgA. The lesions and immunohistochemical signals declined in intensity after 35 days.

In one study, a definitive diagnosis of Mycoplasma pneumoniae of swine was based on the demonstration of MH in lung sections using specific antisera or successful culture of the organism. Utilizing these techniques, it was found that up to 19% of grossly normal lungs may be infected with MH. Conversely, the organism could not be demonstrated in about 33% of the lungs of pigs from herds thought to be affected with MH pneumonia, even though typical gross lesions were present. The sensitivity of these techniques may be surpassed by newer PCR methods. The organism can also be detected in formalin-fixed paraffin-embedded porcine lung by the indirect immunoperoxidase test.

The results of immunofluorescence tests performed on piglets with experimentally induced pneumonia revealed that MH organisms are located primarily on bronchial and bronchiolar epithelial surfaces of lungs with gross lesions of pneumonia. Fluorescence was most intense 4 to 6 weeks after infection and began to decrease at 8 to 12 weeks. This suggests a decrease in the number of MH in the more advanced stages of the disease. When assessing plucks at slaughter to determine the severity of pneumonia in a group, it must be remembered that in most instances the lesions observed represent a chronic, partially resolved disease process. Therefore the clinical effects of the infection may have caused a greater degree of respiratory compromise than is apparent at slaughter.

In a recent study the histopathology of lungs in slaughter pigs vaccinated with different vaccines has been described. Lung lesion scores and MH loads differed widely between the three different vaccine groups but were correlated with each other.

DIAGNOSIS

Typical epidemiology and a dry hacking cough are suggestive of MH. Typical lesions need to be investigated at the margins of the lesions and culture attempted. Recently farms have been described that have more than 1 strain of MH. Tracheal bronchial swabbing associated with RT-PCR could be an accurate diagnostic method. The most sensitive sampling methods for detecting MH in live, naturally infected pigs were tracheobronchial swabbing or washing compared with oropharyngeal brushing and nasal swabbing.

Samples for Confirmation of Diagnosis

- Touch preparations using Giemsa stained slides have been used.
Diseases

- Histology—formalin-fixed lung (LM, IHC). Simple histopathology may not always indicate MH infection. For example, Aujeszky’s disease together with P multocida may be difficult to differentiate from MH. Lesions may be characteristic but not pathognomonic.

Detection in lung tissue is either by FA or IHC, and these are rapid and cheap and more often used than ISH. The more fresh the material or immediately fixed material gives better results.

In experimentally infected pigs MH could be reisolated from liver and spleen of experimentally infected pigs and contact pigs.

Indirect immunofluorescence (IF) and indirect immunoperoxidase (IHC) for MH in tissues are extremely useful. However, IF has a lack of sensitivity and IHC is time consuming and expensive.

Mycoplasma lung (MCULT, FAT, PCR). Isolation of MH is complicated by the overgrowth that occurs from M. hyorhinis and M. flocculare. The organism is fastidious, and 4 to 8 weeks are sometimes needed for growth. It also requires specialized media, including swine serum. For these two reasons it is not so commonly used now. Many animals that are culture positive do not have gross or microscopic lesions.

PCRs have become a sensitive and specific method for identifying MH. Lung tissue, bronchial swabs, or bronchial washings are the best sites. Nested PCRs raise the activity, is better absorbed orally and is more widely distributed in tissues than the first-generation tetracyclines (oxytetracycline, tetracycline, and chlorotetracycline). Tetracyclines given as a preventative in-feed are more effective than giving tetracyclines once clinical signs of coughing have started. This is particularly true when using the drug around times of stress and acquisition of the organisms (ie, in the nursery and at weaning). A recent study has shown that CTC when administered at the onset of clinical signs via the feed at a dosage of 500 ppm during two alternate weeks was able to decrease the prevalence of pneumonia lesions and numerically reduced the performance losses and clinical signs.

In some early studies, a mixture of tylrocin tartrate at a dose of 50 mg/kg BW and tiamulin at 10 mg/kg BW orally daily for 10 days significantly reduced the pulmonary lesions associated with the experimental disease. However, the use of 60, 120, or 180 mg of tiamulin per liter of drinking water for 10 days was not effective in suppressing the lesions of experimentally induced MH pneumonia or infection in disease-free pigs.

The newer fluoroquinolones have good in vitro activity against MH and exhibit superior activity to tylrocin, tiamulin, oxytetracycline, and gentamicin. Ciprofloxacin is particularly active against MH.

Tilmicosin is particularly effective because it appears to prevent the attachment of MH to the surface of the epithelial cells.

Tetracyclines will either prevent transmission or suppress lesion formation in experimental pigs but the levels required are high and in an infected herd continuous administration would be necessary, which would be uneconomic. Treatment is generally restricted to individual pigs showing acute respiratory distress as a result of a severe infection or secondary invaders. Broad-spectrum antimicrobials are used, usually tetracyclines, but the response is only moderately good. The occurrence of severe signs within a group of pigs may necessitate treatment. Tetracyclines, tylrocin, or spiramycin fed at 200 mg/kg feed for 5 to 10 days is recommended. A combination of 300 g of oxytetracycline and 30 g of tiamulin per ton of finished feed fed for 2 to 3 days/week over a 16-month period has been used to reduce the incidence of enzootic pneumonia in a large herd. Lung lesions were reduced, average daily gain increased, and efficiency of feed conversion increased, with an overall increase in profitability. Valnemulin may prove to be effective in the treatment of enzootic pneumonia. There is a higher susceptibility to valnemulin and tiamulin when used in conjunction with doxycycline as a treatment.

Tulathromycin administered as a single injection at a standard dosage of 2.5 mg/kg is effective in the treatment of swine pneumonia associated with mycoplasmosis.

Oral florfenicol feed supplementation (20 g/ton) reduces the effects of MH infection. There is no evidence for resistance to lincomycin/spectinomycin, oxytetracycline, doxycycline, gentamicin, florfenicol, and tiamulin. There is evidence for some resistance from the field to tetracyclines, macrolides, lincosamides, and fluoroquinolones.

CONTROL

Control strategies have been reviewed. In all cases recommended management procedures such as all in/all out pig flow, medicated and segregated early weaning, and multisite operations further facilitate control of respiratory disease.

MH infects only pigs and transmission requires close pig-to-pig contact. If transmission can be prevented, it is possible to limit or even eradicate the disease from a herd. There are thus two levels at which control can be practiced: (1) Complete eradication of the disease or (2) Controlling the disease and its effects at a low level.

The principles of control of MH include the following strategies:

- Regular inspection of the herd for clinical evidence of disease and slaughter checks of lungs
- Rigorous biosecurity of animals being introduced into the herd and control of visitors
- Provision of adequate environmental conditions, including air quality, ventilation, temperature control, and stocking density
- The use of the all-in, all-out system of production in which groups of pigs by age or stage of production are moved through the herd from the gestation barn, farrowing barn, nursery rooms, and finishing units as groups and the pens previously occupied are cleaned, disinfected, and left vacant for several days before animals are reintroduced. Because most infection is believed to occur between 4 to 12 weeks, nursery depopulation has become an effective way of controlling the infection in nursery pigs.

Control by Eradication

Control by eradication is the most satisfactory and is probably mandatory for large breeding companies, herds supplying replacement stock to other herds, and for large intensive farrow-to-finish enterprises. It is based on the principle that the source of infection for the young pig is the gilt or the sow and this chain of infection must be interrupted to prevent infection. In the past, the 10-month cutoff point has been used in eradication programs, but in view of the colonization studies, this may be too soon. This is especially so in off-site production systems where the time of infection is delayed.
There are three different principle methods. First, there is total depopulation followed by restocking with noninfected stock (Danish SPF system). Second, the test and removal of all positives and inconclusive. Third, complete eradication without total depopulation and restocking.

Eradication without restocking has been described, and here the secret was to wait until farrowing finished, then vaccinate all sows and treat with tiamulin at 6 mg/kg daily for 3 weeks and then monitor with blood tests.

Specific Pathogen-Free or Minimal-Disease Pigs
Several methods of eradication have been attempted, but the most satisfactory is repopulation with specific-pathogen-free (SPF) pigs. The principle underlying this method is that the piglet in utero is free of infection with MH. If it is taken from the uterus at term by suitable sterile hysterectomy or hysteroatomy techniques and reared artificially in an environment free of pigs, it will remain free of this infection. In practice this has been carried out in special units, and the piglets have been subsequently used to repopulate existing farms where all pigs have been removed 30 days before the introduction of the SPF pigs and a thorough cleaning program completed. This method was initially developed for the control of MH and atrophic rhinitis. Moreover, if suitable precautions are taken and if the piglets are used to populate new units that have had no previous exposure to pigs, then freedom from other important diseases such as internal and external parasitism, leptospirosis, brucellosis, swine dysentery, and others can be achieved. The progeny of these primary SPF herds can subsequently be used to repopulate other or secondary SPF herds known as minimal disease pigs.

Because of the cost and technical difficulty of this method, other methods of eradicating MH have been attempted, but they are generally less satisfactory and have a higher failure rate. These include “snatching” of pigs at birth and isolated farrowing. In the former the piglets are caught and removed from the sow immediately at birth and reared as previously described or foster-suckled on SPF sows in another environment. Although MH may be eliminated by this method, fecal contamination during parturition of the vulva and vagina and consequently of the piglet is common, and this method is less satisfactory for disease control than removal by hysterectomy.

Isolated Farrowing
Isolated farrowing techniques have proved successful in small herds but have a high failure rate when practiced on a large scale. Older sows believed to be free of infection are farrowed in isolation in individual pens erected outside on pasture and each sow and litter is kept as a separate unit. The litter is inspected clinically at regular intervals, and subsequently a proportion of the litter, usually excess males and gilts undesirable for breeding, will be examined at slaughter for evidence of pneumonia. Any litters with clinical, pathologic, or laboratory evidence of pneumonia are eliminated from the program. Litters that pass inspection are kept for repopulation of the herd. Because of the difficulties in detecting carrier pigs without lesions, eradication by methods using these principles frequently fails.

Minimal Disease Herds
Minimal disease herds have been established in most countries with significant pig populations, either by breeding companies or private purebred breeders. As a result, in most countries there is a nucleus of MH-free stock. The establishment of primary SPF herds is technically difficult and very costly and should not be undertaken lightly. There is also a considerable delay in cash flow between the time of initial population and buildup of herd numbers to the time when significant numbers of pigs are available for sale. If eradication by repopulation is intended, it is preferable to purchase pregnant gilts from established primary SPF herds unless the maintenance of existing genetic lines dictates otherwise. Before recommending eradication by this method it is essential that the pig owner understands the principles of this method of control and the restrictions that will need to apply if it is to be successful. Farrow-to-finish enterprises established by this method should be run as closed herds, and if further genetic material is required it should be introduced by hysterectomy techniques or by purchase from the initial source herd. The use of artificial insemination is an alternate method; however, isolation of MH from semen has been recorded.

The problem of certifying and maintaining herds free of MH is a major task.

Reinfection of Herds
Reinfection of MH-free pig herds occurs despite high standards of isolation and strict precautions when complete protective clothing and showering routines are required for all visitors entering the unit. All visitors are debarred entry if they have been to a possible source of infection during the previous 48 hours and even up to 7 days. Also, the majority of breakdowns occur in herds that have not imported infected stock recently. In reinjected herds that imported stock there was no concurrent evidence of breakdown in the parent herds, which supported the contention that the importation of infected pigs was an unlikely source of the infection. An epidemiologic investigation of these reinfections suggests that close proximity of uninfected herds to infected herds may be an important factor. The organism does not survive for more than a few days under dry conditions; however, it can survive in diluted tap water and rainwater for 2 to 3 weeks, and it has been suggested that the organism may be transported in moist air and that airborne infection between pigpens is a possible method of transmission. In Switzerland, 107 farms were reinjected of the 3983 that were eradicated during the period 1996 to 1999 (2.6%). The significance of known risk factors such as farm size, high density of pigs, and farm type was confirmed in this analysis.

Some preliminary estimates of risk indices based on the proximity of other pig units has indicated that the most important factor was the reciprocal of the square of distance to the nearest other unit. The crucial distance for maximum survival was about 3.2 km. A breakdown was described recently in which a whole variety of measures were included in an attempt to control the disease.

Antimicrobial Prophylaxis
Eradication has also been attempted by antimicrobial treatment of newborn piglets with oxytetracycline on days 1, 7, and 14, which were weaned on day 14 and moved to offsite nursery. This is known as a low-cost modified medicated-early-weaning program. This can be followed by serologic testing of the breeding herd and culling of positive reactors. Control by vaccination on the one hand and by the use of tilmicosin on the other produced similar results when measured by serologic results and the prevalence of macroscopic lung lesions. Lincomycin with or without vaccination considerably improves the growth and performance. Doxycycline in the feed at 11 mg/kg BW is effective in controlling pneumonia caused by P. multocida and MH in feeder pigs.

Low-Level Disease
The alternative to eradication is to limit the effects of the disease in those herds where eradication is either not desirable or feasible. The effects of the disease are generally less severe in nonintensive rearing situations, in small herds where individual litters are reared separately, and where litters from older sows can be reared separately from other pigs. Where litters are grouped at weaning, a low stocking density with less than 25 pigs in initial pen groups and 100 pigs in a common airspace may also reduce the severity of the disease. Temperature, humidity and ventilation also have an important influence on the disease. It is possible to determine an optimal air temperature zone for growing-finishing pigs based on the measurement of behavioral and health-related problems. The subject is too broad for treatment here, and the requirements for pigs at different ages and under different housing situations may be found in standard texts on pig
housing and production. The environmental risk factors associated with the incidence of MH should be assessed in each circumstance. Some important environmental variables that should be assessed and modified include the following:

- Number of pigs per shed
- Number of pigs per pen
- Airspace per pig
- Floor space per pig
- Cleaning and disinfection techniques used
- Number of air changes per hour
- Waste disposal system
- Number of temperature fluctuations in a 24-hour period
- Direction of the flow of air in the building
- Concentrations of ammonia and hydrogen sulfide in the building
- Dust levels
- Feeding and watering systems
- Whether or not the all-in, all-out system is being used effectively

Medication of Breeding Stock

The original medicated early weaning program was based on medication of the sows with tiamulin at the time of farrowing and the early weaning of the piglets to an off-site location. A variation of this method is to prevent the spread of infection by the following means:

- Isolation of the breeding stock
- Strategic antimicrobial medication of the breeding stock
- Reintroduction of the breeding stock to the original but empty and disinfected gestation barn
- Separate rearing of the piglets before and after initiating the program
- Regulation of flow of animals through the herd. Farrowing barns are emptied out when possible and cleaned, disinfected, and left empty. After weaning their piglets, sows are transferred to the dry sow barns. Sows about to farrow are treated with tiamulin and moved to the farrowing barn.

Medication and vaccination was used to eradicate MH without total depopulation.

Source of Feeder Pigs

Where possible the purchase of weaners or pigs for finishing units should be from herds free of the disease or from a single source. Purchase through saleyards or the purchase of coughing or uneven litters is not advisable. When pigs from infected herds are purchased it may be necessary to medicate the feed prophylactically with one of the tetracycline group of antibiotics or tylosin or spiramycin at 100 to 200 mg/kg of feed for a 2-week period after introduction. Medication of the feed of finishing pigs with tiamulin at 20 and 30 mg/kg of feed over an 8-week period on farms with histories of severe complicated enzootic pneumonia resulted in improved weight gains and feed efficiency, but the extent and severity of the lung lesions did not change. The level of 30 mg/kg in the feed was superior to the level of 20 mg/kg. Tiamulin at 100 mg/kg combined with chlorotetracycline at 300 mg/kg of feed for 7 days was effective in herds with a history of MH complicated by the presence of P multocida and Actinobacillus pleuropneumoniae.

Introduced pigs should be isolated from the rest of the herd and preferably they should be reared as a batch through a house on the all-in, all-out system. A high stocking density should be avoided and internal parasites should be controlled.

Vaccination

A general observation was that Ascaris sum infection affected the response to vaccination for MH. Vaccination reduces the macrophage infiltration in bronchus associated lymphoid tissue infected with a virulent MH strain. In the same study MH was reduced in the lungs in the vaccinated pigs, and the high-virulence strain was inhibited more than the low virulence strain. Vaccination significantly reduces clinical signs macroscopic and microscopic lung lesions especially infected with avirulent strain. The effect was less pronounced with a less virulent strain. Vaccination does not, however, reduce the transmission to other pigs.

MH vaccines are generally bacterins consisting of outer membrane proteins or whole organisms. The vaccines give little protection against initial infection and often incomplete protection against clinical pneumonia. The vaccines produce a TH1 response and also IgA and IgG in the lavage fluids. Natural maternal antibodies do not seem to inhibit vaccination, but vaccination of sows may inhibit subsequent immunity.

Vaccination with killed MH induces protection in pigs against experimental challenge exposure with the organism. A cost-benefit analysis shows that the vaccination is economically beneficial. The relationships between maternally derived antibodies, age, and other factors in vaccine response have been discussed.

Intranasal vaccination of attenuated MH adjuvanted with bacterial DNA may be effective in evoking the local cellular and humoral response and the systemic immune response.

A killed MH vaccine evaluated in a single herd reduced the prevalence of pneumonic lesions in slaughter pigs from 69% to 36% and the prevalence of pleuritis from 20% to 13%. There was a small decrease in the number of days to market. It usually results in a 2% to 8% increase in daily gain. The mortality rate is usually only better numerically. Feed conversion efficiency increases by about 2% to 3%. Other limited studies indicate that vaccination can reduce the severity and prevalence of lung lesions detected at slaughter (4%–6% compared with 12% in controls). It improves feed efficiency and increases average daily gain during the finishing period. In other studies the average daily gain was not improved. Under experimental conditions the transmission in nursery pigs was only numerically lower in vaccinated pigs and the vaccination does not prevent the establishment of MH in the lung.

Vaccination of piglets improved pulmonary health, but vaccination of sows alone did not prove to be sufficient.

Vaccination of sows against MH reduced the prevalence of positive piglets at weaning and could be used to control MH infections as judged by a nested PCR. PRRS vaccination does not interfere with MH vaccination. Needle-less intraderal vaccination has also been described. Double-vaccinated pigs showed a lower percentage of MH-compatible gross lesions and a lower MH prevalence in the URT compared with single vaccinated animals.

Both dual and single injection vaccines are available, but the protection obtained is similar. The single dose vaccine gives protection for up to 23 weeks. The level of protection will probably last 4 months. Vaccination is economically attractive.

DNA vaccination using a p42 heat-stable protein gene has also been used, and this induces rises in IL-2, IL-4, and IFN-γ, which indicates that it induces both a Th1 and a Th2 response. Vaccination for mycoplasma generally induces local mucosal immunity, humoral and cellular immunity. A recent study has shown that inactivated vaccine produced both systemic and mucosal cellular and humoral immune responses. It appears to prime the immune response, but this may not become fully operational until natural exposure takes place.

Sow vaccination strategies are still undergoing study but it has been shown that the severity of the pneumonia in piglets born to vaccinated sows was reduced. It increased the percentage of seropositive sows and piglets at weaning but did not affect the sow or piglet colonization. Maternal antibodies do not interfere with vaccination unless they are very high.

PRRSV infection may reduce the response to vaccination, but this may depend on the strains of both agents. In a study there were no significant differences between the protective efficacy of a combined PRRSV/MH vaccine and the two single vaccines.

Intraderal vaccination was successful in reducing lesions by 10.4% compared with controls, and 6% in the intramuscular injection group. Intraderal vaccination afforded greater protection especially with regard to morbidity, lung lesion, and pleuritis scores.

Subunit vaccines may be developed in the future, and other immunodominant antigens other than P97 should be taken into account.

PORCINE RESPIRATORY DISEASE COMPLEX AND MYCOPLASMAL PNEUMOCOSIS OF PIGS

Mycoplasma hyopneumoniae (MH) is a significant contributor to the porcine respiratory disease complex (PRDC), together with PRRS, PCV2, SIV, and secondary bacterial agents such as Pasteurella multocida (PM), Actinobacillus pleuropneumoniae (APP) and H. parasuis (HPS). E. coli, Klebsiella, Trueperella pyogenes, Bordetella bronchiseptica, streptococci, and staphylococci. In the study in Denmark, five bacterial species, five viruses, and two Mycoplasma species were found in different combinations. The study in Germany found that among a variety of pathogens, PCV2 and alpha-hemolytic streptococci were most frequently detected. There were also more associations between the organisms in clinical cases than in the healthy pigs. Porcine respiratory disease complex is a better name for what was once called enzootic pneumonia. This term really means pneumonia that occurs naturally in the population and includes a complex of many bacterial and viral agents with the occasional addition of parasites and protozoa.

Some primary pathogens such as MH and APP are not usually isolated from healthy pigs and may be responsible for subclinical infections. A Danish study found that Actinomyces hyovaginalis was a common isolate from pyemic lungs in pigs. The authors did a study in the 1960s involving full viral, bacteriologic, and environmental and management analyses, which showed that each farm was an individual with its own set of variables, and that the only significant factor was that MH was associated with clinical disease and economic loss.

Mycoplasma has been reported to be present in pigs infected with other agents. The authors have suggested that Mycoplasma pneumoniae is associated with clinical disease and economic loss.

Simultaneous occurrence of Aujeszky’s disease increases the severity of acute mycoplasmal pneumonia. The jury is still out as to whether TTV has a role to play in PRDC. In a recent study, lipoteichoic acid of Staphylococcus aureus was shown to be a primary pathogen but also its ability to act synergistically with other infecting agents to produce significant respiratory disease. MH causes a mild pneumonia, whereas P. multocida is not pathogenic alone but aggravates the pneumonia initiated by the former pathogen. The epidemiologic associations between MH and Actinobacillus pleuropneumoniae antibody titers, and lung lesions in pigs at slaughter have been examined. Only titers to the Mycoplasma pneumoniae were associated with lesions.

The extent of the lesions produced by MH in PRDC may be influenced by other contributing factors to account for the variations in severity of lesions. Concurrent infection with lungworm, migrating ascars, and an adenovirus has resulted in lesions of greater severity and secondary invasion of pneumonia lesions by Pasteurella, Streptococci, Mycoplasma, and Bordetella bronchiseptica;
Klebsiella pneumoniae is very common and largely influences the outcome of the disease in individual pigs. In some abattoir surveys of lungs, P. multocida can be cultured from 16% of normal lungs and from 55% of lungs with lesions resembling those of enzootic pneumonia. P. multocida and Haemophilus spp. may also be found in conjunction with MH in the lungs of slaughter-weight swine affected with pneumonia and examined at the abattoir. Those lungs with both MH and P. multocida had the most macroscopic pneumonia, and those lungs with either of the agents alone had much less pneumonia. MH renders the lungs susceptible to P. multocida colonization and infection.

Along with MH, other Mycoplasma species, such as M. hyorhinis, Acholeplasma granulatum and Acholeplasma laidlawii, have been isolated from the lungs of pigs at slaughter, but their significance is unclear. MH and Mycoplasma hyorhinis have been isolated from 30% and 50% of pneumonic lungs, respectively, from pigs examined at slaughter. MH was also isolated from 12% of lungs with no gross lesions of pneumonia. In a survey in Norway, MH, P. multocida and M. hyorhinis were detected in 83%, 43%, and 37% of the pneumonic lungs respectively. Most of the macroscopic pneumonia—up to 25%—occurred in lungs with all three pathogens. M. flocculare was the most frequently isolated organism in the nonpneumonic lungs.

MH potentiates the severity of PCV2-associated lung and lymphoid lesions and increases the amount and perhaps the presence of PCV2 antigen. It also increases the incidence of PMWS in pigs.

Several environmental and management factors are associated with a high prevalence of pneumonic lesions at slaughter. They include continuous versus all-in, all-out production, open herds, large temperature fluctuations, semisolid pen partitions, and large numbers of pigs in a common airspace. These factors may operate individually or in combination synergistically. Housing pigs in a clean, isolated, disease-free and low-stress environment positively influences the health of pigs. Complex animal production systems in the industrialized world have been reviewed.

The primary and secondary pathogens of the disease produce their most detrimental economic effects and the highest level of morbidity and mortality during the finishing period when the economics of production necessitates indoor housing and intensification.

Four main groups of environmental factors that contribute to high levels of clinical disease and lesions at slaughter include:
1. Meteorologic factors include wide fluctuations in the temperature indoors, wide variations in relative humidity, irregular ventilation rates, and winter housing. However, experimentally, elevated concentrations of ammonia and fluctuating ambient temperature did not influence the severity of the pneumonia or its effect growth rate. The noninfectious factors associated with pneumonia and pleuritis in slaughtered pigs in 143 farrow-to-finish farms in France were analyzed.

2. Population factors that contribute to an increased prevalence of pneumonia are increasing herd size, increased population density, and decreased airspace and floor space per pig. All management practices influence the microclimate, and the quality of housing and management influences the incidence of pneumonic lesions at slaughter. Larger-than-average swine farms milling their own feed and with characteristics of modern buildings (mechanized inlets, slatted floors) and in close proximity to other farms tend to have a higher risk of enzootic pneumonia. Extensively housed pigs with above-average pen space and air volume have a reduced prevalence of enzootic pneumonia lesions.

3. Management factors associated with enzootic pneumonia include family farms that feed pigs on the floor and feeder barns that obtain pigs from multiple sources compared with those with good facilities and where the pigs originate directly from breeding units. The disease is a particular problem in continuous-flow herds. In pigs reared in all-in, all-out groups in the farrowing house, nursery, and growing-finish unit, any Mycoplasma transmitted from sows to pigs or between pigs do not necessarily result in clinical signs or lesions of pneumonia. Pigs reared in all-in, all-out systems do not have lesions or minimal lesions at slaughter and gained at a faster rate than litter-mate pigs reared in a continuous system. Risk factors in suboptimal housing in Australia were described.

In small herds, the factors commonly associated with a high prevalence of enzootic pneumonia were larger numbers of pigs per pen section, larger group sizes, and drafty farrowing and weaner accommodation. A study of housing density on species diversity and number of airborne microorganisms at fattening facilities has shown that the total number of bacteria and fungi did not exceed 10^4 and 10^3 CFU per m^3 respectively. The number of organisms correlated with housing density. The most numerous were gram-positive bacteria and then gram-negative bacteria and fungi.

4. Airborne pollution in pig houses is thought to contribute to an increased incidence of clinical disease and prevalence of lesions at slaughter. The pollutants include microorganisms, endotoxoc cell wall constituents, and ammonia. Ammonia is the most important because it is a powerful cilio-toxic agent in its own right before determining its effects on microorganisms. Toxic levels of ammonia, high concentrations of aerial dust, and high colony counts of aerial bacteria may contribute to an increased incidence and prevalence of pneumonia, but these factors have not been quantified and are commonly based on subjective evaluations by the observer. A large study of 960 pigs has shown that there are no influences of ammonia or dust on the respiratory health of pigs. Environmental air contaminants such as dust, ammonia, carbon dioxide, and microbes in swine barns measured over a period of 12 months were associated with lesions of pneumonia and pleuritis at slaughter.

In a study of experimentally infected animals, it was found that 6/114 long-distance samples were positive for MH. Three samples collected at 3.5, 6.8, and 9.2 km from the herd of origin were infectious.

In large herds, factors associated with a high prevalence were higher pen stocking rate, airspace stocking rate, and a trend toward higher atmospheric ammonia levels in the summer months. The trend to increased herd size has not been accompanied by the satisfactory control of pneumonia. It has been shown that pig-shed air polluted by alpha-hemolytic cocci and ammonia causes subclinical disease and production losses.

Combination and Interaction of Environmental Risk Factors
A computer-based guide can indicate how the prevalence of the disease can be influenced by the combined effect of risk factors. The expected prevalence is estimated by consideration of 11 risk factors that include the following:

1. Number of pigs in the same room
2/3. All-in, all-out versus continuous flow of pigs
4. Type of partitions separating adjacent pens
5/6. Presence or absence of diarrhea as a clinical problem
7/8. Liquid versus solid manure disposal
9. Ascarid control efficiency
10/11. Presence or absence of active Aujeszky's disease.

The temperature and humidity influence the penetration into the lungs of both primary and secondary pathogens by influencing the size of infected aerosol particles and the protective mechanism in the respiratory tract. Temperature and humidity also influence the sedimentation of infected particles in the air and the ventilation and stocking density. Pigs kept at high stocking densities and subjected to environmental temperature fluctuations, cold drafty conditions, and poor nutrition are more likely to suffer greater adverse effects from this disease.
range between 3.32% and 74.5% for the monic lesions from pigs at slaughter and calculate a mean value for the herd sample. assess the percentage of lung involved and results of studies of correlations between the method of measuring the extent or prevalence of pneumonia and just as informative as detailed dissection of the lungs. Because the prevalence of pneumonia peaks at about 60 to 65 kg BW and then declines steadily to a very low level in pigs that are 125 kg or more, the age and weight at slaughter must be considered when evaluating the effects of the lesions on performance and when comparing results between different observations. Weight losses are more substantial in pigs affected early in life. In some studies, lung lesion scores detected at slaughter did not significantly correlate to growth indicators during any season. The gross lesions of mycoplasmal pneumonia heal over a 2-month period, which may explain why significant correlations are not found between growth indicators and lung lesions scores. The effects of the lesions on mean daily gains over an entire growth period may vary from one study to another because of the different times during growth when the lesions exerted their effects and in part to compensatory regrowth following recovery from the lesions. Radiographic examination of the lungs of pigs from 21 to 150 days of age, and gross examination of the lungs at slaughter revealed that lesions progress and regress dynamically throughout the life of the animals and examination at slaughter is an inadequate indicator of lifetime pneumonia.

**CLINICAL SIGNS**

There are very basically four signs of respiratory disease:

- **Sneezing** is indicative of afflication of the nasal cavity gas, dust, or infection (PRCV, PCMV, or PAR).
- **Coughing** is indicative of afflication of the larynx, trachea, and mainstem bronchi and upper bronchial tree because coughing is the only way to clear large amounts of infected debris (SIV, MH).
- **Dyspnea or difficult breathing** is indicative of the terminal bronchioles and alveoli being affected (APP, PM, PRRS, and PCV2)
- **Parameters of growth may be affected when fever is involved or tissue damage is extensive**, in which case the CNS (hypothalamus) instructs the systems to shut down so appetite, and therefore, growth, is reduced. Growth rate is reduced, daily gain falls, days to slaughter increases, and feed efficiency falls as growth is replaced by immunologic recovery.

The principle sign of PRDC is pneumonia manifested as coughing, labored breathing, fever, lethargy, recumbency, anorexia, discoloration of the extremities/cyanosis, weight loss and slow growth, nasal and ocular discharges, and death. In small batches the disease may affect the group over a short period of time, and most may recover, leaving a few to become chronically affected, hospitalized, or having to be euthanized. In the larger batches with different age groups, there may be rolling waves of infection, or pneumonias may progress to pleurisy. Some pigs affected with the chronic form of mycoplasmosis may later develop acute pneumonia as a result of secondary invasion with Pasteurella or other organisms.

A series of investigations has shown that PRRSV does not predispose to MH infection, although lesions are more severe in those pigs that both infections. MH does potentiate PRRSV induced disease and lesions. There may be an association between the seroconversion to PRRSV and the transmission of MH.

**PATHOLOGY**

Proliferative and necrotizing pneumonia (PNP) is a form of interstitial pneumonia that occurs in weaning and postweanling pigs. In an Italian study of 28 pigs PRRSV was found in 11 pigs, PCV2 in 4 pigs, and both viruses in the lungs of 8 pigs; in the other 5 pigs nothing was detected. A granulomatous lymphadenitis and pneumonia has been associated with Actinobacillus porcinoteritis in a slaughter pig. This organism was previously thought to be nonpathogenic.

In the study in Denmark, no clear cut associations were found between pathogens and histologic lesions. They came to the conclusion that PRDC was more common than Mycoplasma pneumonia in Danish finishing pigs.

**TREATMENT**

There are many variables in an outbreak of PRDC, and it is essential to approach the problem in a sensible way. The first thing to do is to establish a diagnosis, probably using postmortem examinations and a variety of laboratory aids, such as IHC, ISH, and PCR. The definition of the primary pathogens from the secondaries and opportunists is the next major step. The third step is to treat the pigs quickly and effectively. The fourth step should be to assess the immune status of the herd and how to improve it. The fifth step is to understand the epidemiology of the agents in the herd and the health background of the herd. The last step is use the latest
knowledge, strong biosecurity techniques, and modern vaccines correctly and to manage the units to use the best in management and environmental control.

**MONITORING**

Monitoring of respiratory disease has been achieved principally by slaughter checks. These involve snout inspection for the presence of progressive atrophic rhinitis. A cross section of the snout at the level of the 1st or 2nd premolar is examined. For the examination of the lungs, the percentage of the lung that is consolidated is calculated that is firm to the touch.\(^3\)\(^,\)\(^3\)\(^,\)\(^9\) Recently examination of digital images has been used.\(^8\)\(^,\)\(^9\) There is a significant negative association between pneumonia score and growth.\(^\)\(^3\)^\(^9\)

In addition, the site of pleuritic lesions on the lungs can also be marked on cards and can be recorded as fresh or old fibrotic adhesions.

**CONTROL**

By definition PRDC is chronic respiratory disease (although there are periods of acute respiratory disease) in the continual production units of breeder/weaner and breeder/feeder herds. In PRDC there are many potential agents, but there are some guiding principles that will help to maintain health. Maternal antibodies from sows on the same farm as the piglets will provide some protection, which wanes quickly. Young pigs then become susceptible, and if the numbers of pathogens are not too high they will develop active immunity without succumbing to disease. Infection follows the usual pattern of colonization, replication, excretion, and immune development. Disease may follow after replication and excretion, and the duration will depend on the level of replication and the agents involved. Older pigs are always a source of infection for younger pigs and will maintain a cycle of infection; therefore, they should be kept away from younger pigs, although sows should not be kept away entirely from young stock because their immunity is not then maintained.

**All-in, All-Out**

The first rule is all-in, all-out by age by building or by room. Complete disinfection after cleaning is then carried out, followed by drying and resting. The pig flow through the buildings must be established and maintained.

**Buildings**

- Ensure buildings are adequately ventilated to remove polluted air and excess heat without draughts or over-ventilation.

**Production**

Review productivity and consider batch production (i.e., a larger number of pigs less often) to enable filling and emptying of buildings. It is to effective to artificially construct a batch of different ages and hospitalized pigs. Evenness of production from the breeding units will prevent overstocking or understocking.

**Sick Pigs**

The sick pig is a welfare problem and a hazard in itself, so always hospitalize a sick pig as early as possible, treat, and culit if no response. The hospital area should be well away from other pigs, and recovered pigs should not be returned to the mainstream.

**Diagnosis**

On farm or laboratory postmortem examinations should be used to achieve diagnosis if there are sudden acute cases. Cross-sectional blood sampling of the herd to establish epidemiologic patterns of pathogens is sometimes necessary. The use of slaughter pig information from the abattoir will indicate patterns of pathology.

**Active Control**

Lack of sound management cannot be compensated by use of medication and vaccination, but these may help. Partial depopulation with medication in Denmark has been described.\(^4\)\(^1\) Protection of your unit by the imposition of effective biosecurity from without and within the unit can be extremely beneficial in limiting the ingress of pathogens. The use of bird-proofing and rodent imposition of effective biosecurity from without and within the unit can be extremely beneficial in limiting the ingress of pathogens. The use of bird-proofing and rodent proofing will also help.

The effect of vaccination for PCV2 in pigs suffering from PRDC has been described.\(^4\)\(^2\) Additional strategies for PRDC will include partial depopulation and full depopulation as discussed for MH.

**REFERENCES**

**PORCINE CYTOMEGALIC VIRUS (INCLUSION-BODY RHINITIS, GENERALIZED CYTOMEGALIC INCLUSION-BODY DISEASE OF SWINE)**

Porcine cytomegalic virus rhinitis (formerly inclusion-body rhinitis), associated with a beta herpesvirus (family Herpesviridae), is an extremely common, but generally minor, disease in young pigs. It was first recognized in 1955. The virus is now called porcine herpesvirus-2. It is associated with the porcine respiratory disease complex-1.

**ETIOLOGY**

The virus (PCMV; SuHV-2) belongs to the subfamily of beta-herpesviruses of the family Herpesviridae. The virions exhibit typical morphology of herpesviruses. There are believed to be no serotypes or genotypes, although there is some antigenic variability. It has not yet been found as a problem in xenotransplantation although it does grow in human fibroblast cultures.\(^1\)

**EPIDEMIOLOGY**

The virus is present in the upper respiratory tract of nearly all herds and pigs (in excess of 90%), and the major infection site is the
conchal (turbinate) epithelium. It does not affect other species. SPF herds established by hysterectomy techniques are not necessarily exempt, and congenital transmission of the virus has been demonstrated. High excretion occurs predominantly in the 2- to 4-week period after infection. Transmission is via the respiratory route through direct contact and aerosol infection, possibly also via urine, and usually perinatally.

When the virus first enters a susceptible herd, both transplacental and horizontal virus transmission takes place. Antibody responses start quickly, so there are often no clinical signs but widespread infection.

PATHOGENESIS
The virus invades epithelial cells, especially those of the nasal mucous glands, to produce destruction of acinar cells and metaplasia of the overlying epithelium, and the major clinical manifestation is that of upper respiratory disease. Following infection, the virus may become generalized. In older pigs, generalization is restricted to epithelial cells of other organ systems, especially those of the renal tubules, and is clinically inapparent. However, in very young pigs the virus also shows a predilection for reticuloendothelial cells, and generalization may result in further clinical abnormality.

The virus also crosses the placenta, so it is possible for intrauterine infection to produce fetal death, along with runting after birth and very early pneumonia, rhinitis, and poor piglet weights at weaning. Congenitally infected animals excrete for life.

CLINICAL SIGNS
The incubation period is generally 10 to 21 days. Clinically, the disease affects piglets up to approximately 10 weeks of age, but the age at manifestation in any herd can depend on the method of husbandry. The disease usually occurs when the virus is introduced into the susceptible herd or if for some reason there is a huge increase in the number of susceptible pigs. A wide age-spectrum of involvement may be seen initially when the disease is introduced into the herd for the first time. In most herds the disease affects pigs in the late suckler and early weaner stage. It is at its most severe in pigs under 2 weeks of age. Sneezing is the most prominent sign and frequently occurs in paroxysms and following play fighting. There is a minor serous nasal discharge that rarely may be blood-stained and also sometimes mucous-purulent, with a brown or black exudation around the eyes. There may be coughing. The clinical course varies approximately from 2 to 4 weeks. All pigs within the group are affected, but there is usually no mortality. Neonatal pigs may die without showing signs.

Generalized cytomegalic inclusion-body disease may occur in pigs exposed to intrauterine infection and usually occurs as an outbreak involving several litters. The syndrome is characterized by sudden death and anemia. There is often a history of scouring within the group within the first week of life, and affected pigs show skin pallor and often superficially appear plump and well developed as a result of edema, especially in the neck and forequarter regions. Death, resulting primarily from anemia, occurs during the week 2 to 3 of life, and mortality within the group may approach 50%. Petechial hemorrhages have been a feature of the experimentally produced disease in gnotobiotic pigs but do not necessarily occur in field outbreaks. A moderate anemia producing a check to growth, but without significant mortality, which may be seen in recently weaned pigs experiencing the disease. Many survivors may be stunted.

More serious effects from generalized infection are seen when piglets are exposed to heavy infection at a very young age. It also occurs when there are new imports and when intercurrent disease and poor nutrition reduce resistance. This commonly occurs in large herds with high-density continual throughput farrowing and weaning houses. In addition to upper respiratory disease, infection at this age may result in enteric disease, sudden death, anemia, and wasting, with a marked unevenness of growth within the litters.

There may be complete blockage of the nasal passages. It is believed that the olfactory epithelium may be damaged so that there is no sense of smell and that piglets may not then eat, explaining the that so many die.

PATHOLOGY
Gross changes are not seen often in pigs over 3 weeks of age. In pigs under 3 weeks it may be possible to see catarhal rhinitis, hydrothorax, and edema in various tissues. In fetal infections there may be stillbirths, mummification, embryonic death, and infertility. Interstitial nephritis and random focal gliosis in the CNS with inclusion bodies can be additional findings, with petechiation in the choroid plexuses, cerebellum, and olfactory lobes. In the acute fatal syndrome most of the basophilic inclusions are seen in the capillary endothelium and sinusoidal cells of the lymphoid tissues. Multifocal hemorrhage and edema results from the vascular damage.

DIAGNOSIS
Inclusion-body rhinitis is not a primary cause of atrophic rhinitis. However, it is probably contributory in lowering local resistance to infection and in predisposing to more severe infection with Bordetella bronchiseptica and other respiratory pathogens.

The diagnosis of inclusion body rhinitis is commonly made following the demonstration of typical intranuclear inclusion bodies in histologic sections from electively slaughtered piglets. Large basophilic inclusion bodies are found in the mucous gland cells of the conchal mucosa and may also be demonstrated in exfoliated cells obtained via nasal swabs from live pigs. Small intranuclear inclusion bodies are found in the reticuloendothelial cells. These are best taken from several pigs at the height of clinical infection. Diagnosis by virus isolation is uncommon because the virus has proved difficult to grow, but it will establish in porcine lung macrophage cultures and immortalized cells.

Antibody to infection may be detected by indirect immunofluorescent techniques. ELISAs have been developed to show both IgM and IgG responses. Recently a PCR has been developed and this showed that 59% of pigs tested positive. However, only 59% of PCR positive pigs had clinical signs and lesions consistent with inclusion-body rhinitis. The original experimentalists described the presence of intranuclear inclusions, cyto-megaly, and karyomegaly as being pathognomonic. Virus isolation and PCRs can be used. The best PM samples are conchal mucosa, lungs, pulmonary macrophages collected by lavage, and the kidneys. PCMV can occasionally be demonstrated in the brain, liver, and bone marrow. Virus isolation is possible on primary or immortalized cells.

Antibodies can be detected by IFA, which peaks at 6 weeks postinfection and remains quite high for 10 to 11 weeks. The development of serum antibody levels coincides with the disappearance of viremia.

DIFFERENTIAL DIAGNOSIS
Differential diagnosis includes CSF, enteroviruses, paroviruses, PRRSV, PCV2, and PRV.

TREATMENT
There is no effective treatment, and none is warranted in most herds. With severe rhinitis, antibiotics may temporarily reduce the severity of secondary bacterial infection.

CONTROL
Control of severe disease rests with management procedures that avoid severe challenge to very young piglets. It is also possible to produce virus-free pigs from hysterotomy-derived pigs, but it is necessary to monitor.

REFERENCE

SWINE INFLUENZA
SYNOPSIS
Etiology Influenza A virus subtypes H1N1, H1N2, and H3N2 of Orthomyxovirus.
INTRODUCTION
Swine influenza is an important cause of broncho-interstitial pneumonia throughout all pig-keeping areas of the world. Real problems are associated with the changing viruses that cause the disease and the ability of rapid genetic change to occur by genetic drift or shift.

ETIOLOGY
Classical clinical swine influenza is associated with influenza A virus subtypes H1N1, H1N2, and H3N2 belonging to the Orthomyxovirus genus of the Orthomyxoviridae family. The three types occur together as in Korea. Other types have been isolated from pigs, but as yet have not established as widespread endemic strains. Only influenza A viruses are important in pigs. They occur in a large number of species, including humans, primates, pigs, horses, sea mammals, and birds. Avian viruses are more stable than mammalian viruses, where the rate of evolution is much greater. Specific subtypes vary in their ability to cross species barriers. Specific gene combinations do have a part to play in influenza virus species specificity. Unstable gene constellations in avian species become stable only in secondary hosts but may then adapt and circulate freely.

The methods by which they cross the species barrier are not well understood and are probably polygenic. An isolate of a Korean H1N1 virus was very similar to a U.S. virus, suggesting that it had been transmitted possibly by birds. When new variants occur in pig husbandry they are usually found in the pig population before they acquire the ability to spread rapidly and become associated with disease. They are named using the following convention: A/species/localization/

Differential diagnosis list:
- Enzootic pneumonia
- Hog cholera
- Inclusion-body rhinitis
- Atrophic rhinitis

Treatment Antimicrobials for secondary infection.
Control No effective measures available. Vaccines are in use in certain parts of the world.

H1N1—CLASSICAL
In the United States, these were found on their own until 1998. They were very similar to the 1918 pandemic virus. Since the appearance of other viruses, particularly the triple reassortants, there seems to have been an increase in the genetic diversity of the H1N1 strains in the United States (as also in the H1N2).

A typical reassortant found in Ohio had genes from human (PB1), swine (NA, HA, NP, M, and NS), and avian (PB2 and PA). Even though the viruses were isolated over only 3 years, there was evidence of antigenic drift.

H1N1—OTHERS
Humanlike H1N1 viruses have been found in Canada, and H1N1 viruses with the human H1 have spread across North America; these have commonly been isolated from swine disease outbreaks in the United States.

A triple-reassortant H1N1 virus was found in China with the NP and NS genes from a classical swine influenza virus, PB1 from a human virus and HA, NA, M, PB2, and PA genes from an avian virus. Five genes were also closely related to H1N2 viruses found in China (NS, NP, PB2, PB1, and PA).

H1N1 AVIAN-LIKE
Wild bird H1N1 viruses were transmitted to pigs in the late 1970s and established a stable lineage displacing the classical H1N1 swine lineage; once this had happened, interspecies transmission was facilitated. An H1N1 isolated from a turkey farm in northern Germany in 2009 showed a high affinity with avian-like porcine H1N1 viruses circulating and suggested that turkeys may be a possible bridge between avian and mammalian hosts.

The predominance of avian-like swine genes in the Thai pig population has been described. An experimental transmission of avian-like swine H1N1 has been described, and the virus transmitted through naïve and vaccinated pigs without causing clinical signs.

H1N1 HUMANLIKE VIRUSES IN PIGS
Humanlike viruses were reported in pigs in China before the pandemic, and it was concluded that pigs may act as reservoirs for older human H1N1 viruses.

H1N1-PANDEMIC 2009
There is no evidence that the 2009 pig H1N1 pandemic existed in pigs before May 2009 and before it was reported in humans. Soon after its discovery in Canada in 2009, it spread rapidly around the world, and most pig cases are believed to originate from humans, although there was often no real proof until 2011. It has been shown that the virus is fully capable of causing a global problem for swine. The initial incursions of this virus into European pigs has been described from separate nonlinked sites, suggesting infection of pigs from humans. The global spread from an animal source has
been described. It has established itself in pig populations in face of relatively high levels of herd immunity to other viruses. In the Norwegian pig population, there was no prevalence of influenza until the infection of pigs from humans with (H1N1) pdm09.

The virus is a reassortant of genes from the most recent triple reassortant in North America and the European avian-like subtype H1N1 viruses.

The precursors of this virus may have existed in swine for a long time, which suggests that the evolution has occurred over a long period. A direct precursor has not been recognized. The situation was summarized. It transmits very effectively between pigs. The evolutionary characteristics of the H1 gene of the pdm2009 virus are different from the seasonal human viruses and the swine H1N1 viruses.

The pandemic virus seems to cocirculate and interact more intensely with the endemic SIVs lineages and gives rise, it seems, to more reassortants, the properties of which have yet to be seen. A mono-reassortant of the NA from an H1N1 with the pandemic occurred in Hungary. In a study in Germany, the N2 was from three different porcine lineages in an H1N1pdm backbone.

Six new strains of the pdm-like (H1N1) 2009 strain of H1N1 were isolated and characterized in Poland. They belong to one lineage. The pigs in finishing and growing sectors experienced acute onset of respiratory signs. There was anorexia, poor conception rates (50% lower), high morbidity (up to 100%), and low mortality at 2% to 3% in growers and 1% to 2% in finishers. At postmortem there were depressed, well-demarcated, pale purple areas of consolidation in all lobes.

Novel reassortants have followed with this 2009 virus, and it was pointed out in 2010 that although the virus may be of swine origin, significant viral evolution may still be ongoing and others starting with a 2010 virus in Hong Kong. In this virus, only the NA gene of the 2009 pandemic was reassorted. A novel swine reassortant has been described in the United Kingdom with all the internal genes from the 2009 virus and HA and NA genes from a swine subtype H1N2 virus. It is not clear if this virus can be transmitted between pigs. A novel reassortant has been found in Canada from ab H3N2 and a pandemic (H1N1) 2009 virus on several pig farms and also in mink.

In another reassortant, the NA glycoprotein of the pdm09 virus has been replaced by the NA gene from either H1N2 or H3N2 European swine viruses.

Other reassortants of the 2009 virus have been discovered since from a variety of countries Italy, Argentina, Germany, China, Thailand, and the United States.

Nine reassortants have been described across the United States.

A reassortant of the pdmH1N1 2009 virus with an H3N2 virus from healthy pigs has been reported in Thailand.

H1N2

Since 2005, the human HA gene in H1N2 has spread across North America. A novel reassortant in H1N2 had the NA and HA from the recent H1N2 isolates in the United States and four internal genes (PB2, PB1, PA, and NS) from the contemporary swine triple reassortants in circulating strains, known as the TRIG, but the NP and the M genes were derived from the 2009 pandemic H1N1. An avian-like H1N2 SIV generated by reassortment of circulating avian-like H1N1 and H3N2 subtypes in Denmark has been described. The Danish H1N2 has an avian-like H1 and differs from most other H1N2s in Europe and North America. These have H1 genes of human or classical swine origin, respectively. The variant is also circulating in Italy and Sweden. The infection dynamics are similar to the those of the assorted H1N2s and similar to the older avian-like H1N1 subtype. A novel reassortant influenza A (H1N2) virus derived from A (H1N1) virus Japanpdm09 has been described for the first time in Japan.

H3N2—CLASSICAL

H3N2 variants arrived in the United States from 1998 onward (North Carolina, Iowa, Minnesota, Texas), although they may have circulated previously and had been unable to establish a stable lineage. Most are triple reassortants from human (HA, NA, and PB1), swine (NS, NP, and M), and avian (PB2 and PA) lineages. By 1999 these were widespread in the United States, and a double assortant that had also been found had not spread widely. These are capable of being placed in one of three phylogenetically distinct humanlike lineages (clusters). The third cluster seems to be dominant and some have developed into a fourth cluster. A study of 97 isolates showed that genetic and serologic differences existed between North American isolates and that they show tendencies to reassortment. Once established, these have spread rapidly and evolved.

H3N2—NOVEL

A noncontemporary H3N2 virus was found to be a wholly human H3N2 virus. Trip and reassortant H3N2 SIVs were isolated from pigs and have formed a stable lineage in Canadian swine.

Novel H3N2 viruses in the United States in humans have been linked visits to state fairs and contact with pigs. Similar occurrences have been found in the past, but these have not had a component of H1N1 in the virus, as does this 2011 variant.

Seven novel H3N2 viruses were isolated from U.S. pigs between winter 2010 and spring 2011 containing internal gene segments from the pandemic H1N1 2009. The evolution of novel H3N2 viruses in North American swine has been described.

A novel avian-like H3N2 containing an H5N1 highly pathogenic segment has been described in southern China.

An influenza A (H3N2) virus from pigs was isolated from pigs and its biological properties reported. The virus produced mild interstitial pneumonia with marked oronasal shedding for about 14 days. Because there is likely to be little cross immunity to these strains, they may cause disease in both humans and pigs in the future.

OTHER VIRUSES

Two H5N1 influenza viruses have been isolated from swine in Jiangsu Province in China, and the authors have suggested that these are naturally infected with H5N1 virus. This was similar to the situation in Indonesia. Quite often these reach pigs from avians, particularly ducks, including H1N1, H3N2, H3N3, H4N6, H5N1, and H9N2.

H2N3 viruses were isolated from farms in central United States and were probably of waterfowl origin. The ability of this virus to live in three different mammalian hosts suggests that it is well adapted.

An H3N1 SIV has been isolated from pigs with respiratory disease in Korea and also in Italy, where the HA has been acquired from a human virus, and the other genes came from the currently circulating viruses in the swine population.

Novel viruses can occur in pigs at any point in time. An avian H4N6 virus appeared in Canada in 1999 and was associated with a lake on which there were large numbers of waterfowl. Ducks shed large amounts of virus, and this can be recovered from lake water.

An avian-like H4N8 SIV was discovered in southern China.

An assessment of the reassortant rates of the European strains of SIV suggested that there was one reassortment every 2 to 3 years, and we should expect these to occur in the future between the swine strains and the new human pandemic strain (2009). A high level of genetic compatibility between swine-origin H1N1 and highly pathogenic avian H5N1 influenza virus was shown.

The avian H5N1 viruses in birds in Indonesia have been transmitted to pigs on numerous occasions but appear to become attenuated.

H5N2 reassortant viruses have been characterized from pigs in Korea. A serologic surveillance of H1N1 viruses in China showed that there was no naturally occurring H5N1 infection in pigs. A highly pathogenic turkey H5N1 virus failed to infect pigs cohoused with infected chicks or chickens.
A H6N6 virus was found in swine in China and seems to have adapted from domestic ducks. The isolation and characterization of two H5N1 influenza viruses from swine in Jiangsu Province in China has been described. The H5N1 virus has spread to a range of avian and mammalian species but has not been fully characterized in the pig. Both swine viruses bound preferentially to avian-type receptors. The findings suggest that pigs are naturally infected with avian H5N1 viruses and are a potential zoonotic threat. In a study of enhanced infectivity of H5N1 highly pathogenic avian influenza virus in pig ex vivo respiratory tract organ cultures following adaptation by in vitro passage, it was suggested that the mutations in the H5N1 virus may provide a replication or infection advantage in pigs in vivo and that pigs may continue to play an important part in the ecology of influenza viruses, including those of avian origin.

An H7N2 virus was isolated in South Korea and was a recombinant from an avian H7N2 and H5N3 virus. H9N2 SIVs have been described in China, where the six internal genes are from H5 viruses and the HA and NA from the H9 lineages. In a survey in China, 54 genotypes were identified including 19 novel genotypes, and there is a continuing evolution of these viruses. In this study, at least five antigenic groups were recognized, and during the period of 2002 to 2003 there was a considerable antigenic drift.

Human H7N9 IV replicates in swine respiratory tissue explants. Three Chinese isolates all replicated in tracheal and bronchial explants. These viruses were originally avian viruses that appeared in humans in China with over 130 cases, with a mortality of 32%. The surface proteins are probably from ducks and the internal genes possibly from chickens. There are two lineages reported at the moment. Collectively these viruses could lead to another pandemic. The infectivity, transmission, and pathology of these viruses in pigs has been described.

An H10N5 virus has been isolated from pigs in central China. There is no evidence as yet that the “bird” viruses H10N8 and H7N9 poultry viruses that have killed people in China are as yet occurring in pigs in China.

EPIDEMIOLOGY

The segmented nature of the viral genome is a critical structural feature that enables the viruses to be reassorted. Since 1998, H1, H3, and PB1 polymerase genes from human viruses; M, NS, and NP genes from classical swine viruses; and PA and PB2 polymerase genes from avian viruses have also been found.

Occurrence

Influenza viruses are ubiquitous in pigs worldwide with the exception of Norway until the 2009 pandemic.

A seroprevalence and genetic characterization of five subtypes of influenza A viruses (H1, H3, H5, H7, and H9) in the Chinese pig population has been described. H1 is the most common, followed by H3.

A study in the United Kingdom suggested that at least 52% of farms had antibodies to at least one type.

A Belgian study involving seven European countries showed all had antibodies, but the Czech Republic, Ireland, and Poland had relatively lower levels.

Both H1N1 and H3N2 are found in Poland but at quite low levels.

Chinese studies suggested that there was 31.1% positive to H1 and 28.6% positive for H388. In a recent study in southern China, over 50% of the pigs tested had a H1 titer to one or more influenza H1N1 viruses, and most commonly pdm/09-like viruses. One group had Eurasian avian-like swine H1N1 surface genes and pdm/09 internal genes.

The viruses were similarly widespread in Korea and also in Malaysia.

In Canada, 83.1% of the sows and 40.3% of the finishing pigs were positive for H1N1 but less than 10% to the Colorado and Texas strains of H3N293. In Argentina, over 70% were positive for H1N1 and H3N294. In Brazil, 46% were positive for H1N1.

Swine influenza first appeared in the United States immediately following the 1918 pandemic of human influenza (Spanish flu), and it was generally believed that it was caused by adaptation of the human influenza virus to swine. Nucleotide sequencing of the genes coding for the internal virus proteins indicates that the human pandemic H1N1 strain and the classic swine strain H1N1 have a common avian ancestor. It is suggested that a virulent avian strain H1N1 entered the human population in 1918, causing the pandemic. The pandemic virus was then introduced into the swine population, where it has persisted unchanged. In contrast, this classical swine influenza was seen in the United Kingdom in 1941 but then disappeared until it was seen in Czechoslovakia in 1950 and Germany in 1959. Influenza was not seen again until observed in swine in Europe in 1979, possibly following importation of pigs from North America, associated with a virus antigenically related to contemporary avian H1N1 strains found in ducks. These avian-like strains have been the most common since 1979.

Swine influenza still occurs in the United States, and viruses of the H1N1 lineage were the dominant cause of SIV from 1930 to the 1990s. These were highly conserved (relatively unchanged), but new antigenic and genetic variants did occur. Classical H1N1 viruses have also been isolated from pigs from South America, Europe, and Asia. Wild pigs also have H1N1. In the 1980s there were many genetic mixings between avian-like H1N1 and human-like H3N2 viruses. In 1992 many outbreaks of classical swine influenza occurred in England, associated with a group of H1N1 viruses that were distinguishable from classical swine viruses, the European swine viruses, and human H1N1 viruses, all of which are known to be circulating in pigs. Influenza A virus subtypes H1N1 and H3N2 are endemic in pigs in Great Britain. Two distinct antigenic variants of H1N1 viruses have been associated with outbreaks of swine influenza, one of which was probably transmitted from birds to pigs in the early 1990s. The H1N2 subtypes isolated from pigs in Great Britain appear to have originated from a human H1N1 virus, which was circulating in the pig population in the 1980s, and from swine H3N2. It is suggested that the H1N1 viruses have disappeared from the human population, and the pig population provides a reservoir for the virus. Swine influenza viruses have also been isolated from a number of human populations in the United States.

Transmission of viruses between pigs and humans and vice versa have shaped the current epidemiology of influenza viruses in North America.

Epidemics of swine influenza have also occurred in Japan, Canada, Belgium, and France. In North America, human H3N2 have been found much less often than in the rest of the world, but the very recent introduction of H3N2 from humans to pigs was probably the major factor in the emergence of the recent strains.

Mixtures of human and classical virus genes have been isolated from pigs in Asia and the United States. H3N2 viruses with human H and N genes and avian internal protein genes have been isolated from pigs in Asia. This type of H3N2 has been found in Korea and is currently the dominant H3N2 virus in pigs in Europe. Since 1998 double and triple reassortants have been isolated from pigs in the United States. The North Carolina virus had three human genes and five swine genes. They include human H and N genes, genes from swine H1N1 viruses, and two others from avians.

All the reassortant viruses found in North America have the triple-assortant gene complex (avian PA, PB2; the NS, NP, and M genes of classical swine lineage; and the PB1 of human gene lineage). This suggests that this set of reassortants can more readily accept changes in NA and HA.

Prior infection with swine influenza viruses is a barrier to infection with avian influenza viruses.

SEASONALITY

A study of circulating viruses in five European countries showed that isolation of viruses was possible throughout the year, especially during winter and spring.
Soon after the occurrence of the H3N2 viruses, new H1N2 viruses arose in the United States, where the human H3 had been replaced by a porcine H1 and then spread. They had been known elsewhere in the world for some time: Japan, France, Germany, and Taiwan. They were described in the United Kingdom, where they were found to be the most severe cause of pathology associated with the SIV viruses. These were all reassociants between human H3N2 and classical H1N1.

Human H3N2 and avian H1N1 were isolated in the United Kingdom and were then found to have spread to Europe. They are usually human H and N and the rest avian genes, but one Italian virus has an avian H1. They have shown considerable genetic drift in Europe.

Subtype H3N2 has been isolated in Canada from pigs with severe proliferative and necrotizing pneumonia (PNP), although this PNP is probably associated with PRRS and PCV2. Serologic surveys indicate the infection is widespread in the swine populations in some countries.

The first unusual virus to be found in pigs was an H9N2 introduced to pigs in South East Asia, probably from land-based poultry.

Further problems occurred in the autumn of 1999 when an avian H4N6 was found in pigs with pneumonia on a commercial swine farm in Canada. Since then the avian H5N1 has appeared in pigs in China and is being carried west by bird migrations into Russia. The potential of avian viruses to spread to pigs and persist in pigs is unknown. Even if the viruses do not replicate, they can contribute viral genes to other pig viruses. This is the reason for continual surveillance of SIV viruses. These were wholly avian viruses that were of North American lineage. It was the first report of an interspecies transmission of an avian H4 virus to domestic pigs under natural conditions.

The disease usually affects young pigs, but all ages may be affected. Typically, sudden-onset epidemics occur with a high morbidity rate but with a low case-fatality rate of less than 5%. Loss of body condition is marked, which is usually the important cause of financial loss, although occasionally death losses may be extensive if the pigs are kept under inadequate conditions or if secondary bacterial infections occur. Abortions and deaths of newborn pigs have also been reported as causes of loss in this disease.

A low level of infection was reported in Poland in 2007 in pigs, wild boar, and animal keepers.

The 2009 pandemic first affected pigs in Canada and has since been found worldwide: Norway, Italy, Canada, Argentina, South Korea, Thailand, and Europe.

**Risk Factors**

**Animal Risk Factors**

In a study in the Netherlands, it was shown that at the end of the finishing period, the seroprevalences in farrow to finish herds and specialized finishing herds were 44.3% and 62.0% for H1N1, 6.6% and 19.3% for H3N2, and 57.2% and 25.6% for H1N2. The incidence for all three types was highest at the beginning of finishing in farrow to finish and at the end in finishing herds.

Risk factors include high pig density, large herd size, high replacement rates, and purchase of pigs.

Young, growing pigs are most susceptible. The viral infection is commonly complicated by bacterial infection caused by *Haemophilus parasuis, A. pleuropneumoniae,* and possibly other opportunists of the upper respiratory tract of the pig. When an epidemic occurs, most of the pigs in the herd are affected within a few days, which suggests that all animals are previously infected and that some risk factor, such as inclement weather, precipitates the epidemic.

The agent also contributes to the PRDC.

In a study in Korea, 14 of 105 cases had SIV, whereas in Iowa it has been reported in 19% of the cases of PRDC.

**Environmental Risk Factors**

Epidemics occur mainly during the cold months of the year, commencing in the late autumn or early winter and terminating with a few outbreaks in early spring. Several days of inclement weather often precede an outbreak. Three risk factors for SIV were identified on a survey of Belgian finishing farms, where H1N1 was found in 71% and H3N2 was found in 22%. There was a close association between H1N1 and H3N2. H1N1 appeared to be associated with fully slatted floors, increasing numbers of pigs in the locality, and dry feeding. H3N2 was associated with the purchase of pigs from more than two herds, increasing numbers of pigs locally, and natural ventilation.

**Pathogen Factors**

It has been shown that prior infection with swine influenza viruses in pigs is a barrier to subsequent infection with avian influenza viruses.

Molecular microbiology has now revealed the antigenic diversity of the virus. Several different H and N antigens have been identified and grouped on the basis of serologic tests, which refine the diagnosis and reveal more about the epidemiologic relationships. The H3N2 strain similar to H3N2 strains found in the human population has been isolated from an outbreak in England.

Two antigenically distinct H1N1 influenza A viruses were isolated during an outbreak of respiratory disease in swine in Canada in 1990 to 1991. One is a variant of the swine H1N1 influenza virus that is widespread in the American Midwest, whereas the other is similar to the virus isolated from swine in 1930. This suggests that influenza viruses can be maintained for long periods in swine herds, especially in certain geographic areas. It is proposed that the antigenic diversity of these viruses may be attributable to the result of drifts in the population of circulating swine influenza viruses in an area. The antigenic diversity oligonucleotide analysis of strains isolated from outbreaks in Sweden indicated a similarity with the Danish strain. One of the Swedish strains was closely related to the U.S. strain.

The H1N1 strain of the virus can be found in pig tissues at slaughter but it does not persist for more than 2 to 3 weeks in deep frozen or refrigerated storage.

Viruses circulation in weaned pigs may maintain infections in herds, and the introduction of susceptible pigs at regular intervals will maintain this circulation.

**Methods of Transmission**

Of most importance is that in birds, influenza viruses mainly affect the intestinal tract (without clinical effects), but in mammals, replication occurs mainly in the respiratory tract (with illness).

The right combination of NA and M genes is necessary for the replication and transmissibility of influenza virus infections in pigs.

The natural reservoir of influenza A virus is aquatic birds. Various subtypes have been established in other species, such as influenza A H1N1 viruses, which infect human and different animal species. The influenza viruses may be transmissible between humans and pigs. Swine are the sole animals known to be susceptible to influenza A viruses of human, swine, and avian origin. Swine may become infected with related type A human influenza strains during epidemics of human influenza, but they show no clinical signs of infection. The human strains have been isolated from pigs in Hong Kong, and pigs may serve as a reservoir for pandemics in humans and a source of genetic information for recombination between human and porcine strains. In Japan, pigs may be seropositive to the H1N1 human viruses relative to human H1N1 influenza epidemics and seropositive to human H3N2 viruses unassociated with human epidemics of disease. In Czechoslovakia, influenza A viruses are brought into pig herds by carrier people.

Pigs can be naturally infected with a range of avian influenza viruses. There have been at least three independent introductions of distinct wholly avian viruses into pigs. The virus in the late 1970s spread throughout Europe and the United Kingdom and became a major cause of SI. These viruses also undergo drift.

Elsewhere in the world antibodies against H4, H5, and H9 viruses have been isolated from Asian pigs and avian H4N6, H3N3, and
H1N1 viruses have been recovered from pigs in Canada.

Aerosol transmission is more efficient at low temperatures and low humidity because the virus is more stable under these conditions.\textsuperscript{109} Aerosol transmission of a novel swine origin H1N1 virus was shown in China.\textsuperscript{111}

In water the avian viruses survive better at low temperature and salinity and high pH.\textsuperscript{112,113} The avian virus survives better on nonporeous surfaces rather than porous ones\textsuperscript{114} and, if there is mucus, much longer.\textsuperscript{115}

Swine are susceptible to both human and avian viruses because they have receptors on their respiratory epithelial cells for both avian (receptor SA 2, 3 Gal) and human (receptor SA α 2, 6 Gal). Several reassortants have been isolated from pigs in the United States and other parts of the world.\textsuperscript{116,117}

Thus swine have an important role in the ecology of influenza A viruses and are regarded as a “mixing vessel” for the introduction of reassorted viruses into the human population.

There is a report claiming that outbreaks of influenza in turkeys followed outbreaks of swine influenza in pigs from nearby swine herds. Swine and other influenza viruses have also been isolated from cattle, and experimental inoculation of calves has been successful. The swine influenza virus may cause natural infection in cattle and the virus can be transferred to un inoculated calves.

The primary route of infection is through pig-to-pig contact\textsuperscript{118,119} via the nasopharyngeal route. Peak shedding occurs 2 to 5 days postinfection (>10\textsuperscript{7} infectious particles/mL at a peak) but also by aerosols and contaminated fomites.\textsuperscript{120}

The rapid spread of infection from pig to pig occurs by inhalation of infectious droplets. The disease may appear almost simultaneously in several herds within an area following the first cold period in late autumn. The virus can persist in infected swine, which can act as convalescent carriers and be the reservoir of the virus between epidemics. However, the experimental inoculation of a swine influenza virus into specific-pathogen-free (SPF) pigs resulted in a mild disease and the period of viral shedding was shorter than 4 weeks.

Water contaminated with bird droppings has been implicated as a source of influenza virus in several swine outbreaks.\textsuperscript{121} Fomites and aerosols\textsuperscript{122} are probably important in the transmission of influenza.\textsuperscript{123}

Insects may be important (certainly in avian influenza)\textsuperscript{124} and blowflies have been implicated.\textsuperscript{125,126}

Long-distance pig travel via transport may help spread.\textsuperscript{126}

International trade may also facilitate the intercontinental spread of viruses.\textsuperscript{127}

**Immunity**

An infection with live virus also stimulates mucosal immunity and cellular immunity, whereas inactivated vaccines only stimulate a limited serologic (HI) response. Preexisting immunity in European pigs to established SIV strains may partially protect against (H1N1) 2009 virus, but the extent of such protection needs to be assessed.\textsuperscript{128}

Many of the host defense cells have sensors that ultimately up-regulate the production of interferons, up-regulate other cells, and activate them through cytokines and in general increase the production of host antiviral proteins. The flu virus survives in part by blocking the release of interferons.

Both cell-mediated immunity and humoral responses are important. A high HI titer provides better protection against challenge than a low HI titer. The levels of IgA seem to be more important in providing some protection against heterologous viral strains. It is the antibody-mediated immune reactions at the mucosal level, not the systemic level, that are important in protecting the respiratory tract. Improved adjuvants may aid the efficacy of inactivated vaccines. They do not prevent infection, but they can mediate the killing of infected cells. The immune response is rapid and completes elimination of the virus within 1 week. Antibodies decline by 8 to 10 weeks. The IgA levels in nasal washes are the most important defense. There is limited cross-protection between different viruses, and protection after vaccination is more virus specific.

Maternal antibody rarely prevents infection with influenza viruses and only provides partial protection. Maternal protection will last from 4 to 14 weeks, with no pigs being completely protected from nasal virus shedding upon challenge, but at least the lung is protected. Pigs with a high maternal antibody level did not develop an immune response. It was reported that there was enhancement of pneumonia by inactivated vaccine used in the face of an H1N1 challenge.\textsuperscript{129} Maternal antibody does not cross protect between subtypes.

Pigs infected or vaccinated with European SIVs frequently have cross-reactive antibodies to pandemic (H1N1) 2009 virus and related North American SIVs.

Prior infection with an H1N1 SIV partially protects pigs against a low-pathogenic H5N1 avian influenza virus.\textsuperscript{130}

**Zoonotic Implications**

Only influenza A viruses are zoonotic. The suspected cases were reviewed.\textsuperscript{131} It is highly likely that in the future, further viruses will emerge from animal species to infect humans and vice versa. People who work with pigs are at an increased risk of zoonotic influenza virus infection\textsuperscript{132} (including farmers, meat processing workers, and veterinarians)\textsuperscript{133,134} and should be vaccinated.\textsuperscript{135} The Ohio outbreak of H1N1 at a state fair is an example. H2 viruses have been absent from the human population since 1968 and as such will present a huge problem if they suddenly turn up as a zoonosis. However, an H2N3 infection in pigs was not transmitted to humans from ill pigs.\textsuperscript{136}

In the United States, there were only 11 reported zoonotic cases between 2005 and 2009.\textsuperscript{137}

The human pandemic 2009 H1N1 virus has its closest relatives in strains of H1N1 in swine from North America and occasionally from turkeys. There are probably at least two swine ancestors for this 2009 pandemic.

Subclinical infections at Ohio fairs from 2009 to 2011 were described.\textsuperscript{138} The influenza A virus (OH07) isolated from humans that attended an Ohio state fair is pathogenic in pigs and fails to cross-react with many swine H1 antisera. The virus gene segments were similar to those circulating in swine viruses, although there were numerous nucleotide changes leading to differences in amino acid composition.\textsuperscript{138}

Swine influenzas pose a significant health risk to humans ever since the first human and porcine outbreaks in the United States in 1918. By 1970, there was evidence that people who came into contact with pigs through their jobs became infected with the viruses, and a virus was isolated from pigs and workers. There is very little evidence of maintenance of human H1N1 in the pig populations, but human H3N2 strains have been recovered regularly from pigs in Asia and Europe. The drift that has taken place in pigs of former human H3N2 has also been minimal compared with the rate of drift in the human population. The viruses from pigs found in humans have been reviewed. Poultry and swine workers should be vaccinated in swine pandemic planning.\textsuperscript{135}

**PATHOGENESIS**

Classical swine influenza was originally described as a disease of the upper respiratory tract, the trachea and bronchi being particularly affected, with secondary bacterial pneumonia as a result of Pasteurella multocida. However, recent descriptions of the lesions in naturally occurring cases and in the experimental disease indicate that the primary lesion is a viral interstitial pneumonia. Viral replication takes place in the epithelial cells of the nasal mucosa, tonsils, trachea, lungs, and tracheo-bronchial lymph nodes. No other sites have been detected, and viremia is of low titer. Inoculation of the H1N1 strain of influenza virus isolated in England from pigs with clinical disease into 6-week-old pigs caused fever, coughing, sneezing, and anorexia. A widespread interstitial pneumonia, with lesions in the bronchi and bronchioles, and hemorrhagic lymph nodes were characteristic. The H3N2 swine influenza virus isolated in Canada is associated with a proliferative and necrotizing pneumonia (PNP) of pigs, and there is evidence the strain may be related to A/Sw/Hong Kong/76H3N2 swine influenza virus.
There is recent evidence that this PNP is more a feature of PRRS and PCV2 than SIV. A new antigenic variant of H1N1 swine influenza A virus isolated in Quebec has been associated with proliferative and necrotizing pneumonia of pigs.

In the United Kingdom, there has also been recorded an H1N7 that included both equine and human influenza genes. It was of low pathogenicity for pigs, found on only one farm, and did not establish in the pig world. Reassortant H3N1 viruses from human and classical swine H1N1 have also been seen in the United Kingdom and also in Taiwan.

The virus causes an acute infection with shedding beginning on day 1 and finishing by day 7. Infected cells in the respiratory tract are reduced by 2 to 3 days postinoculation. Most of the effects of the infection are caused by the production of proinflammatory cytokines (IFN-α, TNF-α, IL-1, and IL-6.).

Pigs have receptors for both avian (sialic acid–α2-3 terminal saccharides (SA-alpha-2.3) and mammalian viruses (SA-alpha-2.6) in the upper respiratory tract. Both types have been detected in major porcine organs.143,144 In experimental infections, SIV was widely distributed in bronchi, but it was also present in epithelial cells of the nose, trachea, bronchioles, and alveolar type I and II cells in severely affected animals. The avian virus was found in the lower respiratory tract, especially in alveolar type II cells and occasionally in bronchiolar epithelial cells. Receptor 2.6 was the predominant receptor in all levels of the tract, but the 2.3 was found only in small numbers in the bronchioles and in the alveoli. The receptor expression of both types of receptors was reduced in influenza-affected areas compared with nonaffected areas.142 The distribution of receptors is similar in the pig to that of humans, and as in humans, avian viruses prefer to infect the alveolar cells. The in vitro attachment of virus to the upper and lower respiratory tract tracts of pigs has been characterized.143

The pathogenicity of SIV lies in its ability to elude host antiviral immune responses. In pigs SIV infection induced long-lived increase of CD8+ T cells and local lymphoproliferative responses.144 The activation of cell-mediated immunity or cytotoxic T-lymphocytes depends on the efficient delivery of signals by antigen presenting cells. Dendritic cells are the most potent APCs. A study on porcine dendritic cells (DCs) has recently been published.145 In one study,146 it was shown that DCs could infect susceptible cells by close contact. The swine, human, or avian viruses differentially activate porcine dendritic cell cytokine profiles.147

There is an important role for IFN-α (induces fever and a transient rise in neutrophil counts) with IL-6 and IL-12 induction and an important role of these three cytokines in the symptoms of swine influenza.148 There is a strong up-regulation of additional cytokines (IFN-α and IL-12) and several acute-phase proteins during the acute stages of a swine influenza virus infection. These produce inflammation, fever, malaise, and loss of appetite. The depth of infection in the lung probably determines how much of these cytokines are produced. Contrary to widespread belief, there is no evidence that the virus causes reproductive failure in swine. The experimental inoculation of seronegative pregnant gilt did not reveal any evidence of transplacental transmission of the virus to the fetus.

The pandemic H1N1 influenza virus causes disease in pigs and up-regulates genes related to inflammatory and immune responses. The virus is effectively shed from the nasal passages. Pigs infected with the pandemic virus mounted an early potent immune response, and it has been shown that such a response is associated with an increased viral pathogenesis. It also produced a higher proinflammatory cytokine response when given to macaques.149 The PB1-F2, which is expressed from a +1 reading frame of the viral RNA polymerase subunit PB1, is able to induce apoptosis and promote inflammation.150 Dysregulation of lipid metabolism also occurs at the site of primary infection.151

The pandemic 2009(H1N1) virus was shown to be more pathogenic in ferrets than the standard seasonal H1N1 virus with more extensive viral replication taking place in trachea, bronchi, and bronchioles and the more normal nasal cavity.152 The virus replicates to higher titers in the lung tissues. It showed less efficient respiratory droplet transmission in ferrets.153

In patients with pandemic A (H1N1) pdm09, it was found that the numbers of dendritic cells and T cells were significantly reduced compared with controls. On the other hand, the frequency of natural killer cells and T-regulatory cells increased.154 The concentrations of plasma interferon (IFN-α/β) and interleukin (IL-15) were significantly higher than in the control group.154

CLINICAL FINDINGS

The patterns of disease in farms may vary considerably from an endemic form, with waves of infection to single epidemic outbreaks depending on the strains of virus involved.155

It is essentially a herd disease. The signs have not changed over the 80 years. After an incubation period of 1 to 7 days (usually 1-3), the disease appears suddenly, with a high proportion of the herd showing fever (up to 41.5° C [107°F]), anorexia, and severe prostration. The animal is disinclined to move or rise because of muscle stiffness and pain. Labored, jerky breathing ("thumps") is accompanied by sneezing and a deep, painful cough that often occurs in paroxysms. There is congestion of the conjunctivae with a watery ocular and nasal discharge. Sometimes there is open-mouth breathing and dyspnea, especially if the pigs are forced to move. Morbidity is usually 100%, but mortality is rarely above 1%. In general, the severity of the illness appears greater than it truly is, and after a course of 4 to 6 days, signs disappear rapidly, depending, in part, on the level of colostral antibody. However, there is much loss of weight, which is slowly regained. Clonic convulsions are common in the terminal stages in fatal cases. The condition may continue to affect the herd for several weeks as the disease spreads, especially so if the herd is outdoors and the population dispersed. The new H3N2 reassortants in the United States have been associated with respiratory disease but also spontaneous abortion in sows and death of adult pigs. The clinical signs are dependent on immune status but are also influenced by age, infection pressure, concurrent infections, climatic conditions, housing, and, most of all, by the secondary infections, particularly bacteria.

The clinical and epidemiologic characteristics of pdmH1N1 2009 virus in pigs have been described.156 There are differences in disease presentation, spread, and duration of infection. These factors include whether they were outdoors or housed, age of the pigs, intercurrent disease, and management. In breeding pigs the infection was mild or inapparent, with a more typical clinical appearance detected in their progeny. Mortality was low unless complicated by other diseases, especially S. suis infections. The virus transmitted very easily. The clinical signs were usually sneezing and coughing.

CONCURRENT INFECTIONS

There is some question as to whether other viruses can predispose to SIV, but experimentally infection with PRCV and H1N1 or H3N2 SIV has not shown this. Pigs with both M. hyopneumoniae and SIV coughed more and had more pneumonia than either of the two agents on their own.

Preinfection with M. hyopneumoniae modifies the outcome of infection with SIV H1N1 but not H1N2. The H1N2 was more pathogenic than the H1N1 with an earlier shedding and greater spread in the lungs. The M. hyo and H1N1 seemed to act synergistically, but the M. Hyo and H1N2 seemed to compete because H1N2 appeared to eliminate M. hyo in the caudal lobes.157

The occurrence of SIV in pigs presents opportunities for an increased impact of bacterial infections such as H. parasuis (HPS). It has been shown that coinfection between H3N2 and both a virulent and nonvirulent strain of HPS and porcine bone marrow dendritic cells was heightened because it raised the levels of IL-1β, TNF-α, IL-6, IL-12, and IL-10 compared with SIV or mock infections.158 With the virulent strain of HPS, IL-12 and IFN-α increased differentially.
CLINICAL PATHOLOGY

Experimental Infections

Following experimental H1N1 infection, it was found that IFN-α, IL-6, IL-1, and TNF-α peaked in bronchoalveolar lavage fluid (BALF) at 24 to 30 hours postinfection, when virus titers and the severity of the clinical signs were maximal. Serum cytokine concentrations were not detectable or 100-fold lower than the BALF readings, but IFN-γ and IL-12 in serum followed the lavage pattern. The acute-phase protein (APP), C-reactive protein, and haptoglobin were raised 24 hours after the cytokine response, and the lipopolysaccharide binding protein only increased in the BALF. The findings suggested that IFN-α and IL-12 play an important part in the pathogenesis of SIV and that APPs are induced by cytokines. Acute-phase proteins and serum amyloid were raised when pigs were simultaneously infected with H1N1 virus and P. multocida.

Experimental infections with the human 1918 pandemic influenza virus produced only a mild disease and pigs, and they did not become moribund, whereas in other mammalian species the effects were lethal. The findings suggested that the virus entered the swine population from humans and then established the classical H1N1 lineage in pigs.

Experimental infection with H1N1 European swine influenza virus protects pigs from infection with the 2009 pandemic H1N1 human virus. Experimental infections with the U.S. isolates of the p(H1N1) 2009 were described, and all the pigs developed clinical signs similar to those induced by endemic SIV viruses.

Within 24 hours of the onset of clinical signs there is a switch of cells in the bronchial lavage from macrophages to over 50% neutrophils.

Serologic Tests

After infection has ceased to circulate in the herd, SIV AB could still be demonstrated after 28 months postinfection.

It is extremely important to make sure that the antigens that are used in the serologic tests are contemporary to the viral strains that may be found in the country. Diagnosis of acute SIV infections requires the use of paired serum samples.

The hemagglutination inhibition test has been the recommended test for many years and still remains so. However, it is tedious and has only moderate sensitivity but high specificity. It has been adapted and modified. One HI test for H1N1 will detect other H1N1 strains, but this is not true for H3N2 when the Midwest strains are compared with the North Carolina strains because they differ considerably. Above 1:80 is usually considered positive, and within 5 to 7 days the titers may reach 1:320 to 1:640 by 2 to 3 weeks postinfection. An ELISA-based test is now available to estimate the hemagglutination titer and can be used at the herd screening level. Antiinfluenza A nucleoprotein antibodies have been detected in pigs using a commercial ELISA developed for avian species.

Detection of Virus

Virus is likely to be found in the nasopharyngeal area during the acute phase of the disease. Swabs should be taken on Dacron, placed in transport medium, and stored at 4°C for no more than 48 hours; if storage will be longer, samples should be frozen at –70°C (–94 F). Viruses can also be isolated from trachea or lung tissues of pigs. They can be grown in hens’ eggs or increasingly in tissue culture. Samples need to be cool and moist. The virus is then detected by hemagglutinating activity in egg fluids about 5 days after inoculation. There are some strains that may not grow in hens’ eggs or require more than one cell line to isolate and identify the virus, which may require 1 to 2 weeks.

Oral Fluids

Pen-based oral fluids provide an easy, effective, and safe collection method for the detection of SI with rapid testing methods, such as RT-PCR. Virus isolation from nasal swabs was more successful than using oral fluids.

The sensitivity of oral fluids for detecting influenza A virus in populations of vaccinated and nonvaccinated pigs has been described. The overall sensitivity of oral fluids was 80%, and virus was isolated from 51% of RRT-PCR positive oral fluids. The method can detect SIV even when pen prevalence is low and when pigs have been vaccinated.

Antigen Detection

A PCR test can be used to detect virus in nasal swab specimens and gives results similar to virus isolation. Recently a gel-based multiplex RT-PCR assay was developed to detect H1 and H3 subtypes of SIV. An RT-n-PCR for the identification of SIV in clinical samples has been described. A real-time RT-PCR assay for differentiating the pandemic H1N1 2009 pandemic from SIVs has also been described. A real-time RT-PCR has been developed for the detection of p(H1N1)2009 and European SIV A infections. A real-time RT-PCR for pandemic influenza A virus (H1N1) 2009 matrix gene has been described.

A multiplex RT-PCR assay for differentiating European SIV subtypes H1N1, H1N2, and H3N2 has been described and used in North American pigs.

Loop-mediated isothermal amplification has been used for the rapid and specific detection of H3 SIV.

There are rapid detection methods for the 2009p(H1N1) using multiplex rtRT-PCR. The virus can be detected by direct immunofluorescence of lung tissue or lavage fluids.

Immunohistochemistry on fixed tissue is also useful. The positivity is mainly in the bronchial and bronchiolar epithelial cells and less intense in the interstitial cells and alveolar macrophages.

NECROPSY FINDINGS

Swelling and marked edema of cervical and mediastinal lymph nodes are evident. There is congestion of the mucosa of the pharynx, larynx, trachea, and bronchi. A tenacious, colorless, frothy exudate is present in the air passages. Copious exudate in the bronchi is accompanied by collapse of the ventral parts of the lungs. This atelectasis is extensive and often irregularly distributed, although the apical and cardiac lobes are most affected, and the right lung more so than the left. It may reach 50% by 4 to 5 days postinfection. The affected tissue is clearly demarcated, dark red to purple, and often reminiscent of enzootic pneumonia. Surrounding the atelectatic areas the lung is often emphysematous and may show many petechial hemorrhages.

Histologically, in acute swine influenza the major feature is necrotizing bronchiolitis. There is a suppurative bronchiolitis and widespread interstitial pneumonia characterized by the early appearance of neutrophils followed by the accumulation of macrophages and mononuclear cells in the alveolar walls. After a few days there is a peribronchial and peribronchiolar infiltration of lymphocytes. In the variant of H1N1 swine influenza in Canada, there is more diffuse damage to the respiratory epithelium, resulting in firm to meaty lungs that appear thymus-like on cut surface.

Microscopically, there is marked proliferation of type II pneumocytes, in addition to the presence of macrophages and necrotic inflammatory cells in the alveoli. The influenza type A virus can be demonstrated by indirect immunofluorescence staining using monoclonal antibody directed to certain protein parts of the human type A influenza virus. The influenza type A virus can be detected and differentiated from the virus of porcine reproductive and respiratory syndrome in formalin-fixed, paraffin-embedded lung tissue using immunogold staining.

Samples for Confirmation of Diagnosis

These are best collected from animals with high fevers and clear nasal discharge. Most pigs may excrete virus for 5 to 7 days postinfection, but the peak load may be around 24 hours postinfection.

- **Histology**—formalin-fixed lung, trachea, turbinate (LM, IHC). After 72 hours there is little IFA or IHC positivity. Histopathology may help in the diagnosis for 2 weeks postinfection.
- **Virology**—nasopharyngeal swab in viral transport media; lung and
trachea (ISO, FAT, PCR) fresh chilled but not frozen. Keep cool. Do not use cotton.

**DIFFERENTIAL DIAGNOSIS**

The explosive appearance of an upper respiratory syndrome, including conjunctivitis, sneezing, and coughing, with a low mortality rate, serves to differentiate swine influenza from the other common respiratory diseases of swine.

Enzootic pneumonia of pigs is most commonly confused with swine influenza, but it is more insidious in its onset and chronic in its course.

Hog cholera is manifested by less respiratory involvement and a high mortality rate.

Inclusion-body rhinitis in piglets may resemble swine influenza quite closely. Atrophic rhinitis has a much longer course and is accompanied by characteristic distortion of the facial bones.

**TREATMENT**

No specific treatment is available. Treatment with penicillin, sulfafoxime, or, preferably, a broad-spectrum antibiotic may be of value in controlling possible secondary invaders. The provision of comfortable, well-bedded quarters, free from dust, is of major importance. Clean drinking water should be available, but feed should be limited during the first few days of convalescence. Medication of the feed or water supplies with a broad-spectrum antibiotic for several days is a rational approach to minimizing secondary bacterial pneumonia.

A novel monoclonal antibody was shown to be effective against lethal challenge with swine lineage and 2009 pandemic H1N1 influenza viruses.178

**CONTROL**

Treatment of human influenza is possible with oseltamivir, but some viruses have become resistant; however, there is no evidence that natural oseltamivir resistance in swine and wild waterbirds is common.179

There are only two options: vaccination and biosecurity. Biosecurity is difficult because there is always the possibility of aerosol infections and wild fowl/poultry infections. It should be aimed at preventing transmission from people to pigs and vice versa.

Eradication following herd closure and partial depopulation has been achieved.180

There was no introduction of replacement animals, replacement gilt deliveries were seronegative and went to quarterly instead of monthly, and the nursery was totally depopulated along with the finishing sites once shedding had finished.181

The perceptions of the pig producers in Australia in response to the occurrence of the pandemic182 suggests that ongoing communications about biosecurity are very important when new outbreaks occur.

Vaccination against swine influenza in a herd experiencing an outbreak of PCVAD is of questionable value.183

A study of vaccination in pigs infected with PRRS at the time of vaccination against SIV showed increased levels of macroscopic and microscopic lesions and also increased clinical disease and shedding of the virus.184

All-in, all-out systems may remove infection with each group of pigs, and the subsequent disinfection may wipe out the virus. Good housing and protection from inclement weather help to prevent the occurrence of severe outbreaks. Once the disease has appeared on a unit, there is little that can be done to prevent spread to other pigs. Recovered animals are intermittently subclinical and can become resistant; however, there is no evidence that enzootic swine pneumonia can become endemic.

Rational approach to minimizing secondary invaders. Biosecurity is difficult because there is always the possibility of aerosol infections and wild fowl/poultry infections. It should be aimed at preventing transmission from people to pigs and vice versa.

There are only two options: vaccination and biosecurity. Biosecurity is difficult because there is always the possibility of aerosol infections and wild fowl/poultry infections. It should be aimed at preventing transmission from people to pigs and vice versa.

Vaccinations are advocated to control SIV.185 The genetic homology of the vaccine strain has been developed that was superior to commercial vaccines.186 A trivalent inactivated swine flu vaccine was shown to be protective for all three strains (H1N1, H1N2, and H3N2).187

Inactivated whole-virus vaccines have limited ability or complete failure to protect against homologous challenge and even poorer cross-protection to heterologous strains.190 They can stimulate both humoral and cellular immunity.191

A trivalent inactivated swine flu vaccine was shown to be protective for all three strains (H1N1, H1N2, and H3N2).191

Inactivated vaccines from U.S. viruses and the new pandemic showed partial protection, but none was able to prevent all shedding or clinical disease.192

**MODIFIED LIVE**

Modified live vaccines or vectored subunit vaccines induce a balanced immune response (humoral and cell-mediated) and will improve homologous and heterologous protection. All vaccinated pigs developed a significant level of HI titer and serum IgG and IgA antibodies.200,201

A modified live vaccine as a master donor strain has been developed for the 2009 pandemic virus,202 and a pandemic virus vaccine was developed that was superior to commercial vaccines.203

Chapter 12

■

Diseases of the Respiratory System

VetBooks.ir

Adjuvanted and nonadjuvanted A(H1N1)
pdm/09 influenza vaccines were shown to
produce strong antibody responses and
included high levels of specific IgG1 and HI
titers to H1 virus. The adjuvanted vaccines
produced a greater response.204
An eight-segment SIV with H1 and H3
was found to be attenuated and protective
against both H1N1 and H3N2 subtypes
in pigs.205
Vaccines, both commercial inactivated
and adjuvanted SIV for IM use, are available
in the United States and Europe. Active
immunization occurs in the face of maternal
derived antibody when titers are less than 10
for H1N1 and less than 40 for H3N2. Some
of the vaccines contain the original H1N1
viruses, but others such as those used in the
United States, contain a monovalent H1N1
virus. Following the outbreaks of H3N2 in
the United States in 1998, both monovalent
and bivalent H1N1/H3N2 SIV vaccines
became available. Autogenous vaccines are
used in the United States.
In Europe, although the viruses have
changed, the old vaccines are still used
because they produce high antibody titers.
There is a need to add H1N2 to the vaccines,
however, because there is no cross protection between the European H1N2 and H1N1
and H3N2 viruses and because it was shown
that there is no current vaccine protection
against H1N2. There is evidence from the
United States showing that there is cross
protection with the U.S. strain of H3N2 for
H1N2 infections. Most animals with titers
greater than160 are probably protected
against viral replication in the lungs and
disease. Sow vaccination is important in
controlling infection in suckling pigs and
often controls the infection in nursery pigs.
Intranasal or IN/IM vaccination of pigs with
formalin-inactivated SIV induces very specific IgM, IgG, and IgA antibodies in their
nasal secretions and sera, resulting in complete protection.
A recent trial of a new H1N1/H3N2
vaccine was successful, with reduced viral
shedding and reduced clinical signs and
pneumonia.
Experimental vaccines continue to be
produced, including a human adenovirus 5
recombinant expressing the hemagglutinin
and nucleoprotein of H3N2 SIV that has
been used experimentally to provide protection against challenge with H3N2. Complete
protection was shown by lack of nasal shedding and by lack of lung lesions following
subsequent challenge.
A DNA vaccine elicited robust serum
antibody and cellular responses after three
immunizations and conferred significant
protection against influenza virus challenge.206 Vaccination with human adenovirus
vector vaccines has been shown to induce
both cell-mediated and humoral immunity,
making them more effective than inactivated
vaccines and nearly as good as live vaccines.

They can also prime the immune response in
the presence of maternal antibody.207
Recently an avian-like H1N1 influenza
virus was shown to be able to transmit efficiently through four pairs of vaccinated pigs
at antibody levels that were thought to be
protective.208
Immunity induced by infection with
European avian-like H1N1 SIV affords protection for pigs against North American SIVs
with a classical H1 and possibly also protects
against the pH1N1.209
Pandemic (H1N1)2009 influenza viruslike particles are immunogenic.210 The vaccinated pigs were protected and showed
reduced lung lesions, reduced viral shedding,
and inhibition of viral replication in the
lungs.

NEWER OPTIONS

Elastase-dependent SIV mutants can be used
as live-virus vaccines against swine influenza
in pigs.211,212
Use of the M2 conserved matrix protein
may have potential as a vaccine but requires
an immune response to the HA protein to
reduce shedding.213
Replicon particle vaccine protects swine
against influenza.214-216
Vaccination with NS1-truncated H3N2
SIV primes T cells and confers cell-mediated
cross-protection against a H1N1 heterosubtypic challenge in pig.217 In addition,
there was a significantly lower level of Th1associated cytokines in infected lungs. A
similar vaccine can be used to differentiate
between infected and vaccinated animals.218

Infection with coronavirus causes a rapid seroconversion to some of the tests for TGE and is responsible for "vaccinating" large populations of pigs worldwide against the threat of TGE. This has coincided with the great reduction in TGE in most countries. It first appeared in Belgium in 1986 and since then has spread worldwide.

**ETIOLOGY**

The virus is very similar to TGE, and the major difference is a 621- to 628-base-pair deletion in the S protein gene causing a truncated S protein and loss of the ability of the TGE to bind sialic acid. It has a tropism for the respiratory tract. It is one of the four swine coronavirus and is a mutant of TGE, first isolated in 1984. The virus has been fully or partially sequenced and has 96% to 98% homogeneity with TGE. Lipoteichoic acid from *S. aureus* exacerbates respiratory disease in PRCV-infected pigs, and coinfection with *B. bronchiseptica* is reported. PRRSV-induced immunosuppression exacerbates the inflammatory response to PRCV in pigs. PRCV-infected pigs produce antibodies that neutralize TGE virus.

**EPIDEMIOLOGY**

The virus distribution is affected by the season and the density of pig farms, and in a dense area there is rapid local spread probably by aerosol. The virus infects pigs of all ages by contact or airborne transmission and in areas of high density can probably spread several kilometers. The virus circulates in the herd, infects pigs less than 10 to 15 weeks of age after the maternal antibodies have declined, and becomes endemic. Experimentally, infected pig shed virus from the nose for less than 2 weeks. The infection can be maintained in herds, cycle regularly, or appear in waves. In Europe, these waves often coincide with the rainy season. There is no evidence of fecal/oral transmission.
Chapter 12  ■  Diseases of the Respiratory System

**PATHOGENESIS**
The virus has a tremendous ability to replicate in the respiratory tract in most of the airway but rarely the alveolar macrophage. The main targets are type 1 and type 2 alveolar epithelial cells, and it induces necrosis in these cells, causing a rise in cytokines that induces a rise in nitric oxide and IFN-α. The shedding from the nose lasts 4 to 6 days. The pneumonia produced and the viral replication peak at 7 to 10 days postinoculation and then resolve with the increasing levels of neutralizing antibody.

**CLINICAL SIGNS**
Most infections are inapparent, but in a susceptible population there may be respiratory signs such as labored breathing and coughing, followed by depression, anorexia, and decreased growth rates.

**LESIONS**
The lesions are usually self-limiting. The major lesions are broncho-interstitial pneumonia with cuffing and syncytial formation from type 2 hyperplasia, followed by necrosis and lymphoid hyperplasia. Necrotic cells and inflammatory cells may obstruct the lumen of the alveoli.

**DIAGNOSIS**
Virus isolation in PK and swine testicle cells is necessary using nasal fluid or lung homogenates, and frequently PRCV produces syncytia in culture. Respiratory samples are required for diagnosis of PRCV. Currently, RT-PCR or qRT-PCR is needed to differentiate TGEV and PRCV. The primers target the S protein. Multiplex PCR has now been developed for TGEV, PRCV, and PEDV and up to eight viruses. Multiplex microarray has also been developed for the rapid differentiation of eight coronaviruses. Blocking ELISAs have been developed to differentiate antibodies of PRCV from TGE and should be used on a herd basis. Recently, new ELISAs have been developed that will also differentiate TGE, PRCV, and the new TGE-like coronaviruses.

**TREATMENT**
There is no treatment for PRCV infections except supportive therapy and control of secondary infections.

**CONTROL**
Neonatal pigs require 6 to 8 days after PRCV exposure to produce partial immunity to TGE. Sows naturally exposed to PRCV reinfected with PRCV during pregnancy secreted TGEV antibodies in milk and provided a high degree of protection.

**LUNGWORM IN PIGS**

**ETIOLOGY**
The lungworms that infect pigs are *Metastrongylus apri* (*M. elongatus*), *M. salmi*, and *M. pudendotectus*. *M. apri* is the most common species, but mixed infestations are not uncommon.

**LIFE CYCLE**
Adult *Metastrongylus* spp. appear much like *D. viviparus* in the bronchi of their host. Their life cycles are also similar, except that *Metastrongylus* spp. eggs are passed in the feces and earthworms act as intermediate hosts. Here development to infective larvae takes about 2 weeks, and transmission occurs when the earthworm is eaten by a pig.

**CLINICAL SIGNS**

**TREATMENT**

**CONTROL**

**REFERENCES**
ivermectin, doramectin, fenbendazole, and flubendazole. Levamisole (8 mg/kg) has been used in the water or feed.

**CONTROL**

Rearing pigs on concrete reduces the risk considerably but, in view of the longevity of the eggs and larvae in the earthworm, little can be done if pigs are kept on contaminated land. Pastures that are known to be contaminated should be left for at least 6 months before restocking, although infested earthworms may persist in hog lots for up to 4 years.

**Respiratory System Toxicoes**

**FURAN (IPOMEANOL AND 3-METHYLINDOLE) TOXICOSES**

4-Ipomeanol (4-IPO) is a furanoterpenoid mycotoxin produced by Fusarium solani (synonym F. javanicum) and F. semitectum growing on garden refuse. It has the effect of causing lesions indistinguishable from those of atypical interstitial pneumonia. Other known causes of these lesions are 3-methylindole and the ketone produced by Perilla frutescens, Ziera arborescens, and one of the fungi Fusarium solani or Orysosporum spp. on Ipomoea batatas (sweet potatoes) tubers and tryptophan-containing plants. Catalysis by the fungus of phytoalexins induced in the tubers produces four closely related ipomeanols: ipomeanine (IPO), 4-ipomeanol (4-IPO), 1-ipomeanol (1-IPO), and 1,4-ipomeadiol (DIOL). These are not toxic until activated by pulmonary microsomal enzymes; 4-IPO and IPO are ultimately the most toxic. Experimental administration of infected potatoes to calves is associated with bronchiolitis and interstitial pneumonia. Unweaned, nursing calves may not be affected.

Animals are exposed to these toxins in a number of ways. Cows gain access to moldy sweet potatoes by grazing plowed potato fields or being fed spoiled sweet potatoes. The toxic dose is 7.5 mg IPO/kg BW, which converts to about 6 kg of spoiled sweet potatoes per adult cow. The mortality rate is often high. Perilla mint (purple mint or beefsteak plant) is widespread in the south-eastern United States and found in Asia and several other parts of the world. All large animal species are susceptible, but poisoning is most widely reported in cattle.

Cows are exposed by eating the leaves and seeds; toxicity is highest in the seed portion of the plant.

In a similar fashion, tryptophan toxicosis occurs in cows grazing on lush pastures with elevated concentrations of tryptophan. Outbreaks often develop several days to a week after cows are moved from poor pastures or forage to early summer pastures with high tryptophan content in the grasses. Rumen microflora convert tryptophan to 3-methylindole, which is then activated by cytochrome p450 in the lung to a reactive compound.

The clinical signs present in ipomeanol and 3-methylindole toxicosis are similar to acute respiratory distress syndrome and atypical interstitial pneumonia. The reactive compounds produced in the lung damage the pulmonary endothelial cells and result in acute pulmonary emphysema and edema. Affected animals have labored breathing, frequently standing with an open mouth and extended neck. Frothy foam from the nostrils or a foam-covered tongue may be present. Treatment is aimed toward reducing edema, supporting respiration, and reducing physical stress. Animals living longer than 48 hours have a good prognosis for survival.

**GALEGINE TOXICOSES**

Galeign, an isoprenoid guanidine, is found in the following plants:

- Galega officinalis: French honeysuckle
- Schoenus aspercorpus: poison sedge (Australia)
- S. rigens (Australia)
- Verbaisina enceloides: crown beard (North America and Australia)

Ingestion of galeign-containing plants is associated with a syndrome of severe dyspnea, frothing from the nose, convulsions, and sudden death in ruminants as a result of pulmonary edema with large fluid accumulations in the thoracic cavity, the result of a direct effect on pulmonary vascular permeability. Sheep may find access via these plants being mixed in with hay or among a standing crop.

**MANURE GAS POISONING AND CONFINEMENT EFFECTS**

**ETIOLOGY**

Confinement housing of cattle and swine is accompanied by manure storage for varying periods of time, often in large holding pits under slatted floors. Oxygen is excluded from the storage so that anaerobic bacteria degrade the organic and inorganic constituents of manure, yielding hydrogen sulfide, ammonia, methane, and carbon dioxide as major gases. When diluted with water to facilitate handling, liquid manure in storage separates by gravity. The solid wastes form a sediment, the lightweight particles float to the top, leaving a middle layer that is relatively fluid. Thorough remixing is necessary before pits are emptied to prevent the fluid fraction from flowing out and the solids remaining. The remixing or agitation results in the release of large quantities of toxic gases from the slurry.

Besides the well-established gaseous toxicants listed, certain other agents with detrimental inhalation risks are present in confinement operations and have been best characterized for swine confinement operations. Total dust is a major contaminant in swine barns and may range from 2 to 7 mg/m. Particulates may adsorb gases and be part of the objectionable odors released and reaching neighbors near confinement operations. Respirable dusts may be 10% or more of the total dusts generated in swine barns. Such dust is contaminated with bacteria, fungi, endotoxins, and glucans. Dusts are primarily composed of feed or fecal material. Both endotoxins and glucans have been suggested as potential contributors to swine respiratory disease and respiratory complications for workers in swine buildings. So far, however, high mortality and acute death losses in confinement operations are most commonly caused by excessive concentrations of hydrogen sulfide and carbon dioxide, whereas subacute or chronic irritation and disease of the upper respiratory tract may also be contributed by elevated ammonia levels. Methane is explosive and may act as an asphyxiant, but is not implicated as a toxicant.

Additional factors that must be considered in a differential diagnosis include possible water loss during electrical storms or equipment failure; this results in the cessation of the artificial ventilation required to cool the building and exhaust carbon dioxide from the animals’ respiration. In these situations, CO2 levels build rapidly, and environmental temperatures increase dramatically as well, especially when weather conditions...
are hot and humid.\(^1\) Acute loses from hyperthermia or heat stroke may be mistaken for manure gas poisoning.\(^1\) This is important for veterinarians because they may be called to establish a diagnosis that affects insurance claims for many thousands of dollars. Besides overheating and CO\(_2\) accumulation, electrocution should be considered whenever there are large numbers of acute losses in a confinement building.

**PATHOGENESIS**

The exposure of humans, cattle, and swine to high concentrations (above 700 ppm of H\(_2\)S) of manure gases, particularly hydrogen sulfide, can be associated with peracute deaths in cattle and swine. Hydrogen sulfide is both an irritant and an acute toxicant. Fatal or severe exposure often is associated with respiratory distress and pulmonary edema. Exposure to low concentrations of hydrogen sulfide over long periods is thought to be associated with reduced performance in cattle and swine. At high concentrations, from 500 to 1000 ppm, carotid-body receptors are stimulated, causing rapid breathing. As high concentrations continue or increase, the respiratory center is depressed, and animals become depressed and die. High concentrations of H\(_2\)S depress olfactory sensors, and the offensive rotten-egg odor is no longer detected as a warning sign.

Ammonia is either an irritant or corrosive agent depending on the concentration. Ammonia combines with tissue moisture to produce ammonium hydroxide, a strong alkali capable of causing tissue necrosis.

**CLINICAL FINDINGS**

In acute hydrogen sulfide poisoning the animals die suddenly. Affected animals may be found dead throughout a building in various postures of lateral or sternal recumbency. There may be little or no evidence of struggle or excitement because high concentrations can be associated with nearly immediate respiratory paralysis. In acute ammonia poisoning the syndrome includes conjunctivitis, sneezing, and coughing for a few days, but pigs will soon acclimatize, after which no effects may be detectable. An increased incidence of pneumonia and reduced daily weight gains in pigs are associated with exposure to a combination of gaseous ammonia at levels of 50 to 100 ppm and the presence of atmospheric dust in barns. Higher concentrations of ammonia (100-200 ppm) are associated with irritation to the conjunctiva and respiratory mucosa. At very high ammonia concentrations (>500 ppm), there is pharyngeal and laryngeal irritation, laryngospasm, and coughing. Concentrations above 2000 ppm can be associated with death within 30 minutes. Carbon dioxide overexposure first is associated with mild to moderate excitement, followed by depression, weakness, coma, and death. Concentrations above 30% in air are serious, and 40% CO\(_2\) for more than a few minutes can cause death.

**NECROPSY FINDINGS**

In cattle that have died from acute hydrogen sulfide poisoning, lesions include pulmonary edema, extensive hemorrhage in muscles and viscera, and bilaterally symmetric cerebral edema and necrosis. Ammonia exposure results in laceration, conjunctivitis, corneal opacity, tracheal hyperemia or hemorrhages, and pulmonary edema. Secondary bacterial pneumonia may be evident in exposed animals. For carbon dioxide, the principal lesions are of cyanosis.

**CONTROL**

Production of hydrogen sulfide in manure can be inhibited by aeration using air as the oxidizing agent or the use of chemical oxidizing agents. The use of ferrous salts virtually eliminates hydrogen sulfide evolution. Adequate ventilation with all doors and windows wide open during remixing and agitation of the slurry will reduce the concentration of hydrogen sulfide to nontoxic levels. Animals and personnel should not enter closed barns when the pits are being emptied. In confinement buildings, ammonia usually does not accumulate to fatal levels, but much of the economic loss is from reduced feed consumption and possibly increased susceptibility to acute or chronic respiratory disease. Limiting protein supplementation to actual needs has been considered a means for reducing nitrogen losses and the resultant production of ammonia in feces and urine.

**FURTHER READING**

**REFERENCES**

**PLANTS CAUSING PULMONARY DISEASE (UNIDENTIFIED TOXINS)**

The following plants have been associated with pulmonary disease. The toxins currently are unidentified.

Dyspnea and pulmonary edema:

- *Glechoma hederacea* (= *Nepeta hederacea*; ground ivy)
- *Gyrostenon* spp.: camel poison

Pulmonary consolidation and fibrosis, characterized by dyspnea and cough (horses):

- *Eupatorium (= Ageratina)* adenophorum: crofton weed
- *E. riparium*: mist flower
- *Lactuca scariola*: prickly lettuce

**Neoplastic Diseases of the Respiratory Tract**

Neoplasms arising as a result of viral infection (nasal adenocarcinoma of sheep, ovine pulmonary adenocarcinoma) and non-neoplastic tumors (equine ethmoidal hematomata) are dealt with under those headings in this chapter.

**PULMONARY AND PLEURAL NEOPLASMS**

Primary neoplasms of the lungs, including carcinomas and adenocarcinomas, are rare in animals and metastatic tumors also are relatively uncommon in large animals. Primary tumors reported in lungs or pleura of the farm animal species include the following:

**Horses**

- Granular cell tumors are the most common tumor arising in the pulmonary tissue of horses.
- Malignant melanomas in adult gray horses
- Pulmonary adenocarcinoma (either primary or as metastatic disease)
- Pulmonary leiomyosarcoma
- Bronchogenic carcinoma, pulmonary carcinoma, bronchogenic squamous-cell carcinoma, pulmonary chondrosarcoma, and bronchial myxoma are all rare tumors in lungs of horses.
- Mesothelioma arise from the visceral or parietal pleura.

**Cattle**

- Pulmonary adenocarcinoma is the most commonly reported primary lung tumor in cattle. The ultrastructure and origin of some of these have been characterized.
- Lymphomatosis in young cattle may be accompanied by pulmonary localization

**Sheep**

- Ovine pulmonary adenocarcinoma (jaagsiekte sheep retrovirus) is locally common in some areas.

**Goats**

- An asymptomatic, squamous-cell-type tumor, thought to be a benign papilloma, has been observed in 10 of a series of 1600 adult Angora goats. The lesions were mostly in the diaphragmatic lobes, were
multiple in 50% of the cases, and showed no evidence of malignancy, although some had necrotic centers.

- Bronchoalveolar carcinoma not related to ovine adenocarcinoma virus is reported. A wide variety of tumors metastasize to the lungs, and these tumors can originate in almost any tissue or organ. A series of thoracic neoplasms in 38 horses included lymphosarcoma, metastatic renal cell carcinoma, primary lung carcinomas, secondary cell carcinoma from the stomach, pleural mesothelioma, and malignant melanoma.

The etiology of the tumors is unknown in most cases, apart from those arising from viral infections. Equine granular cell tumors arise from the Schwann cells of the peripheral nervous system in the lungs. Characteristically, primary pulmonary or pleural tumors arise in middle-aged to old animals. The prevalence of these tumors is not well documented, although they are rare in abattoir studies of horses. The tumors occur sporadically, with the exception of those associated with infectious agents (bovine lymphomatosis, ovine pulmonary adenocarcinoma).

The pathogenesis of pulmonary tumors includes impairment of gas exchange, either by displacement of normal lung with tumor tissue and surrounding atelectasis and necrosis or by obstruction of the large airways (e.g., granular cell tumor in horses).

**CLINICAL FINDINGS**

Clinical findings are those usually associated with the decrease in vital capacity of the lungs and include dyspnea that develops gradually, cough, and evidence of local consolidation on percussion and auscultation. There is no fever or toxemia, and a neoplasm can be mistaken for a chronic, encapsulated pulmonary abscess. Major clinical findings included weight loss, inappetence, and dyspnea and coughing. An anaplastic small-cell carcinoma of the lung of a 6-month-old calf located in the anterior thorax caused chronic bloat, anorexia, and loss of body weight. Some tumors, notably mesothelioma and adenocarcinoma, cause accumulation of pleural fluid. Hypertrophic pulmonary osteopathy occurs in some animals with pulmonary tumors.

Ovine pulmonary adenocarcinoma can metastasize to liver, kidneys, skeletal muscle, gastrointestinal tract, spleen, skin, and adrenal glands.

**Granular cell tumors** in horses present as chronic coughing and exercise intolerance in horses without signs of infectious disease. As the disease progresses, there is increased respiratory rate and effort and weight loss, suggestive of severe heaves. However, horses are unresponsive to treatment for heaves. The disease can progress to cor pulmonale and right-sided heart failure. A bronchial mass is evident on endoscopic or radiographic examination (Figs. 12-34 and 12-35). There are no characteristic hematologic or serum biochemical changes.

Hemangiosarcomas of the thoracic cavities of horses occur and are evident as excess pleural fluid with a high red blood cell count.

**Thymoma, or lymphosarcoma** as a part of the disease bovine viral leukosis, is not uncommon in cattle and can resemble pulmonary neoplasm, but there is usually displacement and compression of the heart, resulting in displacement of the apex beat and congestive heart failure. The presence of jugular engorgement, ventral edema, tachycardia, chronic tympany, and hydropericardium can cause a mistaken diagnosis of traumatic pericarditis. Mediastinal tumor or abscess (cranial thoracic masses) can have a similar effect. Metastasis to the bronchial lymph nodes can cause obstruction of the esophagus with dysphagia, and in cattle chronic ruminal tympany. This tumor is also common in goats, many of which show no clinical illness.

**Radiographic or ultrasonographic** examination is useful in demonstrating the presence of a mass in the lungs or thorax. **Endoscopic examination** is useful for detection of tumors that invade the larger airways, such as granular cell tumors of horses. Thoracoscopy and pleural biopsy can be useful in the diagnosis of lesions at the pleural surfaces.

The nature of the tumor can sometimes be determined by examination of pleural fluid, into which some tumors shed cells, or of tumor tissue obtained by biopsy. Examination of pleural fluid for the presence of tumor cells is not very sensitive because many tumors do not shed sufficient numbers of cells to be detectable, but it is quite specific in that detection of abnormal cells is diagnostic.

**TREATMENT**

There is no effective treatment, with the exception of resection of localized tumors. Granular cell tumors in horses have been successfully treated by lung resection or transendoscopic electrosurgery.

REFERENCES

Congenital and Inherited Diseases of the Respiratory Tract

CONGENITAL DEFECTS

Primary congenital defects are rare in the respiratory tracts of animals. Congenital defects of the soft palate of foals have been sporadically reported; horses with minor defects can grow normally and may be able to have a successful athletic career for their intended use. Hypoplasia of the epiglottis is detected occasionally in horses. Tracheal hypoplasia is recognized in calves and miniature horses. Bronchogenic cysts are rare in foals and calves and result from the abnormal development of the tracheobronchial system during the embryonic period. Bronchogenic cysts can cause respiratory distress and dysphagia, particularly when located in the cervical region. Secondary defects, which are associated with major defects in other systems, are more common. Most of the defects are associated with defects of the oral cavity, face, and cranial vault, particularly cleft palate. Accessory lungs are recorded occasionally, and if their bronchi are vestigial, the lungs can present themselves as tumor-like masses occupying most of the chest. Pulmonary hypoplasia has been associated with congenital diaphragmatic hernia. Retrosternal hernia (Morgagni hernia), which is a right ventral diaphragmatic defect, has been surgically corrected in adult horses as a result of incarceration of the large colon; in all cases the defect was thought to be congenital.

How to Use This Book

We would like you to get the most out of this book. To do that, you should follow the directions provided in this section. And if you keep doing this every time you use the book, you will develop a proper diagnostic routine of going from:

1. **Clinical sign**
2. **System involved**
3. **Location and type of lesion**
4. **Specific cause of the disease**

... and become what we wish for every one of you: a thinking clinician.

**FOR EXAMPLE**

A yearling bull has a sudden onset of dyspnea, fever, anorexia, abnormal lung sounds, and nasal discharge.

**Step 1** The bull's problem is dyspnea. Go to the index and find the principal entry for dyspnea.

**Step 2** The discussion on dyspnea will lead you to respiratory tract dyspnea and cardiac dyspnea.

**Step 3** Via the index, consult these and decide that the system involved is the respiratory system and that the lungs are the location of the lesion in the system.

**Step 4** Proceed to diseases of the lungs and decide on the basis of the clinical and other findings that the nature of the lesion is inflammatory and is pneumonia.

**Step 5** Proceed to pneumonia, and consult the list of pneumonias that occur in cattle. Consult each of them via the index and decide that pneumonic pasteurellosis is the probable specific cause.

**Step 6** Proceed to the section on pneumonic pasteurellosis and determine the appropriate treatment for the bull and the chances of saving it.

**Step 7** Don't forget to turn to the end of the section on pneumonic pasteurellosis and remind yourself of what to do to protect the rest of the herd from sharing the illness.

**Guidelines for Selection and Submission of Necropsy Specimens for Confirmation of Diagnosis**

In this edition we continue with the subheading **Samples for Confirmation of Diagnosis** to serve as a rough guideline for the collection of samples at necropsy. Several points must be emphasized with regard to this section. First and foremost, collection of these samples is not advocated as a substitute for a thorough necropsy examination. Furthermore, the samples listed are selected to confirm the diagnosis, but a conscientious diagnostician should also collect samples that can be used to rule out other disease processes. Even the best of practitioners can make an incorrect tentative diagnosis, but it is an even more humbling experience if there are no samples available to pursue alternate diagnoses. Also, recall that some diseases may be the result of several different etiologic factors (e.g., neonatal diarrhea of calves), and the veterinarian who samples to confirm one of these factors but does not attempt to investigate others has not provided a good service to the client.

A huge variety of veterinary diagnostic tests have been developed, but each veterinary diagnostic laboratory (VDL) offers only a selected panel, chosen after consideration of a number of factors. Such factors may include cost, demand, reliability, sensitivity and specificity, and the availability of appropriate technology at the lab. The array of diagnostic tests is constantly improving, and it is beyond the scope of this text to list all the tests available for a given disease or to recommend one test method to the exclusion of others. Under the **Samples for Confirmation of Diagnosis** sections, we have merely listed some of the more common tests offered. Advances in molecular biology are providing exciting avenues for disease diagnosis, but many of these tests have limited availability in VDLs at present. For optimal efficiency in the confirmation of a diagnosis at necropsy, the practitioner must contact the VDL to determine what tests are offered and to obtain the preferred protocol for sample collection and submission to that particular laboratory. Most VDLs publish user guidelines, which include the tests available and the samples required. The guidelines listed here are broad, and individual VDLs may have very specific requirements for sample handling.

Several general statements can be made with regard to the submission of samples to VDLs:

- The samples should be accompanied by a clearly written and concise clinical history, including the signalment of the animal and feeding and management information. Failure to provide this information deprives the owner of the full value of the expertise available from the laboratory staff.
- If a potentially zoonotic disease is suspected, this should be clearly indicated in a prominent location on the submission form.
- All specimens should be placed in an appropriate sealed, leak-proof container and clearly labeled with a waterproof marker to indicate the tissue/fluid collected, the animal sampled, and the owner's name. At some VDLs, pooling of tissues within a single bag or container is permitted for specific tests (such as virus isolation), but in general, all fresh samples should be placed in separate containers. When packaging samples for shipment, recognize that condensation from ice packs and frozen tissues will damage any loose paper within the package; the submission sheet should be placed within a plastic bag for protection or taped to the outside of the shipping container.
- Samples for histopathology can be pooled within the same container of 10% neutral-buffered formalin. An optimal tissue sample of a gross lesion should include the interface between normal and abnormal tissue. For proper fixation, tissue fragments should not be more than 0.5 cm in width, and the ratio of tissue to formalin solution should be 1:10. If necessary, large tissues such as brain can be fixed in a larger container and then transferred to a smaller one containing only a minimal quantity of formalin for shipping to the laboratory. To speed fixation and avoid artifactual changes, formalin containers should not be in direct contact with frozen materials during shipment.
In the Samples for Confirmation of Diagnosis sections, the tests are listed under various discipline categories (bacteriology, virology, etc.). The appropriate sample(s) is noted, followed by the types of test that might be applied to these samples. The following is a list of these different tests, including any abbreviation used in this section of the text. A brief discussion of how the samples collected for each test should be handled is also provided. Again, it must be emphasized that this is by no means a complete listing of diagnostic tests available, and different VDLs often have differing sample handling procedures.

- **Aerobic culture** = (CULT). These samples should generally be kept chilled during shipment. If a transit time of greater than 24 hours is anticipated the samples should be frozen, then packaged appropriately so that they are still frozen upon arrival at the VDL. Various bacterial species cannot be recovered using routine culture techniques, and most of these are highlighted in the text by the phrase "special culture requirements."

- **Agar gel immunodiffusion** = (AGID). A type of serologic test. Chilled or frozen serum may be submitted.

- **Anaerobic culture** = (ANAEROBIC CULT). Confirmation of the diagnosis requires that any swabs be transported in special transport media and that the VDL attempts to grow bacteria from the samples under anaerobic culture conditions. Transport requirements are as for (CULT) (aerobic culture) specimens.

- **Analytical assay** = (ASSAY). This refers to a broad range of tests in which a substance is quantitatively measured. The substance to be assayed is listed in brackets, e.g. (ASSAY [Ca]) denotes a test for calcium levels. The method used to perform the assay is not listed, but in general, frozen samples may be submitted for most of these analytical assays.

- **Bioassay** = (BIOASSAY). This typically refers to tests in which the sample material is administered to an animal under experimental conditions. Preserved material is inappropriate, and some bioassays cannot be performed using samples that have been frozen. The VDL performing the test should be contacted for instructions prior to sample collection.

- **Complement fixation** = (CF). A serologic test. Ship chilled or frozen serum.

- **Cytology** = (CYTO). Air-dried impression smears are usually adequate. Keep dry during transport.

- **Direct smear** = (SMEAR). The type of test is usually given in brackets (e.g., [Gram]). Air-dried smears are usually adequate but must be kept dry during shipment.

- **Enzyme-linked immunosorbent assay** = (ELISA). Chilled or frozen samples are usually acceptable. There are many variants of ELISA (e.g., antigen-capture, kinetic, indirect, direct, etc.), and the specific type used is not specified in this portion of the text.

- **Electron microscopic examination** = (EM). Appropriate sample collection and handling varies with the specimen being examined. Most of the diagnostic specimens submitted to VDLs for EM are fecal samples, and these do not require any special preservative.

- **Fecal floatation** = (FECAL). Sample can be fresh, chilled, or frozen.

- **Fluorescent antibody test** = (FAT). This may refer to either a direct or indirect method of antigen detection. Generally, cryostat sections are utilized, and therefore the tissue received by the laboratory should still be frozen upon arrival to provide the best results. Freeze/thaw cycles should be avoided. If impression smears are being shipped, they should be kept dry.

- **Fungal culture** = (FCULT). Special media is required. Transport as per (CULT) specimens.

- **Immunohistochemical testing** = (IHC). Many of these tests can be performed on formalin-fixed material, but in some instances frozen tissues must be delivered to the laboratory. In such instances the test is listed under a heading distinct from histology (e.g., virology, bacteriology, etc.).

- **Indirect hemagglutination** = (IHA). A serologic test. Ship chilled or frozen serum.

- **In-situ hybridization** = (IN-SITU HYBRID). Samples should be shipped chilled, although some test methods can use formalin-fixed material. These tests utilize nucleic acid probes that bind with complementary nucleic acid sequences in the specimen. Although not widely used in routine diagnostics at present, these methods may gain more prominence as their use is refined.

- **Virus isolation** = (ISO). Samples should be kept chilled during shipment or maintained in a frozen state if prolonged transit times are anticipated.

- **Latex agglutination** = (LATEX AGGLUTINATION). Fresh, chilled, or frozen samples are acceptable.

- **Light microscopic examination** = (LM). Formalin-fixed tissues are preferred. The shipment of fresh tissues to the VDL permits more tissue autolysis prior to fixation, resulting in less useful specimens. If Bouin’s fixative is available, it is the preferred preservative for eye globes.

- **Microagglutination test** = (MAT). A type of serologic test. Ship chilled or frozen serum.

- **Mycoplasmal culture** = (MCULT). These types of organism have specific growth requirements that are usually not met by standard bacteriologic culture techniques. Transport as per (CULT) specimens. Culture swabs cannot be submitted in media containing charcoal or glycerol.

- **Polymerase chain reaction** = (PCR). Tissues should be frozen and maintained in that state until arrival at the VDL. Swabs and fluids submitted for PCR testing should be chilled but not frozen. These tests are capable of detecting minute quantities of nucleic acid, so if multiple animals are tested, the samples should be “clean” to avoid false positives through cross-contamination (i.e., blood/tissue from one animal contaminating the sample from another)

- **Serum urea nitrogen** = (SUN). A useful test to determine degree of renal compromise. Sample can be shipped chilled or frozen.

- **Virus neutralization** = (VN). A serologic test. Ship chilled or frozen serum.

Diseases of the Urinary System

Introduction

Diseases of the bladder and urethra are more common and more important than diseases of the kidneys in farm animals. Occasionally, renal insufficiency develops as a sequel to diseases such as pyelonephritis, embolic nephritis, amyloidosis, and nephrosis. Knowledge of the physiology of urinary secretion and excretion is required to properly understand disease processes in the urinary tract. The principles of renal insufficiency presented here are primarily extrapolated from research in other species, particularly human medicine. Although generally these principles probably apply to farm animals, the details of renal function and renal failure in farm animals have just started to be studied in depth.

Principles of Renal Insufficiency

The kidneys excrete the end products of tissue metabolism (except for carbon dioxide), and maintain fluid, electrolyte, and acid-base balance, by varying the volume of water and the concentration of solutes in the urine. For conceptual purposes it is helpful to think of the kidney as composed of many similar nephrons, which are the basic functional units of the kidney. Each nephron is composed of blood vessels, the glomerulus, and a tubular system that consists of the proximal tubule, the loop of Henle, the distal tubule, and the collecting duct.

The glomerulus is a semipermeable filter that allows easy passage of water and low molecular weight solutes, such as electrolytes, glucose, and keto acids, but restricts passage of high molecular weight substances, such as plasma proteins. Glomerular filtrate is derived from plasma by simple passive filtration driven by arterial blood pressure. Glomerular filtrate is identical to plasma except that it contains little protein or lipids. The volume of filtrate, and therefore its content of metabolic end products, depends on the hydrostatic pressure and the plasma oncotic pressure in the glomerular capillaries and on the proportion of glomerular capillaries and on the proportion of glomeruli, which are functional. Because these factors are only partially controlled by the kidney, in the absence of disease, the rate of filtration through the glomeruli is relatively constant.

Epithelial cells in the renal tubules actively and selectively reabsorb substances from the glomerular filtrate while permitting the excretion of waste products. Proximal...
Renal dysfunction tends to be a dynamic process so the degree of dysfunction varies with time. If renal dysfunction is so severe that the animal’s continued existence is not possible, it is said to be in a state of renal failure, and the clinical syndrome of uremia will be present.

CAUSES OF RENAL INSUFFICIENCY AND UREMIA

The causes of renal insufficiency, and therefore of renal failure and uremia, can be divided into prerenal, renal, and postrenal groups.

Prerenal causes include congestive heart failure and acute circulatory failure, either cardiac or peripheral, in which acute renal ischemia occurs in response to a decrease in renal blood flow. Proximal tubular function is affected by renal ischemia to a much greater extent than the glomerulus or distal tubules; this is because of the high metabolic demands of the proximal tubules. However, those parts of the tubules within the medulla are particularly susceptible to hypoxic damage because of the low oxygen tension in this tissue, the dependency of blood flow on glomerular blood flow, and the high metabolic rate of this tissue. Renal medullary necrosis is a direct consequence of these factors.

Renal causes include glomerulonephritis, amyloidosis, pyelonephritis, embolic nephritis, and interstitial nephritis. Acute renal failure can be produced in any of the farm animal species by administration of a variety of toxins (see the section Toxic Nephrosis). The disease is also secondary to sepsis and hemorrhagic shock. Experimental uremia has also been induced by surgical removal of both kidneys but the results, especially in ruminants, are quite different from those in naturally occurring renal failure. The clinical pathology is similar, but there is a prolonged period of normality after the surgery.

Postrenal uremia may also occur, specifically complete obstruction of the urinary tract by vesical or urethral calculus, or more rarely by bilateral urethral obstruction by transitional cell carcinoma located in the trigone region of the bladder. Internal rupture of any part of the urinary tract, such as the bladder, ureters, or urethra, will also cause postrenal uremia.

PATHOGENESIS OF RENAL INSUFFICIENCY AND RENAL FAILURE

Damage to the glomerular epithelium destroys its selective permeability and permits the passage of plasma proteins into the glomerular filtrate. The predominant protein is initially albumin, because of its negative charge and a lower molecular weight than globulins; however, with advanced glomerulonephritis (such as renal amyloidosis) all plasma proteins are lost. Glomerular filtration may cease completely when there is extensive damage to glomeruli, particularly if there is acute swelling of the kidney, but it is thought that anuria in the terminal stages of acute renal disease is caused by back diffusion of all glomerular filtrate through the damaged tubular epithelium rather than failure of filtration. When renal damage is less severe, the remaining nephrons compensate to maintain total glomerular filtration by increasing their filtration rates. When this occurs, the volume of glomerular filtrate may exceed the capacity of the tubular epithelium to reabsorb fluid and solutes. The tubules may be unable to achieve normal urine concentration. As a result, an increased volume of urine with a constant specific gravity is produced and solute diuresis occurs. This is exacerbated if the tubular function of the compensating nephrons is also impaired. The inability to concentrate urine is clinically evident as polyuria and is characteristic of developing renal insufficiency.

Decreased glomerular filtration also results in retention of metabolic waste products such as urea and creatinine. Although marked increases in serum urea concentrations are probably not responsible for the production of clinical signs, because urea readily crosses cell membranes and therefore is an ineffective osmole, the serum urea nitrogen (SUN) concentration can be used to monitor glomerular filtration rate. However, the utility of SUN concentration as a measure of glomerular filtration rate is reduced because serum urea concentrations are influenced by the amount of protein in the diet, by hydration, and by gastrointestinal metabolism of urea. Serum urea concentrations are substantially higher in animals on high-protein diets, and dehydration increases serum urea concentration by increasing resorption of urea in the loop of Henle, which is independent of effects of hydration of the glomerular filtration rate. Urea is excreted into saliva of ruminants and metabolized by ruminal bacteria. In contrast, creatinine is excreted almost entirely by the kidney, creatinine originates from the breakdown of creatine phosphate in muscle, and serum concentrations of creatinine are a useful marker of glomerular filtration rate. The relationship between serum creatinine concentration and glomerular filtration rate is hyperbolic (a reduction in glomerular filtration rate by half results in a doubling of the serum creatinine concentration). Phosphate and sulfate retention also occurs when total glomerular filtration is reduced and sulfate retention contributes to metabolic acidosis in renal insufficiency. Phosphate retention also causes a secondary hypocalcemia, due in part to an increase in calcium excretion in the urine. In horses, the kidneys are an important route of calcium excretion; thus the decreased glomerular filtration rate present in horses with chronic renal failure usually results in hypercalcemia. Variations in serum potassium concentrations also occur and appear to...
Depend on potassium intake. Hyperkalemia is not usually a serious complication of renal insufficiency in ruminants because affected animals often have decreased appetites and therefore reduced potassium intakes, and excess saliva can be excreted by the salivary glands and ultimately the feces.

Loss of tubular resorptive function is evidenced by a continued loss of sodium and chloride; hyponatremia and hypochloremia eventually occur in all cases of renal failure. The continuous loss of large quantities of fluid from solute diuresis can cause clinical dehydration. More often it makes the animal particularly susceptible to dehydration when there is an interruption in water availability or when there is a sudden increase in body water loss by another route, as in diarrhea.

The terminal stage of renal insufficiency, renal failure, is the result of the cumulative effects of impaired renal excretory and homeostatic functions. Sustained excretion of large volumes of dilute urine results in dehydration. If other circulatory emergencies arise, acute renal ischemia might result, leading to acute renal failure. Prolonged hypoproteinemias result in rapid loss of body condition and muscle weakness. Acidemia secondary to metabolic acidosis and hypoproteinemia can also be a contributory factor to muscle weakness and mental attitude. All these factors play some part in the production of clinical signs of renal failure, which are typically manifested as weakness, lethargy, inappetence and, with extensive glomerular lesions, dependent edema caused by hypoproteinemia. However, the clinical syndrome is variable and rarely diagnostic for renal failure. Bleeding diathesis can also be present in severely uremic animals and has been associated with a lack of antithrombin (a small protein readily lost through the skin) and hypoproteinemia. Therefore, in addition to the preceding list, platelet dysfunction, or disseminated intravascular coagulation.

Renal failure is seen as the clinical state of uremia. Uremic animals exhibit clinical signs of disease, which should be compared with azotemic animals that have an increase in the plasma or serum concentrations of urea and creatinine and retention of other solutes as described earlier, but do not necessarily have clinical signs of disease.

Clinical Features of Urinary Tract Disease

The major clinical manifestations of urinary tract disease are

- Abnormal constituents of urine
- Variations in daily urine flow
- Abdominal pain, painful urination (dysuria), and difficult urination (dysuria and stranguria)
- Abnormal sized kidneys

- Abnormalities of the bladder and urethra
- Acute and chronic renal failure

ABNORMAL CONSTITUENTS OF THE URINE

Laboratory analysis of urine is initially done using dipstick and refractometry on a voided or catheterized urine sample and microscopic examination of the sediment from a centrifuged urine sample. Urine dipsticks and refractometry (optical and digital) provide excellent low-cost point-of-care tests for evaluation of the urinary system. Widely available urine dipsticks typically measure 1 factor (acetoacetate), 5 factors (blood, glucose, acetone, pH, and protein) or 10 factors (blood, glucose, bilirubin, acetoacetate, pH, protein, specific gravity, urobilinogen, nitrite, and leukocytes). Specific information regarding tests of renal function and injury conducted on urine, such as specific gravity and osmolality, enzymuria, and quantitative proteinuria and glycosuria, are discussed later in this chapter.

VARIATIONS IN DAILY URINE FLOW

An increase or decrease in urine flow is often described in animals, but accuracy demands physical measurement of the amount of urine voided over a 24-hour period. This is not usually practicable in large-animal practice, and it is often necessary to guess whether the flow is increased or decreased. Accurate measurement of the amount of water consumed is often easier and is usually used to estimate 24-hour urine production. Care should be taken to differentiate increased daily urine flow from increased frequency in urination without increased daily flow. The latter is much more common. Decreased urine output rarely, if ever, presents as a clinical problem in agricultural animals.

Normal urine production is highly variable in large animals and is dependent to a large extent on diet, watering systems, and the palatability of the water. Pregnant mares housed in tie stalls consume approximately 53 ± 6 mL of water per kilogram body weight (BW) per day, of which 50 ± 8 mL/kg is from drinking water with the remainder being water in feed. However, most of this water is excreted in the feces, with fecal and urinary water excretion being 34 ± 8 (mL/kg)/day and 8 ± 2 (mL/kg)/day, respectively. Neonatal foals produce urine at an average rate of 150 (mL/kg)/day.

Polyuria

Polyuria occurs when there is an increase in the volume of urine produced over a 24-hour period. Polyuria can result from extrarenal causes, such as when horses habitually drink excessive quantities of water (psychogenic polydipsia) and, much less common, in central diabetes insipidus, when there is inappropriate secretion of ADH from the pituitary, or when there is failure of the tubules to respond to ADH (nephrogenic diabetes insipidus). Polyuria occurs in horses with tumors of the pars intermedia of the pituitary gland. Although the cause of the polyuria is not known, it might be secondary to osmotic diuresis associated with the glucosuria or to central diabetes insipidus. Central diabetes insipidus is reported in sibling colts but is extremely rare in other species with isolated reports in a ram and a cow. Another extrarenal cause is administration of diuretic drugs, including corticosteroids.

Kidney disease results in polyuria when the resorptive capacity of the remaining tubules is exceeded. Polyuria can also occur when the osmotic gradient in the renal medulla is not adequate to produce concentrated urine. Nephrogenic diabetes insipidus causes polyuria because the tubules fail to respond to ADH.

When polyuria is suspected, a urine sample should be collected to determine specific gravity or osmolality. If urine is isoosmotic with a constant specific gravity of 1.008 to 1.012 (the specific gravity of plasma), then the presence of renal disease should be strongly considered. Serum urea and creatinine concentrations should be determined to evaluate glomerular filtration. If serum urea and creatinine concentrations are within normal limits, a water deprivation test can be performed to assess the animal’s ability to produce concentrated urine.

Oliguria and Anuria

Reduction in the daily output of urine (oliguria) and complete absence of urine (anuria) occur under the same conditions and vary only in degree. In dehydrated animals, urine flow naturally decreases in an effort to conserve water as plasma osmolality increases. Congestive heart failure and peripheral circulatory failure may cause a reduction in renal blood flow that oliguria follows. Complete anuria is most common in urethral obstruction, although it can also result from acute tubular necrosis. Oliguria occurs in the terminal stages of all forms of nephritis. Anuria and polyuria lead to retention of solutes and disturbances of the acid-base balance that contribute to the pathogenesis of uremia.

Pollakiuria

This is an increase in the daily number of postures for urination and is usually accompanied by a decreased volume of urine. Pollakiuria may occur with or without an increase in the volume of urine excreted and is commonly associated with disease of the lower urinary tract such as cystitis, the presence of calculi in the bladder, urethritis, and partial obstruction of the urethra. Other causes of pollakiuria include equine
Diseases

VetBooks.ir

perineum and tail head. Efforts at urination accompanied by grunting may occur with painful urination, and the animal may remain in the typical posture after urination is completed. Differentiating pain caused by urinary disease from pain caused by other causes depends largely on the presence of other signs indicating urinary tract involvement.

**Stranguria** is slow and painful urination associated with disease of the lower urinary tract including cystitis, vesical calculus, urethral obstruction, and urethritis. The animal strains to pass each drop of urine. Groaning and straining may precede and accompany urination when there is urethral obstruction. In urethritis, groaning and straining occur immediately after urination has ceased and gradually disappear and do not recur until urination has been repeated.

Urine scalding of the perineum or urinary burn is caused by frequent wetting of the skin with urine. It may be the result of urinary incontinence or the animal’s inability to assume normal posture when urinating.

**Morphologic Abnormalities of the Kidneys and Ureters**

Enlarged or decreased size of kidneys may be palpable on rectal examination or detected by ultrasonography. In cattle, gross enlargement of the posterior aspect of the left kidney may be palpable in the right upper flank. Abnormalities of the kidneys, such as hydronephrosis in cattle, may also be palpable on rectal examination. Increases in the size of the ureter may be palpable on rectal examination and indicate ureteritis or hydronephrosis.

**Palpable Abnormalities of the Bladder and Urethra**

Abnormalities of the bladder that may be palpable by rectal examination include gross enlargement of the bladder, rupture of the bladder, a shrunken bladder following rupture, and palpable abnormalities in the bladder such as cystic calculi. Abnormalities of the urethra include enlargement and pain of the pelvic urethra and its external aspects in male cattle with obstructive urolithiasis and obstruction of the urethral process of male sheep with obstructive urolithiasis.

**Acute and Chronic Renal Failure**

The clinical findings of urinary tract disease vary with the rate of development and stage of the disease. In most cases, the clinical signs are those of the initiating cause. In horses, depression, colic, and diarrhea are common with oliguria or polyuria. Clinical signs in cattle with uremia are similar and in addition are frequently recumbent, and in severe and terminal cases cattle may have a bleeding diathesis. In chronic renal disease of all species, there is a severe loss of BW, weakness, anorexia, polyuria, polydipsia, and ventral edema.

**Uremia**

Uremia is the systemic state that occurs in the terminal stages of renal insufficiency. Anuria or oliguria may occur with uremia. Oliguria is more common unless there is complete obstruction of the urinary tract. Chronic renal disease is usually manifested by polyuria, but oliguria appears in the terminal stages when clinical uremia develops. The uremic animal is depressed and anorexic with muscular weakness and tremor. In chronic uremia, the body condition is poor, probably as a result of continued loss of protein in the urine, dehydration, and anorexia. The respiration is usually increased in rate and depth but is not dyspneic; in the terminal stages it may become periodic in character. The heart rate is markedly increased because of terminal dehydration, but the rectal temperature remains normal except in infectious processes and some cases of acute tubular nephrosis. An ammoniakal or uriniferous smell on the breath is often described in textbooks but is rarely clinically detectable. **Uremic encephalopathy** occurs in a small proportion of cattle, goats, and horses with chronic renal failure that involves an unknown metabolic pathway. It is associated with seizures, tremors, abnormal behavior, and muscle weakness, and histologic evidence of myelin vacuolation may be present.

The animal becomes recumbent and comatose in the terminal stages of uremia. The temperature falls to below normal and death occurs quietly; the whole course of the disease is one of gradual intoxication. Necropsy findings, apart from those of the primary disease, are nonspecific and include degeneration of parenchymatous organs, sometimes accompanied by emaciation and moderate gastroenteritis.

Uremia has been produced experimentally in cattle by bilateral nephrectomy and ureteral ligation. There is a progressive increase in serum urea concentration (mean daily increase of 53 mg/dL), serum creatinine concentration (mean daily increase of approximately 3.5 mg/dL), and serum uric acid concentration. Similar findings are reported in prerenal uremia in cattle. Interestingly, serum phosphate and potassium concentrations were for the most part unchanged because of increased salivary secretion of both factors, and acidemia and metabolic acidosis were not evident. Serum potassium concentrations were mildly increased after 5 to 7 days of bilateral nephrectomy.
Special Examination of the Urinary System

Lack of accessibility limits the value of physical examination of the urinary tract in farm animals. Palpation per rectum can be performed on horses and cattle and is described in Chapter 7 and 8. In small ruminants and calves the urinary system is largely inaccessible to physical examination, although the kidneys may be palpated transabdominally and the urethra palpated digitally with the finger for periodic contractions that are common in male sheep and goats with obstructive urolithiasis. Urinalysis and determination of the serum or plasma concentration of urea nitrogen or creatinine is a required component of any examination of the urinary system.

TESTS OF RENAL FUNCTION AND DETECTION OF RENAL INJURY

The simplest and most important test of urinary function is the determination of whether or not urine is being voided. This can be accomplished in large animals by keeping them on a clean, dry floor that is examined periodically. Placing an absorbent cloth under recumbent foals and calves will also help determine whether urine is being passed.

Renal function tests evaluate the functional capability of the kidney and generally assess blood flow to the kidneys, glomerular filtration, and tubular function. These tests depend on whether they are based on the examination of serum/plasma, urine, or both, and assess either function or the presence of injury. The most practical screening tests for the presence of decreased renal function are determination of serum creatinine concentration and urine specific gravity. Determination of both factors assists differentiation of renal azotemia from prerenal azotemia. In prerenal azotemia, tubular function remains intact and renal conservation of water is optimized, resulting in the production of concentrated urine. Animals with prerenal azotemia therefore have increased serum concentrations of creatinine and urea and increased urine specific gravity. For comparison, animals with some degree of renal azotemia have increased serum concentrations of creatinine and urea and a lower than expected value for urine specific gravity. Determination of urine specific gravity should therefore be routinely performed in all dehydrated animals before the initiation of treatment, because oral or intravenous (IV) fluid therapy will directly change urine specific gravity.

COLLECTION OF URINE SAMPLES

Collection of urine samples can be difficult. Free-flow and catheterized samples are equally useful for routine urinalysis. Urine samples for analysis should be collected by midstream voiding, or cystocentesis in small male ruminants, preferably with ultrasonographic guidance. Bethanechol (0.075 mg/kg subcutaneously) has occasionally been used to produce urine in reluctant individuals, but a spontaneously voided sample is preferred for initial screening, which is routinely done using urine dipsticks.

Horses will often urinate shortly after they are walked into a freshly bedded box stall. Cows urinate if they are relaxed and have their perineum and vulval tip massaged upward very gently, without touching the tail. Success rates in obtaining a urine sample can approach 100% if cows are recumbent and quietly encouraged to stand before attempting perineal stimulation to induce urination. Steers and bulls may urinate if the preputial orifice is massaged and splashed with warm water. Ewes often urinate immediately after rising if they have been recumbent for some time. Occluding their nostrils and threatening asphyxia may also induce urination just as they are released and allowed to breathe again; however, this is a stressful procedure and should not be performed in sick or debilitated sheep. An IV injection of furosemide (0.5–1.0 mg/kg BW) produces urination in most animals in about 20 minutes. The sample is useful for microbiologic examination but its composition has been drastically altered by the diuretic. Diuretics should be used with extreme caution in dehydrated animals.

Urine samples obtained by bladder catheterization using a urethral catheter are preferred for microbiologic examination, provided aseptic technique is applied, including bandaging the tail of female horses or holding the tail of cattle out of the way. The perineal region should then be cleaned with dilute povidone iodine or chlorhexidine to minimize urinary tract contamination, and there should be routine use of sterile surgical gloves and lubrication. Rams, boars, and young calves usually cannot be catheterized without fluoroscopy because of the presence of a suburethral diverticulum and the small diameter of the urethra. A precurved catheter and fluoroscopic guidance can be used to facilitate catheterization of rams and bucks. Ewes and sows can be catheterized, but their vulvas are often too small to allow access to the urethra. Cows can be catheterized relatively simply provided that a fairly rigid, small-diameter (0.5-cm) catheter is used, such as an artificial insemination pipette. A finger can be inserted into the suburethral diverticulum on the ventral aspect to direct the tip of the catheter over the diverticulum and into the external urethral orifice (Fig. 13-1). For longer term catheterization of adult cattle (3 days), 24- to 28-French Foley catheters are placed into the bladder using the same insertion method; however, insertion of Foley catheters is facilitated by application of sterile lube on the outside of the catheter and placement of an insemination pipette into the catheter lumen to increase rigidity. Retention of Foley catheters in cows is facilitated by using a balloon volume of 60 to 75 mL; use of smaller balloon volumes permits the catheter to move into the urethra, leading to pollakiuria.

Fig. 13-1 Lateral view of the urethra (a), vagina (b), and suburethral diverticulum (c) in adult female cattle as viewed from the left. A finger is inserted into the suburethral diverticulum on the ventral aspect to direct the tip of the catheter over the diverticulum and into the external urethral orifice. (Reprinted with permission from Rosenberger G. Clinical examination of cattle. Berlin: Parey; 1979; 453.)
stranguria, and potential catheter extrusion. The incidence of urinary tract infection with indwelling Foley catheters in dairy cows is 3% per catheterized day; the urine should therefore be periodically examined for evidence of cystitis and antimicrobial treatment instituted whenever indicated. Mares can be catheterized easily, either by blindly passing a rigid catheter into the external urethral orifice or by using a finger as a guide for a flexible catheter. Long-term catheterization of the bladder of the mare requires a similar technique to that described for cows.

Male horses can also be catheterized easily if the penis is relaxed. When urethral obstruction is present, the penis is usually relaxed, but administration of an ataractic drug (acepromazine is often used) makes manipulation of the penis easier and often results in its complete relaxation. Because of the long urethra, the catheter must be well lubricated. The catheter should be rigid enough to pass through the long urethra but flexible enough to pass around the ischial arch. In all species, catheterization overcomes the natural defense mechanisms that prevent infectious organisms from ascending the urinary tract. As a result, attention to hygiene during catheterization is essential.

TESTS OF URINE SAMPLES
Urinalysis is an essential component of the examination of the urinary system. The reader is referred to a textbook of veterinary clinical pathology for details of the biochemical and microscopic examination of the urine. Cytologic examination of urine should take place as soon after collection as possible because casts (cylindrically shaped molds that indicate tubular injury) are fragile and can rapidly disintegrate. The common abnormalities of urine are discussed later.

The urine sample should be centrifuged; the supernatant should be used for laboratory analysis and the sediment and remaining supernatant for routine urine analysis.

Specific Gravity
Specific gravity of urine is the simplest test for urine concentration and is a preferred test of urine concentrating ability because there is a linear relationship between urine specific gravity and osmolality and urine specific gravity explains 52% of the variation in urine osmolality. The 95% confidence interval for predicting osmolality from the specific gravity measurement is ±157 mOsmol/kg.

pH
The pH of urine can be measured using pH papers calibrated in 0.2 to 0.3 pH units or urine dipstick point-of-care tests that are calibrated in 0.5 pH units. The physiologic range of urine pH is 4.5 to 9.0, with herbivore urine typically being between 7.0 and 8.5. Cattle on high-grain diets may have slight aciduria (pH 6.0–7.0), and ruminants and horses ingesting an acidogenic diet will have aciduria, with urine pH as low as 5.0. Urine pH on free-catch samples is typically 0.1 to 0.2 pH units lower than anaerobically collected samples; the difference is most likely caused by the loss of CO₂ from urine during voided, which is accompanied by an increase in pH. It is for this reason that some research studies collect urine using a Foley catheter into a glass jar with mineral oil on the surface. For clinical use, it is sufficient to completely fill a screw top container with urine and minimize the air at the top of the container before urine pH is measured.

An interesting and consistent finding is that aciduria is always accompanied by increased urine excretion of calcium. Low luminal pH in the distal convoluted tubule and connecting tubule decreases the number of epithelial Ca channels (transient receptor potential vanilloid member 5 [TRPV5]); the TRPV5 channel is considered to be the primary gatekeeper of active calcium reabsorption in the distal region of the urinary tract. Low luminal pH also decreases the pore size of the TRPV5 channel, resulting in decreased calcium uptake from the tubular lumen into the epithelial cell. The low luminal pH-induced decrease in TRPV5 number and activity result in decreased calcium absorption in the distal convoluted tubule and connecting tubule, directly resulting in hypercalcuria.

Net Acid Excretion
The kidney plays a central role in acid-base homeostasis by adjusting urine electrolyte excretion to maintain constant blood pH. Measurement of urinary net acid excretion (NAE) provides a sensitive and clinically useful method for evaluating acid-base balance. This is because NAE provides an estimate of endogenous acid production and the magnitude of dietary acidification when an acidogenic diet is fed. The term NAE is commonly used in studies of renal physiology in humans, other omnivores, and carnivores, in which urine pH is typically acidic, compared with plasma pH in a healthy animal (7.40). The term net base excretion (NBE) is more appropriate in cattle and other herbivores because urine pH is usually alkaline. It should be recognized that NBE = −NAE, with both measured in milliequivalents per liter.

Urinary NAE is the most sensitive index of acid-base status and is clinically underutilized. The Jørgensen method is often used to measure NAE and involves laboratory titration of urine to a standardized endpoint in which the temperature is 37°C, PCO₂ is 0 mm Hg, and pH is 7.40 (equivalent to plasma pH in a clinically normal animal). The method involves acidification of the urine sample to pH <4.0 to convert all HCO₃⁻ to CO₂ and dissolve the phosphate sediment, heating to a boil, cooling, and alkalinization back to pH 7.40 to determine measurable titratable acidity (TA). Measured TA is defined as the number of milliequivalents of OH⁻ (as NaOH) that must be added to a bicarbonate-free urine sample to increase the pH to 7.40. Formaldehyde is then added to the urine sample (which decreases the urine pH to below 7.40) and the sample titrated with NaOH back to pH 7.40 to determine the ammonium concentration ([NH₄⁺]). NAE is then calculated as NAE = TA + [NH₄⁺]. Accurate results are obtained with the Jørgensen method if urine is anaerobically stored at −20°C for up to 30 days and thawed at room temperature (20°C) for 2 hours, or anaerobically stored at 4°C for <3 days.

NAE for healthy pasture-fed or silage-fed cattle is usually less than −210 to −90 mEq/L, but is usually expressed as the negative of NAE, which is called NBE, where NBE = −NAE (i.e., NBE is usually +90 to +210 mEq/L). Mean NAE for grain-fed cattle with subclinical rumen acidosis (mean rumen pH 5.8–6.0) ranged from +80 to +140 mEq/L (i.e., NBE = −80 to −140 mEq/L). Urine pH and −NAE are related in herbivores, where pH = 6.1 + log₁₀(NBE + [NH₄⁺]), with NBE expressed in mEq/L and the urine ammonium ion concentration ([NH₄⁺]) expressed in mEq/L (Fig. 13-2).

Hematuria
Hematuria can be from prerenal causes when vascular damage occurs, such as trauma to the kidney, sepsis, and purpura hemorrhagica. Renal causes include acute glomerulonephritis, renal infarction, embolism of the renal artery, tubular damage from toxic insult, and pyelonephritis. Postrenal
Relationship between urine pH and net base excretion (equivalent to the negative value for net acid excretion) for cows fed diets of different dietary cation-anion difference. The dashed lines indicate that net base excretion = 0 mEq/L (by definition) when pH 7.40. Notice that urine pH is poorly associated with net base excretion at pH <6.3 (dotted line); at this urine pH renal ammonium ion concentration ([NH₄⁺]) becomes markedly increased. (Reproduced with permission from Constable PD, Gelfert CC, Fürl M et al. Am J Vet Res 2009; 70(7):915-925.)

Hematuria occurs particularly in urolithiasis and cystitis. A special instance of hematuria is enzootic hematuria of cattle when hemorrhage originates from tumors of the urinary bladder. In affected cattle, the strength of the urine dipstick reaction for blood is associated with the number and severity of tumor nodules (hemangiomas). Hematomas of the bladder wall (cystic hemATOMA) cause hematuria in neonatal foals. Treatment of foals with cystic hematomata can include medical and surgical approaches based on the degree of urinary tract obstruction and other signs. Typically, lesions of the kidney, bladder, and proximal urethra cause hemorrhage throughout or toward the end of urination, whereas lesions of the middle and distal urethra are responsible for bleeding at the beginning of urination. In severe cases of hematuria, blood may be voided as grossly visible clots, but more often hematuria causes a deep red to brown coloration of the urine. Less severe cases may show only cloudiness that settles to form a red deposit on standing. The hematuria may be so slight that it is detectable only on microscopic examination of the sediment from a centrifuged urine sample. In females, free-flow urine samples may be contaminated by blood from the reproductive tract, and it may be necessary to collect a sample by urethral catheterization in order to avoid the chance of contamination of the urine occurring in the vagina.

Blood in urine is always positive on biochemical tests for hemoglobin and myoglobin. Because red blood cells can be lysed in dilute urine, red-colored urine should be examined microscopically for the presence of erythrocytes. The presence of a heavy brown deposit is not sufficient for a diagnosis of hematuria, because this may also occur in hemoglobinuria. If the bladder or urethra is involved in the process that causes hematuria, abnormalities may be detectable on physical examination.

Gross hematuria persisting for long periods may result in severe blood loss anemia. Severe urinary tract hemorrhage of undetermined origin in aged mares has been recorded. The syndrome is widely recognized, although not well documented, in Arabian mares. Endoscopic examination reveals hemorrhage in one ureter, but ultrasonographic examination of the kidneys does not reveal any significant abnormalities. Surgical removal of the affected kidney is not recommended, because the hemorrhage sometimes recurs in the remaining kidney. Treatment is nonspecific. Severe hematuria can also occur in horses with pylonephritis.

Hemoglobinuria
False hemoglobinuria can be seen in hematuria when erythrocytes are lysed and release their hemoglobin. In this case erythrocytes can be detected only by microscopically examining urine sediment for cellular debris. True hemoglobinuria causes a deep red to brown coloration of urine and gives a positive reaction to biochemical tests for hemoglobin. There is no erythrocyte debris in sediment. Dipstick tests for proteinuria may not be positive unless the concentration of hemoglobin is very high. There are many causes of intravascular hemolysis, which is the source of hemoglobinuria. The specific causes are listed later.

Normally, hemoglobin liberated from circulating erythrocytes is converted to bile pigments in the cells of the reticuloendothelial system. If hemolysis exceeds the capacity of this system to remove the hemoglobin, it accumulates in the blood until it exceeds a certain renal threshold and then passes into the urine. Some hemoglobin is reabsorbed from the glomerular filtrate by the tubular epithelium but probably not in sufficient amounts to appreciably affect the hemoglobin content of the urine. Hemoglobinuria will only be present when the plasma concentration exceeds the renal threshold. Consequently, hemoglobin is grossly visible in plasma by the time hemoglobinuria is visible. Hemoglobin precipitates to form casts in the tubules, especially if the urine is acidic, resulting in some plugging of tubules, but the chief cause of uremia in hemolytic anemia is ischemic tubular nephrosis.

Myoglobinuria
The presence of myoglobin (myohemoglobin) in the urine is evidence of severe muscle damage. The only notable occurrence in animals is azoturia of horses. Myoglobinuria is not common in enzootic muscular dystrophy, possibly because there is insufficient myoglobin in the muscles of young animals. The myoglobin molecule (molecular weight 16,500 g) is much smaller than hemoglobin (molecular weight 64,000 g) and passes the glomerulus much more readily, so a detectable dark brown staining of the urine occurs without very high plasma levels of myoglobin. There is no detectable discoloration of the serum as seen in hemoglobinemia. Inherited congenital porphyria is the other disease that causes a red-brown discoloration of urine. In porphyria, the plasma is also normal in color, but it is differentiated from myoglobinuria based on a negative reaction to the guaiac test and the characteristic spectrograph. The porphyrins in inherited congenital porphyria are the only pigments that fluoresce under ultraviolet light.

The presence and type of pigment in the urine can be determined accurately by spectrophotographic examination, but this is rarely clinically available. Myoglobinuria is usually accompanied by clinical signs and clinical biochemistry abnormalities of acute myopathy, and clinical differentiation of myoglobinuria from hemoglobinuria is usually made on the basis of the clinical signs and serum biochemical findings, including measurement of muscle-derived enzymes such as creatin kinase. As with hemoglobin, myoglobin can precipitate in tubules and may contribute to uremia.

Ketonuria
Ketonuria is a common finding in sick ruminants and is seen in starvation; acetonemia of lactating dairy cattle; and pregnancy toxemia of ewes, does, and beef cattle. A small amount of ketonuria is normally present in dairy cows in early lactation. As a result, it is important that the assay method used to demonstrate ketonuria is appropriate for urine, because there may be a risk for false-positive reactions on some tests. The standard test is sodium nitroprusside, which turns an intense purple color in the
presence of acetone, one of the three keto acids.

**Glucosuria**

Glucosuria occurs in acute tubular nephrosis as a result of failure of tubular resorption, and is one of the most sensitive indices for the presence of a proximal tubule. Glucosuria is occasionally detected in severely ill ruminants, particularly those with abomasal volvulus or a small intestinal obstruction. Glucosuria in combination with ketonuria occurs only in diabetes mellitus, an extremely rare disease in ruminants. Glucosuria might be seen in ruminants in association with enterotoxemia caused by *Clostridium perfringens* type D and can occur after parenteral treatment with dextrose solutions, adrenocorticotropic hormones, or glucocorticoid analogs. Horses with tumors of the pars intermedia of the pituitary gland often have glucosuria.

Glucose is freely filtered by the glomerulus and reabsorbed from the filtrate in the proximal tubules, with the renal threshold approximating 150 mg/dL in horses and cattle. Glucosuria in the face of a normal serum glucose concentration therefore indicates the presence of abnormal proximal tubular function. Glucosuria occurs early in the development of aminoglycoside-induced proximal tubule nephropathy and provides a useful inexpensive and practical screening test for nephrotoxicity in animals without hyperglycemia.

**Proteinuria**

Proteinuria can be prerenal, renal, or postrenal in origin, and it is clinically helpful to identify the anatomic source of protein loss.

**Prenatal proteinuria** is caused by an abnormal plasma content of proteins that traverse glomerular capillary walls, and the proteins have normal permselectivity properties (such as hemoglobin, myoglobin, and immunoglobulin light chains). **Renal proteinuria** is caused by abnormal renal handling of normal plasma proteins and is functional or pathologic.

**Functional renal proteinuria** is mild and transient as a result of altered renal physiology during or in response to a transient phenomenon, such as high-intensity exercise or fever. **Pathologic renal proteinuria** is caused by structural or functional lesions within the kidney, regardless of their magnitude or duration. There are three subcategories of pathologic renal proteinuria: glomerular, which is caused by lesions altering the permselectivity properties of the glomerular capillary wall; tubular, which is caused by lesions that impair tubular recovery of plasma proteins that ordinarily traverse glomerular capillary walls that have normal permselectivity properties (typically low molecular weight proteins); and interstitial, which is caused by inflammatory lesions or disease processes (such as acute interstitial nephritis) that result in exudation of proteins from the peritubular capillaries into the urine.

**Postrenal proteinuria** is caused by entry of protein into the urine after it enters the renal pelvis and is urinary or extrarrenal. **Urinary postrenal proteinuria** is caused by the entry of proteins derived from hemorrhagic or exudative processes affecting the renal pelvis, ureter, urinary bladder, and urethra. **Extrarrenal postrenal proteinuria** is caused by entry of proteins derived from the genital tract or external genitalia during voiding or in the process of collecting urine for analysis.

Constituents in glomerular filtrate depend on the size, shape, and charge of the filtered particles, with most plasma constituents (such as electrolytes and glucose) readily filtered by the glomerulus; consequently, glomerular filtrate concentrations are usually similar to that of plasma. Proteins with molecular weights less than 60 kilodaltons (kDa = 60,000 g) pass through the glomerulus to some extent, but albumin (molecular weight 65 kDa) is usually not present in glomerular filtrate. Hemoglobin and myoglobin are small pigmented proteins (17 kDa) that are freely filtered and present in the glomerular filtrate; ultimately they are visible as hemoglobinuria or myoglobinuria.

**Tamm-Horsfall protein** is a glycoprotein produced by tubular cells in the loop of Henle. The urine concentration of Tamm-Horsfall protein is usually low but may be increased in inflammatory diseases of the kidney, and the glycoprotein can be incorporated into urinary casts.

Normal urine contains only small amounts of protein that are insufficient to be detected using standard dipstick tests. It should be noted that the highly alkaline urine produced by herbivores always produces a false-positive reaction (trace or 1+) for protein on urine dipstick tests. Prenatal proteinuria may be detected using standard dipstick tests in animals with hemoglobinuria and myoglobinuria, because both compounds are proteins. Functional renal proteinuria is observed in normal foals, calves, kids, and lambs in the first 40 hours after they receive colostrum. Pathologic renal or postrenal proteinuria and hematuria may be present when urinary tract infections are present. Postparturient cows usually have protein present in a free-catch urine sample as a result of washout of uterine fluids that are expelled during urination or traces remain in the caudal vagina; this is a classic example of extraurinary postrenal proteinuria. Demonstration that proteinuria originates in the kidney is easier if abnormal elements that form in the kidney, such as tubular casts, are also present in the urine, or morphologic abnormalities of the kidneys are palpable per rectum or identified ultrasonographically.

Proteinuria is most accurately quantified by determining the amount of protein passed in a 24-hour period, but this is impractical in clinical cases. Proteinuria is more easily quantified by indexing the protein concentration to creatinine concentration in a single urine sample; this has been shown to provide an accurate representation of 24-hour protein loss in the urine.

Chronic pathologic renal proteinuria may cause hypoproteinemia as in chronic glomerulonephritis and acute tubular nephrosis in horses and in amyloidosis of cattle. When proteinuria originates from pyelonephritis or cystitis, other clinical and clinicopathologic evidence of these diseases is usually present.

Urinary protein concentrations in animals without lower urinary tract disease or hematuria are normally much lower than serum protein concentrations and similar to cerebrospinal fluid (CSF) protein concentration. Glomerular filtrate normally contains low concentrations of low molecular weight proteins such as albumin (molecular weight, 65,000 g) and globulins from the glomerular filtrate; normally functioning proximal tubules reabsorb these low molecular weight proteins, leading to very low urine protein concentrations. Alterations in tubular function can therefore lead to proteinuria, but typically glomerular injury produces much larger increases in urine protein concentration than those produced by altered proximal tubule function. A transient and marked proteinuria is reported in foals for the first 2 days of life after ingestion of colostrum; the proteinuria is attributed to the presence of low molecular weight proteins in colostrum that, after active absorption by small intestinal epithelial cells, end up in the glomerular filtrate.

Determination of urine protein concentrations requires a sensitive analytical test, such as the Coomassie brilliant blue method. Urinary protein concentrations may be indexed to the urine creatinine concentration to account for denominator effects of changes in urine volume. Dividing the urinary protein concentration (mg/dL) by the creatinine concentration (mg/dL) produces a unitless ratio, which provides a sensitive and reliable diagnostic method for the detection and quantification of proteinuria and is well correlated with 24-hour protein excretion in urine samples without evidence of blood.

The normal urinary protein to creatinine ratio in the horse appears to be less than 1.0,8 and small increases in the ratio (from 0.1–0.4) are observed in horses during the developmental stage of experimentally induced laminitis in horses.1 In animals with massive proteinuria, a urinary protein to creatinine concentration ratio of less than 13 is considered to be more indicative of tubular than glomerular proteinuria. Generally, increased
urinary concentrations of albumin and β2-microglobulin indicate glomerular proteinuria and tubular proteinuria, respectively. Proteinuria is massive and sustained in cattle and sheep with advanced renal amyloidosis and animals with advanced glomerulonephritis (glomerular proteinuria) but is mild in animals without glomerular disease but with proximal tubular injury (tubular proteinuria). Microalbuminuria does not appear to have been evaluated as an early and sensitive test of glomerular disease in large animals, but increases in urine albumin concentration would be expected in animals with glomerular disease.

Casts

Casts are organized, tubular structures that vary in appearance depending on their composition. They occur only when the kidney is involved in the disease process. Casts are present as an indication of inflammatory or degenerative changes in the kidney, where they form by agglomeration of desquamated cells and Tamm–Horsfall proteins. Casts may not form in all cases of renal disease. In addition, casts readily dissolve in alkaline urine and are best detected in fresh urine samples.

Cells and Pyuria

Leukocytes, erythrocytes, and epithelial cells in urine may originate in any part of the urinary tract. Leukocytes or pus in urine (pyuria) indicates inflammatory exudation at some point in the urinary tract, usually the renal pelvis or bladder. Pyuria may occur as grossly visible clots or shreds, but is often detectable only by microscopic examination of urine sediment. Individual cells and leukocytic casts may be present. Pyuria is usually accompanied by the presence of bacteria in urine.

Bacteriuria

Diagnosis of a urinary tract infection is based on finding a clinically relevant bacteriuria in urine collected by free catch (midstream collection into a sterile container), catheterization, or cystocentesis. In horses and adult cattle, collection of urine is limited to free catch and transurethral catheterization of the bladder, because the size of the animal and intrapelvic position of the bladder prevents cystocentesis. In contrast, cystocentesis can be performed under ultrasonographic guidance in calves, small ruminants, and pigs. When culturing a urine sample obtained by catheterization, the first 20 mL or so should be discarded because of the potential for contamination from vaginal or distal urethral flora.

Marked bacteriuria suggestive of bacterial infection is usually defined as more than 30,000 colony forming units (cfu)/mL from free-catch specimens (some laboratories use 10,000 or 100,000 cfu/mL), and more than 1000 cfu/mL from catheterized specimens. It is important to quantify the number of bacteria in urine samples, because the number of cfus is usually associated with disease severity in animals with bacterial cystitis or pyelonephritis. For example, 13% of urine samples obtained directly from the bladder of slaughtered male and female cattle using a sterile needle and syringe were positive for bacteria associated with urinary tract infection in cattle; however, gross or histologic evidence of infection was not identified in any animal.

Rapid detection of urinary tract infection can be accomplished using the Uriscreen test, which is a solution of 10% H2O2 and a coloring agent. It provides a low-cost point-of-care test that detects catalase activity in a fluid sample placed in a tube by the development of a ring of foam within the tube within 2 minutes. The Uriscreen test has been used successfully to identify bacteriuria in sheep calves and has the potential for wider use in the detection of bacteriuria in other large animals.

Crystalluria

Crystalluria should not be overinterpreted in farm animals. Crystals in the urine of herbivorous animals have no special significance unless they occur in very large numbers and are associated with clinical signs of irritation of the urinary tract. Calcium carbonate and triple phosphate crystals are common in normal urine. If they occur in large numbers, it may suggest that the urine is concentrated and indicate the possible future development of urolithiasis. The presence of calcium carbonate crystals in the peritoneal fluid of a neonatal foal has been used to confirm a diagnosis of ruptured bladder.

The ventral aspect of the equine bladder may contain a calcium carbonate–rich sediment (called sabulous material), especially when horses are fed alfalfa hay. This sediment is observed toward the end of urination when the bladder is fully contracted, as evidenced by a change in urine clarity from clear to opaque.

Enzymuria

A clinically useful index of proximal tubular injury is determining the γ-glutamyl transferase (GGT) activity in urine. Most enzymes present in serum and plasma have a molecular weight greater than that of albumin (i.e., >65,000 g) and are normally not detectable in the glomerular filtrate; the presence of high molecular weight enzymes in urine such as GGT (molecular weight 330,000 g) is called parenchymatous enzymuria. For comparison, the presence of low molecular weight enzymes (such as lysosome) in urine is called tubular enzymuria because damage to the proximal tubule impairs its ability to reabsorb enzymes from the glomerular filtrate.

Most of the GGT activity in urine originates from the luminal brush border of the proximal tubular epithelial cells of the kidney. High levels of GGT activity in the urine result from an increase in the rate of proximal tubular epithelial cell destruction, and GGT is released into the urine during the active phase of tissue destruction; an increase in urine GGT activity therefore reflects parenchymatous enzymuria. The activity of GGT (or other high molecular weight enzymes such as β-N-acetylglucosaminidase, β-glucuronidase, and N-acetyl-β-glucosaminidase [NAD]) in urine can therefore be used to detect the presence of proximal renal tubular epithelial cell damage before the onset of renal dysfunction. GGT is the preferred enzyme for identifying the presence of parenchymatous enzymuria, because the assay is inexpensive and widely available and the kidney has the highest content of GGT of any organ in the body, increasing the sensitivity of the test.

Urine GGT activity is frequently indexed to an indicator of urine concentration, such as urine creatinine concentration, to correct for denominator effects induced by changes in urine volume, and a GGT to creatinine ratio higher than 25 IU/g creatinine is considered abnormal in the horse. However, it may be more appropriate to calculate the fractional clearance of GGT (which compares the extent of tubular damage with the amount of functioning kidney mass) instead of the urinary GGT to creatinine ratio (which compares the amount of tubular damage with muscle mass). Indexing serum/plasma GGT activity to serum/plasma creatinine concentration is not physiologically valid, because enzymes present in urine are not normally filtered through the glomerulus; using the urine GGT activity alone therefore appears to be more appropriate. Interestingly, urine GGT activity appears more sensitive as an index of tubular injury than the urine GGT to creatinine ratio in horses and sheep and appears to be the most sensitive indicator of tubular injury in animals treated with aminoacyl glycosides.

Other enzymes, such as alkaline phosphatase, lactate dehydrogenase, NAD, matrix metalloproteinase (gelatinases localized to renal tubules, such as MMP-2), and membrane-associated carbonic anhydrase VI have been examined in urine as potential indicators of tubular injury. None of these enzymes have consistently proven superior to urine GGT activity in detecting tubular injury, and a systematic review of acute renal injury in humans identified urine GGT activity (indexed to urine creatinine concentration) as the preferred test.

TESTS OF SERUM

These tests depend on either the accumulation, in cases of renal insufficiency, of metabolites normally excreted by the kidney or the excretion of endogenous substances by the kidney.
Serum Urea Nitrogen and Creatinine Concentration

Determination of SUN and creatinine concentration is an essential component of any evaluation of the urinary system. These serum indices of function are simple estimates of glomerular filtration because urea and creatinine are freely filtered by the glomerulus. Serum concentrations of urea and creatinine do not rise appreciably above the normal range until 60% to 75% of nephrons are destroyed.

Serum urea and creatinine concentrations are influenced by blood flow to the kidneys and may be increased in prerenal uremia. They also suffer from the disadvantage that their serum concentrations can vary with the rate of protein catabolism (and protein intake in the case of serum urea concentration) and are not dependent only on renal function. In cattle, for example, serum urea concentrations caused by prerenal lesions may be higher than those resulting from renal disease, because salivary secretion of urea, rumen metabolism of urea, and decreased feed intake (and therefore decreased protein intake) may lower serum urea concentration in chronic disease. Urea is usually expressed in terms of urea nitrogen, where 1 mg/dL = 0.337 mmol/L.

Creatinine in herbivores is essentially totally derived from endogenous creatine. Creatine is produced by the liver from amino acids and circulates in the plasma before being taken up by skeletal muscle, in which it stores energy in the form of phosphocreatine. Creatine is converted to creatinine by a nonenzymatic irreversible process and is distributed throughout the body water. Creatinine is therefore released from skeletal muscle at a constant rate in animals without myonecrosis and is therefore an indirect index of muscle mass; this is the reason why serum creatinine concentrations are highest in intact males, intermediate in adult females, and lowest in neonates and cachectic animals. Serum creatinine concentrations are constant within an animal because they reflect muscle mass, which does not change rapidly; an increase in serum creatinine concentration of more than 0.3 g/dL should be considered to be clinically significant. The units for creatinine are reported as mg/dL or µmol/L, where 1 mg/dL = 88.4 µmol/L.

Creatinine in serum is routinely measured using the Jaffe reaction, in which a colored product is formed from creatinine and picate in an alkaline solution. However, the alkaline picate reaction has poor specificity, because it also detects a number of noncreatinine chromogens in serum, which do not appear to be present in urine. In other words, the creatinine concentration may be overestimated in serum but is accurately measured in urine. The former induces some error in the calculation of fractional clearance of electrolytes. The progression of renal failure may be monitored by plotting the reciprocal of serum creatinine concentration against time. Extrapolation of the resultant linear relationship to the x-axis intercept provided some clinically useful prognostic information in a horse with advanced renal failure.

Glomerular Filtration Rate

The accepted gold standard measurement for renal function is measurement of the glomerular filtration rate using inulin clearance. Inulin, a metabolically inert carbohydrate, crosses freely across the glomerulus and is neither absorbed nor secreted by renal tubules. Endogenous creatinine clearance has also been used to estimate glomerular filtration rate; however, this test suffers from inaccuracies related to the presence of noncreatinine chromogens in plasma and the tubular secretion of creatinine in some species. Exogenous creatinine clearance mimizes the errors induced by noncreatinine chromogens in plasma but requires the IV injection of creatinine and is therefore complicated and expensive. Although the renal clearances of inulin or creatinine are the preferred research methods for measuring renal excretory function, these techniques are impractical in clinical patients and male ruminants because they require urethral catheterization, rinsing and removal of the bladder contents, and timed urine collections.

Renal excretory function is more practically assessed in clinical patients by measuring the plasma clearance of water-soluble, nonmetabolized compounds of exogenous origin that have low plasma protein binding (such as iohexol, iodixanol, phenolsulfonphthalein, or sodium sulfanilate), because these techniques do not require urine collection. A practical test to determine glomerular filtration rate is the IV injection of the radiologic contrast agent iohexol at 150 mg/kg, followed by collection of serum samples at 3 and 4 hours, or 4 and 6 hours, postinjection. An alternative test protocol used in calves is the IV injection of the radiologic contrast agent iodixanol at 40 mg/kg, followed by collection of serum samples at 1, 2, and 3 hours postinjection. Plasma clearance of iohexol has also been evaluated in horses, but the technique requires measurement by a gamma camera and is therefore not suitable for use in the field. Plasma clearance tests have been evaluated in cattle, goats, sheep, and horses and provide a useful clinical test to monitor renal function in an individual animal over time, particularly iohexol clearance. Iohexol has become the most popular of these tests because iohexol is freely filtered at the glomerulus, neither secreted nor absorbed by the kidneys, has a low degree of protein binding, and is not toxic but is widely available, relatively inexpensive, and easily assayed. However, the accuracy of plasma clearance techniques of exogenously administered compounds may not be sufficiently adequate for research studies.

TESTS OF URINE AND SERUM

Urine Osmolality to Serum Osmolality Ratio

A urine to plasma osmolality ratio of 1 indicates isoosmotic clearance of materials by the kidney. A ratio less than 1 indicates that the kidneys are diluting the urine, and a ratio more than 1 indicates that the urine is being concentrated. Because the plasma osmolality is much more constant than urine osmolality, the important clinical factor is whether urine osmolality is less than, equal to, or greater than, 300 mOsm/kg. Measurement of urine osmolality requires a dedicated laboratory unit and is rarely indicated in the clinical management of renal disease because of the widespread availability of handheld refractometers; measurement of urine osmolality is needed only in research studies.

Water Deprivation Test

This can be used to assess renal concentrating ability in animals that have isosthenuria with urine specific gravity of 1.008 to 1.012 but do not have azotemia. Water deprivation tests should not be performed on animals that are already azotemic and should be undertaken with extreme caution and frequent (hourly to every 2 hours) monitoring in animals that are polyuric but not azotemic. Animals that are unable to conserve water because of renal disease can rapidly become dehydrated and develop prerenal uremia as a result.

In brief, the water deprivation test monitors the animal's ability to detect an increase in serum osmolality, release ADH, and produce a concentrated urine as a result of the action of ADH on the kidney. The test usually requires documentation that the animal has polyuria and polydipsia, with water consumption greater than cohorts of the same age, lactation stage, and diet, when housed under the same conditions. Before conducting the water deprivation test, the animal is weighed and a Foley catheter is placed in the bladder (females), or the animal is housed in a dry stall (males). Access to water is prevented and the urine and serum are tested every 1 to 2 hours or when voided in males. The test should be stopped when the urine specific gravity increases to more than 1.015 to 1.020, when there is an increase in serum/plasma creatinine concentration of 0.3 g/dL or greater, or when there has been a decrease in BW of 5% or more.
Animals that concentrate their urine after water deprivation are diagnosed with psychogenic polydipsia and their water availability is gradually decreased. Animals that fail to concentrate their urine after water deprivation are diagnosed with diabetes insipidus; nephrogenic diabetes insipidus can be ruled out if the animal produces concentrated urine within a few hours of an intramuscular (IM) injection of exogenous vasopressin (0.15–0.30 U/kg BW). In the latter case, the diagnosis is neurogenic diabetes insipidus as a result of a defective release of ADH. Such cases are extremely rare in large animals and have been attributed to pituitary neoplasia (particularly pituitary adenoma in horses) or encephalitis. Determination of plasma vasopressin concentrations using a radioimmunoassay may assist in differentiation of nephrogenic from neurogenic diabetes insipidus; if the former the plasma vasopressin concentration increases during the water deprivation test. However, because the assay for plasma vasopressin concentration is not widely available and has not been validated for all large animals, the response to exogenous vasopressin is the preferred clinical test for differentiating nephrogenic from neurogenic diabetes insipidus. Two related horses have been diagnosed with nephrogenic diabetes insipidus, suggesting that this may be inherited as an X-linked disorder.

Water deprivation tests are not needed if urine specific gravity is below 1.008, because the presence of hyposthenuria indicates that tubular function is acting to conserve solute and produce dilute urine. In other words, a specific gravity below 1.008 is a better clinical sign than a constant specific gravity of 1.008 to 1.012, because a low specific gravity indicates the presence of some tubular function. Low specific gravity may occur in diabetics insipidus, following excessive water intake or fluid administration, or following diuretic administration. Neonatal animals on fluid diets and dairy cows in early lactation often produce dilute urine.

Renal Clearance Studies

In animals with renal disease, serum/plasma creatinine and urea nitrogen concentrations are insensitive indicators of renal dysfunction and exceed the upper limit of the reference range only after extensive loss of nephron function. Increases in serum concentrations of creatinine or urea nitrogen cannot be used to distinguish between prerenal, renal, and postrenal azotemia. Urine specific gravity can be used to differentiate prerenal from renal azotemia. However, results of urinalysis do not reflect the magnitude of the disease and they are not specific for specific renal disease.

Calculation of renal clearance of creatinine, urea nitrogen, and electrolytes, along with measurement of specific enzyme activity in the urine, is a more sensitive indicator of damage to the tubules than serum biochemical analysis. Urinary diagnostic indices have been used to evaluate renal function and to detect and estimate the extent of renal damage in agricultural animals. For example, it can be clinically useful to determine the urine to serum concentration, the ratio of urinary creatinine to urea nitrogen, the renal clearance of creatinine and urea nitrogen, the urine to serum osmolality ratio, the urine protein concentration or urine protein to creatinine ratio, the fractional clearances of electrolytes, and urine enzyme activity. Early diagnosis of renal injury facilitates initiation of appropriate treatment and reduces the incidence of irreversible renal failure. Sequential measurement of these indices can aid in the determination of prognosis and allows monitoring and evaluation of the extent of recovery of renal function. The tests require simultaneous sampling of blood and urine. Samples can also be collected daily for several days and weekly to determine any age-related changes. Analytical methods can have a large impact on measured values for urinary electrolytes. Urine samples need to be acidified (usually with HCl) to accurately measure urine calcium concentration; however, this can be problematic if measurement of urine chloride concentration is required. Accurate measurement of urine sodium and potassium concentrations using ion-selective potentiometry requires at least 20-fold dilution to minimize salt type binding in urine. Occasionally such dilution is not sufficient to provide accurate potassium measurements because of the formation of zwitterion complexes. Accurate measurement of urine chloride concentration by ion-selective potentiometry because the electrode used is also sensitive to bicarbonate concentration, which is abundant in herbivore urine. As a consequence, urine chloride concentrations measured by potentiometry should be assumed to be an undermeasurement when performed in alkaline urine.

Fractional Clearance

The fractional clearance from plasma of a given substance is calculated by comparing the amount of the substance excreted in the urine with the amount filtered through the glomerulus. The formula used to calculate fractional clearance of substance X (FCX) is

$$FC_{X}(\%) = \left(\frac{[U_{X}]}{[S_{X}]}\right) \times 100 \left(\frac{[U_{\text{creatinine}}]}{[S_{\text{creatinine}}]}\right)$$

where $[U_{X}]$ and $[S_{X}]$ are the urine and serum (or plasma) concentrations of X, respectively, and $[U_{\text{creatinine}}]$ and $[S_{\text{creatinine}}]$ are the urine and serum (or plasma) concentrations of creatinine, respectively. The fractional clearance provides information regarding the action of tubular transport mechanisms on the filtered substances; a value below 100% indicates net reabsorption, whereas a ratio above 100% indicates net secretion. Fractional clearance has been erroneously called fractional excretion; the latter term is confusing, inappropriate, and has no scientific basis.

Sodium and inorganic phosphate are reabsorbed from the glomerular filtrate by the renal tubules; therefore, the fractional clearance of sodium and phosphate provide clinically useful indices of tubular function and both can be accurately measured. Sodium retention is an important proximal tubular function, and the fractional clearance of Na is usually less than 1% for animals (and often <0.2%) unless they have a high oral or IV sodium intake, when fractional clearance values can be increased to 4%. Renal phosphorus excretion is affected by acid-base status and body calcium and phosphate status and is therefore a less specific indicator of tubular function than fractional clearance of sodium. Values for the fractional clearance of phosphorus normally vary from 0.1% to 0.4%, although higher values may be seen in ruminants with high phosphate intakes. Typically, tubular function can be adequately characterized by determining the fractional clearance of sodium alone, or sodium and phosphorus; the fractional clearance of chloride rarely adds useful information in clinical cases because it is highly correlated to the fractional clearance of sodium, and determination of the fractional clearance of potassium is hampered by methodologic limitations associated with zwitterion formation in urine. Determination of the fractional clearance of calcium can be useful when dietary intake and metabolism of calcium are evaluated. Substantial variations in fractional clearance values are present in horses over a 24-hour period as a result of the electrolyte load ingested with feed. Some standardization of the time of urine collection in relation to feeding is therefore needed in research studies but is clearly impractical in clinical cases.

Fractional clearance values for a number of electrolytes have been determined for horses, foals, cattle, and sheep. The urinary excretion of endogenous substances and other urinary diagnostic indices of renal function have been measured in healthy neonatal foals. The urine volume of neonatal foals is proportionately greater than that of calves, and the normal neonatal foal produces dilute urine. Compared with normal values in adult horses, fractional clearance of electrolytes was similar for sodium but higher for potassium, phosphorus, and calcium. Renal function in newborn calves is similar to adult cattle within 2 to 3 days of birth, and calves can excrete large load volumes in response to water overload and conserve water in response to water deprivation as efficiently as adult cattle.

Animals with acute renal azotemia have a low urinary creatinine to serum creatinine and urine nitrogen to serum nitrogen; animals with acute prerenal azotemia have a
normal to high urinary creatinine to serum creatinine ratio and urinary nitrogen to serum nitrogen ratio. However, animals with acute renal azotemia also have a low urine specific gravity relative to the serum creatinine concentration, and it remains to be determined whether measurement of urinary creatinine and urea concentrations and serum urea concentrations provide any more information in clinical cases than that provided by urine specific gravity and serum creatinine concentration.

Summary of Renal Function Tests
In summary, the serum (or plasma) creatinine or urea nitrogen concentration provides a useful screening test for the presence of urinary tract disease, with an increase in serum creatinine concentration of 0.3 mg/dL or more over baseline providing a useful clinical test for the presence of nephrotoxicosis in normally hydrated animals treated with potentially nephrotoxic agents. Azotemia can be prerenal, renal, or postrenal in origin; the cause is most practically differentiated in azotemic animals by measuring the specific gravity of urine before any treatment has been administered. In animals suspected of having urinary tract disease, the urinary protein concentration and protein to creatinine ratio provide clinically useful indices of glomerular and tubular function and injury, the urine specific gravity and fractional clearance of sodium and phosphorus provide clinically useful indices of tubular function in animals not on IV or oral fluids and consuming a normal diet, and determination of urine GGT activity and analysis of urine for protein concentration and protein to creatinine ratio provide clinically useful indices of tubular function. The results of most other laboratory tests rarely provide additional information in an animal suspected to have urinary tract disease and are not currently recommended for routine clinical use. A summary table for indices of renal function in the horse is presented in Table 13-1.

DIAGNOSTIC EXAMINATION TECHNIQUES
Ultrasoundography
Transcutaneous and transrectal ultrasonography is commonly used to detect and characterize anatomic abnormalities of the kidneys, ureters, bladder, and urethra in horses, cattle, and small ruminants. Ultrasoundography is an effective screening test for diagnosing obstructive conditions of the urinary tract, including hydronephrosis, hydroureter, and bladder distention and can be used to visualize the kidney and guide the biopsy needle during renal biopsy. Removal of the hair coat and the use of an ultrasonographic coupling gel assist in obtaining acceptable acoustic coupling, whereas saturation of a foal’s hair coat with alcohol or coupling gel may be adequate when clipping is not desirable. Ultrasonography should be performed before endoscopy, because the latter introduces air into the bladder and urethra, which interferes markedly with ultrasonographic images.

Techniques for ultrasonographic evaluation of the urinary system of the horse have been described, and extensive information is available that documents age-related changes in renal dimensions. Generally, a 5- to 10-MHz linear probe is used transrectally to image the left kidney and a 2.5- to 3-MHz sector transducer used transcutaneously to image the right kidney in adult horses. The right kidney is easy to visualize through the dorsolateral aspect of the last two to three right intercostal spaces. The left kidney is harder to visualize transcutaneously and is usually located medial to the spleen in the paralumbar region between horizontal lines drawn from the tuber coxae and tuber ischii. A transumbilical approach using a 3.5-MHz transducer has also been used for ultrasonography in adult horses. Kidneys are imaged in both cross-sectional and axial planes and are usually <18 cm long. Ureteral tears have been identified using transrectal ultrasonography. Uroperitoneum is readily diagnosed in foals by ultrasonographic examination of the ventral abdomen, as is the underlying lesion in the bladder or urachus. Ultrasonography has been used to visualize the renal changes in foals following administration of phenylbutazone.

In cattle, the right kidney is easily accessible to ultrasonography from the body surface. Generally, a 5- to 10-MHz linear probe is used transrectally and a 2.5- to 3.5-MHz sector transducer used transcutaneously in adult cattle. Images of the right kidney are visualized best using a transcutaneous approach with the transducer placed in the lumbar or paralumbar region, whereas images of the left kidney are best obtained using a transrectal approach. A report of a transcutaneous approach for imaging the left kidney is available (Fig. 13-3). Ultrasonographic changes in the cow with pyelonephritis include a dilated renal collecting system, renal or ureteral calculi, echogenic material within the renal collecting system, and subjective enlargement of the kidney with acute disease or a small irregular kidney with chronic disease. Cattle

with enzootic bovine hematuria caused by chronic bracken fern ingestion have a thickened bladder wall (normally <2 mm) on transrectal ultrasonography and irregular sessile masses (transitional cell papilloma) extending into the bladder lumen. A complete description of the ultrasonographic examination of the bovine urinary tract is available.20

Techniques for ultrasonographic evaluation of the urinary system of the sheep and more recently the goat21 have been described using a 5-MHz linear transducer. Kidneys were most easily detected from the 12th intercostal space on the right side and dorsal right flank. The right kidney was 8.0 ± 0.7 cm long (mean ± SD) and the left kidney was 8.4 ± 0.6 cm long. The bladder was 5.1 ± 1.4 cm in length, and the largest cross-sectional diameter was 2.6 ± 1.1 cm. The ureters could not be identified, but the urethra could be identified in most goats as echogenic lines with no visible lumen.

Endoscopy

Transurethral endoscopy can be easily performed in mares, stallions, geldings, and cows to examine the urethra and bladder and flow of urine from both ureters. Horses and cows are sedated and adequately restrained for the procedure, using a flexible endoscope of 12 mm or less outer diameter and a minimum length of 1 m for stallions and geldings. The tail of female horses and cattle should be bandaged or held out of the way and the perineal region cleaned with dilute povidone iodine or chlorhexidine to minimize urinary tract contamination. The endoscope should be disinfected using a glutaraldehyde-based product, including the accessory channel, and rinsed with sterile water.

The endoscope should pass easily along the urethra into the bladder. Air insufflation of the bladder is needed for adequate visualization. Biopsy of diseased tissue or mechanical disruption of calculi can be attempted under endoscopic guidance. Identification of an ectopic ureter may be assisted by IM administration of azosulfamide (2 mg/kg BW, provides a red color) or IV administration of sodium fluorescein (10 mg/kg BW, provides a green color), phenolsulfonphthalein (1 mg/kg BW, provides a red color), or indigo carmine (0.25 mg/kg BW, provides a purple blue color) to color the urine being produced. 5 to 20 minutes before endoscopy, which assists visualization of the urine stream. The ureters are identified at 10 and 2 o'clock and empty periodically in spurts; separate urine samples can be collected from each ureter to evaluate left and right kidney function.

Venous embolism has been reported during urinary tract endoscopy of a standing gelding.22 Routine sedation and endoscopic procedures were used with the bladder and urethra distended to 20 mm Hg. The horse collapsed 30 minutes after the start of the procedure, exhibiting ataxia, generalized muscle twitching, and horizontal nystagmus. The horse recovered after an additional 30 minutes, and ultrasonographic examination the next day revealed the presence of gas in both ureters and the renal pelvis of both kidneys. Venous air embolism is reportedly more likely to occur in humans when the operative site is more than 5 cm above the right atrium, which was the case in this gelding.

Renal Biopsy

Percutaneous renal biopsy can be performed in sedated and adequately restrained cows and horses. A coagulation profile should be run before renal biopsy is attempted in animals with severe and chronic renal disease or those animals suspected to have a coagulopathy. Renal biopsy is contraindicated in animals with documented pyelonephritis because of the risk of perirenal abscessation after the biopsy procedure.

The left kidney is usually biopsied because it is more accessible. In cows, the left kidney is moved to the right paralumbar fossa and fixed in position by rectal manipulation. In horses, the left kidney is identified using transabdominal ultrasonography and fixed in position by palpation per rectum. The skin over the biopsy site is aseptically prepared and 5 to 10 mL of local anesthetic is infiltrated along the proposed track for the biopsy needle. A small stab incision is made in the skin with a scalpel, and a renal biopsy sample is collected by introducing a biopsy needle through the abdominal wall and manipulating it into the caudal pole of the kidney. The depth of insertion is typically 3 cm for the right kidney and approximately 7 cm for the left kidney (depth is more variable). The renal biopsy is fixed in 10% formalin and submitted for examination and histologic diagnosis. Biopsy of the caudal pole is thought to minimize the risk of trauma to the renal pelvis, renal artery, and renal vein, but a biopsy location effect has not been demonstrated in large animals. Laparoscopic biopsy of the kidneys, with or without the development of pneumoperitoneum, with the horse in a standing position has been reported.23 Clear advantages of laparoscopic biopsy over an ultrasonographically guided percutaneous biopsy method have not been identified.

Possible complications of renal biopsy are hemorrhage and bowel penetration in all animals and abscessation in animals with pyelonephritis. Hemorrhage after renal biopsy can be extensive, is usually perirenal, and can be life-threatening, with fatality rates reported of 2.1% (1/48)24 in cattle using laparoscopic biopsy, 0% (0/82) in cattle using nonultrasound-guided biopsy25 and 0% (0/25) in cattle using percutaneous ultrasound-guided biopsy of the right kidney,26 and 0.7% (1/151)26 in horses using percutaneous biopsy. These fatality rates should be compared with a fatality rate of 0.2% in humans undergoing renal biopsy. Occasionally, severe hematuria is present for hours after the biopsy procedure but usually resolves within a few days. Because of the potential for life-threatening sequelae, renal biopsy should only be performed when the etiology is uncertain and histologic examination will direct treatment or when an early and accurate prognosis is desired. In animals with acute tubular injury, electron microscopic examination of the basement membrane is required to provide an accurate prognosis on return to normal function.

Test of Uroperitoneum and Bladder Rupture

Ultrasonographic examination of the abdomen is most useful in detecting the presence of excessive fluid, and this examination frequently allows visualization of the lesion in the bladder or urethra. Further testing is sometimes needed to confirm that the fluid is urine. Generally, in uroperitoneum, substantial quantities of fluid can be easily obtained by abdominoenterostomy. Warming the fluid may facilitate detection of the urine odor, although this is a subjective and poorly sensitive diagnostic test. If there is doubt that the fluid is urine, its creatinine concentration can be compared with that in serum. If creatinine in the fluid is at least twice the serum value, the fluid is confirmed as urine, although ruptured bladder should be suspected whenever the abdominal fluid creatinine concentration exceeds that of serum. In animals with uroabdomen or suspected to have uroabdomen, the administration of 30 mL of sterile 1% methylene blue into the bladder via a urethral catheter or cystocentesis has been used to confirm that the bladder is the site of urine leakage. Abdominal paracentesis is performed some minutes after administration and the fluid examined visually for the presence of a blue tinge. Absence of a blue color suggests the presence of ureteral or renal rupture.

Radiography

Radiographic examination has limited value for the diagnosis of urinary tract disease in farm animals with the potential exception of radiolucent particles in the bladder of ruminants with urolithiasis. Contrast studies may be used to examine the lower urinary tract in neonatal animals. With the widespread availability of ultrasonography and endoscopy, the indications for radiography have become more limited. A positive-contrast urethrogram was of value in diagnosing urethral recess dilatation in a bull calf, and IV urography was successful in diagnosing a dilated ureter in a 4-month-old heifer calf. Historically, excretory urography, positive contrast cystography, and urethrogram have been used, particularly in foals, but these tests are expensive, not widely available, and
Cystometry and Urethral Pressure Profile

Urodynamic tests in the mare permit comparison of the normal micturition reflex with that of the incontinent patient. Cystometry involves measurement of luminal pressure during inflation of the bladder with measured volumes of 0.9% NaCl or carbon dioxide. The pressure–volume relationship during filling with fluid or gas provides information on bladder capacity, maximal luminal pressure during the detrusor reflex, and stiffness of the bladder wall. The urethral pressure profile involves measurement of pressure along the urethra while withdrawing a fluid-filled or gas-filled catheter at constant rate. The catheter tip pressure is graphed against distance, and the maximum urethral closure pressure is determined as the maximum urethral pressure minus bladder luminal pressure. The functional urethral length is defined as the length of the urethra in which urethral pressure exceeds bladder luminal pressure.

The test can be performed in restrained mares with or without xylazine sedation (1.1 mg/kg BW, intravenously), but sedation is recommended. Values for cystometry and urethral pressure profiles in female horses and pony mares are available.

Computed Tomography

Computed tomography (CT) is considered the method of choice in human medicine for the imaging diagnosis of pyelonephritis, renal tumors, and renal trauma. CT urography is also the preferred technique for evaluating urinary tract disorders in humans. Consequently, there is interest in applying CT to urinary tract diseases of large animals, such as obstructive urolithiasis in goats and sheep. A CT study of 28 healthy female Saanen goats indicated that CT was a useful imaging modality that provided visualization of the kidneys, ureters, and urinary bladder. The clinical utility of CT in obstructive urethral conditions of large animals remains to be determined.

Principles of Treatment of Urinary Tract Disease

Fluid and Electrolytes

Treatment of acute renal failure in all species is aimed at removing the primary cause and restoring normal fluid balance by correcting dehydration, acid-base disorders, and electrolyte abnormalities. The prognosis for acute renal failure will depend on the initiating cause and severity of the lesion. If the acute disease process can be stopped, the animal may be able to survive on its remaining functional renal tissue. When toxic nephrosis is suspected, an attempt should be made to identify and remove the initiating cause or to move the animal from the suspect environment.

Ruminants with chronic renal failure typically have mild to marked hypoponotremia and hypochloremia; the serum calcium and potassium concentrations may be decreased because of inappetence, serum magnesium concentration may be normal or increased, and serum phosphate concentration may be normal or increased, because urine provides a route of excretion of magnesium and phosphorus. The acid-base status is characterized by acidaemia and metabolic acidosis in severely affected cases to metabolic alkalosis in mildly affected cases. Ruminants with acute renal failure have similar clinicopathologic changes, although the serum phosphorus concentration is usually markedly elevated in acute renal failure, because many cases are initiated by decreased renal blood flow.

Horses with acute or chronic renal failure have similar electrolyte changes to those in ruminants, with the marked difference being the presence of hypercalcemia and hypophosphatemia in some horses. Hypercalcemia in horses with renal disease is attributed to poorly regulated intestinal calcium absorption, with urine being the predominant route of calcium excretion. Decreases in the function of nephrons in the horse will therefore decrease the urinary loss of calcium and result in hypercalcemia. The hypercalcemia is marked and is thought to result directly in hypophosphatemia in horses with renal failure.

Balanced electrolyte solutions or isotonic (0.9% NaCl) saline supplemented with potassium (if hyperkalemia is not present) and calcium (if hypercalcemia is not present) can be used to correct fluid and electrolyte deficits. The required volume of replacement fluid can be determined on the basis of clinical signs as outlined in Chapter 5. As the fluid deficit is corrected, the patient should be observed for urination. The healthy horse produces 15 to 30 mL urine/kg BW each day, which is equivalent to 7.5 to 15.0 L/day for a 500-kg horse. If anuria or oliguria is present, the rate of fluid administration should be monitored to prevent overhydration. If the patient has anuria or oliguria after the fluid volume deficit is corrected, a diuretic should be administered to help restore urine flow.

Furosemide (1–2 mg/kg BW IV or IM every 2–6 hours) or mannitol (0.25–2.0 g/kg BW in a 20% solution administered IV over 15–20 minutes) may be used, but furosemide is preferred because of its much lower cost and ease of administration. Mannitol administration has not been proven to be effective in humans and is no longer recommended for treatment of oliguric acute renal failure in humans. Diuretics should not be used until dehydration has been corrected and furosemide administration should be used with caution in horses with acute renal failure caused by aminoglycoside toxicity, because furosemide may augment the nephrotoxicity. After urine flow is restored, the resulting diuresis will increase the maintenance fluid requirement. B vitamins should be frequently administered because their rate of loss in the urine is anticipated to be higher than normal in animals with renal failure.

Animals nonresponsive to fluid loading and diuretics could be administered low-dose (“renal dose”) dopamine as a continuous IV infusion (3–5 µg/kg BW/min) with dopamine diluted in 0.9% NaCl, 5% dextrose, or lactated Ringer’s solution. Dopamine is an α1, β1, β2, DA1, and DA2 agonist and therefore has a complex pharmacodynamic profile that is dependent on species, organ, and cardiovascular status. Dopamine is theoretically the preferred pharmacologic agent to selectively increase renal blood flow and therefore glomerular filtration rate in animals with renal failure, although low-dose dopamine infusion does not alter creatinine clearance (an index of glomerular filtration rate) in healthy adult horses and has not been shown to be of benefit in treating renal failure in humans. Dopamine acts primarily as an inotropic agent at low doses (<5 µg/kg BW/min) and primarily as a vasopressor at higher doses. The mean arterial blood pressure and electrocardiogram should therefore be monitored during dopamine administration to ensure that dopamine infusion does not lead to hypertension or clinically significant cardiac arrhythmias. Although there are good theoretical grounds for use of dopamine in animals with renal failure, this is no longer the practice in human medicine because of the lack of efficacy of the drug in preventing or treating acute renal failure. Fenoldopam mesylate, a dopamine-1 receptor agonist, at 0.04 µg/kg BW/min may have a role in the treatment of anuria and oliguria in sick foals, because this rate of infusion increased urine output without altering systemic hemodynamics and cardiac output in healthy foals. IV infusion of norepinephrine (0.1 µg/kg BW/min), with or without dobutamine (5 µg/kg BW/min), does not alter urine output, endogenous creatinine clearance, or fractional clearance of electrolytes in neonatal foals, suggesting minimal therapeutic effects in foals with anuria or oliguria. Animals that remain anuric after IV fluid administration of furosemide/mannitol and dopamine have a grave prognosis and can only be managed with peritoneal dialysis or hemodialysis.

Intermittent-flow peritoneal dialysis has been used successfully in a foal with a ruptured urinary bladder. A urinary catheter was placed in the bladder and secured to the perineal region. An area of the ventral midline was clipped and prepared for aseptic surgery. Local anesthetic was infused, and a
A 11-French peritoneal dialysis catheter was placed in the stab incision then forced into the abdomen. The rigid stylet was removed, the catheter was secured to the skin, and the stab incision site was bandaged. Peritoneal fluid was allowed to drain; dialysis was then accomplished by infusing 2 L of a hypertonic dialysis solution, clamping the catheter for 1 hour, then opening the catheter and allowing drainage to occur for 2 to 3 hours. Dialysis was repeated 9 times over a 36-hour period. Intermittent-flow peritoneal dialysis has also been used in 4 adult horses with acute renal failure using a similar catheterization technique (24-French de Pezzer or 28-French catheter secured using a purse-string suture followed by a Chinese finger trap suture pattern) and periodic infusion of 10 to 15 L of warmed, sterile, acetated Ringer’s or lactated Ringer’s solution. The fluid was left for 0.5 to 1 hour and then allowed to drain back into the fluid bag from which it was delivered. Not all of the infused fluid is usually recovered; attachment of a Heimlich valve to the catheter for several hours permits drainage of additional fluid.

**Continuous-flow peritoneal dialysis** has been used successfully in an adult horse with azotemia refractory to IV fluids, furosemide, and then allowed to drain back into the fluid bag from which it was delivered. Not all of the infused fluid is usually recovered; attachment of a Heimlich valve to the catheter for several hours permits drainage of additional fluid.

Ringer’s with 1.5% glucose was continuously infused through the catheter in the left flank at approximately 3 L/h, with abdominal fluid collected into a sterile closed collection system from the catheter in the ventral midline of the abdomen. The quantity of intraabdominal fluid was controlled by positioning the collection bags relative to the level of the withers to maintain a constant and modest intraperitoneal pressure.

**Hemodialysis** (renal replacement therapy) has been used successfully to treat a foal with presumed oxytetracycline nephrotoxicosis. Venovenous hemodialysis was performed under isoflurane anesthesia after surgical placement of a Teflon/Silastic arteriovenous shunt in the median artery and vein using a dialysis delivery system, a hollow-fiber artificial kidney, and acetate-base dialysate. Anticoagulation during dialysis was accomplished with a loading dose of heparin (100 U/kg BW IV) and then hourly boluses of 20 U/kg BW or a continuous rate infusion of 50 IU/kg each hour to prolong the activated clotting time. Three dialysis treatments, lasting 4 to 6 hours, were administered over a 4-day period, resulting in a marked reduction in azotemia. The safety and efficacy of venovenous hemodialysis has been investigated in five adult horses. Renal replacement therapy is more efficient than intermittent or continuous-flow peritoneal dialysis and requires shorter treatment intervals but does require vascular access, anticoagulation treatment, sterile filters and tubing, a peristaltic pump, and potentially a method for warming the fluids to core body temperature immediately before IV infusion.

The treatment of chronic renal failure will depend on the stage of disease and the value of the animal. In chronic failure, therapy is aimed at prolonging life. In food-producing animals, emergency slaughter is not recommended because the carcass is usually unsuitable for human consumption. Animals in chronic failure should have free access to water and salt, unless edema is present. Stresses such as sudden environmental and dietary changes should be avoided. The ration should be high in energy-giving food and properly balanced for protein. Acute renal failure may occur in patients in chronic failure and can be treated like other cases of acute renal failure.

**Antimicrobial Agents**

Selection of antimicrobial agents for the treatment of urinary tract infections should be based on quantitative urine culture of a catheterized urine sample. A clinically relevant bacterial concentration indicative of cystitis or pyelonephritis is 1000 cfu/mL or 30,000 cfu/mL of urine from a catheterized or midstream free-catch sample, respectively.

The ideal antimicrobial for treatment of urinary tract infections should meet several criteria. It should:

- Be active against the causal bacteria
- Be excreted and concentrated in the kidney and urine
- Be active at the pH of urine
- Have low toxicity, particularly nephrotoxicity
- Be easily administered
- Be low in cost
- Have no harmful interactions with other concurrently administered drugs

Appropriate first-line antimicrobials include penicillin, ampicillin, amoxicillin, cefotiofur, and ceftiofur in ruminants and trimethoprim-sulfonamides and cefotiofur in horses. Antimicrobial therapy for lower urinary tract infections should continue for at least 7 days; for upper urinary tract infections 2 to 4 weeks of treatment is often necessary. Success of therapy can be evaluated by repeating the urine culture 7 to 10 days after the last treatment.

Manipulation of urine pH should be considered as part of the treatment of bacterial urinary tract infections. Generally, *Escherichia coli* attach best to urinary epithelial cells at pH 6.0, whereas *Corynebacterium renale* attaches best in alkaline urine. In other words, when treating an *E. coli* pyelonephritis or cystitis, the diet should be altered to ensure an alkaline urine pH. Likewise, urine pH should be acidic when treating urinary tract infections caused by *C. renale*.

Diseases of the Kidney

GLOMERULONEPHRITIS

Glomerulonephritis can occur as a primary disease or as a component of diseases affecting several body systems, such as equine infectious anemia and chronic swine fever. In primary glomerulonephritis, the disease involves only the kidney, predominantly affecting the glomeruli, although the inflammatory process extends to affect the surrounding interstitial tissue and blood vessels.

Primary and secondary glomerulonephritis are rare causes of clinical disease in farm animals. The disease is sometimes associated with other chronic, systemic illness such as in cows with John’s disease, bovine virus diarrhea, fascioliasis, or leptospirosis; pigs with hog cholera or African swine fever; and horses with equine infectious anemia. Proliferative glomerulonephritis is reported as an incidental finding in normal sheep, cattle, goats, and pigs. Clinical disease from glomerulonephritis is rare in these species but has been reported in cattle and as a congenital condition in sheep, as described later. Proliferative glomerulonephritis can cause chronic renal failure in horses. Glomerulonephritis is present in animals with amyloidosis, which is a generalized deposition of antibody–antigen complexes. Amyloidosis is discussed in detail in Chapter 11.

The immune system plays a major role in the pathogenesis of glomerular lesions. Glomerular injury can be initiated by an immune response in which antibodies are directed against intrinsic glomerular antigens or by foreign antigens planted in the glomerulus. Alternatively, and more commonly, circulating antigen–antibody complexes may be deposited in the glomerulus. As the complexes accumulate, they stimulate an inflammatory response that damages the glomerular filtration system. Inflammatory damage to the glomerulus alters the selective permeability of the filtration system allowing plasma protein, particularly albumin, to pass into the glomerular filtrate. In horses, the glomerular lesion is thought to be caused by the deposition of circulating antigen–antibody complexes, but the origin of these complexes is unknown. Infections with streptococci and equine infectious anemia virus may be involved but are not likely to be involved in all cases.

Glomerulonephritis is a common cause of chronic renal failure in horses. Several forms of glomerulonephritis are recognized in horses: membranous glomerulonephritis, poststreptococcal glomerulonephritis, membranoproliferative glomerulonephritis, and focal glomerulosclerosis. As discussed earlier, most are probably immune mediated and associated with circulating antibody–antigen complexes. Over 80% of horses with equine infectious anemia have glomerular lesions, and viral antigen–antibody complexes are present in the glomerular basement membrane. Purpura hemorrhagica is associated with glomerulonephritis.

The nephrotic syndrome is seen in some advanced cases of glomerulonephritis and is a clinical syndrome characterized by proteinuria, hypoproteinemia leading to generalized edema, and hypercholesterolemia. Nephrotic syndrome is rarely diagnosed in large animals for unknown reasons, relative to the dog and human, but is most common in cattle with advanced renal amyloidosis. Hypercholesterolemia is attributed to increased hepatic synthesis of proteins in response to chronic proteinuria, but appears to be an inconsistent finding in cattle.

Dermatitis–nephropathy syndrome is a systemic necrotizing vasculitis and glomerulonephritis syndrome of growing pigs in the UK and Canada. The cause is unknown, but an immune-mediated pathogenesis is suspected. Growing pigs are affected with a morbidity ranging from 1% to 3%. The skin is affected with a popular dermatopathy with a characteristic distribution of bluish red spots at least 1 cm in diameter beginning first in the perineal region and then extending to the pelvic limbs and along the ventral body wall to the neck and ears. In the glomeruli, there are extensive granular complement deposits with scattered immunoglobulins.

Porcine dense deposit disease, porcine membranoproliferative glomerulonephritis type II, is a common cause of early loss of newborn piglets in the Norwegian Yorkshire breed. The disease is associated with extensive complement activation caused by a deficiency of factor H, a plasma protein that regulates complement. Affected piglets are clinically normal at birth and for the first few weeks of life. Thereafter they become unthrifty and die of renal failure within 72 days of birth. In the kidneys there is extensive glomerular proliferation and marked thickening of the glomerular capillary wall. Large amounts of dense deposits are consistently found within the glomerular basement membrane. This disease is inherited with a simple autosomal recessive pattern and complete penetrance. A pathogenetic mechanism of a defective or missing complement regulation protein is hypothesized. A spontaneous glomerulonephritis of unknown etiology and unrelated to any breed has been recorded in pigs. A necrotizing glomerulonephritis is listed as occurring in pigs fed a waste product from an industrial plant producing a proteolytic enzyme. Glomerulonephritis has also been recorded in pigs in the absence of clinical illness, although an association with the “thin sow” syndrome is suggested.

In Finnish Landrace lambs less than 4 months of age there is an apparently inherited mesangiocapillary glomerulonephritis that is remarkably similar to forms of human glomerulonephritis. Affected lambs appear to absorb an agent from colostrum that induces an immunologic response, followed by the granular deposition of immune complexes and complement within the glomerular capillary walls; this initiates a fatal mesangiocapillary glomerulitis. Many affected lambs are asymptomatic until found dead. Some have signs of tachycardia, edema of the conjunctiva, myasthenia, walking in circles, and convulsions. The kidneys are enlarged and tender. There is severe proteinuria and low plasma albumin. SUN concentration is markedly increased with hyperphosphatemia and hypocalcemia. At necropsy the kidneys are large and pale and...
have multifocal pinpoint yellow and red spots throughout the cortex. On histopathologic examination, there are severe vascular lesions in the choroid plexuses and the lateral ventricles of the brain. The disease is thought to be conditioned in its occurrence by inheritance and to be limited to the Finnish Landrace breed; however, cases have also occurred in crossbred lambs.

**Glomerulopathy and peripheral neuropathy in Gelbvieh calves** is a familial and probably heritable disease causing illness in calves of this breed of less than 13 months of age. The initial physical abnormality is posterior ataxia that progresses to generalized paresis and recumbency. The neurologic deficits include loss of conscious proprioception and diminished or absent peripheral reflexes but maintained consciousness. Affected animals continue to eat and drink normally. Serum creatinine and urea concentrations are markedly elevated. Necropsy examination reveals neuropathy, myelopathy, and glomerulopathy. The disease is terminal.

**REFERENCE**

**PYELONEPHRITIS**
Pyelonephritis usually develops by ascending infection from the lower urinary tract. Clinically pyelonephritis is characterized by pyuria, hematuria, cystitis, ureteritis, and suppurative nephritis.

**ETIOLOGY**
Pyelonephritis may develop in a number of ways:
- Secondary to bacterial infections of the lower urinary tract
- Spread from embolic nephritis of hematologic origin such as septicemia in cattle associated with *Pseudomonas aeruginosa*
- Specific pyelonephritis associated with *C. renale*, *C. pilorum* (formerly *C. renale* type 2), and *C. cystitidis* (formerly *C. renale* type 3) in cattle and *C. suis* in pigs
- Secondary to anatomic abnormalities of the kidneys or distal structures permitted ascending infection of the kidney
- In association with nephroliths, although whether the nephrolith or the pyelonephritis occurred first is uncertain

**PATHOGENESIS**
Pyelonephritis develops when bacteria from the lower urinary tract ascend the ureters and become established in the renal pelvis and medulla. Bacteria are assisted in ascending the ureters by urine stasis and reflux of urine from the bladder. Urine stasis can occur as a result of blocking of the ureters by inflammatory swelling or debris, by pressure from the uterus in pregnant females, and by obstructive urolithiasis. Initially the renal pelvis and medulla are affected because they are relatively more hypoxic, and localized tissue hypotonicity depresses the phagocytic function of leukocytes. Infection in advanced cases may extend to the cortex. Pyelonephritis causes systemic signs of toxemia and fever and, if renal involvement is bilateral and sufficiently extensive, uremia develops. Pyelonephritis is always accompanied by pyuria and hematuria because of the inflammatory lesions of the ureters and bladder.

Pyelonephritis in cattle caused by *C. renale* used to be very common, but clinical disease has decreased markedly, with the majority of pyelonephritis cases in cattle now caused by *E. coli*. The reason for the decrease in *C. renale* isolation from clinical cases is unclear but is probably related to a change in diet toward concentrates with an associated decrease in urine pH. Other potential reasons could be the widespread use of β-lactam antibiotics and the marked decrease in urethral catheterization to obtain a urine sample in cows suspected to be ketotic. Transmission of *C. suis* in pigs may occur after mating with infected boars, because many boars carry *C. suis* in their preputial sac fluid. Field observations suggest that slight trauma at breeding, especially in small gilts, may be an important factor in transmission.

**CLINICAL FINDINGS**
The clinical findings in pyelonephritis vary between species. In sows there may be an initial period during which a vaginal discharge is noted, but most affected animals die without premonitory illness. Characteristically, affected pigs will lose weight and eventually become emaciated. The disease in cattle usually has a protracted course and is characterized by fever, pyuria or hematuria, and intermittent episodes of abdominal pain (see previous section *Bovine Pyelonephritis*).

The disease in horses is often chronic, although acute disease occurs. Gross hematuria is recognized in some horses with pyelonephritis, although this is not a common finding. Ultrasonographic examination of the kidneys can confirm the diagnosis, based on the presence of abnormally shaped kidneys with loss of the corticomedullary gradient, hypoechoic or hyperechoic abnormalities in the renal cortex, and increased echogenicity. These findings should prompt examination of the urine for leukocytes, casts, protein, and bacteria.

**CLINICAL PATHOLOGY**
Erythrocytes, leukocytes, and cell debris are present in the urine on microscopic examination and may be grossly evident in severe cases, particularly in horses. Quantitative urine culture is necessary to determine the causative bacteria.

**NECROPSY FINDINGS**
The kidney is usually enlarged, and lesions in the parenchyma are in varying stages of development. Characteristic lesions are necrosis and ulceration of the pelvis and papillae. The pelvis is usually dilated and contains clots of pus and turbid urine. Streaks of gray, necrotic material radiate out through the medulla and may extend to the cortex. Affected areas of parenchyma are necrotic and may be separated by apparently normal tissue. Healed lesions appear as contracted scar tissue. Infarction of lobules may also be present, especially in cattle. Histologically the lesions are similar to those of embolic nephritis except that there is extensive necrosis of the apices of the papillae. Necrotic, suppurrative lesions are usually present in the bladder and ureters.

**TREATMENT**
General principles of treatment of urinary tract infections were presented earlier. A specific treatment for severe asymmetric pyelonephritis is unilateral nephrectomy, but this should only be done in nonazotemic animals. An overlooked component of treatment is alteration in urinary pH, which will affect the ability of the bacteria to attach to epithelial cells. As a generalization, *C. renale* attaches best in alkaline urine and *E. coli* attaches best in acidic urine.

**DIFFERENTIAL DIAGNOSIS**
The presence of pus and blood in the urine may suggest cystitis or embolic nephritis as well as pyelonephritis. It may be difficult to distinguish between these diseases, but renal enlargement or pain on rectal palpation of the kidney indicates renal involvement. Ultrasonographic changes associated with pyelonephritis include a dilated renal collecting system, renal or ureteral calculi, increased echogenicity, loss of corticomedullary echogenicity, and subjective enlargement of the kidney with acute disease or a small irregular kidney with chronic disease. Parenchymal hyperechogenicity can be caused by tubular degeneration and replacement fibrosis.

**REFERENCE**

**NEPHROSIS**
Nephrosis includes degenerative and inflammatory lesions primarily affecting the renal tubules, particularly the proximal convoluted tubules. Nephrosis is classified into two main groups: (1) tubular injury caused by ischemic insult and (2) cell death or damage to the tubules caused by nephrotoxins (toxic agents that preferentially damage renal
ISCHEMIC NEPHROSION
Reduced blood flow through the kidneys usually is caused by general circulatory failure. There is transitory oliguria followed by anuria and uremia if the circulatory failure is not corrected.

ETIOLOGY
Any condition that predisposes the animal to marked hypotension and release of endogenous pressor agents potentially can initiate hemodynamically mediated acute renal ischemia and renal failure. Ischemia may be acute or chronic.

Acute Renal Ischemia
- General circulatory emergencies such as shock, dehydration, acute hemorrhagic anemia, and acute heart failure; renal failure secondary to calf diarrhea has been described
- Embolism of renal artery, recorded in horses
- Extreme ruminal distension in cattle

Chronic Renal Ischemia
- Chronic circulatory insufficiency such as congestive heart failure

PATHOGENESIS
Acute ischemia of the kidneys occurs when compensatory vasoconstriction affects the renal blood vessels in response to a sudden reduction in cardiac output. As mean arterial blood pressure decreases below 60 mm Hg (the lower limit for autoregulation of renal blood flow), glomerular filtration decreases, and metabolites that are normally excreted accumulate in the bloodstream. The concentration of urea nitrogen in plasma or serum increases, giving rise to the name prerenal uremia. As glomerular filtration falls, tubular resorption increases, causing reduced urine flow. Up to a certain stage, the degenerative changes are reversible by restoration of renal blood flow, but if ischemia is severe enough and of sufficient duration, the renal damage is permanent. Proximal tubules are highly sensitive to ischemia because they are one of the energetically most active cells in the body. Acute circulatory disturbances are more likely to be followed by degenerative lesions than chronic congestive heart failure.

The parenchymatous lesions vary from tubular necrosis to diffuse cortical necrosis in which both tubules and glomeruli are affected. The nephrosis of hemoglobinuria appears to be caused by the vasoconstriction of renal vessels rather than a direct toxic effect of hemoglobin on renal tubules. Uremia in acute hemolytic anemia and in acute muscular dystrophy with myoglobinuria may be exacerbated by plugging of the tubules with casts of coagulated protein, but ischemia is also an important factor.

CLINICAL FINDINGS
Renal ischemia does not appear as a distinct disease, and its signs are masked by the clinical signs of the primary disease. Oliguria and azotemia will go unnoticed in most cases if the circulatory defect is corrected in the early stages. However, renal insufficiency may cause a poor response to treatment with transfusion or the infusion of other fluids in hemorrhagic or hemolytic anemia, in shock or dehydration. In these cases, unexplained depression or a poor response to therapy indicates that renal involvement should be investigated. The general clinical picture is one of acute renal failure and is described under uremia.

CLINICAL PATHOLOGY
Laboratory tests can be used to evaluate renal function once the circulatory condition has been corrected. Urinalysis as well as SUN and creatinine concentrations are common indices. Serum biochemistry on serially collected samples may also be used to monitor the response to therapy. On urinalysis, proteinuria is an early indication of damage to the renal parenchyma. The passage of large volumes of urine of low specific gravity after a period of oliguria is usually a good indication of a return of normal glomerular and tubular function.

NECROPSY FINDINGS
Lesions of renal ischemia are present primarily in the cortex, which is pale and swollen. There may be a distinct line of necrosis visible at the corticomedullary junction. Histologically there is necrosis of tubular epithelium and, in severe cases, of the glomeruli. In hemoglobinuria and myoglobinuria hyaline casts are present in the tubules. Severe ischemic injury can disrupt the basement membranes of the proximal tubules.

TREATMENT
Treatment must be directed at correcting fluid, electrolyte, and acid-base disturbance as soon as possible. If renal damage has occurred, supportive treatment as suggested for the treatment of acute renal failure should be instituted.

DIFFERENTIAL DIAGNOSIS
Evidence of oliguria and azotemia in the presence of circulatory failure suggests renal ischemia and the possibility of permanent renal damage. It is important to attempt to differentiate the early reversible prerenal stage from the stage in which degeneration of renal parenchyma has occurred. When ischemic renal lesions are present, urinalysis may be helpful in diagnosis, particularly if the urine is not appropriately concentrated in a dehydrated patient. After irreversible ischemic changes have occurred, it is impossible to differentiate clinically between ischemia and other primary renal diseases such as glomerulonephritis and toxic nephrosis. History and clinical signs of chronic disease will help determine whether the acute syndrome is superimposed on chronic renal disease.

TOXIC NEPHROSION
The kidneys are particularly vulnerable to endogenous and exogenous toxins because they receive a large proportion of the total cardiac output (typically 20%) and because substances are concentrated in the kidney for excretion.

ETIOLOGY
Most cases of nephrosis are caused by the direct action of toxins, but hemodynamic changes may contribute to the pathogenesis.

Toxins
- Metals: mercury, arsenic, cadmium, selenium, and organic copper compounds; nephrosis can be reproduced experimentally in horses by the oral administration of potassium dichromate and mercuric chloride, including topical blistering agents containing mercuric chloride
- Antimicrobials, such as aminoglycosides, and overdosing with neomycin and gentamicin in the treatment of calves; treatment with tetracycline preparations accidentally contaminated by tetracycline degradation compounds and repeated daily dosing with long-acting oxytetracycline preparations may induce toxicity; treatment with sulfonamides
- Horses treated with vitamin K3 (menadione sodium bisulfite) administered by IM or IV injection
- Horses treated with vitamin D2 (ergocalciferol) and cholecalciferol (D3)
- Treatment of horses with nonsteroidal antiinflammatory drugs (NSAIDs), including phenylbutazone and flunixin meglumine; dose rates of more than 8.8 mg/kg BW of phenylbutazone per day for 4 days are likely to cause nephrosis; doses of 4.4 mg/kg BW are considered to be safe, but toxicity is enhanced by water. The usual presentation of NSAID toxicosis in horses is gastrointestinal ulceration, including right dorsal colitis
- Ketoprofen in sheep at 30 mg/kg IV, once; renal toxicity may be facilitated
PATHOGENESIS
In acute nephrosis there is obstruction to the flow of glomerular filtrate through the tubules caused by interstitial edema and intraluminal casts. If there is sufficient tubular damage, there may be back leakage of glomerular filtrate into the interstitium. There may also be a direct toxic effect on glomeruli, which decreases glomerular filtration. The combined effect is oliguria and uremia. In subacute cases, impaired tubular resorption of solutes and fluids may lead to polyuria.

CLINICAL FINDINGS
Clinical signs may not be referable to the urinary system. In peracute cases, such as those caused by vitamin K3 administered by injection, there may be colic and stranguira. In acute nephrosis there is oliguria and proteinuria with clinical signs of uremia in the terminal stages. These signs include depression, dehydration, anorexia, pyrexia, a slow or an elevated heart rate, and weak pulse. Diarrhea may be present that is sufficiently intense to cause severe clinical dehydration. In cattle there is a continuous mild hyponatremia with signs reminiscent of that disease, which responds, in a limited way, to treatment with calcium. Cattle with advanced and severe nephrosis may exhibit a bleeding diathesis. Polyuria is present in chronic cases. Many systemic diseases such as septicaemia cause temporary tubular nephrosis. The degree of renal epithelial loss is not sufficient to cause complete renal failure and, provided the degree of renal damage is small, complete function is regained.

CLINICAL PATHOLOGY
In acute tubular nephrosis, urinalysis abnormalities are usually present before serum or plasma urea and creatinine concentrations are increased. Proteinuria, glucosuria, enzynuria, and hematuria are initial changes on urinalysis in experimental toxic nephrosis. The earliest indication of tubular epithelial damage in experimentally induced nephrosis is the detection of the proximal tubule enzyme GGT in urine. Hypoprothrominemia may be present. In acute renal disease of horses, hypercalcemia and hypophosphatemia can be present, although this is not the usual finding. In the chronic stages the urine is isosthenuric and may or may not contain protein. Azotemia occurs when uremia is present. Ultrasonographically, renal changes are seen in foals receiving high daily doses of phenylbutazone.

NECROPSY FINDINGS
In acute cases the kidney is swollen and wet on the cut surface and edema, especially of perirenal tissues, may be apparent. Histologically there is necrosis and desquamation of tubular epithelium, and hyaline casts are present in the diluted tubules. In phenylbutazone poisoning the renal lesion is specifically a renal medullary necrosis. There may also be ulcers in all or any part of the alimentary tract from the mouth to the colon if phenylbutazone was administered orally.

TREATMENT
Treatment should be directed at general supportive care for acute renal disease as outlined earlier. If the toxin can be identified, it should be removed. Treatment for specific toxins may be available, as described elsewhere in the text. Hemodialysis was used successfully to treat a foal with presumed oxytetracycline nephrotoxicosis.

DIFFERENTIAL DIAGNOSIS
Clinical differentiation from acute glomerulonephritis is difficult, but clinical signs of involvement of other organs in the toxic process may be present:
- A combination of polyuria and glycosuria is an uncommon finding in large animals and is usually caused by nephrosis.
- Diabetes mellitus is rare in horses and extremely rare in ruminants.
- Cushing’s syndrome (chronic hyperadrenocorticism pituitary pars intermedia dysfunction) is more common in horses and includes characteristic signs of polyuria, glycosuria, debilitation, hirsutism, polyphagia, and hyperglycemia.
- Diarrhea in terminal stages of uremia in a horse can be confused with the other causes of acute diarrhea. It requires a blood urea and creatinine estimation and a urinalysis for differentiation.

RENAL TUBULAR ACIDOSIS
Renal tubular acidosis (RTA) is a rare disease of large animals that is characterized by normal glomerular function but abnormal tubular function. RTA should be suspected whenever there is a hyperchloremic strong ion (metabolic) acidosis and normal anion gap with no discernible extrarenal cause; it is important to note that a common extrarenal cause of hyperchloremic strong ion acidosis is aggressive IV administration of 0.9% NaCl. This means that extreme caution needs to be exercised when attempting to diagnose RTA in sick animals receiving IV fluids.

Four major types of tubular functional defect exist in humans: (1) nephrogenic diabetes insipidus, in which the collection ducts do not respond to ADH (vasopressin); (2) distal RTA (type I), which is a defect in the ability to secrete hydrogen ions in the distal convoluted tubules against a concentration gradient (in humans, type III is now considered a variant of type I); and (3) proximal RTA (type II), which is characterized by decreased bicarbonate reabsorption in the proximal convoluted tubules. A variant of proximal RTA that does not appear to have been reported in large animals is Fanconi’s syndrome, which is a genetic defect in humans related to the tubular resorption of glucose, various amino acids, urate, and phosphate. (4) hyperkalemic distal RTA (type IV) is caused by the resistance of distal nephron cells to aldosterone, resulting in hyperkalemia, natriuresis, and the inability to concentrate urine. Type IV RTA has not been reported in domestic animals.

Only a small number of RTA cases have been documented in horses, and these have been predominantly distal RTA (type I). Differentiating between RTA type I and type II is difficult and unreliable in horses, and a report exists of a horse that may have both types. The urine of humans with proximal RTA (type II) is acidic, whereas the urine of humans with distal RTA (type I) is very alkaline, regardless of the serum bicarbonate concentration, but aciduria is rarely present in herbivores suspected to have proximal RTA (type II). There is one report of RTA in a lethargic 3-month-old calf with Salmonella enterica serovar Agona that was more consistent with RTA type I than type II. The calf responded to IV sodium bicarbonate.
Nephrogenic Diabetes Insipidus

This is a very rare condition with reports in three colts, of which two were related. Clinical signs are chronic and extreme polydipsia and polyuria, poor body condition, and growth rate. Diagnosis in nonanesthetized normally hydrated animals includes the inability to concentrate urine in response to IV hypertonic saline (7.5% NaCl, 1–2 mL/kg BW), which increases plasma osmolality and triggers released of ADH. Another diagnostic test is the administration of exogenous aqueous vasopressin (0.25–0.5 U/kg BW, IM) or desmopressin acetate (0.05 µg/kg, IV), a potent synthetic analog of vasopressin. An increase in urine specific gravity to greater than 1.025 within 2 hours is supportive of a diagnosis of central diabetes insipidus, and their hydration status, BW, and urine specific gravity and volume should be monitored frequently.

Specific treatment protocols in horses with nephrogenic diabetes insipidus have not been identified but should focus on restricted water and sodium intake and the long-term administration of thiazide diuretics.

Distal Renal Tubular Acidosis (Type I)

Horses with distal RTA (type I) have a profound strong ion acidosis caused by hyperchloremia (normal anion gap metabolic acidosis), hypokalemia, an alkaline urine pH (typically >8.0), and increased fractional clearance of sodium. A practical diagnostic test for distal RTA (type I) involves examining the ability of the distal convoluted tubules to excrete hydrogen ions by the oral administration of ammonium chloride (0.1 g/kg BW in 6 L of water via nasogastric tube). Inability to achieve an acidic urine (pH <6.5) after oral ammonium chloride administration is consistent with a diagnosis of distal RTA (type I).

Treatment of horses and a calf with distal RTA (type I) has been symptomatic and focuses on oral or IV administration of sodium bicarbonate. Spontaneous recovery has been reported in horses.

Proximal Renal Tubular Acidosis (Type II)

The classic explanation for this disorder is a failure to reabsorb bicarbonate in the proximal tubules, resulting in excessive loss of bicarbonate in the urine and metabolic acidosis (reduced plasma bicarbonate concentration) but variable urine pH. Because the molecular basis for this defect has not been identified, it has been proposed that proximal RTA (type II) may result from channel dysfunctions of strong electrolytes in proximal renal tubule cells. Reabsorption of bicarbonate requires energy, therefore, disease processes that lead to proximal tubular damage have the potential to result in proximal RTA (type II).

A practical diagnostic test for proximal RTA (type II) in humans is measuring the change in urine Pco₂ during oral or IV sodium bicarbonate administration, but this test does not appear to have been performed in horses. Normally, urine and plasma Pco₂ are similar but, during bicarbonate diuresis, urine Pco₂ becomes greater than plasma Pco₂. The urine to plasma Pco₂ gradient during IV sodium bicarbonate administration is therefore measured; one horse with proximal RTA developed a urine to plasma Pco₂ gradient of 29 mm Hg during bicarbonate loading. Treatment of horses with proximal RTA (type II) is uncertain.

Hemolytic Uremic-Like Syndrome

Glomerular and tubulointerstitial disease, consistent with profound microangiopathy and glomerular degeneration in humans with hemolytic–uremic syndrome, has been diagnosed in two horses. Both horses were in oliguric renal failure and had clinicopathologic evidence of intravascular hemolysis and morphologic evidence of arteriolar microangiopathy and intravascular coagulation. The mortality rate is expected to be extremely high. The pathogenesis in horses is unclear, although hemolytic–uremic syndrome in humans is caused by toxins produced by E. coli O157:H7.

Hydronephrosis

Hydronephrosis is a dilatation of the renal pelvis with progressive atrophy of the renal parenchyma. It occurs as a congenital or an acquired condition following obstruction of the urinary tract. Any urinary tract obstruction can lead to hydronephrosis, but the extent and duration of the obstruction are important in determining the severity of the renal lesion. Urinary tract obstructions that are chronic, unilateral, and incomplete are more likely to lead to hydronephrosis. Acute obstructions of bladder or urethra that are corrected promptly are not usually associated with significant kidney damage. As a result, recurrence of the obstruction rather than renal failure is the major sequel to urolithiasis in ruminants. In cases of acute complete obstruction the clinical picture is dominated by signs of anuria, dysuria, or stranguria.

Chronic or partial obstructions cause progressive distension of the renal pelvis and pressure atrophy of the renal parenchyma. If the obstruction is unilateral, the unaffected kidney can compensate fully for the loss of function and the obstruction may not cause kidney failure. Unilateral obstruction may be detectable on palpation per rectum of a grossly distended kidney. Chronic bilateral obstructions, although they are rare in large animals, can cause chronic kidney failure. Hydronephrosis and chronic renal failure have been recorded in a steer suffering from chronic partial obstruction of the penile urethra by a urolith. Partial obstruction of the ureters by papillomas of the urinary bladder has been recorded in a series of cows. Compression by neoplastic tissue in cases of enzootic bovine leukosis may also cause hydronephrosis. Ultrasonography can be used as an aid to diagnosis.

Interstitial Nephritis

Interstitial nephritis is rarely recognized as a cause of clinical disease in farm animals, although it is a frequent postmortem finding in some species. Interstitial nephritis may be diffuse or have a focal distribution. In calves, focal interstitial nephritis (white-spotted kidney) is a common incidental finding at necropsy but does not present as a clinical urinary tract disease. Focal interstitial nephritis of cattle is not associated with leptospirosis or active bacterial infection. In pigs, diffuse interstitial nephritis is observed following infection by Leptospira spp. and is important clinically because of the resultant destruction of nephrons that occurs. The kidney is an important reservoir for Leptospira spp. in other species, particularly cattle, but renal disease is not a common clinical problem in carrier animals.

Chronic interstitial fibrosis is a common postmortem finding in horses suffering from chronic renal failure. This is thought to represent an end-stage condition rather than primary interstitial disease. The initiating cause of the renal disease is usually not evident, but most cases are thought to begin with acute tubular nephrosis. Horses with chronic interstitial nephritis have the clinical syndrome of chronic renal failure with uremia.

Chronic interstitial nephritis with diffuse zonal fibrosis (CINF) occurs in Japanese Black cattle (Wagyu) as an autosomal recessive disorder leading to death before puberty. Clinically there is growth retardation between 3 and 5 months of age. A genome-wide scan using microsatellite markers in a Wagyu pedigree segregated for CINF mapped the CINF locus to bovine chromosome 1.
EMBOLIC NEPHRITIS

Embolic lesions in the kidney do not cause clinical signs unless they are very extensive, in which case septicemia may be followed by uremia. Even though embolic nephritis may not be clinically evident, transient proteinuria and pyuria may be observed if urine samples are examined at frequent intervals.

ETIOLOGY

Embolic suppurative nephritis or renal abscess may occur after any septicemia or bacteremia when bacteria lodge in renal tissue.

Emboli may originate from localized septic processes such as:
- Valvular endocarditis, in all species
- Suppurative lesions in uterus, udder, navel, and peritoneal cavity in cattle or be associated with systemic infections such as:
  - Septicemia in neonatal animals, including Actinobacillus equuli infection in foals and E. coli septicemia in calves
  - Erysipelas in pigs and C. pseudotuberculosis in sheep and goats
  - Septicemic or bacteremic Streptococcus equi infection in horses

PATHOGENESIS

Bacterial emboli localize in renal tissue and cause the development of focal suppurative lesions. Emboli can block larger vessels and cause infarction of portions of kidney, with the size varying with the caliber of the occluded vessel. Infarcts are not usually so large that the residual renal tissue cannot compensate fully and they usually cause no clinical signs. If the urine is checked repeatedly, the sudden appearance of proteinuria, casts, and microscopic hematuria, without other signs of renal disease, suggests the occurrence of a renal infarct. The gradual enlargement of focal embolic lesions leads to the development of toxemia and gradual loss of renal function. Clinical signs usually develop only when multiple emboli destroy much of the renal parenchyma, or when there are one or more large infected infarcts.

CLINICAL FINDINGS

Usually there is insufficient renal damage to cause signs of renal disease. Signs of toxemia and the primary disease are usually present. The kidney may be enlarged on rectal examination. Repeated showers of emboli or gradual spread from several large, suppurative infarcts may cause fatal uremia. Spread to the renal pelvis may cause signs similar to pyelonephritis. Large infarcts may cause bouts of transient abdominal pain.

CLINICAL PATHOLOGY

Hematuria and pyuria are present in embolic nephritis, but microscopic examination may be necessary to detect these abnormalities when the lesions are minor. Proteinuria is present but is also normally present in neonatal animals in the first 30 to 40 hours of life. Culture of urine at the time when proteinuria occurs may reveal the identity of the bacteria infecting the embolus. Hematology usually reveals evidence of an acute or chronic inflammatory process.

NECROPSY FINDINGS

In animals that die of intercurrent disease, the early lesions are seen as small gray spots in the cortex. In later stages these lesions may have developed into large abscesses, which may be confluent and in some cases extend into the pelvis. Fibrous tissue may surround longstanding lesions, and healed lesions consist of areas of scar tissue in the cortex. These areas have depressed surfaces and indicate that destruction of cortical tissue has occurred. Extensive scarring may cause an obvious irregular reduction in the size of the kidney.

TREATMENT

General information on treatment of urinary tract infections was presented earlier. Antimicrobials should be selected on the basis of quantitative urine culture and susceptibility testing. In treating septicemic neonatal animals, particular care must be taken to avoid the use of potentially nephrotoxic drugs. Antimicrobial treatment should be continued for a fairly lengthy period (7–14 days). In embolic nephritis, the primary disease and the renal disease must be controlled to prevent recurrence of the embolic lesions. In neonatal animals this may involve treatment for septic shock. The urine culture should be repeated at intervals after treatment is completed to ensure that the infection has been completely controlled.

DIFFERENTIAL DIAGNOSIS

Differentiation from pyelonephritis is difficult unless the latter is accompanied by signs of lower urinary tract infection such as cystitis or urethritis. The kidney is enlarged in both conditions, and the findings on urinalysis are the same when embolic nephritis invades the renal pelvis. Many cases of embolic nephritis go unrecognized clinically because of the absence of overt signs of renal involvement.

- Severely dehydrated neonatal animals may experience prerenal uremia and are susceptible to ischemic tubular nephrosis. The presence of other signs of sepsis should increase suspicion of the presence of embolic nephritis.
- The sudden occurrence of bouts of acute abdominal pain in some cases of renal infarction may suggest acute intestinal obstruction, but defecation is usually unaffected and rectal examination of the intestines is negative.

LEPTOSPIROSIS

SYNOPSIS

ETIOLOGY

Leptospirosis is caused by leptospira species. There are many distinct serovars found in various regions. Leptospires are spirochetes in the family Leptospiraceae and are important agents of infectious diseases in humans and animals. They are transmitted to hosts through contact with infected urine or body fluids of infected animals or humans. The organism is characterized by its distinctive hooked ends.

Epidemiology

Leptospirosis is a worldwide disease and is found in various regions. It is transmitted through contact with infected urine or body fluids of infected animals or humans. The organism is characterized by its distinctive hooked ends.

Clinical signs

Clinical signs of leptospirosis include fever, anemia, changes in milk, stillbirths, abortion in all species (especially pigs), weak neonates, infertility, milk drop syndrome, and periodic ophthalmia (recurrent uveitis in horses).

Diagnosis

Diagnosis of leptospirosis is based on the demonstration of leptospires in body fluids or tissues using various methods. These methods include the cultural agglutination test, ELISA, and DNA probes. Leptospirosis is a zoonotic disease, and humans can be infected through contact with infected urine or body fluids of infected animals or humans.

ETIOLOGY

Leptospirosis is caused by leptospira species. There are many distinct serovars found in various regions. Leptospires are spirochetes in the family Leptospiraceae and are important agents of infectious diseases in humans and animals. They are transmitted to hosts through contact with infected urine or body fluids of infected animals or humans. The organism is characterized by its distinctive hooked ends. The genus Leptospira was initially divided into two species: L. interrogans sensu lato, which comprises the pathogenic strains, and L. biflexa sensu lato, comprising all saprophytic strains of the organism. Within the
two *Leptospira* spp., different serovars are differentiated based on the cross-agglutination absorption test (CAAT). For this classification, two strains are considered different if, after cross-absorption with adequate amounts of heterologous antigen, 10% or more of the heterologous titer regularly remains in either of the two antisera. The serovar is considered the basic systematic unit for *Leptospira* spp., and antigenically related serovars are grouped into serogroups. Currently over 250 pathogenic serovars and 24 pathogenic serogroups are recognized. However, the CAAT is cumbersome and time-consuming to perform and few diagnostic laboratories are able to perform it. Isolated strains are therefore not routinely identified at the serovar but only at the serogroup level, which can be determined by means of the microagglutination test (MAT). Serogroups have no taxonomic status, but are convenient for application such as diagnosis and epidemiology.

With molecular typing techniques becoming more available the taxonomy of Leptospira spp. has been reorganized based on genomic DNA-DNA hybridization, and the pathogenic strains previously comprised in the *Leptospira interrogans* sensu lato complex are now divided into 13 different species based on DNA hybridization studies. These are *L. alexanderi*, *L. alstonii*, *L. borgpetersenii*, *L. inadai*, *L. interrogans* (sensu stricto), *L. jaimei*, *L. kirschneri*, *L. licerasiae*, *L. noguchi*, *L. santarosai*, *L. terpstra*, *L. wellii*, and *L. wolffii*. However, the correlation between the serologic and the genotypic classification is poor, which makes the taxonomy of *Leptospira* spp. confusing. Not only can pathogenic and saprophytic strains be part of the same genotypic species, but a single serovar and serogroup can also pertain to different genotypic species. So are the antigenically similar serovars *Hardjo-bovis* and *Hardjo-prajitno* (serogroup *Hardjo*) now classified into two different genotypic species, which are *L. borgpetersenii* (for serovar *Hardjo-bovis*) and *L. interrogans* (sensu stricto, for serovar *Hardjo-prajitno*). The novel molecular classification is often conceived as impractical by clinical microbiologists, which is the reason the serologic taxonomy is still widely used.2

**EPIDEMIOLOGY**

**Risk Factors**

- **Animal Risk Factors**
- **Serovars and Species Susceptibility**

The epidemiology of leptospirosis is most easily understood by classifying the disease into two broad categories: host-adapted and non-host-adapted leptospirosis. An animal infected with a host-adapted species of the organism, is a “maintenance” or “reservoir” host. Exposure of susceptible animals to non-host-adapted serovars results in accidental or incidental disease. Each *Leptospira* species is adapted to one or a few particular maintenance host(s), although it may cause disease in any mammalian species. The organism is maintained in nature by chronic infection of renal tubules of maintenance hosts.2 A specific species behaves differently within its maintenance host species than it does in other, incidental or accidental hosts. A maintenance host is characterized by:
- A high susceptibility to infection
- Endemic transmission within the host species through direct contact
- Relatively low pathogenicity for its host
- A tendency to cause chronic rather than acute disease, producing insidious economic loss through reproductive losses
- Persistence of the strain in the kidney and sometimes the genital tract with chronic excretion of the pathogen in urine
- Prevalence of chronic excretion in urine increases with age
- A low antibody response to infection, with difficulties in diagnosis

Examples of this relationship are serovar Bratislava in swine, and serovar Hardjo-Bovis in cattle. In contrast, an incidental host is characterized by:
- Relatively low susceptibility to infection but high pathogenicity for the host
- A tendency to cause acute, severe rather than chronic disease
- Sporadic transmission within the host species and acquisition of infection from other species, sometimes in epidemic form
- A short kidney phase
- A marked antibody response to infection, making for ease of diagnosis
- An example of this relationship is serovar Pomona (*kennewicki*) infection in cattle.

Some common leptospiral serovars and their maintenance hosts are seen in Box 13-9.

Calves and lambs are highly susceptible to infection, and septicemia is likely to occur.

**Pathogen Risk Factors**

The mechanisms through which leptospires cause host tissue damage and disease are currently not well understood. Virulent strains were found to adhere to cultured renal tubular epithelial cells, and adhesion is enhanced by subagglutinating concentrations of homologous antibody because they are commonly found in infected maintenance hosts. The corresponding adhesin allowing this attachment has not been identified.1 Leptospires are phagocytosed by macrophages and neutrophilic polymorphonuclear leukocytes in the presence of specific antibody and complement but are resistant to complement and killing in nonimmune hosts. Virulent strains were found to attach to neutrophils without being killed, suggesting that the outer membrane of such strains may possess an antiphagocytic component.2

There is no unequivocal evidence for a classical exotoxin that would be secreted by *Leptospira* spp., but the outer membrane of the organism contains a lipopolysaccharide (LPS or endotoxin) that resembles the standard gram-negative LPS chemically and immunogenically. However leptospiral LPS was found to be considerably less potent than LPS from gram-negative bacteria in standard tests for endotoxin activity such as the rabbit pyrogenicity or the mouse lethality test.2 Leptospiral LPS possesses an antiphagocytic component and stimulates adherence of neutrophils to endothelial cells and platelets causing aggregation and suggesting a role in the development of thrombocytopenia.1 In mice, apoptosis of lymphocytes is elicited by LPS via induction of tumor necrosis factor-α (TNF-α).3

Along with LPS, the leptospiral outer cell membrane contains several outer membrane proteins (OMPs) that are highly immunogenic. Indeed an inverse association between the expression of OMPs and virulence has been demonstrated for the serovar grippotyphosa. Downregulation of the expression of OMPs reduces the humoral immune response, facilitating the evasion from the host’s immune system.

Some virulent strains were found to produce either cell-associated or extracellular phosphomyelinas, a class of substances that functions as hemolysin. Furthermore, these strains exhibit chemotaxis toward hemoglobin. The presence of a specific antibody prevents hemolysis.

**Environmental and Management Risk Factors**

The prevalence of a specific leptospiral serovar depends on the availability of a maintenance host species, which can be a domestic or wildlife species.

The occurrence of indirect disease transmission through contaminated soil, water, or other fomites is determined by a number of
environmental factors. Leptospira spp. can survive for prolonged periods in a moist environment at warm temperatures (optimal around 28°C (82°F) and neutral or mildly stagnant water. In contrast, survival is impaired at temperatures below 10°C (50°F) or above 35°C (95°F) or on dry soil. Ground surface moisture and water is the most important factor governing the persistence of the organism in bedding or soil; it can persist for as long as 183 days in water-saturated soil but survives for only 30 minutes when the soil is air-dried. In soil, under average conditions, survival is likely to be at least 42 days for L. Pomona. It survives in free, surface water for long periods; the survival period is longer in stagnant than in flowing water, although persistence in the latter for as long as 15 days has been recorded. Contamination of the environment and capacity of the organism to survive for long periods under favorable conditions of dampness may result in a high incidence of the disease on heavily irrigated pastures, in areas with high rainfall and temperate climate, in fields with drinking water supplies in the form of easily contaminated surface ponds, and in marshy fields and muddy paddocks or feedlots. Numerous outbreaks of leptospirosis have occurred following heavy rainfall events and floods.7 Stagnant waters have been incriminated as a possible source of infection in pastured animals in tropical regions.6 Exposure of humans, pets, or livestock to rodents and rats that are adapted hosts for certain serovars (e.g., Icterohaemorrhagiae or Grippotyphosa) has been shown to be an important risk factor for infection in many species.6

Certain management factors have been identified that pose risks of L. Hardjo infection being introduced into dairy herds: • Purchase of infected cattle • Cograzing or common grazing with infected cattle or sheep • Purchase or loan of an infected bull • Access of cattle to contaminated water supplies such as streams, rivers, flood, or drainage water

Occurrence and Prevalence of Infection
Leptospirosis is a disease affecting most animal species, including humans, and has a worldwide occurrence. It is considered the most common bacterial zoonosis worldwide with increasing incidence in industrialized and developing countries and has been classified as a reemerging infectious disease of humans, particularly in tropical and sub-tropical regions.5 Leptospirosis has a higher prevalence in tropical and subtropical regions with seasonal occurrence. Peaks in disease incidence are observed during the warm months of the year in temperate climates and during the rainy season in the tropics.5 Although more than 250 pathogenic serovars have been identified, generally few serovars prevail in a particular region, which largely depends on the presence of an adapted host species. Most leptospiral infections are subclinical, and infection is more common than clinical disease.

Numerous infection prevalence studies have been published for different species in different geographic regions. Reported values are, unfortunately, not easy to compare because some studies are based on serology, whereas others determine the occurrence of bacterial DNA in urine or renal tissue. Furthermore, there is no consensus on the criteria for positive or negative serology, and cutoff values for seropositivity differ between studies. It is generally assumed that serologic studies tend to underestimate the infection prevalence because isolation of bacterial DNA from seronegative individuals was commonly reported in different animal species.6 The occurrence and infection prevalence of leptospirosis will be discussed for different animal species.

Serologic surveys of cattle in the African continent reveal evidence of antibodies against numerous leptospiral serovars and some previously not described strains of serovars. In West Africa, serosurveys of dairy herds revealed 45% of cattle were positive to one or more serovars, which probably represented natural infection because vaccination had not been practiced. Leptospirosis is common in farm animals in Portugal. Outbreaks of clinical disease have been recorded in cattle and pigs, in sheep and goats, and, to a lesser extent, in horses. In Italy, serologic surveys indicate that sheep, horses, pigs, and dogs have the highest number of positive responses.

Cattle
Serovars of Leptospira spp. of major importance in cattle include L. Hardjo and L. Pomona. Depending on the geographic region other serovars such as Icterohaemorrhagiae or Grippotyphosa, have been shown to be an important risk factor for infection in many species.

The morbidity rate for clinical disease may vary from 10% to 30%, depending on the clinical manifestation of infection, and the case–fatality rate is usually low at about 5%. The case–fatality rate in calves is much higher than in adult cattle. A high rate of abortions (up to 30%) and loss of milk production are the major causes of loss, but deaths in calves may also be significant.

Recent serologic studies from Europe revealed comparatively low seroprevalence rates in dairy cattle below 1.6% in dairy cattle in Sweden and Bosnia-Herzegovina.11,12 The most prevalent serovars in Bosnia-Herzegovina were Pomona, followed by Hardjo and Grippotyphosa; in Sweden cattle were found to be free of serovar Hardjo. In a serologic survey of dairy cows conducted in herds with suboptimal reproductive efficiency in a region in Spain, L. Bratislava and L. Grippotyphosa were the most prevalent serovars. The risk of seroconversion against L. Grippotyphosa was higher during the spring season, whereas L. Bratislava did not differ among seasons. The prevalence of L. Hardjo was low, which indicates that the reproductive inefficiency was unassociated with Hardjo. In surveys of dairy and beef cattle in Spain, L. Bratislava is the most estimated with 29% for serovar Hardjo, 23% for serovar Pomona, 19% for serovar Icterohaemorrhagiae, and 11% for serovar Canicola.10 Seroprevalence surveys in Ontario found Hardjo was most common in beef cattle, whereas Pomona was most common in dairy cattle. In Prince Edward Island, 14% of dairy cows were serologically positive for serovar Hardjo. Serologic surveys of cattle farms in Alberta found infection with Hardjo was widespread across the province, and the prevalence has increased. In contrast, Pomona reactors were found usually on single premises within a locality compared with the clustering of Hardjo reactor herds. Surprisingly, the seroprevalence of unvaccinated beef cattle kept on community pastures in western Canada was 9.6% for serovar Pomona, 6.7% for serovar Grippotyphosa, 6.1% for serovar Icterohaemorrhagiae, and 5.2% for serovar Canicola but only 0.2% for serovar Hardjo.

In beef cattle in Queensland, Australia, the major serovars in order of decreasing crude seroprevalence were Hardjo (15.8%), Tarassovi (13.9%), Pomona (4.0%), and Szwajzak (2%). Vaccinates were not included in the Hardjo and Pomona seroprevalence; and the seroprevalence for Hardjo and Pomona tended to increase with the age of the animals. The data indicate that serovars other than Hardjo, Pomona, and Tarassovi are unlikely to have a significant role in bovine infertility, and cattle are unlikely to be a source of human infection in central Queensland. In New Zealand, a seroprevalence rate in beef cattle of 40% for serovar Hardjo and 7% for serovar Pomona has been reported.

The seroprevalence for Hardjo and Pomona differ among seasons. The prevalence has increased. In contrast, Pomona reactors were found usually on single premises within a locality compared with the clustering of Hardjo reactor herds. Surprisingly, the seroprevalence of unvaccinated beef cattle kept on community pastures in western Canada was 9.6% for serovar Pomona, 6.7% for serovar Grippotyphosa, 6.1% for serovar Icterohaemorrhagiae, and 5.2% for serovar Canicola but only 0.2% for serovar Hardjo.11

In beef cattle in Queensland, Australia, the major serovars in order of decreasing crude seroprevalence were Hardjo (15.8%), Tarassovi (13.9%), Pomona (4.0%), and Szwajzak (2%). Vaccinates were not included in the Hardjo and Pomona seroprevalence; and the seroprevalence for Hardjo and Pomona tended to increase with the age of the animals. The data indicate that serovars other than Hardjo, Pomona, and Tarassovi are unlikely to have a significant role in bovine infertility, and cattle are unlikely to be a source of human infection in central Queensland. In New Zealand, a seroprevalence rate in beef cattle of 40% for serovar Hardjo and 7% for serovar Pomona has been reported.12

The case–fatality rate in calves is much higher than in adult cattle. A high rate of abortions (up to 30%) and loss of milk production are the major causes of loss, but deaths in calves may also be significant.

Recent serologic studies from Europe revealed comparatively low seroprevalence rates in dairy cattle below 1.6% in dairy cattle in Sweden and Bosnia-Herzegovina.11,12 The most prevalent serovars in Bosnia-Herzegovina were Pomona, followed by Hardjo and Grippotyphosa; in Sweden cattle were found to be free of serovar Hardjo. In a serologic survey of dairy cows conducted in herds with suboptimal reproductive efficiency in a region in Spain, L. Bratislava and L. Grippotyphosa were the most prevalent serovars. The risk of seroconversion against L. Grippotyphosa was higher during the spring season, whereas L. Bratislava did not differ among seasons. The prevalence of L. Hardjo was low, which indicates that the reproductive inefficiency was unassociated with Hardjo. In surveys of dairy and beef cattle in Spain, L. Bratislava is the most
frequently detected serovar, whereas Hardjo is at a relatively low seroprevalence compared with similar studies in western European countries. In Spain, serovars Grippotyphosa, Tarassovi, and Copenhagani are more frequent in dairy herds, probably related to management practices and geographic location of these herds, which facilitate the contact with maintenance hosts for these serovars.

In Turkey, L. Hardjo is the dominant serovar identified in serologic surveys of cattle, but L. Grippotyphosa is the dominant serovar causing clinical disease in cattle, the disease is uncommon in sheep.

In South Africa a seroprevalence of leptospirosis in cattle originating from communal grazing areas of 19.4% has been reported. Although serovar Pomona was most prevalent (22%), a wide variety of other serovars including Tarassovi (19%), Bratislava (15%), Canicola (13%), Hardjo (13%), Icterohaemorrhagiae (12%), Szwajizak (4%), and Grippotyphosa (2%) were common.15

Sheep and Goats

The disease in sheep and goats has been reported in many countries. Reported prevalences range from 5% to 42%. Predominant serovars isolated in Australia and Italy included Castellonis, Poi, Sejroe, Hardjo, Copenhagani, and Cynopteri.11,12 In Guyana, serovars Pomona, Grippotyphosa, Hardjo, and Bratislava, and in Trinidad serovars Copenhagani and Autumnalis were predominant.12,20 Infection with L. Hardjo occurs but is unlikely to be a source of infection for cattle herds. Sheep are not natural maintenance hosts for pomona or hardjo and are likely to have infections of relatively short duration, producing severe pathologic effects. However, persistent leptospirosis was caused by Hardjo in sheep in which no contact with cattle has occurred suggests that sheep may be a maintenance host for this serovar. This could complicate control of Hardjo infection in cattle, which are free of this serovar, and infected sheep are a potential zoonotic risk to abattoir workers, sheep farmers, and shearers, which previously had not been considered. Infection with serovar Hardjo is widespread in Merino stud rams in South Australia.

Seroprevalences reported for goats range among 2.1% in northern Italy, over 13.1% in Nigeria, and 20.8% in Brazil,11,21,22 which involved Icterohaemorrhagiae and Copenhagani serovars.

Pigs

Leptospira serovars most common in pigs are Bratislava, for which this species is the maintenance host, and Pomona, and grippotyphosa; less common serovars include Icterohaemorrhagiae, Canicola, and Hardjo. In infected herds the prevalence of positive serologic reactors is high, and in large infected pig populations it is about 20%. In Iowa, 38% of sera from National Animal Health Monitoring System herds were positive for 1 or more of 12 serovars. The most common serovar antibodies found in pigs in Prince Edward Island swine herds were L. Icterohaemorrhagiae, L. Bratislava, L. Autumnalis, and L. Pomona. In Trinidad an individual animal seroprevalence of 5% with a farm prevalence of 33.3% has been reported. Predominant serovars were Bratislava of the Australis serogroup (2.0%) and members of the Icterohaemorrhagiae serogroup (2.5%).13

The Australis serogroup of leptospires is now important because of an increasing awareness that antibodies to Bratislava are widespread in the pig populations of many countries, the recovery of Lora, Muenchen, and Bratislava from pigs, and the involvement of Bratislava and Muenchen in reproductive problems of swine herds. All of the pig isolates of the Australis serogroup have been identified as either Bratislava or Muenchen, and there are also differences at the subserovar level, which may be important in understanding the epidemiology of the Australis serogroup, the development of efficacious vaccines, and the pathogenesis of disease. Economic losses are about equally divided between abortions and deaths of weak and unthrifty newborn pigs. Infection of pigs at slaughter is associated with multifocal interstitial nephritis, which results in condemnation of kidneys.

Swine are affected by several leptospiral serovars, and the clinical signs often associated with these infections include poor reproductive performance. Serumpositive sows have a greater risk of weak newborn pigs and have more weak newborn piglets per litter. In some areas suboptimal reproductive performance was associated with certain serovars, such as Grippotyphosa, and not others, such as Autumnalis, Bratislava, Pomona, and Icterohaemorrhagiae. Pigs in intensive housing present a different problem from those in more conventional housing or at pasture. In large pig units the possibility for cross-infection is high because of high population density. The movement of pigs from pen to pen and access to effluent from other pens are the critical means of spread in these circumstances. The spread of infection within pig-herds is encouraged by mixing infected pigs with uninfected pigs, which results in epidemics within the pens. Transmission from infected to susceptible grower pigs occurs continuously in grower houses, with a constant proportion of pigs becoming infected each week. Introduction onto a farm may be via an imported boar; boars are frequently found to harbor leptospires in the genital tract. Leptospira were found commonly in the kidneys of slaughter fattening pigs in Vietnam but are not considered to be the cause of the white-spotted kidneys of pigs.

Horses

Although the precise prevalence of infection in horse populations of different geographic regions is not known, serologic evidence suggests leptospiral infection is common in horses. Predominant serovars occurring in this species include the serovars Bratislava, Pomona, Icterohaemorrhagiae, and Grippotyphosa. Because of the relatively frequent occurrence of L. Bratislava, horses are thought to be maintenance hosts for this serovar.

Serologic surveys of Thoroughbred and Standardbred horses in Ontario revealed a higher prevalence of Bratislava, which increased with age. In a survey of horses in Alberta, titers to L. Icterohaemorrhagiae, Bratislava, Copenhagani, and Autumnalis were common (94.6, 56.6, 46.5, and 43.5%, respectively). The prevalence to other serovars ranged from 0.8% to 27.2%. The probability of being seropositive increased by approximately 10% with each year of life. Horses managed as individuals (e.g., race-track horses) were about half as likely to be seropositive as those managed in groups (e.g., rodeo horses).

A Swedish study determined a seroprevalence of 16.6% for Bratislava, 8.3% for Icterohaemorrhagiae, 1.2% for Sejroe, 0.5% for Pomona, and 0.4% for Grippotyphosa. An increase of the seroprevalence with age was found for serovars Bratislava and Icterohaemorrhagiae.23 A bacteriologic survey of kidneys from abattoir horses in Portugal found serogroups L. autumnalis and L. pomona, which were identified as L. Bratislava, and L. kirschneri serovar Tsaratsovo, respectively.

Rodent exposure was associated with risk of exposure to all serovars. Management was associated positively with the risk of exposure to serovars Pomona and Bratislava, but not with risk of exposure to Autumnalis. Soil and water had a positive association with risk of exposure to Pomona and Autumnalis but not to Bratislava. The wildlife index value and the population density of horses turned out
together were associated with risk of exposure to *Autumnalis*. For the serovar Bratislava a Swedish study reported highest seroprevalences from April to June and from October to December and for serovar Icterohaemorrhagiae from October to December.25

**Economic Importance**

Leptospirosis is not only considered the most important bacterial zoonosis worldwide but also presents a major cause of economic loss in farm animals. The majority of leptospiral infections are subclinical and associated with fetal infections causing abortions, stillbirths, and the birth of weak neonates with a high death rate in cattle, sheep, horses, and pigs. In cattle, epidemics of abortions, infertility, and increased culling rate cause major economic losses. Epidemics of agalactia in dairy herds (the milk drop syndrome) are associated with infection with *L. hardjo.*

**Zoonotic Implications**

Leptospirosis is probably the most prevalent zoonotic disease in the world predominantly affecting tropical and subtropical regions. It is now recognized as an emerging, potentially epidemic disease associated with excess rainfall in tropical settings, representing a significant public health hazard. Most recent outbreaks were reported from Nicaragua in 2007, Sri Lanka in 2008, and the Philippines in 2009).24

Annual incidences of clinical leptospirosis vary greatly with highest rates on the Seychelles (43.2/100,000 population), Trinidad and Tobago (12/100,000), Barbados (10/100,000), Jamaica (7.8/100,000), and Costa Rica (6.7/100,000).25 In the United States the Centers for Disease Control and Prevention estimate that between 100 and 200 clinical cases are diagnosed every year (0.1/100,000), half of which are in Hawaii. In Europe, the highest incidence rates have been reported from Croatia (1.7/100,000), Portugal (0.7/100,000), Denmark (0.6/100,000), and Slovenia (0.5/100,000).

Although most cases of leptosomal infection are asymptomatic or only associated with mild clinical disease, mortality in humans remains significant, particularly in developing countries because of delays in diagnosis caused by lack of diagnostic infrastructure and adequate clinical suspicion when patients are presented for medical diagnosis and care. The overall case-fatality rate ranges between 1% and 5%, depending on the clinical presentation and the age of the patient. The icteric form of the disease, which occurs in 5% to 10% of all patients, has an overall mortality of 5% to 15%, whereas mortality rates of over 50% have been reported in cases with myocardial involvement. Mortality is higher in the elderly.26

Leptospirosis can be prevented through appropriate hygiene, sanitation, and animal husbandry. It is essential to educate people working with animals or animal tissues about measures for reducing the risk of exposure to such zoonotic pathogens as leptospira.

Humans are considered to be purely incidental hosts for leptospirae and have rarely been implicated in spreading the disease.27 Leptospirosis is an important zoonosis and is an occupational hazard to butchers, farmers, hunters, pet traders, rodent catchers, veterinarians, and sewer workers. In recent decades the epidemiology has undergone major changes, with a shift away from the traditional occupational disease in developed countries to a disease associated with recreational exposures. Human infection is most likely to occur by contamination with infected urine or urine contents. Veterinarians may become infected by handling the tissues and urine of sows that have aborted from poma mona infection. Although leptospirae may be present in cow’s milk for a few days at the peak of fever in acute cases, the bacteria do not survive for long in the milk and are destroyed by pasteurization. However, farm workers who milk cows are highly susceptible to *L. interrogans* serovar Hardjo infection, and one New Zealand survey found 34% of milkers were seroreactive, mostly to *L. interrogans* serovar Hardjo, but a high proportion were also positive to *L. interrogans* serovar Pomona. This has aroused alarm, and leptospirosis became known as “New Zealand’s No.1 dairy occupational disease.” A campaign of vaccination of dairy cattle across the country resulted in a marked decrease in the incidence of the disease in humans. In most situations, dogs, cats, and horses are unlikely to contribute to human infection.

The epidemiology of leptospirosis in New Zealand has been changing. The annual incidence of human leptospirosis in New Zealand from 1990 to 1998 was 4.4 per 100,000. Incidence was highest among meat-processing workers (163/100,000), livestock farm workers (91/100,000), and forestry-related workers (24/100,000). The most commonly detected serovar was ballum (11.9%). The annual incidence of leptospirosis declined from 5.7/100,000 from 1990 to 1992 to 2.9/100,000 from 1995 to 1998. The incidence of serovar Hardjo and serovar Pomona infection declined, whereas the incidence of serovar Ballum infection increased. The increasing incidence of serovar Ballum suggests changing transmission patterns via direct or indirect exposure to contaminated water.

Veterinary students may be exposed to leptospirosis by taking courses in food inspection and technology, on-farm clinical work experiences, contact with pets (especially carnivores), and contact with animal traders. In a 1-year period, the seroprevalence of leptospirosis in veterinary students in a veterinary school in Spain increased from 8.1% to 11.4%. The incidence of the disease during the study was 0.039.

**Methods of Transmission**

The source of infection is an infected animal that contaminates pasture, drinking water, and feed by infective urine, aborted fetuses, and uterine discharges. All of the leptospiral types are transmitted within and between species in this way. A viable infected neonate can harbor the infection for several weeks after birth. The semen of an infected bull may contain leptospirae, and transmission by natural breeding or artificial insemination can occur but is uncommon. In rams, the semen is likely to be infective for only a few days during the period of leptospirosis; in boars there is no evidence of coital transmission. *L. interrogans* serovar Hardjo is excreted from the genital tract of aborting cows for as long as 8 days after abortion or calving and is detectable in the oviducts and uterus for up to 90 days after experimental infection and in naturally infected cows. It may also be present in the genital tract of bulls, and veneral spread of the infection is possible. Young pigs may act as carriers for 1 year and adult sows for 2 months. Because of the high intensity and long duration of the infection in pigs, they play an important role in the epidemiology of leptospirosis.

**Leptospirosis**

**Source**

Urine is the chief source of contamination because animals, even after clinical recovery, may shed leptospirae in the urine for long periods. All animals that have recovered from infection may intermittently shed organisms in the urine and act as “carriers.” In cattle, leptospirosis may persist for a mean period of 36 days (10–118 days) with the highest excretion rate in the first half of this period. Sheep and horses are not common sources of infection because of low-grade and intermittent leptospirosis. In any species, the leptospirae may persist in the kidney for much longer periods than they can be recovered from the urine by routine laboratory methods. Urine drinking by calves is not an uncommon form of pica in some dairy herds and is a means of transmission.

**Wildlife as Source of Infection**

Although surveys of the incidence of leptospirosis in wildlife have been conducted and the pathogenic effects of *L. Pomona* on some species (particularly deer and skunks) have been determined, the significance of wildlife as a source of infection for domestic animals is uncertain. Variable rates of seroprevalence to leptospirae have been documented in white-tailed deer, mule deer, pronghorns, moose, red deer, and elk. There is a high prevalence of infection in feral pigs, and in wild brown rats trapped on farms in the UK the prevalence of *L. icterohaemorrhagiae* and Bratislava was about 14%. *L. Canicola* is known to spread from domestic dogs and jackals to cattle and, when hygiene is poor, even from humans to cattle. The serovar Bratislava has been associated with severe...
interstitial nephritis in raccoons in a recreational area in Quebec, which were also serologically positive to Pomona, Hardjo, and Grippotyphosa.

The expanding wild boar population in urban and suburban areas has been incriminated as a possible source of infection for humans, domestic animals, and livestock in some countries. Infection prevalence rates in wild boars have been reported from Japan and Germany with 15.2% (positive polymerase chain reaction [PCR] on kidney tissue) and 18% (serology), respectively.26,27 The most prevalent serovars in the German study were Pomona and Bratislava; in the Japanese study the predominant genospecies were L. interrogans and L. borgpetersenii.

**Portals of Entry of Organisms**

Entrance of the organism into the body occurs most probably through cutaneous or mucosal abrasions. Transplacental transmission is uncommon, but neonatal infection in utero has occurred. Oral dosing is an unsatisfactory method for experimental transmission compared with injection and installation into the nasal cavities, conjunctival sac, and vagina.

**PATHOGENESIS**

Leptospirosis manifests itself as a disease in several different ways. Leptospires invade the host across mucosal surfaces or softened skin. They have the ability to bind to epithelial cells and attach to the constituents of the extracellular matrix through an active process involving surface proteins. Pathogenic leptospires are found extracellularly between cells of the liver and kidney. Release of lymphokines such as TNF-α from monocytes through the endotoxic activity of the leptospiral LPS may be an important virulence mechanism. Induction of TNF-α release may help explain the damage to endothelial cells with resultant hemorrhage seen in severe leptospirosis.

Leptospirosis can occur as an acute and severe disease caused by septicaemia with evidence of endotoxemia such as hemorrhages, hepatitis, nephritis, meningitis; as a subacute moderately severe disease with nephritis, hepatitis, agalactia, and meningitis; or as a chronic disease characterized by abortion, stillbirth, and infertility. In the occult form, there is no clinical illness. The form of the disease depends largely on the species of the host as set out in Table 13-2. Variations between serotypes of L. interrogans in their pathogenicity also affect the nature of the signs that appear. For example, in L. Pomona infections, intravascular hemolysis and interstitial nephritis are important parts of the disease. However, L. Hardjo does not produce hemolysin and does not cause interstitial nephritis, but it does cause clinical infection in sexually mature, lactating or pregnant females. Thus infection occurs in the pregnant uterus and lactating mammary gland resulting in septicemia, abortion, and mastitis. The pathogenesis of the disease associated with L. Pomona is set out as follows.

### Acute Form

After penetration of the skin or mucosa, the organisms multiply in the liver and migrate to, and can be isolated from, the peripheral blood for several days until the accompanying fever subsides. At this time, serum antibodies begin to appear and organisms can be found in the urine.

### Septicaemia, Capillary Damage, Hemolysis, and Interstitial Nephritis

During the early period of septicaemia, sufficient hemolysin may be produced to cause overt hemoglobinuria as a result of extensive intravascular hemolysis. This is an unlikely event in adult cattle but is common in young calves. If the animal survives this phase of the disease, localization of the infection may occur in the kidney. Hemolysis depends on the presence of a serovar that produces hemolysin. Capillary damage is common to all serovars and during the septicemic phase petechial hemorrhages in mucosae are common. Vascular injury also occurs in the kidney and if the hemolysis is severe, anemic anoxia and hemoglobinuric nephrosis may occur. There is some evidence that the leptospiral LPS may exacerbate the vascular lesions. The infection localizes in the renal parenchyma, causing an interstitial nephritis, and persistence of the leptospires in these lesions results in prolonged leptospiuria. The renal lesion develops because the infection persists there long after it has been cleared from other tissue sites. In the acute phase of the disease, the animal may die of septicaemia or hemolytic anemia or both. Subsequently, the animal may die of uremia caused by interstitial nephritis.

Focal chronic interstitial nephritis, also called white-spotted kidney, is a common finding in clinically healthy cattle at slaughter and has frequently been assumed to be related to current or prior infection with *Leptospira* spp. However, studies of white-spotted kidney in cattle at the abattoir indicate that neither *Leptospira* spp. nor active infection by other bacteria are associated with the lesions.

### Abortion

Following systemic invasion, abortion may occur because of fetal death, with or without placental degeneration. Abortion usually occurs several weeks after septicaemia because of the time required to produce the changes in the fetus, which is usually auto­lyzed at birth. Abortion occurs most often in the second half of pregnancy, probably because of the greater ease of invasion of the placenta at this stage, but may occur at any time from 4 months on. Although abortion often occurs in both cattle and horses after either the acute or the subacute form of the disease, abortion without prior clinical illness is also common. This is particularly the case in sows and occurs to a lesser extent in cows and mares; this may be from degenerative changes in the placental epithelium. Leptospires are rarely present in the aborted fetuses; however, if the aborted fetus has survived the infection long enough to produce antibodies, these may be detectable.

Experimental infection of serologically negative pregnant cattle with a north Queensland strain of L. borgpetersenii serovar Hardjo resulted in seroconversion and shedding of the organism in the urine. Elective cesarean sections were done 6 weeks after challenge. There was no evidence of L. Hardjo infection of the fetuses. Some of the fetuses had histopathologic lesions consistent with *Neospora* sp. infection.

### Encephalitis

Localization of leptospires in nervous tissue is common in sheep and goats and may result in the appearance of signs of encephalitis.

### Subacute and Occult Forms

In the subacute form, the pathogenesis is similar to that of the acute septicemic form, except that the reaction is less severe. It occurs in all species, but the common form is found in adult cattle and horses. Occult cases, with no clinical illness but with rising antibody titers, are common in all animals. These are difficult to explain but may be associated with strains of varying pathogenicity, but with leptospirosis, characteristically, differences between groups may be associated with prior immune status.
Periodic Ophthalmia (Recurrent Uveitis) in the Horse

There is some evidence of a causal relationship between leptospirosis infection and periodic ophthalmia in the horse. The incidence of serologically positive reactors is higher in groups of horses affected with periodic ophthalmia than in normal animals. Agglutinins are present in the aqueous humor in greater concentration than in the serum. Serologic surveys indicate that leptospira infection is not a major factor in the etiology of equine anterior uveitis in the UK, but serologic evidence of Pomona is associated with uveitis in horses in the United States. The opacity in both cornea and lens is a consequence of the antigenic relationship between leptospires and components of the ocular tissues and does not require the presence of living bacteria. A 52-kDa protein appears to be involved in the antigenic relationship between the leptospires and equine ocular tissues and is located inside the bacterium. The uveitis alters the composition of the aqueous humor and impedes the nutrition of the ocular structures, leaving sequelae such as iris atrophy, synchiae, and corneal opacity.

Retinal immunopathology in horses with uveitis has been described and may be a primary immunologic event in equine uveitis, providing evidence that leptospira-associated uveitis may be a distinct subset of equine uveitis.

Pulmonary Hemorrhage

Respiratory manifestation of leptospirosis associated with severe respiratory distress, pulmonary hemorrhage, and high case fatality has been described in humans, dogs, and horses. The pathogenesis of this clinical presentation only occurs in a small subset of infected patients and is poorly understood. Endothelial damage of small pulmonary blood vessels and fibrin deposition along alveolar walls have been reported as consistent findings. Furthermore, lung lesions were found to be associated with the expression of TNF and endothelial nitric oxide synthase in experimentally induced leptospirosis in hamsters, suggesting a role of local or systemic inflammatory mechanism in the pathogenesis of this pulmonary form of the disease. Immune-mediated mechanisms have also been proposed as a possible cause for pulmonary hemorrhage, but corroborating evidence is not yet available.

Immune Mechanisms

Following infection, specific antibodies are induced that opsonize leptospires, facilitating their elimination from most parts of the body. However, leptospires that reach the proximal renal tubules, genital tract, and mammary glands appear to be protected from circulating antibodies. They persist and multiply in these sites and may be excreted and transmitted to susceptible, in-contact animals, primarily by urine. Furthermore, and of major importance, the level of serum antibody commonly declines to undetectable levels in animals that are persistently infected.

The first serologic response with L. Hardjo infection is the production of immunoglobulin M (IgM) antibodies. These rise rapidly but usually decline to undetectable concentrations by 4 weeks after infection. Within 1 to 2 weeks of infection, IgG, antibodies appear, and at 3 months they represent 80% of antibodies detected in the MAT. The MAT titer peaks 11 to 21 days after infection but may vary from 1:3200 to an undetectable concentration. It declines gradually over 11 months, but the persistence is variable. Vaccination induces antibodies that are mainly of the IgG class with levels peaking at 2 weeks after a two-dose vaccination but decreasing rapidly to levels lower than those after natural infection. Approximately 95% of vaccinated heifers do not have MAT antibodies 20 weeks after the second of two vaccinations given 4 weeks apart, but the absence of titer is not necessarily an indication that protection has waned. Vaccinated animals are protected from natural challenge for many months after their MAT titers become undetectable. The serologic response of calves vaccinated at 3 months of age is lower than those vaccinated at 6 months of age because of the presence of maternal antibody. Transfer of passive immunity antibodies to newborn calves occurs via the colostrum, and the antibodies persist in the calves for 2 to 6 months.

Although antibodies against leptospiral LPS give passive protection in some animal models, cattle vaccinated against serovar Hardjo with pentavalent vaccines are vulnerable to infection with serovar Hardjo despite the presence of high titers of anti-LPS antibody. It is now known that peripheral blood mononuclear cells (PBMCs) from cattle vaccinated with an L. interrogans serovar Hardjo vaccine, which protects against serovar Hardjo, proliferated in vitro in response to Hardjo antigens. Thus a cell-mediated immune response to serovar Hardjo is probably necessary for protection. A protective killed vaccine against serovar Hardjo induces a strong antigen-specific proliferative response by PBMC from vaccinated cattle 2 months after the first dose of vaccine. This response was absent from unvaccinated cattle. The mean response peaked by 2 months after completion of the two-dose vaccination regimen, and substantial proliferation was measurable in vitro cultures throughout 7 months of the study period. Up to one-third of the PBMCs from vaccinated animals produced interferon gamma (IFN-γ) after 7 days in culture with antigen. One-third of the IFN-γ-producing cells were gamma delta lymphocytes, with the remainder cells being CD4+ T cells. Thus a very potent Th1-type immune response was induced and sustained following vaccination with a killed bacterial vaccine adjuvanted with aluminum hydroxide and the involvement of gamma delta T cells in the response. The induction of this Th1-type cellular immune response is associated with the protection afforded by the bovine leptospiral vaccine against L. borgpetersenii serovar Hardjo.

The immune response of naive and vaccinated cattle following challenge with a virulent strain of L. borgpetersenii serovar Hardjo has been examined. Beginning at 2 weeks after challenge, IFN-γ was measured in antigen-stimulated PBMC cultures from nonvaccinated animals, although the amount produced was always less than that in cultures of PBMC from vaccinated animals. IFN-γ cells were also evident in antigen-stimulated cultures of PBMC from vaccinated animals but not from nonvaccinated animals throughout the postchallenge period. Naive and vaccinated animals had similar levels of antigen-specific IgG, following challenge; vaccinated animals had twofold more IgG. It is evident that although infection may induce a type 1 response, it is too weak to prevent establishment of chronic infection.

Clinical Findings

The clinical findings in leptospirosis are similar in each animal species and do not vary greatly with the species of Leptospira; except infection with icterohaemorrhagiae usually causes a severe septicemia. For convenience the various forms of the disease are described as they occur in cattle, and comparisons are made with the disease in other species. In all animals the incubation period is 3 to 7 days.

Cattle

Leptospirosis in cattle may be subclinical, acute, subacute, or chronic and is most often associated with serovars hardjo or pomona.

Acute Leptospirosis Associated With pomona

Calves up to 1 month old are most susceptible to the acute leptospirosis. The disease is manifested by septicaemia, with high fever (40.5–41.5°C; 105–107°F), anorexia, petechiation of mucosae, depression, acute intravascular hemolysis with hemoglobinuria, jaundice, and pallor of the mucosae. Because of the ensuing anemia, tachycardia, loud heart sounds, and a more readily palpable apex beat are present; dyspnea is also prominent. The case–fatality rate is high, and if recovery occurs then convalescence is prolonged. In adult cattle, abortion caused by the systemic reaction may occur at the acute stage of the disease. Milk production is markedly decreased, and the secretion is thickened, red-colored, or may contain blood clots. The mammary gland is limp and soft. Mastitis as

Infectious Diseases of the Kidney

1121
part of leptospirosis has often been described in cattle and a high somatic cell count in grossly abnormal milk suggests mastitis, but these changes are caused by a general vascular lesion rather than local injury to mammary tissue. Severe lameness caused by synovitis is recorded in some animals and a necrotic dermatitis, probably caused by photosensitization, is recorded in others.

Subacute Leptospirosis Associated With L. pomona
The subacute form of leptospirosis differs from the acute form only in degree. Similar clinical findings are observed in a number of affected animals, but not all of the findings are present in the same animal. The fever is milder (39–40.5°C; 102–105°F), and depression, anorexia, dyspnea, and hemoglobinuria are common, but jaundice may or may not be present. Abortion usually occurs 3 to 4 weeks later. One of the characteristic findings is the marked drop in milk production and the appearance of bloodstained or yellow-orange, thick milk in all four quarters without apparent physical change in the udder.

Chronic Leptospirosis Associated With L. pomona
The clinical findings in the chronic form of leptospirosis are mild and may be restricted to abortion. Severe “storms” of abortions occur most often in groups of cattle that are at the same stage of pregnancy when they are exposed to infection. The abortions usually occur during the last trimester of pregnancy. Apart from the abortion, there is no depression of reproductive efficiency in cattle affected by leptospirosis. Many animals in the group develop positive MATs without clinical illness.

There are occasional reports of leptospiroplasm meningitis in cattle. In coordination, excessive salivation, conjunctivitis, and muscular rigidity are the common signs.

Leptospirosis Associated With L. hardjo
Infertility and milk drop syndrome occurs only in pregnant or lactating cows because the organism is restricted to proliferation in the pregnant uterus and the lactating mammary gland. There is a sudden onset of fever, anorexia, immobility, and agalactia. The milk is yellow to orange and may contain clots. The udder is flabby, there is no heat or pain, and all four quarters are equally affected. The sudden drop in milk production may affect up to 50% of cows at one time and cause a precipitate fall in the herd’s milk yield. The decline may last for up to 8 weeks but an individual cow’s milk production will return to normal within 10 to 14 days. The milk may have a high leukocyte count, which subsides over a period of about 14 days as milk production returns. In some cases, there is no evidence of mastitis, no change in the consistency of the milk, and no changes in the udders of affected cows, but leptospiruria may be present in up to 30% of affected cows. The herd fertility status incorporating the first service conception rate, the number of services per conception for cows conceiving, the calving-to-conception interval, and the culling rate usually reveals a low reproductive performance, especially during the year of the diagnosis. The effect is also temporary and not easily detected. Exposure of nonvaccinated dairy cows to L. Hardjo can be associated with a subsequent reduction in fertility, as indicated by a greater time from calving to conception and a higher number of breeding times per conception.

Abortion may occur several weeks after the initial infection and may also occur as the only evidence of the disease; in some areas or circumstances it is the principal clinical manifestation of leptospirosis caused by serovar Hardjo and the principal cause of abortion in cattle. In others it is thought to be an uncommon cause of abortion. This may be related to different strains of the serotype or to the degree to which the disease has become enzootic. Thus outbreaks of milk yield drop and systemic illness appears to be the characteristic clinical picture when the disease first appears in an area. However, as natural immunity develops in adult cows only heifers become newly infected, and the only sign is abortion. Furthermore, many cows have subclinical infections with hardjo in which only a fall in milk yield may be detectable.

Pigs
Leptospira serovars Pomona and Bratislava are the most common causes of infection, and chronic leptospirosis is the most common form of the disease in pigs. Pigs are the maintenance host for serovar Bratislava, which generally does not cause clinical disease other than reproductive failure, including occasional abortions and stillbirths. Serovar Pomona is of intermediate pathogenicity for pigs and is characterized by abortion and a high incidence of stillbirths. Acute disease may be observed in young pigs infected with serovar Pomona. Clinical signs include fever, anorexia, hemolytic anemia with hemoglobinuria, and jaundice. In an infected herd, the rearing rate may fall as low as 10% to 30%. An abortion “storm” may occur when the disease first appears in a herd, but abortions diminish as herd immunity develops. Most abortions occur 2 to 4 weeks before term. Piglets produced at term may be dead or weak and die soon after birth. Serovar Hardjo may be a sporadic cause of reproductive disease. There was no association between infertility and antibodies to serovars autumnalis andicterohaemorrhagiae. Icterohaemorrhagiae infection causes septicemic leptospirosis with a high mortality rate.

Sheep and Goats
The disease is rare in sheep and goats so that good descriptions of the naturally occurring disease in them are lacking; most affected animals are found dead, apparently from septicemia. Affected animals are febrile, dyspneic, snuffle, and hang their heads down. Some have hemoglobinuria, pallor of mucosa, and jaundice and die within 12 hours. Lambs, especially those in poor condition, are most susceptible. The chronic form may occur and is manifested by loss of bodily condition, but abortion seems to be almost entirely a manifestation of the acute form when the infection is pomona. With Hardjo, abortion has been recorded as the only clinical sign, and oligalactia and agalactia, similar to the bovine milk drop syndrome, have been observed in lactating ewes.

Horses
Although clinical leptospirosis in horses is uncommon, serologic surveys suggest that subclinical infection frequently occurs. These serologic studies revealed that bratislava is among the most prevalent serovars in the horse population in many countries, and it has been proposed that horses are the reservoir host for this serovar, which is rarely associated with clinical disease. Clinical leptospirosis is in most cases caused by serovars Pomona and Grippotyphosa and is associated with abortions, stillbirths, severe systemic disease in foals, intravascular hemolysis, renal and liver disease, and recurrent uveitis.

Abortion
L. interrogans serovar Pomona is a major cause of abortions and stillbirths in the equine population. The gestational ages at which abortion occurs ranges from 140 days to full-term mean (250 days) and typically follows 2 to 3 weeks after an episode of mild clinical illness with fever, anorexia, and in rare instances with jaundice.

Periodic Ophthalmia
Recurrent uveitis in horses (periodic ophthalmia, moon blindness, or recurrent iridocyclitis) is a late complication of systemic leptospirosis in horses with signs beginning months to years after naturally acquired or experimentally induced infection. It is often associated with infection with L. interrogans serovar Pomona. Clinically there are recurrent episodes of ocular disease including photophobia, lacrimation, conjunctivitis, keratitis, a pericorneal corona of blood vessels, hypopyon, and iridocyclitis. Recurrent attacks usually terminate in blindness in both eyes. There is a strong relationship between uveitis and leptospiral seroactivity in horses. Seropositive horses with uveitis are at increased risk of losing vision, compared with seronegative horses with uveitis, and Appaloosas are at an increased risk of developing uveitis and associated blindness, compared with that in non-Appaloosas. The disease has been produced experimentally by
producing infection with Pomona. Infection with pomona in foals has been observed in association with *Rhodococcus equi* to cause a very heavy mortality rate. The foals died of a combination of interstitial nephritis and uremia and pulmonary abscission and chronic enteritis. Leptospirosis has been suspected as a cause of renal dysfunction in a horse and hematura and leptospiruria described in a foal.

Nonulcerative keratouveitis associated with leptospirosis infection has been described in horses. Photophobia, epihora, and blepharoapasm are common. Hyperemia of the bulbar conjunctiva, edema of the paraorbital cornea, paurrpillary block, and iris bombe are also present. As the disease progresses, there may be hyphema, hypopyon, and organized fibrin in the anterior chamber, miosis, and dyscoria caused by posterior synchia, and the cornea may become opaque and vascularized. The cornea retains no fluorescein dye.

**Neonatal Foal Disease**

Acute leptospirosis in foals is the most severe form of the disease in horses characterized by vasculitis with petechial hemorrhages and intravascular hemolysis with hemoglobinuria, jaundice, and anemia. Renal failure, severe hepatopathy, and severe pulmonary hemorrhage have been reported in some instances.32

**CLINICAL PATHOLOGY**  
**General Considerations**

Laboratory procedures used in the diagnosis of leptospirosis include culture or detection of leptospiras or leptospiral DNA in blood or body fluids and detection and measurement of antibody in blood and body fluids such as urine, CSF, and cervicovaginal mucus. Culture of leptospires is laborious and can take up to 13 weeks. Serologic and microbiologic detection of chronically infected animals is difficult, as is the confirmation of leptospirosis as a direct cause of reproductive losses in a herd. A positive diagnosis of leptospirosis in individual animals is often difficult because of the variation in the nature of the disease, the rapidity with which the organism dies in specimens once they are collected, and their transient appearance in various tissues. During the septicemic stage, leptospiras are present only in the blood and there may be laboratory evidence of acute hemolytic anemia and increased erythrocyte fragility and often hemoglobinuria. A leukopenia has been observed in cattle, and in other species there is a mild leukocytosis. However, the only positive diagnostic measure at this stage of the disease is culture of the blood. If abortion occurs, the kidney, lung, and pleural fluid of the aborted fetuses should be examined for the presence of the organism. Serologic testing at the time of abortion is often unreliable because the acute titers have already peaked and are declining.

In the stage immediately after the subsidence of the fever, antibodies begin to develop and the leptospiras disappear from the blood and appear in the urine. The leptospiruria is accompanied by albuminuria of varying degrees and persists for varying lengths of time in the different species.

The diagnosis of leptospirosis is much easier on a herd basis than in a single animal, because in an infected herd some animals are certain to have high titers and the chances of demonstrating or isolating the organism in urine or milk are increased with samples being taken from many animals. On the other hand, in a single animal, depending on when the infection occurred, the titer may have declined to a low level and be difficult to interpret. This becomes particularly important for the clinician confronted with a diagnosis of abortion caused by leptospirosis in which the infection may have occurred several weeks previously and the serum may be negative or the titers too low for an accurate interpretation. Examination of the urine may be useful in these cases, but intermittent shedding of the pathogen by chronically infected animals must be taken into account.

**Serologic and Related Tests**

**Acute and convalescent sera** taken 7 to 10 days apart should be submitted from each clinically affected animal, or from those with a history of abortion, and sera should also be taken from 15% to 25% of apparently normal animals. Ten blood samples should be taken from each of the yearlings, the first-calf dams, the second-calf dams, and the mature age group to determine the infection status across the herd. If possible, wildlife or rodents known to inhabit the farm and use nearby water supplies should be captured and laboratory examinations of their tissues and blood performed and the results compared with those obtained in the farm animals.

**MAT** is the most common serologic test for the diagnosis of leptospirosis. It is the reference test against which all other serologic tests are evaluated and is the prescribed diagnostic test for international trade.32 It is a serovagroup-specific test, and a serovar representative of each expected serogroup in the region should be tested. Although the MAT does not usually cross-react with antibodies against other bacteria, there is significant cross-reactivity between serovars and serogroups of *Leptospiira*. Therefore, MAT cannot be used to definitively identify a serovar causing infection.32

In animals that survive infection, acute leptospirosis can readily be diagnosed on the basis of demonstrating a rising antibody titer against specific serovars in acute and convalescent sera. MAT is particularly useful in diagnosis of disease associated with incidental, non-host-adapted serovars or acute disease associated with host-adapted serovars. It is less useful in the diagnosis of chronic disease in maintenance hosts, because antibody response to infection may be negligible in chronic infections or may persist from subclinical infections. In pigs, MAT has an adequate sensitivity for some serovars, such as pomona, but is insensitive to infection associated with bratislava. The herd serologic response to infection is often more helpful than the individual’s response in chronic infections in maintenance hosts.

A major concern is the failure of the MAT to differentiate between titers after vaccination and those after natural infection because the titers may be of similar magnitude; however, titers after infection are generally higher and persist longer than vaccination titers. In any case, the vaccination history must be taken into account when interpreting positive MAT results.33 MAT is not a measure of immunity to infection because vaccination results primarily in an IgG response, with low (1:100–1:400) and transient (1–4 months) titers, but immunity is common in vaccinated animals long after MAT titers are negative. There is no consensus on the appropriate cutoff value for seropositivity; a MAT titer of 1:100 is frequently considered positive, and a fourfold rise in titer on a paired sample taken 2 weeks apart is diagnostic. In abortion associated with incidental serovars, MAT titers against pomona and other incidental serovars are high, often 1:3000. Paired sera are of limited value in chronic infections or in cases of aborting cattle because abortion occurs after infection and titers are static or declining. If several aborting cows have high titers (1:3000), this is evidence for the diagnosis of leptospirosis in unvaccinated herds.

The antibody enzyme-linked immunoabsorbent assay (ELISA) test is sensitive but lacks the serovar specificity of the MAT.34 It has convenient technical features including automation and can be used efficiently as a screening test for large numbers of serum samples. ELISA can be useful for detection of recent infection (IgM) before agglutinating antibodies (IgG) are present, but it is of limited use in regions where vaccination with leptospiral vaccine is common practice.34 Specific ELISAs for IgM or IgG antibodies are available. A positive IgM-specific ELISA result can therefore indicate that infection occurred within the previous month. For a diagnosis of leptospiiral abortion in cattle, a titer of 1:3000 is proposed as the threshold for Pomona, but no similar critical figure is available for Hardjo. ELISAs have also been developed for the use in milk of individual cows or in bulk milk to detect antibodies against serovar Hardjo.

An indirect ELISA has been developed for the detection of bovine antibodies to multiple *Leptospiira* serovars including Canicola, Copenhageni, Grippotyphosa, Hardjo, Pomona, and Sejrooe. An *antibody capture ELISA* is available to detect antibodies to a protective LPS
fraction of *L. borghaei* serovar Hardjo in cattle.

An ELISA has been used to detect a specific antibody to *L. Hardjo* in the cervicovaginal mucus as early as 2 weeks after natural or experimental infection and may reach high levels after 8 weeks. This may show some promise in diagnosis but has not yet been evaluated.

A commercially available ELISA and the ImmunoComb Leptospirosis Kit, which detect *L. hardjo* antibodies, have been compared with the MAT. The ImmunoComb and ELISA tests both exceeded the positive results obtained with the MAT. The ImmunoComb is very simple and quick, requiring no sophisticated equipment.

Aqueous Humor Antibody
Measurement of aqueous humor antibody titers against leptospires in horses offers a more accurate means of establishing a diagnosis of leptospiral-associated uveitis than serology alone.

Demonstration or Culture of Organism
A number of tests are available to detect leptospires or leptospiral DNA in tissues or body fluids.

Culture of Urine
Of all the laboratory diagnostic tests for leptospirosis, the examination of urine samples for the organism probably offers the best opportunity to demonstrate the presence of infection. Failure to demonstrate the presence of *Leptospira* in a urine sample does not rule out chronic infection because intermittent shedding is common. In individual animals, negative tests on three consecutive weekly urine samples has been considered to be good evidence that the animal is not a chronic renal carrier.

Collection of urine following treatment with a diuretic such as furosemide was found to increase the chances of detecting the organism in voided urine. Treatment with antimicrobials in the recent past decreases the chances to recover the pathogen from urine of a chronically infected patient. For maximum efficiency, one-half of each urine sample should be submitted with added formalin (1 drop to 20–30 mL of urine) and the other half submitted in the fresh state. The formalin prevents bacterial overgrowth, and the fresh urine sample may be used for culture. A liquid culture medium of 1% bovine serum albumin solution containing 5-fluorouracil at 100 to 200 µg/mL should be used as transport medium. *Leptospira* are fastidious and slow growing and culture requires incubation on special growth media for at least 16 and preferably 26 weeks. The time required for detection varies with the serovar and the number of organisms present in the sample.

Examination of urine using **dark-field microscopy or fluorescent antibody test** are useful tests. The fluorescent antibody test is more sensitive than dark-field microscopy, detects degenerated as well as intact leptospires, and may be serovar specific.

*Leptospira* in tissue can be identified by a variety of **immunohistochemical staining techniques**, such as immunofluorescence, or by various immunohistochemical techniques. These immunostain techniques are rapid and can be performed on material unsuitable for culture but require a minimum amount of bacterial antigen. Because the number of *Leptospira* present in tissue of chronically infected animals is low and often localized these methods are less suitable to identify chronic carrier states.

**PCR-based assays** provide rapid and sensitive diagnostic techniques for detection or leptospiral DNA in body fluids and tissues. A variety of primers are used, some of which are only specific for the genus *Leptospira* and others designated to identify only pathogenic species. These PCR assays do not identify the infecting serovar, although it is possible to identify a specific species by sequencing the PCR amplicons. Detection of leptospirosis DNA with PCR-based assays in urine was found to be highly sensitive and specific to identify chronically infected and shedding cattle and horses. Several studies reported a considerable number of seronegative individuals that were *Leptospira* positive by urine PCR. A multiplex PCR is highly sensitive for detection of the organism in aborted bovine fetuses. Using a *Leptospira* PCR assay, *L. kirschneri* has been identified as a potential cause of abortion in a fetal foal born on a farm with a history of repeated abortions. Further confirmation of *L. kirschneri* was done by DNA sequence analyses of the PCR-amplified DNA fragment.

Using PCR to detect the presence of *Leptospira* DNA, 70% of horses with uveitis were positive for *Leptospira* DNA, and 28% were culture positive for leptospires from the aqueous humor; only 6% of horses free of uveitis used as controls were positive. The serologic results did not correlate well with the presence of *Leptospira* DNA or organisms in the aqueous humor.

**NECROPSY FINDINGS**

Acute bovine leptospirosis is characterized by anemia, jaundice, hemoglobinuria, and subserosal hemorrhages. There may be ulcers and hemorrhages in the abomasal mucosa. Pulmonary edema and emphysema are also common in this species. Histologically, there is focal or diffuse interstitial nephritis and centriflobular hepatic necrosis and in some cases, there are vascular lesions in the meninges and brain in subacute to chronic infections. *Leptospirae* may be visible in silver-stained sections, especially in the proximal convoluted tubules of the kidney. In acute infections, there may be minimal inflammation, with only hemoglobin-filled renal tubules and centriflobular hepatic necrosis evident microscopically.

In the later stages, the characteristic finding is a progressive interstitial nephritis manifested by small, white, cortical foci that are initially raised but become slightly depressed as the lesion ages. Many clinically normal cattle presented to abattoirs have these lesions, which may represent sequela to episodes of bacteremia from a variety of pathogens and should not be considered pathognomonic for leptospirosis.

Aborted bovine fetuses are usually auto­lyzed to the point where no lesions or bacteria can be demonstrated. Even in a fresh fetus the positive identification of leptospires in lesions is not an easy task. Culture of these organisms is difficult, and *L. interrogans* serovar Hardjo is particularly fastidious in its cultural requirements. The use of a fluorescent antibody technique assists in the demonstration of organisms, but false positives are common unless the test is interpreted by an experienced diagnostician. Dark-field microscopy may be attempted but is not well suited to tissues collected at necropsy. PCR techniques show considerable promise, although sample processing requirements are stringent, and the use of multiple primer sequences may be required in some cases. Immunoperoxidase techniques are highly useful in the demonstration of leptospires in formalin-fixed tissues, although this test is not serovar specific. Traditional silver-based staining of fixed material is also successful in a few cases. Antibodies to leptospires are detectable in the serum of some aborted fetuses.

Gross placental lesions in cases of equine abortion and stillbirth associated with leptospirosis include nodular cystic allantoic masses, diffuse edema, and areas of necrosis with a mucoid exudate on the chorionic surface. The liver is enlarged, mottled, and pale-red to yellow. The kidneys are swollen and edematous with pale, radiating streaks in both cortex and medulla. Microscopic changes may include a supplicative and nonsuppurative nephritis, dissociation of hepatocytes, a mixed leukocytic infiltration of portal triads, a giant cell hepatopathy, pneumonia, and myocarditis. Thrombosis, vascu­laritis, and a mixed population of inflammatory cells are evident in the placenta. A variety of tests, as described for cattle, are available to try to confirm the diagnosis.

Aborted piglets are usually severely autolytic, with bloodstained fluid in the subcutis and filling the body cavities. Multiple necrotic foci, 1 to 4 mm in diameter and irregular in outline, are found in the liver of approximately 40% of aborted fetuses. Microscopic inflammatory changes may also be found in the kidneys. The fetal membranes are thick and edematous. *Leptospirae* can be demonstrated using the battery of tests already mentioned for cattle.
The zoonotic potential of this organism should be noted when handling carcasses and submitting specimens.

Differential Diagnosis

The differential clinical diagnosis of the common forms of leptospirosis in each species is as follows.

**Cattle**
- Acute leptospirosis: Must be differentiated from those diseases causing hemolytic anemia with or without hemoglobinuria (Table 13-3), which include babesiosis, anaplasmosis, rape and kale poisoning postpartum and hemoglobinuria, and baccillary hemoglobinuria.
- Chronic leptospirosis causing abortion: Must be differentiated from all other causes of abortion in cattle; most diagnostic surveys reveal that a specific cause is identifiable in only about 30% of fetuses submitted to a diagnostic laboratory. The vaccination history of the aborting cattle is a crucial part of the history since, for example, outbreaks of abortions caused by infectious bovine rhinotracheitis occur primarily in unvaccinated cows. The specific causes of abortion in cattle vary depending on geographic location. Other common causes of abortion in cattle include infectious bovine rhinotracheitis and protozoal abortion (Sarcocystis sp., Toxoplasma gondii, and Neospora caninum). Less common causes are brucellosis, bovine viral diarrhea, pine needle abortion, mycotic placentitis, campylobacter, ureaplasma, and possibly mycoplasma.
- Milk drop syndrome: Characterized by a sudden drop in milk yield in up to 30%-50% of the cows within several days. Must be differentiated from other causes of a decline in milk production of the herd including (1) change of feed, (2) change of management, and (3) epidemic of infectious disease such as bovine respiratory disease.

**Sheep and goats**
Chronic copper poisoning and poisoning caused by rape in sheep may present a clinical picture similar to that in leptospirosis, but there will be no febrile reaction. Anaplasmosis associated with Anaplasma ovis may be accompanied by fever and hemoglobinuria but is more commonly a chronic, emaciating disease.

**Horses**
- Abortion, stillbirths, and perinatal deaths of foals: Causes include Streptococcus zooepidemicus, Salmonella abortoovarquina, Escherichia coli, and Actinobacillus equuli. Other bacterial infections include equine herpes virus, equine viral arteritis, and fungal infections. Diagnosis depends on laboratory examination of fetal tissues and fluids including bacterial culture, direct fluorescent antibody test for equine herpes virus and leptospires, serologic examination of fetal fluids for leptospiral antibodies using the microagglutinin test, and special stains to demonstrate leptospires in fetal tissues.
- Isoimmune hemolytic anemia: Within 36 hours after birth, there is weakness, hemoglobinuria, pallor, failure to suck, tachycardia, high case–fertility rate, and cross-matching blood tests.
- Infectious equine anemia: Symptoms include chronic relapsing fever, anemia, weakness, jaundice, edema, oral mucous membrane hemorrhages, and a Coggins serologic test is used for diagnosis.
- Exertional rhabdomyolysis: Symptoms include acute onset of stiff gait, weakness, sweating, distress, myoglobinuria, and creatine kinase test is used for diagnosis.
- Periodic ophthalmia: Differentiate from other causes of infectious conjunctivitis of horses, and conjunctivitis, keratitis, and hypopyon, which may occur in equine viral arthritis.

**Pigs**
- Abortion in the last trimester: The common manifestation of leptospirosis in pigs must be differentiated from all other causes of abortion, mummification, and stillbirths in swine. Other common causes of abortion in swine are parvovirus and porcine reproductive respiratory syndrome. Less common causes are brucellosis; pseudorabies; and the infertility virus.

**TREATMENT**

Treatment objectives can be to treat individuals with clinical disease or to treat chronically infected animals that may be clinically normally but chronically or intermittently shedding leptospires in urine.

**Antimicrobial Therapy**
In vitro studies indicate that leptospires are highly susceptible to ampicillin, amoxicillin, penicillin G, cefotaxime, erythromycin, and fluoroquinolone ciprofloxacin and have a good susceptibility to streptomycin, tetracycline, and tetracycline.

For infections caused by pomona, dihydrostreptomycin (12 mg/kg IM twice daily for 3 days) is effective in the treatment of the systemic infection. For the elimination of leptospiuria in cattle and pigs, a single dose of dihydrostreptomycin (25 mg/kg IM) has been recommended. In an outbreak in cattle, the simultaneous treatment of all animals with dihydrostreptomycin (25 mg/kg IM as single dose) and vaccination has been successful in preventing new cases and abortion when pregnant cow is involved. A similar approach is recommended for outbreaks in swine. Annual revaccination and regular serologic testing for new infections, combined with controlling the source of new infections, will usually successfully control further outbreaks. A surveillance system in the area is necessary; however, to detect the introduction of new serotypes. The use of streptomycin/dihydrostreptomycin in food-producing animals has been discouraged because their administration, even at label dose, had the potential to lead to residue violations, and these substances are no longer available for the use in food-producing animals in some countries. Ofloxacin, amoxicillin, telminasin, and cefetilurofur are also effective for resolving leptospirosis in cattle.

Dihydrostreptomycin G (25 mg/kg IM for 1 day, 3 days, or 5 days), or oxytetracycline (40 mg/kg IM daily for 3 days or 5 days), tylosin (44 mg/kg IM daily for 5 days), or erythromycin (25 mg/kg IM daily for 5 days) are all effective for treatment of persistent leptospirosis caused by Pomona in swine, although these dose protocols exceed label recommendations. In groups of pigs, the feeding of oxytetracycline (800 g/t of feed for 8–11 days) is claimed to eliminate carriers. Antimicrobial feeding should begin 1 month before farrowing to avoid the occurrence of abortion.

For outbreaks of leptospiral abortion in horses, treatment of pregnant mares with dihydrostreptomycin (50 mg/kg) IM daily for 3 to 5 days can minimize further abortions; this treatment regimen, however, has not been extensively evaluated.

For equine periodic ophthalmia, most recommended treatments have little effect on the course of the disease. A course of a suitable antibiotic systemically, and the administration of a corticosteroid, either parenterally in an acute episode or subconjunctivally in a chronic case, is most likely to be satisfactory. Nonulcerative keratouveitis requires long-term and intensive medication and recurs with tapering of treatment. Topical and subconjunctival corticosteroids are recommended in controlling nonulcerative keratouveitis. Intravitreal implantation of cyclosporine is effective. Atropine eye ointment is also usually applied three times daily to maintain dilatation of the pupil.

**Blood Transfusions**
Blood transfusions (5–10 L/450 kg BW) are indicated as treatment for the hemolytic anemia in acute leptospirosis in cattle. The clinical indications for a blood transfusion include obvious pallor of the mucous membranes, weakness, and tachycardia.
Myoglobinuria occurs occasionally in young cattle affected with enzootic-nutritional muscular dystrophy and may be confused with hemoglobinuria.

Dihydrostreptomycin (25 mg/kg IM every 24 hours for 3–5 days) (R-2)

Oxytetracycline (20 mg/kg IM every 24 hours for 3–5 days) (R-2)

Oxytetracycline, long acting (20 mg/kg IM as a single dose to all positive reactors) (R-2)

Tilmicosin (20 mg/kg SC as a single dose to all positive reactors) (R-2)

Tulathromycin (2.5 mg/kg SC as single dose) (R-2)

Vaccination with multivalent vaccines of exposed animals in an infected herd (R-2)

Vaccination with multivalent vaccines of replacement heifers within 4–6 months of age (R-2)

The common causes of hematuria in cattle are pyelonephritis and cystitis caused by Corynebacterium renale, nonspecific cystitis, and enzootic hematuria. Myoglobinuria occurs occasionally in young cattle affected with enzootic-nutritional muscular dystrophy and may be confused with hemoglobinuria.

</table>

The first step in control is to identify the source of the original source of infection and to interrupt transmission. Sources of infection include clinically affected animals, aborted fetuses, placentas, carrier animals, wildlife, dogs and cats, and environmental sources such as water supplies. Education about leptospirosis is an effective method for reducing its incidence and its effects. Intensive well-directed education and publicity campaigns in New Zealand, used in conjunction with a campaign for immunization of cattle, reduced the incidence of leptospirosis. Groups to which educational efforts should be directed include professionals in human and veterinary medicine and public health, primary human and animal health care practitioners, wildlife and conservation scientists, water and sewage engineers and planners, health administrators and educators, and last but not least, the public at risk.

**Three main considerations** are important when assessing the risks and likely financial implications of the disease to dairy producers:

1. Likelihood of a herd being infected
2. Likely effects of the disease on the dairy enterprise, both physically and financially, following the initial infection compared with a leptospirosis-free herd
3. Likely longer term effects of the disease

The probability of infection of cattle by *L. Hardjo* is increased by **four factors**:

1. Purchase of infected cattle
2. Cograzing or common grazing with infected cattle or sheep
3. Use of natural service with an infected bull
4. Access of cattle to contaminated water such as streams, rivers, flood, or drainage water

Assessment of the risks facing different types of herds suffering losses from *L. hardjo* can then be used to help support decisions concerning control of the disease.

Producers with one or more of the main risk factors should consider strategies that
can be taken to eliminate hardjo infection:

1. Judicious combination of group serologic testing
2. Segregation of age classes
3. Selective vaccination
4. Possibly artificial insemination
5. Isolation of the herd from outside sources of infection.

Bulls suspected of spreading infection should be treated to reduce the level of urinary shedding regardless of subsequent vaccination. Exposure of cattle to herds, heavily infected with leptospirosis, for example, on communal grazing pastures should be avoided. The herd should be monitored periodically, coincident with other serologic testing. In endemic areas, all cattle over 6 to 9 months of age should be vaccinated, and vaccination should be continued for up to 5 years to minimize the number of susceptible cattle until no long-term shedders remain in the herd. Simple management procedures to limit the infection in beef cows until their second calves are born and the culling of older carriers can greatly decrease and possibly eradicate the infection from a herd. Virgin yearling bulls are used on virgin yearling heifers, and young cows are segregated from older cows until 38 to 39 months of age when they go to pasture after being bred with their second calf. This delays direct exposure of heifers to infected cattle until their third breeding. These practices must be combined by monitoring infection by serologic and other laboratory methods.

If eradication is attempted and completed, introduced animals should be required to pass a serologic test on two occasions at least 2 weeks apart before allowing them to enter the herd. Urine examination for leptospirosis should be performed if practicable.

**Hygiene**

Control of the source of the organism is achieved by appropriate hygienic strategies. If the environmental sources of infection are identifiable, in the form of yards, marshes, and damp calf pens, every attempt must be made to avoid animal contact with these infective surroundings. Wet areas should be drained or fenced and pens disinfected after use by infected animals. The possibility that rats and other wild animals may act as a source of infection suggests that contact between them and farm animals should be controlled.

**Vaccination**

Vaccination against leptospirosis in cattle and swine is in general use and an effective method for control of the disease. In New Zealand, a publicity campaign to promote the widespread vaccination of cattle resulted in a marked reduction in the incidence of human leptospirosis. Most of the vaccines are formalin-inactivated bacteria containing one or more serotypes. Vaccines containing Freund’s complete adjuvant induce higher serologic responses but not necessarily superior protection. The immune response is serotype specific and protection is dependent on the use of bacteria containing serotypes prevalent in the area. The bacteria induce a low titer to the MAT, which appears early and declines after several weeks; however, protective immunity against the disease and renal infection persists for at least 12 months in cattle. Regular serologic testing in herds vaccinated annually can be used to monitor new infections because these will induce a titer to the MAT. However, neither the ELISA nor the MAT can reliably differentiate serologic responses in cattle after leptospiral vaccination from those following natural infections.

**Cattle**

The difficulty of keeping purebred herds free of Hardjo infection increases as the reservoir of infection increases. Several control measures can be applied, especially in large herds that are at high risk. In endemic areas, transmission in commercial herds can be suppressed by annual vaccination of bulls, replacement heifers, and 2- and 3-year-old females a few weeks before release of the bulls. Potential replacement heifer calves should be handled and raised in segregation from the adult herd after weaning and vaccinated a month before exposure to older cattle. Herd sires should be purchased from uninfected herds or at least purchased subject to a negative serologic test.

Vaccination as part of a herd health program should start with the calves at 4 to 6 months of age, followed by revaccination annually. Such programs should provide significant rises in calving rates, but have little or no effect on perinatal or postnatal losses.

**Bovine Leptospiral Vaccines and Their Efficacy**

Current bovine multivalent leptospiral bacterins are inactivated whole-cell vaccines containing *L. interrogans* serovar Hardjo, Canicola, Pomona, and Icterohaemorrhagiae and *L. kirschneri* serovar Grippotyphosa and generally induce protective immunity against infection with non–host-adapted strains. In contrast, protection against the host-adapted serovar Hardjo is more elusive with conflicting evidence about vaccine efficacy. Vaccination of cattle with a pentavalent leptospiral vaccine containing either Hardjo-bovis or Hardjo-prajitno failed to protect cattle from experimental infection with hardjo-bovis 6 months after vaccination. They also failed to prevent abortion, stillbirth, and vertical transmission of infection when vaccinated cows were challenged with *L. borgpetersenii* serovar Hardjo during pregnancy, and the infection rates for control and vaccinated cattle did not differ. The Hardjo-bovis vaccine is more antigenic than the hardjo-prajitno as measured by higher antibody titers in vaccinated animals. Calves as young as 4 weeks of age, vaccinated in the
presence of maternally derived antibody, can be fully protected against homologous virulent challenge. However, monovalent vaccines with a field isolate of *L. borgpetersenii* serovar Hardjo and another with *L. interrogans* serovar Hardjo found these vaccines prevented infection and colonization following challenge with *L. borgpetersenii* serovar Hardjo strains from the United States and Europe.

A protective killed vaccine against serovar hardjo induced a strong, sustained Th1 or cell-mediated response. The vaccine is composed of a whole-cell bovine isolate of *L. borgpetersenii* serovar Hardjo and aluminum hydroxide and is given as two doses subcutaneously 4 weeks apart. Following vaccination, a Th1 cell-mediated response occurred characterized by the production of IFN-γ cells including CD4+ and WCI gamma delta T cells.

A monovalent *L. borgpetersenii* serovar Hardjo (type Hardjo-bovis) vaccine commercially available in Australia, New Zealand, Ireland, and the UK, given as two doses, 4 weeks apart, protected heifers against renal colonization and urinary shedding when challenged with *L. borgpetersenii* serovar Hardjo strain 203, 4 months after vaccination. None of the animals shed leptospires in their urine or kidneys at necropsy. In contrast, all nonvaccinated control heifers became infected with serovar Hardjo and shed organisms in their urine. A pentavalent leptosporial vaccine with serovar Hardjo (type Hardjo-bovis) also containing BHV1, BVDV, PI-3, and BRSV fractions against important viral respiratory pathogens was found to protect heifers vaccinated at 1 month of age from colonization of the kidney and to reduce leptosporial shedding with urine in experimentally challenged animals for at least 1 year.

Two monovalent hardjo vaccines provided protection from infection against *L. borgpetersenii* serovar Hardjo, whereas a pentavalent vaccine containing the Hardjo organisms did not. The protective monovalent vaccines produced strong cell-mediated immune responses in vaccinated cattle as demonstrated by proliferation of lymphocytes and production of IFN-γ by their PBMCs in response to culture with serovar hardjo antigens. This response is generally much lower or absent in antigen-stimulated cultures of PBMC from cattle vaccinated with the pentavalent vaccine and nonvaccinated cattle.

In conclusion, protective immunity to serovar Hardjo correlates with induction of a substantial immune response that is characterized by antigen-specific IFN-γ-producing T cells. There is no cross-immunity between *L. Pomona* and Hardjo, and in areas where both diseases occur, a bivalent vaccine is used routinely. If separate vaccines are used the *L. Pomona* vaccine should be administered at least once annually, but the *L. Hardjo* vaccine provides some protection against *L. szwajczerzak*.  

**Swine**

Vaccination of sows and gilts before breeding with a bivalent vaccine, containing pomona and tarassovi, protects them against infection and the development of leptospirosis and is widely practiced, especially in large intensive piggeries. In the United-States, vaccination of gilts and sows with two doses of a bacterin containing five or six leptospiiral serovars, one of which contained Bratislava, before the first breeding and thereafter before each breeding improves reproductive performance. *L. Bratislava* is an important cause of abortions in sows in North America and Europe, and vaccination is effective. Vaccination of pregnant gilts and sows can provide protection to the piglets for the first several weeks after birth.

**Vaccination and Antimicrobial Strategies**

Whether or not to vaccinate depends on the cost of the procedure relative to the losses that can be anticipated. If the disease is spreading rapidly, as evidenced by the frequent appearance of clinical cases with a high range of titers or rising titers in a number of animals, then (1) all clinical cases and positive reactors should be treated, (2) the negative animals vaccinated, and (3) the herd should be moved on the first day of treatment to a clean field. Retesting a group to determine the rate of spread would be an informative procedure, but active measures must usually be commenced before this information is available. Another variation of this program, and a highly practical one, is the vaccination of all cattle in the herd and the treatment with one dose of dihydrostreptomycin (25 mg/kg IM) of all pregnant cows to eliminate renal infection and leptospirosis. However, antimicrobial therapy is not highly efficacious, especially in cattle infected with Hardjo.

A successful control strategy has been described for Hardjo infection in a large, closed herd beef. All animals were treated with dihydrostreptomycin once followed by removal to a clean pasture to prevent new cases and annual vaccination of the whole herd for 5 years. All cattle introduced into the herd were treated with the antimicrobial and quarantined; at the end of the trial all the herd were treated with the antimicrobial for 5 years. All cattle introduced into the herd were treated prophylactically with the antimicrobial and then (1) all clinical cases and positive reactors on the first day of treatment to a clean field.

If only sporadic cases occur, it may be more profitable to attempt to dispose of reactors or treat them to ensure that they no longer act as carriers. A degree of immunity is likely to occur in pigs after natural infection, and when the disease is endemic “herd immunity” may significantly decrease incidence of clinical disease.

One of the theoretical disadvantages of vaccination is the possible development of renal carrier animals that are sufficiently immune to resist systemic invasion but not colonization of the kidney, which leads to the development of a carrier animal with transient leptospirosis. This may occur but not frequently enough to invalidate vaccination.

**REFERENCES**

**FURTHER READING**

ETIOLOGY
Corynebacterium renale and Escherichia coli are the most common causative agents.

Epidemiology
There is incidental disease with worldwide occurrence. Organisms pertain to normal flora of the lower urogenital tract. Ascending infection is most common in adult cows within weeks after calving, occasionally in calves as a complication of omphalourachitis. Predisposing factors are vaginal/uterine infection or immunosuppression.

Clinical findings
Periodic episodes of hematuria, pyuria, colic, straining to urinate, fever, loss of condition, and drop in milk production are observed. Palpable abnormality of kidney, ureters, and bladder on rectal examination. Cystitis is determined by endoscopic examination and pyelonephritis by ultrasound examination.

Clinical pathology
Cloudy urine with hematuria, proteinuria; on microscopic examination there is increased cellularity of sediment with bacteria. Elevated serum total protein, globulin and fibrinogen, and low serum albumin. Cases with markedly elevated serum creatinine and urea nitrogen concentrations have poor prognosis.

Necropsy findings
Cystitis and pyelonephritis are found.

Diagnostic confirmation
Gross changes in urine, together with palpable abnormalities in the urinary tract, and the presence of bacteria in the urine are seen.

Treatment
Prognosis is fair at best, prolonged course of antimicrobial therapy, and nephrectomy in unresponsive cases.

Control
Avoidance of urinary catheterization and artificial insemination.

BOVINE PYELONEPHRITIS

SYNOPSIS

ETIOLOGY
Corynebacterium renale and Escherichia coli are the most common causative agents.

EPIDEMIOLOGY
Occurrence
Although the disease is widespread in Europe, North America, Australia, Africa, Japan, and Israel and probably occurs all over the world, it seldom constitutes an important problem in any herd or area. As a rule, clinical cases are sporadic, even in herds found to harbor a significant number of carriers. Differences in disease prevalence can probably be explained by differences in predisposing management factors. One study in 7 herds found an annual incidence that varied from 0.5% to 1.5% and in one herd was 16%. A slaughterhouse survey conducted in the United States estimated the prevalence of pyelonephritis in the dairy cattle population with less than 1%. Subclinical infection may be more frequent than first recognized, and 13% of adult cattle have bacteria associated with pyelonephritis in their bladder at slaughter, in the absence of gross or histologic evidence of pyelonephritis or cystitis. Chronic cystitis and pyelonephritis (etiologic untested) have been found in 5.3% and 0.2% of cattle at slaughter.

Although pyelonephritis is considered to be a predominantly a bovine disease, sheep are occasionally affected.

SOURCE OF INFECTION AND TRANSMISSION
Both C. renale and E. coli pertain to the resident flora of the lower urogenital tract of cattle. C. renale can be isolated from urine of affected or carrier animals and in Japan has been isolated from the vagina or vaginal vestibule of approximately 6% of healthy cows. Clinically and subclinically infected cattle can shed C. renale with urine for prolonged periods into the environment, in which it can survive for over 50 days. The incidence of cows excreting C. renale in their urine is higher in herds where the disease occurs than in herds where the disease is unknown.

In cattle, infection can be transmitted by direct contact, by the use of contaminated brushes, or by the careless use of catheters.

VENEREAL TRANSMISSION of C. renale infection has also been proposed. This is suggested by the occasional occurrence of a series of cases in a herd, usually related to the use of a particular bull, and the cessation of cases when artificial insemination is used. The organism can often be isolated from the prepuce, urethra, and semen of bulls that have no detectable lesions in the prepuce. C. renale can be a cause of balanoposthitis in bulls.

Ascending infection of the urinary tract with E. coli has generally attributed to fecal contamination of the urinary tract, frequently in association with impaired urinary tract defense.

Risk Factors

ANIMAL RISK FACTORS
Pyelonephritis is most common in adult cows in the weeks to months following parturition. In young calves pyelonephritis can often be traced back to an ascending umbilical infection. Female cattle are more susceptible to ascending urinary tract infections than males presumably because of a shorter and wider urethra. In bulls and steers pyelonephritis may occur as a complication of a urinary tract obstruction.

Approximately 75% of clinical cases occur in postparturient cows following abortion, dystocia, or puerperal infection, suggesting that inflammation and infection of the lower urogenital tract presents as an important predisposing factor.

PATHOGEN RISK FACTORS
C. renale and E. coli are normal inhabitants of the lower urogenital tract of ruminants, but certain strains possess pili, a virulence factor facilitating the colonization of the mucosa of the urinary tract and the progression of the infection. Piliated strains of both bacteria occur and have a greatly enhanced ability to adhere to epithelial cells of the urinary tract.

ENVIRONMENTAL RISK FACTORS
An increase in clinical cases is usually found in the colder seasons of the year and heavily fed, high-producing dairy herds appear to show an increased susceptibility.

The systematic use of urinary catheters to collect urine from cows in early lactation with suspect ketosis has been associated with increased occurrence rates of pyelonephritis. Although not intentionally produced, the disease occurred in 10% of a group of cattle used to teach veterinary students the technique of urinary catheterization.

In Israel, the ingestion of rock rose (Cistus salviifolius) is reported to produce urinary retention and predisposes cattle to pyelonephritis.

ECONOMIC IMPORTANCE
Unless appropriate treatment is instituted early, the disease is highly fatal and economic loss is mainly caused by the deaths of affected animals.
PATHOGENESIS
Pyelonephritis usually develops as an ascending urinary tract infection involving successively the bladder, ureters, and kidneys. Trauma to the urethra, urine stasis, or a patent urachus in calves may facilitate ascending infection. The destruction of renal tissue and obstruction of urinary outflow ultimately result in uremia and the death of the animal.

Piliated and nonpiliated forms of C. renale are present in infected animals, but their relative importance to the pathogenesis of the disease is uncertain. Piliated forms of C. renale and E. coli have a greater ability to attach to urinary tract epithelium, are more resistant to phagocytosis, and are probably important to the carriage of the organism and to the initial ascending infection. However, in the course of an infection there is a shift from piliated to nonpiliated forms, which may reflect a response to the development of antipilus antibodies.

CLINICAL FINDINGS
Early signs vary considerably from case to case. The first sign observed may be the passage of bloodstained or cloudy urine in an otherwise normal cow. In other cases, the first sign may be an attack of acute colic, manifested by swishing of the tail, treading of the feet and kicking at the abdomen, and straining to urinate. The attack passes off in a few hours. Such attacks are caused by obstruction of a ureter or renal calyx by pus or tissue debris and may be confused with acute intestinal obstruction. More often the onset is gradual with a fluctuating temperature (about 39.5°C; 103°F). capricious appetite, loss of condition, and drop in milk yield over a period of weeks. Other than this, there is little systemic reaction, and the diagnostic signs are associated with the urinary tract.

The most obvious sign is the presence of blood, pus, mucus, and tissue debris in urine, particularly in the last portion voided (Fig. 13-5). Urination is frequent, may occur in a dribble rather than a stream, and may be painful. Periods during which the urine is abnormal may be followed by apparent recovery with later remissions.

In the early stages, rectal examination may be unremarkable, but later there is usually detectable thickening and contraction of the bladder wall and enlargement of one or both ureters. These are not normally palpable, but in chronic cases they may be felt in their course from the renal pelvis of the left kidney to the bladder. The terminal portion of the ureters may also be palpated through the floor of the vagina over the neck of the bladder. The palpable left kidney may show enlargement, absence of lobulation, and pain on palpation; the right kidney may be palpable in small ruminants if it is significantly enlarged. In many cases there are no distinct clinical signs referable to the urinary tract, and the history and clinical signs may be weight loss and suspected gastrointestinal disease. In these cases, examination of the urine is essential to diagnosis. The course is usually several weeks or even months and the terminal signs are those of uremia.

Endoscopic examination of the urethra and bladder can be diagnostic. Ultrasound examination shows cystic changes in the affected kidney, a reduction in renal pelvis diameter, a reduction in renal parenchyma, a widened ureter, and a hyperaemic bladder wall.5

CLINICAL PATHOLOGY
Urine analysis reveals proteinuria and hematuria, and the latter is grossly apparent in most cases. Urine pH is greater than 8.5 in most but not all cases, whereas the specific gravity has been recorded between 1.008 and 1.021.7 Microscopic examination will show pyuria. The presence of bacteria in suspected urine can be confirmed by culture, specific immunofluorescence, or direct microscopic examination.

Hematologic and blood biochemical examination reveals hypoalbuminemia and hypergammaglobulinemia in advanced cases. Neutrophilia may be present but is not constant in all cases. Serum creatinine and BUN are elevated in advanced and severe cases, but these parameters are not reliable indicators for the presence of pyelonephritis in mild or early cases.7 Serum creatinine and BUN concentrations above 1.5 and 100 mg/dL, respectively, carry a grave prognosis.

Ultrasonography was found useful to confirm the diagnosis and determine the extent of the disease. In particular this allows examination of the right kidney, which is not accessible by rectal examination. Ultrasonography may demonstrate cystic changes in the affected kidney, dilated renal sinuses and ureters, and a thickened echogenic bladder.25

NECROPSY FINDINGS
With pyelonephritis, the kidneys are usually enlarged and the lobulation less evident than normal (Fig. 13-6). The renal calyces and grossly enlarged ureters contain blood, pus, and mucus. Light-colored necrotic areas may be observed on the kidney surface. Changes visible on the cut surface include excavation of papillae, abscessation, and wedge-shaped areas of necrosis that extend from the distal medulla into the cortex. The bladder and urethra are thick walled and their mucous membranes are hemorrhagic, edematous, and eroded (Fig. 13-7). Histologically, the renal lesions are a confusing mixture of acute supplicative changes and various degrees of fibrosis with mononuclear cell infiltration.

Samples for Confirmation of Diagnosis
- Bacteriology: kidney; culture swab from ureter (CULT)
- Histology: formalin-fixed kidney, ureter, bladder (LM)

TREATMENT
Treatment recommendations for pyelonephritis reported in the literature are empirical, and unfortunately strong data supporting their clinical efficacy are not available. Common wisdom holds that pyelonephritis caused by C. renale is best treated with penicillin administered parenterally daily for at least 2 to 3 weeks. For cases of suspected or confirmed infection with E. coli a broad-spectrum antimicrobial should be chosen. A number of antimicrobials, including ampicillin, amoxicillin, tetracycline, trimethoprim-sulfa, ceftiofur, and gentamycin have been proposed.

In early cases where little structural damage has occurred, permanent recovery can be expected following such a course of treatment. Generally, a good prognosis is suggested by an improvement in condition, appetite, and milk yield and clearing of the urine. However, in well-established cases with extensive tissue destruction the prognosis is fair at best, relief is only transient, and relapses are common. For valuable animals, in which ultrasound has established the diagnosis and confirmed that the contralateral kidney is unaffected, unilateral nephrectomy may be an alternative with reasonable prognosis.9 The surgical technique...
Procedures such as urinary catheterization should be avoided, and routine vaginal examinations should be conducted with proper hygienic precautions. Where natural breeding is practiced, some reduction in occurrence may be achieved by the introduction of artificial insemination.

REFERENCES

URINARY DISEASE IN SWINE

Glomerulonephritis
In pigs, glomerulonephritis occurs sporadically and may be associated with immunologic, thrombotic, toxic, or unknown mechanisms. It has been seen as a sporadic event following infectious diseases such as African swine fever, classical swine fever, streptococcal infections, and cytomegalic virus infections. There is also a specific condition of glomerulonephritis in Yorkshire pigs in Norway. The condition of porcine dermatitis and nephropathy syndrome is a specific condition seen in many countries after the advent of porcine circovirus 2 infections but reaching its most severe in the UK. It is immune mediated, possibly through a type III hypersensitivity reaction, and is discussed in more detail in relation to porcine circovirus.

Nephrosis
Acute tubular necrosis (nephrosis) is a feature of a number of pig disorders including pig weed toxicity, nephrotoxins, and antibiotic use.

Embolic Nephritis
It is important to remember that the pig kidney has a wide range of congenital deformities, such as cystic kidneys, which persist into adult life. Most importantly it has a nephrogenic zone, which gives rise to new glomerular units in the 3 months after birth, and these are readily visible under the capsule of the kidney. They are readily involved in kidney lesions associated with sepsis and thrombosis, and involvement of these pathologic processes in the occurrence of the “Turkey egg” kidney has now been associated with over 30 different etiologic agents. The most important of these conditions are Actinobacillus suis, Streptococcus suis, staphylococci, E.coli, Erysipelothrix rhusiopathiae, and T. pyogenes.

Interstitial Nephritis
One of the common causes of interstitial nephritis is leptospirosis and another is PCV2 infection. They may only be visible on histologic examination.
Other Conditions

These include urolithiasis, which is found in pigs that are sometimes on unusual diets or where there is a shortage of water. The bladder of sows sometimes also contains some sediment and there may be infection-induced calculi. Uric acid and urates are sometimes found in the kidneys of piglets. The kidney worm (Stephanurus) is a cause of kidney problems in some parts of the world, and mineralization of the kidneys in vitamin D toxicosis may also be seen very occasionally. Chronic salt intoxication has recently been seen in growing pigs and is characteristically seen as diffuse bilateral interstitial fibrosis.

**PORCINE CYSTITIS AND PYELONEPHRITIS**

**SYNOPSIS**

**Etiology** 
*Actinobaculum suis* is the specific cause, but a range of other bacteria (principally Escherichia coli) may also cause the condition.

**Epidemiology** 
Infection of male pigs causes the disease in sows. The organism is in the prepuce and environment. Transmission is venereal and through dirty farrowing houses. Trauma to the urogenital tract of females predisposes to disease.

**Clinical findings** 
Unexpected death in acute cases. There is pain on urination, bloodstained, turbid urine accompanied by vaginal discharge; often after service; cystitis on endoscopic examination.

**Clinical pathology** 
Hematuria, pyuria, proteinuria, bacteraemia are seen. Urine pH >8.5. Demonstration of organism by culture or immunofluorescence; azotemia, increased concentrations of urea and creatinine, hyperkalemia, and hyponatremia.

**Necropsy findings** 
Purulent cystitis and pyelonephritis.

**Diagnostic confirmation** 
Urinalysis, endoscopic examination, and demonstration of *A. suis*.

**Treatment** 
Unrewarding unless early in the course of the disease—antimicrobials and supportive therapy; humane destruction of cases.

**Control** 
Antimicrobials by injection, in water, or in feed; ensure adequate water supply for lactating sows to aid urination and improve postfarrowing hygiene.

**ETIOLOGY**

Cystitis and pyelonephritis are associated with a variety of agents including *E. coli* and others (*Pseudomonas aeruginosa*, staphylococci, streptococci, *Proteus* spp., *Klebsiella* spp., enterococci, and *A. pyogenes*). Infections with most of these organisms result in catarrhal/purulent cystitis.

The genotypic and phenotypic characterization of *E. coli* strains associated with porcine pyelonephritis has been described. The specific disease is most commonly associated with *Actinobaculum suis*. This was formerly known as *Eubacterium suis* and before that as *Corynebacterium suis*. This organism is a large gram-positive rod that is difficult and slow to grow and requires special culture media.

**EPIDEMIOLOGY**

All these organisms causing cystitis and pyelonephritis are thought to produce the condition as a result of ascending infection. The disease is a particular problem when sows are in stalls or tethered. The condition may not be so serious when associated with all the species other than *A. suis* and in these cases may be seen as frequent urination, the presence of blood or pus in the urine, and a progressive loss of condition. It is in postpartum sows that have bred.

**Occurrence**

The infection may be common but the disease is better viewed as sporadic. The disease is probably worldwide in outdoor and indoor units. There are no details of prevalence, although it has been described as the most important cause of sow deaths, with up to 25% associated with urinary tract infection. It probably occurs more frequently than is recognized because there is a considerable subclinical infection rate. In a recent study in the United States, *A. suis* was isolated from 4.7% of the bladders of sows collected at random at a slaughterhouse.

In small herds, the disease tends to occur in small outbreaks when a small number of sows become infected after being mated to a single boar. Often, the clinical outbreak may be 2 to 3 weeks after the use of the suspected boar. More serious outbreaks can occur in large, intensive piggeries. The disease can also occur sporadically and be a normal feature of sow mortality.

In a recent study of 1745 pregnant sows, 28.3% were found to have urinary infections and *A. suis* was found in 20.6% of these. It was less prevalent (13.7%) in the sows with urinary infections than in those without (23.1%). In an abattoir survey in the Netherlands, the prevalence of cystitis in slaughtered sows was 11%, with a variation depending on group from 0% to 35%. In this study of 114 bladders, *A. suis* was not isolated, but *E. coli* was the most commonly isolated together with *S. dysgalactiae*, *A. pyogenes*, *Acrococcus viridans*, and *S. suis*.

**Source of Infection and Transmission**

*A. suis* is a normal inhabitant of the porcine prepuce and can be isolated from the preputial diverticulum of boars of various ages. The prevalence of the infection in adult males may be as high as 90%, and the organism can be isolated from the floor of the pens containing infected boars. Infection and colonization of the preputial diverticulum may occur in pigs as early as 5 weeks of age if they are housed with older pigs. Frequently, this infection may occur from pen floor contamination because of poor hygiene. Piglets can also become infected, at an early age, from sows that have chronic cystitis and pyelonephritis, and the infection can spread rapidly to other male pigs when they are grouped at weaning. Although infection is common in the male pig, cystitis and pyelonephritis is extremely uncommon in females. *A. suis* is rarely isolated from the urogenital tract of the healthy female pig.

Clinical disease is almost entirely restricted to the female pig that has bred. Venereal transmission is thought to be the primary if not the sole method of infection of the sow. Trauma to the vagina may be an important predisposing factor allowing infection to establish, and trauma at parturition with infection from the environment may also be important.

There is no doubt that, where conditions in stall houses are rife with fecal contamination and poor drainage from the rear half of the stall, perineal and vulval contamination is much greater.

**Risk Factors**

Clinical signs may occur at any age but are common at 3 to 4 weeks postservice. The disease is more common in sows kept in intensive confinement conditions than in those that are kept in open lots, pens, or pasture, but it does occur in these systems if the hygiene is poor. Differences in feeding patterns and exercise that occur in the different management systems can influence the frequency and volume of water intake. This in turn has an important effect on the frequency of urination and the residual volume of urine in the bladder following micturition, which is one of the factors that may predispose to the establishment of urinary tract infection. Because many lactating sows will only stand when they are fed, usually twice a day, they will also only urinate and drink twice a day. If they cannot take in enough water from either a trough or a tap during this period at the correct flow rate, they may be suffering from an inadequate water intake. It has also been shown that crystalluria may well damage the mucosa and aid the formation of cystitis and that the crystals also support infection of the bladder, particularly where there is an insufficient water supply.

**Economic Importance**

In one of the best studies of sow mortality in the UK it was reported that the principal cause of death in up to 25% of the sows was urinary tract infection. If the sow mortality is below 5% then cystitis/pyelonephritis...
is unlikely to be an important problem in the herd.

Cystitis and pyelonephritis is of great importance because it is a major cause of death (annual death rate may be in excess of 5%) in sows in both Great Britain and the United States and, even more important, a cause of serious culling; the recommendation is to cull affected sows because they will always be a source of infection. Considerable prevention, treatment, and hygiene costs will also ensue.

**PATHOGENESIS**

The organism is widespread in the prepuce of boars, is introduced into the sow at service, but it usually rapidly dies out. In healthy sows, *A. suis* can be isolated from the vagina, but not from the bladder, for a short period after an infected service. In experimental infections of normal sows, it rapidly dies out. The factors that allow it to establish in the urogenital tract are unknown, but trauma to the vagina and urethral opening and service into the bladder are supposed factors. The other organisms listed may also act synergistically to damage the mucosa and facilitate colonization by *A. suis*. This may be true, because *A. suis* possesses two sorts of pili by which it attaches to damaged bladder epithelium. Cystitis results in damage to the ureterovesical junction facilitating ascending infection from the bladder to the kidneys. In infected sows, tortuosity and blockage of the ureters is fairly common. This and the changes in the kidney may lead to chronic renal failure and the inability to retain sodium with potassium retention in the blood and sudden death and even acute renal failure if the blockage is complete and bilateral.

**CLINICAL FINDINGS**

Mildly affected sows may only show transient inappetence, and other animals are recognized because they are uremic. In the more severely affected groups, the presentation is either as an acute case, usually postservice, or as a chronic one, which can occur at any time.

Most commonly sows present as acute renal failure and sudden death. Sows are suddenly severely ill, unwilling to rise, show profound depression and circulatory collapse, and die within 12 hours. In one series of cases, 40% of the affected sows presented as unexpected deaths, and in the remainder the mean interval between presenting signs and death was 1.6 days and the longest interval was 5 days. The condition may occur in older sows (fourth parity sows and above).

Where the surveillance is good, the sows are observed to be depressed, anorectic, mildly febrile (normal to 39.5°C; 103°F), and sometimes show arching of the back, twitching of the tail, and painful urination. There is frequent passage of bloodstained, turbid urine accompanied by vaginal discharge. Examination with a vaginal speculum will confirm the bladder as the source of the bloody discharge.

The case–fatality rate is high. Sows that survive the acute disease develop chronic renal failure with weight loss and polydipsia and polyuria. They are usually culled for poor performance.

Endoscopic examination of the bladder in acute cases may show little other than mild inflammation, but in more serious cases there are ulcerative and erosive bladder lesions. In sows large enough to allow rectal examination, it may be possible to feel the large and thickened bladder and dilated tortuous ureters in chronic cases. Boars are usually unaffected clinically but intermittent, hematuric episodes lasting several days have been recorded.

The condition can be seen as a sequel to any locomotor, particularly central brain or spinal condition in which there is an inability to stand to drink or micturate, e.g., organophosphorus poisoning.

**CLINICAL PATHOLOGY**

Sows’ urine is frequently turbid (83.1%) and usually this can be associated with the presence of crystals (96.1%).

Urinalysis usually shows hematuria, pyuria, proteinuria, and a pronounced bacteriuria (usually in excess of 10^5 cfu/mL of urine). A Gram stain on a smear of the urine or pus may show the organisms. The urine is alkaline with a pH of more than 8.5 and usually approaching 9 as a result of urease, which cleaves urea to produce ammonia. Midstream urine contains 10^5 cfu/mL or more. A number of species of bacteria may be found as suggested in the introduction, but *A. suis* requires special culture media. It is now possible to use immunofluorescence for a more rapid and specific diagnosis. Examination of blood shows a pronounced azotemia, with increased concentrations of urea and creatinine and also hyperkalemia and hyponatremia. NAD concentrations are elevated, indicating proximal renal tubular damage.

**NECROPSY FINDINGS**

A very varied pathology may be visible in these cases. In some sows, there may be an extensive purulent nephritis and pyelitis with similar changes in the dilated ureters and the bladder. In others there may be severely hemorrhagic kidneys and blood in the pelvis.

In acute cases, the bladder wall is swollen, edematous, and hyperemic and may be covered by a gritty, mucinous material. In other cases, the bladder wall may just be thickened, inflamed, and covered by extensive thick mucus. In some of these cases, the ureterovesical valves may have been completely destroyed by necrosis. There may be minimal gross changes in the kidneys in acute cases but there may be microscopic changes of a diffuse tubular and interstitial nephritis.

In the chronic case, there are ulcerative and erosive lesions in the bladder wall and there may be pus in the bladder, thick-walled ureters, and an obvious pyelonephritis.

**Samples for the Confirmation of Diagnosis**

- Bacteriology: kidney, bladder, and ureter for aerobic and anaerobic culture and special media for *A. suis*. A special urea-enriched medium with polymixin or nalidixic acid is necessary in which dry colonies of *A. suis*, about 2 to 3 mm in diameter, grow after 2 days’ incubation
- Histology: formalin-fixed bladder, ureter, and kidney

**DIAGNOSIS**

Diagnosis is based on high mortality; clinical findings; history of service; and clinical pathology, particularly bacteriology; immunofluorescence for specific bacteria, or isolation by culture have a similar sensitivity and specificity.

**DIFFERENTIAL DIAGNOSIS**

- Other causes of sudden and unexpected deaths
- Hematuria
- *Stephanurus dentatus* (where it occurs)
- The separation of the condition associated with *Actinobaculum suis* from those associated with other bacteria can only be achieved by bacterial culture and other laboratory techniques.

**TREATMENT**

Early treatment with antibiotics is recommended, but if there is acute renal failure then the case–fatality rate is high. Penicillin given at 15,000 IU/kg IM daily for 7 to 10 days has been successful in early cases. The IM injection of streptomycin at 10 mg/kg has also been used successfully. The isolation of other organisms may indicate the need for other broad-spectrum antibiotics. A recent outbreak of cystitis and endometritis associated with a falling conception rate from 88% to 75% and thought to be caused by *E. coli* (together with staphylococci and streptococci) was successfully treated with an ammonium chloride urinary acidifier, whereas the amoxicillin used previously was without effect. Enrofloxacin at the rate of 10 mg/kg I.V. in the feed for a period of 10 days has also proved effective, as has 2.5 mg/kg in the food for at least 20 days.

The response can be monitored by the reduction in the urine pH. Treated sows should be loose housed with access to plenty of water. The treatment should be continued for at least 2 to 3 weeks after the outbreak has appeared to finish clinically. Oral electrolyte therapy is also beneficial. In chronic cases, the lesions are well advanced and the organisms may be contained in the calculi and
then therapy is not successful and relapses may occur. In many cases, humane destruction is the best option, especially because it is not possible, except in very early cases, to eliminate the organism. Preputial washing on a regular basis may prevent the carriage of organisms by boars, especially because it has been shown that semen may be frequently contaminated by A. suis, and up to 50% of boars in some studs may be affected.

**CONTROL**

Routine prophylactic administration of antibiotics has proved of little value in the long-term control of the disease. A temporary solution has been the use of sow treatment with oxytetracycline followed by in-feed medication with 400 g/t for 21 days. It is not possible to eradicate the infection from the prepuce of a boar, although daily infusions may help reduce the infection. Artificial insemination with the semen treated with antibiotics is a further option.

Trauma to the vagina at mating should be reduced by boar management and the supervision of mating. There should be nonslip floors in the service areas. Animals showing distress, pain, or bleeding after mating should be treated.

The service areas should have very good hygiene with regular cleaning and disinfection after every use. The perineal region of each sow should be cleaned before mating. Farrowing accommodation and crates should also be properly cleaned and disinfected and allowed to dry before sows are introduced. The major organism (A. suis) will persist on bad floors but is susceptible to phenolic, quaternary ammonium, and formalin-based products.

Other control procedures involve the provision of an adequate water intake. This should preferably be from mains without provision of an adequate water intake. This is not possible, except in very early cases, to eliminate the organism. Preputial washing on a regular basis may prevent the carriage of organisms by boars, especially because it has been shown that semen may be frequently contaminated by A. suis, and up to 50% of boars in some studs may be affected.

**KIDNEY WORM DISEASE IN PIGS CAUSED BY STEPHANURUS DENTATUS**

**ETIOLOGY**

Stephanurosis is a disease of swine caused by the migration of larvae and young adults of the nematode parasite *Stephanurus dentatus* through the body.

**SYNOPSIS**

**Etiology** The nematode parasite *Stephanurus dentatus*.

**Epidemiology** Eggs are shed in urine; infective larvae enter pig when swallowed or by skin penetration; earthworms can act as transport hosts; prepatent period is at least 6 months.

**Signs** Poor growth; emaciation in severe cases with stiffness of gait.

**Clinical pathology** Eggs in urine; eosinophilia.

**LIFE CYCLE**

*S. dentatus* are large (2-5 cm) thick roundworms that inhabit the perirenal tissues and less often inhabit the other abdominal organs and spinal canal of the pig. Adult worms lie in cysts around the renal pelvis and the wall of the ureter. The cysts communicate with the urinary passages, and the eggs are passed out into the urine of the host. They are very prolific egg layers; an infective adult sow may void as many as a million eggs in a day. Under suitable environmental conditions the eggs hatch and, after undergoing two molts, the larvae develop to the infective third stage in about 4 days. The eggs and larvae are very sensitive to cold and desiccation; eggs in a dry situation die within an hour. Exposure to temperatures below 10°C (50°F) is damaging and 4°C (40°F) is lethal. Most larvae in optimum conditions of moisture, warmth, and shelter from sunlight survive for about 3 months and some for as long as 5 months. Larvae may survive for long periods as facultative parasites in earthworms, and this may enable the larvae to survive even when the soil microclimate is adverse.

**Larvae may penetrate the skin** or be ingested. Larvae that are ingested cross the wall of the stomach, or more commonly the small intestine, and reach the liver via the portal vessels; from the skin the larvae reach the systemic circulation and pass to the liver via the lungs in 1 to 6 weeks. In the liver the larvae migrate from the blood vessels through the parenchyma and eventually, about 3 months after infestation, having undergone a fourth molt, penetrate the capsule of the liver and reach the perirenal tissues to establish themselves as adults. Egg laying usually commences about 6 months after infestation, but the prepatent period may be much longer and individual worms appear to live as long as 2 years.

**During their migration** the larvae often follow an erratic path and cause the development of atypical lesions and clinical signs. These larvae often reach maturity in these aberrant sites, and prenatal infection can occur in this way.

**EPIDEMIOLOGY**

Kidney worms are common in most tropical and subtropical countries such as Africa, the East and West Indies, Brazil, Hawaii, the Philippines, the southern United States, and Australia, where the climate is sufficiently mild to permit the survival of eggs and larvae.

**PATHOGENESIS**

The principal effect of these worms is the damage caused by the migrating larvae and young adults. The migrating worms cause a great deal of necrosis, fibrosis, and occasional abscess formation along the path of their migration. This is most marked in the perirenal tissues and the liver. *S. dentatus* have been observed rarely in cattle. Experimentally dosed calves develop severe hepatic injury similar to that which occurs in pigs, but the life cycle is not completed and no perirenal lesions develop.

**CLINICAL FINDINGS**

The mortality rate is not high; production losses and condemnation of parts or all of the infested carcases are of greatest economic significance. Poor growth in spite of a good appetite may be the only sign in mild cases. Badly affected animals become emaciated and develop ascites. In the early stages, nodules in the skin of the belly wall and enlargement and soreness of the peripheral lymph nodes may be evident. Many apparently unrelated clinical signs are produced by aberrant larvae. For example, thrombi may be induced in blood vessels, such as the portal veins, hepatic artery, and posterior vena cava, and paralysis may result if larvae invade the spinal cord. Involvement of the psoas muscles causes local pain and stiffness of gait. The passage of larvae through the peritoneum and pleura gives rise to adhesions. Larvae may also become encysted in the lung. Weakness and eventual paralysis of the hindlegs occur in a number of cases. Passage through the peritoneum and pleura causes the formation of adhesions, and many larvae become encysted in the lung.

**CLINICAL PATHOLOGY**

Large, thin-walled, embryonated eggs are present in the urine when adult worms are present in the ureter wall. An eosinophilia is seen 2 to 3 weeks after infection, peaking at 6 to 7 weeks and still elevated at 20 weeks. However, this has little specific diagnostic significance. Anemia does not occur. Only a transient rise in aspartate aminotransferase...
is seen, and serum enzymes seem to be of little value in diagnosis.

**NECROPSY FINDINGS**
The common findings include fibrosis and abscess formation in perirenal tissues with large adult worms present and occasionally in the pelvis of the kidney and ureter; infarcts and scars in the kidney; and enlargement and scarring of the liver, sometimes accompanied by ascites. The hepatic lesions include irregular whitish tracks in the parenchyma, extensive fibrosis, hemorrhage, and eosinophilic abscess formation. The liver may be covered with a diphtheritic membrane. Larvae may also be present in peripheral lymph nodes and cutaneous nodules, in small abscesses in the lung and pancreas, and in thrombi of blood vessels, particularly in the liver and lungs. Pleurisy and peritonitis, if they are present, are usually manifested by adhesions.

**DIAGNOSTIC CONFIRMATION**
A definite diagnosis of stephanurusosis may be made by finding eggs in the urine or by necropsy. Young pigs with a heavy infestation of larvae may present a problem in diagnosis because adult worms and characteristic renal lesions may not yet be present. An ELISA test can detect infection from 2 weeks after infection, but serologic tests are not likely to become a routine diagnostic procedure.

**DIFFERENTIAL DIAGNOSIS**
- Other causes of poor growth and emaciation in pigs, e.g., poor nutrition and chronic bacterial diseases such as necrotic enteritis and swine dysentery, but these are accompanied by intermittent diarrhea.
- Other parasitic diseases such as ascariasis and hystrongylosis.
- Other causes of posterior weakness in pigs such as vitamin A deficiency, osteodystrophy, sometimes fracture of a lumbar vertebra, brucellosis, erysipelas when intervertebral joints are involved, or by spinal cord abscess or lymphoma.

**TREATMENT**
Single doses of ivermectin (SC) or doramectin (IM) at 0.3 mg/kg, or fenbendazole at 3 mg/kg in the feed for 3 days, are effective against migrating and adult stages, whereas levamisole at 8 mg/kg removes the adults only, preventing egg output for at least 4 weeks.

**CONTROL**
Regular anthelmintic treatment of all pigs with fenbendazole or ivermectin at 4-month intervals should prevent further contamination of the environment with eggs. The free-living stages should then eventually die out, but this may take some time as infected earthworms may survive for at least 1 year.

Management techniques may also be used for controlling kidney worm. Because the prepatent period of *S. dentatus* is at least 6 months, one method is to breed entirely from gilts until the transmission cycle is broken. Under this system the gilts are raised, allowed to farrow, and sent to market as soon as the litter is weaned and before any eggs are shed. Boars are confined on concrete to prevent contamination of the soil by eggs in their urine. This technique has the advantage of maintaining a fully stocked farm while control is achieved, but it has obvious economic penalties.

Other management techniques depend on the provision of dry ground in which eggs and larvae are less likely to survive. Sleeping shelters should be placed on high ground, preferably bare of vegetation. Because pigs in yards commonly urinate against fences, a 2- to 3-m strip of earth inside the boundary should be kept free of herbage. Muddy spots and water holes should be filled in and drainage provided. Water and feed troughs should be on a concrete apron. Young animals should be segregated from adults and fields rested for 3 to 6 months after the adults are removed. Such programs are rewarding if performed diligently and intelligently, but the extra work involved has mitigated against general acceptance of this approach. Because of the importance of mature animals as sources of infestation, early replacement of breeding stock is recommended in problem herds.

**Toxic Agents Affecting the Kidney**

**CITRININ TOXICOSIS**
Citrinin (CTN or CIT) is most widely known as a nephrotoxin produced by *Penicillium citrinum*, *P. verrucosum*, *Monascus ruber*, *Aspergillus ochraceus*, and *A. terreus*. It is commonly found in combination with ochratoxin A (OTA) as a contaminant in human and animal feeds. The concentration of CTN often exceeds that of OTA. When present as cocontaminants the effects of OTA and CTN are generally additive; at higher concentrations, the effects may be more than additive.

The signs and lesions associated with poisoning by OTA and CTN are generally similar. The target organ is the kidney, but the liver and bone marrow have been implicated as well. In mice and rats, CTN is embryocidal, fetotoxic, and has an adverse effect on reproduction. An increase in testicular and preputial weight, abnormal sperm, and decreased numbers of live sperm were noted in mice treated with CTN. Females mated to CTN-treated mice had a lowered pregnancy rate. Information on carcinogenicity is rare, with benign renal tumors reported in mice receiving CTN for 60 to 80 weeks.

CTN is rapidly absorbed and distributed, in particular to the liver and kidney. In humans it is metabolized to dihydrocitronone (DE-CIT), which may be the primary method of detoxification. Excretion is through the urine and feces. The presence of CTN in human and animal food and food products can be identified by several methods and in human urine and plasma by liquid chromatography mass spectrometry (LC-MS/MS).

CTN may play a different role in the pyrexia-pruritus-hemorrhagic syndrome in cattle. Serious outbreaks of this idiopathic disease have been recorded in the UK since 1977 and may be related to CTN in moldy citrus pulp cubes. Clinical signs in affected cows include pruritus, hair loss, papular dermatitis, variable appetite with roughage being taken but not concentrates, fever (40–41.5°C; 104–106.7°F), and mucosal petechiation. Dermatitis is widespread, exudative, initially papular, and itchy. It occurs principally on the head, neck, perineum, and udder. Pruritus is variable in degree, but is often so marked that the skin becomes raw and bleeds. The dermatitis subsides but the fever persists, and over a period of 4 to 7 weeks the animal becomes so unthrifty that it is usually sent for slaughter. The morbidity rate is usually 10%, but may be as high as 100%. Seriously affected animals die. A similar but more severe syndrome occurs in which there is petechiation in all tissues, especially subserosally. In these cases, there are multiple hemorrhages in all mucousae and free blood at the anus and other orifices.

ETHYLENE GLYCOL TOXICOSIS

Accidental poisoning with ethylene glycol may occur in swine, goats, cattle, and horses.\(^1\,2\) Although the most common source is antifreeze or windshield deicers, ethylene glycol is also found in paints, solvents, detergents, and some pharmaceuticals.\(^1\) The toxic dose rates determined experimentally for cattle are 5 to 10 mL/kg BW in adults and 2 mL/kg in nonruminant calves.\(^1\)

The pathogenesis of the disease is dependent on the development of acidosis and oxalate nephrosis. In swine this is manifested by ascites, hydrothorax and hydropericardium, depression, weakness, and posterior paresis. In cattle there is dyspnea, incoordination, paraparesis, recumbency, and death.

Metabolic acidosis, hypocalcemia, and uremia are hallmarks of intoxication. Calcium oxalate crystals are present in large numbers in the kidney (renotubular) and vasculature. Signs of acute renal failure are seen within the first 24 hours.\(^1\) The treatment of disease is dependent on the development of acidosis and oxalate nephrosis. In swine this is manifested by ascites, hydrothorax and hydropericardium, depression, weakness, and posterior paresis. In cattle there is dyspnea, incoordination, paraparesis, recumbency, and death.

A variety of diagnostic tests are available including quantitation in serum. The presence of the chemical in tissue can be detected by chromatography. Kidney cortex (5–10 g) should be frozen in a Whirl-Pak before submission.\(^3\)

OCHRATOXINS (OCHRATOXICOSIS)

SYNOPSIS
Etiology Ochratoxin A produced primarily by Aspergillus ochraceus and Penicillium verrucosum.

Epidemiology Worldwide distribution; pigs and chickens are commonly affected.

Clinical pathology Increased serum concentrations of creatinine and urea nitrogen; glucosuria and proteinuria; decreased urine specific gravity.

Lesions Renal toxicity with damage to epithelial cells of proximal tubules.

Diagnostic confirmation High-performance liquid chromatography or liquid chromatography mass spectrometry on tissues (kidney, liver, and muscle).

ETIOLOGY
Ochratoxins are a group of isocoumarin derivative mycotoxins (A, B, and C) produced primarily by Aspergillus ochraceus and Penicillium verrucosum and less often by several other species of Aspergillus and P. norticum.\(^1\,3\) Ochratoxin A (OTA) is the most toxic member of the group; ochratoxin B (OTB) and ochratoxin C (OTC) are less toxic and rarely occur.\(^2\) OTA is a well-known nephrotoxin with neurotoxic, carcinogenic, genotoxic, immunotoxic, and teratogenic properties.\(^2,4\)

EPIDEMIOLOGY
Occurrence
Cereal and cereal products are most often contaminated, but OTA can be found in a variety of other products including beer, chocolate, pork and pork products, poultry, raisins, and wine.\(^4\) Feed contamination by OTA occurs worldwide from temperate to tropical climates with the incidence in the Northern Hemisphere considerably higher than the Southern Hemisphere.\(^7\) Aspergillus spp. are present in the more tropical regions of the world and Penicillium spp. in temperate regions.\(^2\) P. verrucosum-contaminated cereals are found more frequently in northern European countries as opposed to those in southern Europe.\(^5\)

Risk Factors
Animal Risk Factors
Swine, dogs, other monogastric animals, and chickens are most often affected from ingestion of OTA-contaminated feeds.\(^7\) Ruminant animals are more resistant to OTA toxicity with goats the possible exception.\(^2\) The oral LD\(_{50}\) of acute OTA toxicity in pigs is 1 mg/kg BW, that of cockerel chicks 3.3 to 3.9 mg/kg BW, and that of turkeys 5.9 mg/kg BW.\(^7\)

Environmental Factors
The amount of OTA in feeds and thus residual in body organs varies from year to year depending on climate conditions, harvesting, and storage.

Human Risk Factors
Ochratoxins are known to be carcinogenic, mutagenic, and immunotoxic and to induce in vivo and in vitro cytogenetic damage.\(^6\) Ochratoxin A has been shown to be a potent inhibitor of several drug metabolizing enzymes.\(^7\)

Environmental factors include exposure to OTA-contaminated feed and the presence of OTA in cow’s milk is scarce, but the carryover is estimated to be less than 1%.\(^1,4,8\)

FARM OR PREMISE RISK FACTORS
The fungus grows primarily on stored barley or corn. Raw animal feed, especially unprocessed feeds, contain much higher amounts of OTA than foods for human consumption. Experimentally, pigs fed diets containing OTA in concentrations as low as 25 μg/kg feed developed decreased feed efficiency and weight loss.\(^8\)

PATHOGENESIS
In pigs, OTA is rapidly absorbed, highly protein bound (99%), undergoes enterohepatic recirculation, and is distributed to kidney, liver, muscle, and fat.\(^3,8,9\) It is metabolized in the liver by carboxypeptidase and trypsin to a less toxic ochratoxin-α (OTα).\(^2\) Elimination is slow, primarily because of high protein binding and renal reabsorption. Excretion is biliary and renal. The serum half-life in pigs is very long (72–150 hours).\(^2\)

Ruminant resistance to OTA toxicity may be caused by decreased absorption and degradation of OTA to less toxic OTα by rumen proteases and microbes.\(^3,7,4\)

Nephrotoxicity from OTA involves several different mechanisms. The principal lesion is a degenerative change in the epithelial cells in the proximal convoluted tubules with impairment of tubular function and fibrosis.\(^9\) Several other mechanisms such as inhibition of RNA synthesis, disruption of renal and hepatic mitochondria, and impairment of antioxidant enzymes also may be involved.\(^9\)

CLINICAL FINDINGS
Affected pigs show a reduced daily weight gain, decreased feed efficiency, lower final BWs, polyuria, and polydipsia.\(^3,4,10\) Ochratoxin is associated with poor sperm quality in boars, and is thought to be associated with fetal death and resorption, and thus abortion.\(^7\)

CLINICAL PATHOLOGY
Creatinine and BUN levels are elevated, glucosuria and proteinuria are evident, and urine specific gravity is low.\(^7,8\)

NECROPSY FINDINGS
The most obvious abnormalities are found in the kidneys with renal enlargement, fibrosis, and necrosis of renal tubular epithelium. Microscopic lesions in the proximal tubules included cloudy swelling, granular or vacuolar degeneration, and desquamation of the epithelial cells.\(^10\) Poisoning by ochratoxin in pigs resembles Balkan endemic nephropathy, a naturally occurring disease of humans.\(^1,10\)

DIAGNOSIS
Assessment of OTA levels in tissue is performed with a variety of methods including immunoassay and spectrometry.\(^2,13\) LC-MS/MS has been demonstrated to be more sensitive and specific for OTA in pig tissues than high-performance liquid chromatography.\(^15\)
Differential Diagnosis

Differential diagnosis list:
- Citrinin toxicity
- Hereditary glomerular disease(s)
- Melamine toxicity
- Polycystic kidney disease
- Porcine dermatitis and nephropathy syndrome

TREATMENT

There is no specific treatment other than removing pigs from the contaminated feed and providing clean, mycotoxin-free food. Residues in the tissue persist for a long period of time, and it may take several months for them to decrease to an acceptable level.

CONTROL

Animal feeds should not be used unless they have levels of OTA less than 10 parts per billion. Several different gastrointestinal adsorbents (activated charcoal, bentonite, and cholestyramine) have been evaluated, but no single product has been effective against most mycotoxins. Strategies should be used to decrease fungal growth (and thus OTA production) during harvesting and storage.

PLANT POISONINGS CAUSED BY KNOWN TOXINS

Iforrestine

Iforrestine, a heterocyclic nephrotoxin, is present in six species of Isotropis. Lamb poison or Bloom poison, e.g., I. forrestii, I. atropurpurea, and I. cuneifolia, is associated with severe renal damage and uremia in cattle and sheep. Clinical signs include anorexia, depression, diarrhea, oliguria, anuria, recumbency, and death. Proteinuria and glycosuria are constant, and there is severe renal tubular necrosis.

PLANT POISONINGS FROM UNIDENTIFIED TOXINS

UREMIA, NEPHROSIS—WITH HIGH BLOOD UREA NITROGEN

- Amaranthus spp.
- Anagallis arvensis
- Azadirachta indica
- Cassine buchananii
- Catha edulis (khat)
- Dimorphandra gardneriana
- Lysimachia eugeniaefolia
- Petiveria alliacea (anamu)
- Psilostrophe spp. (paperflowers)
- Sapium sebiferum (Chinese tallow tree)
- Sarcocouloous globosus
- Sartwellia flaviana

POLYDIPSIA, POLYURIA

- Orobanche minor (broom rape).

RED URINE CAUSED BY A PIGMENTED SUBSTANCE FROM THE PLANT

- Haloragis odontocarpa (raspwort)
- Swartzia madagascariensis
- Trifolium pratense (red clover); in deer
- Xanthorrhoea minor; in cattle; probably associated with plant resins.

CYSTITIS

- Gyrostemon (= Didymotheca) cupressiformis (double-seeded emu bush).

Fungi Lacking Identified Toxins

Grain infected with Tilletia tritici (wheat smut) fungus should not be included in rations for pigs because it is thought to be associated with glomerulonephritis and failure to gain weight. Estimates of the maximum safe content of infected grain that can be fed in the ration vary from 5% to 30%.

FURTHER READING

Renal Neoplasia

Primary tumors of the kidney are rare. Renal carcinomas occur in cattle and horses and nephroblastomas occur in pigs. Enlargement of the kidney is the characteristic sign; in cattle and horses neoplasms should be considered in the differential diagnosis of renal enlargement. In pigs, nephroblastomas may be so big they cause visible abdominal enlargement. Renal adenocarcinomas are very slow growing but are not usually diagnosed until the disease is well advanced. The gross and histologic description of a series of primary renal cell tumors in slaughter cattle has been recorded.

In horses, the most common signs are weight loss, reduced appetite, hematuria, and intermittent bouts of abdominal pain. Some affected horses have massive ascites and hemoperitoneum. Metastasis of the tumor to the axial skeleton can result in lameness, which can be the clinical abnormality that is recognized first. The tumor can also metastasize to the lungs and mouth. Masses on the left kidney of horses are usually readily palpable on rectal examination. Horses with renal carcinoma can have clinically apparent periods of hypoglycemia, which is confirmed by measurement of serum glucose concentration and is attributable to production of insulin-like growth factor by the neoplastic tissue. Ultrasonographic examination of the kidney and renal biopsy confirm the diagnosis. Unilateral nephrectomy was successful in the treatment of an 11-year-old female alpaca with hematuria caused by a transitional cell papilloma in the renal pelvis.

Metastatic neoplasms are fairly common in the kidney, particularly in enzootic bovine leukosis, but they do not cause clinical renal disease. Tumor masses may be palpable as discrete enlargements in the kidneys of cattle or may involve the kidney diffusely, causing generalized enlargement of the kidney.

RENAL HYPOPLASIA

Developmental abnormalities of the kidneys are classified as renal agenesis, hypoplasia, and dysplasia, with agenesis and hypoplasia representing different degrees of the same condition. Renal hypoplasia is defined as a decrease in total renal parenchyma of one-third or more, with a proportionately greater loss of medullary than cortical tissue. The diagnosis of renal hypoplasia is straightforward in neonates but can be difficult to differentiate from renal dysplasia in adults.

Renal agenesis results from failure of the ureteral bud to contact the metanephric blastema during organogenesis and has been
reported to occur in cattle and alpacas.\(^1\)

Bilateral renal agenesis is fatal shortly after birth, but unilateral renal agenesis may be clinically undetectable except for compensatory hypertrophy of the remaining kidney.

Bilateral renal hypoplasia with or without agenesis is recorded in Large White piglets; the piglets die at birth or die in the first 3 months of life. Clinical signs exhibited by older pigs included lethargy, shivering, anorexia, diarrhea, and a slow rate of growth. The disease was suspected to be inherited in a simple autosomal recessive manner, and the basic defect appeared to be failure of development of mesonephric mesenchyme.

Cases of bilateral renal hypoplasia have been recorded in four horses 1 day to 3 years of age that had common histories of stunting, poor growth rate, anorexia, depression, and lethargy. Evidence of chronic renal failure was present on clinicopathologic examination. Transrectal and transabdominal ultrasonography revealed small kidneys and small renal medulla and pelves and was considered a useful diagnostic test.

Renal hypoplasia is part of a congenital multisystem disorder of Poll Merino/Merino sheep that has been named *brachynathia*, cardiomegaly, and renal hypoplasia syndrome (BCRHS).\(^2\) The abnormalities are described in detail in Chapter 21.

POLYCYSTIC KIDNEYS

In most species this is a common congenital defect. If it is extensive and bilateral the affected animal is usually stillborn or dies soon after birth. In some cases, bilateral defects are compatible with life, and clinical signs may not present until the residual nephron mass is gradually exhausted and the animal is adult. If it is unilateral no clinical signs appear because of compensatory activity in the other kidney, but in an adult the enormously enlarged kidney may be encountered during rectal examination.

In adult horses, polycystic disease may also be acquired rather than congenital. The disease is rare, but affected animals present in varying stages of chronic renal failure.

A high incidence of renal defects has been recorded in sucking pigs from sows vaccinated during early pregnancy with attenuated hog cholera virus; bilateral renal hypoplasia has been observed as a probably inherited defect in Large White pigs. Most polycystic kidneys in pigs appear to be inherited in a polygenic manner and have no effect on the pig’s health or renal function. However, there is a record of the defect in newborn pigs in one herd in which it caused gross abdominal distension caused by moderate ascites and gross cystic distension of the kidneys and tract. There was no evidence that the disease was inherited in this instance, and a toxic origin was surmised.

Isolated cysts occur in the kidneys of all species and are of no clinical significance. The increased availability of ultrasonographic examination of the kidneys of animals facilitates antemortem identification of these cysts. The cysts are usually solitary and unilateral.

**Congenital polycystic kidney disease of lambs** occurs as an autosomal recessive trait.\(^1\) The disease is recognized in Romney, Perendale, and Coopworth sheep in New Zealand and most likely originated in the Romney breed 50 years ago. Lambs die at or shortly after birth and there is no apparent sex predisposition. Necropsy examination reveals an abdomen distended by the enlarged kidneys (3.5–14 cm in length), which contain large numbers of fluid-filled 1- to 5-mm cysts. There are gross and histologic abnormalities of the liver and pancreas, and dysplastic changes and associated cyst formation are observed in bile ductal, pancreatic, and epididymal tissues. A likely candidate gene for the disorder is polycystic kidney hepatic disease 1. A pathologically similar disease is reported in a Nubian goat.

REFERENCE

RENAL DYSPLASIA

Renal dysplasia is defined as disorganized development of the renal parenchyma caused by anomalous differentiation. Each kidney is formed from separate metanephric and uretic buds, and an appropriate interaction between these buds is required for the development of normal renal architecture.\(^1\) Histologically, renal dysplasia is characterized by persistence of abnormal mesenchymal structures, including undifferentiated cells, cartilage, immature collecting ductiles, and abnormal lobar organization, and the lack of normal nephrons and collecting ducts. Affected kidneys do not function normally and azotemia develops.

Renal dysplasia is very rare in horses with isolated reports in several breeds. It is most commonly identified in foals but less severely affected animals can survive to adulthood. Clinicopathologic findings include azotemia, oliguria, and increased serum phosphorus concentrations, and oliguria. At necropsy, the main lesion was dysplasia of the proximal tubule epithelial cells, with secondary interstitial fibrosis with a reduction in the numbers of glomeruli and tubules in older cattle. An autosomal recessive mode of inheritance has been determined associated with a deletion of the paracellin-1 gene on chromosome 1,\(^1\) which has been renamed the claudin-16 (CL-16) gene. Bovine CL-16 deficiency is classified as type 1 or type 2 depending on the site of the gene mutation.\(^1\) The CL-16 gene encodes a protein that is part of the tight junction of renal epithelial cells that restricts diffusion of solutes through the paracellular pathway. Deletion of the CL-16 gene is considered to be the cause for the renal tubular dysplasia, and a DNA-specific test for this mutation has been developed. Heterozygotes are usually clinically normal and have normal renal function, although one report indicated that some heterozygotes have histologic renal lesions.\(^1\) Renal dysplasia with nephrosclerosis appears to be a different condition in cattle and has been reported in six calves with poor growth rates aged 3 to 6 months.\(^1\) Renal dysplasia has also examination of the kidneys revealed a poor distinction between the cortex and medulla caused by a hyperechoic medulla, which was caused by fibrosis. Histologic changes in both horses were indicative of interruption of nephrogenesis after the initiation, but before the complete differentiation, of the metanephric blastema. There is one report of multiple renal cysts being present in a 9-day-old Thoroughbred filly with renal dysplasia.\(^2\)

**Inherited cystic renal dysplasia** has been identified in lambs sired by carrier Suffolk rams out of mixed ewes. Signs include recumbency and coma by days 2 to 3. Abortions and stillbirths occurred in the flocks at the same time. The kidneys are enlarged and cystic. The condition may have been caused by an autosomal dominant gene.

Congenital renal dysplasia has been recorded in two successive years in a Leicestershire sheep flock crossbred with Suffolk and Swaledale rams. Affected lambs were born alive, were reluctant to stand or move, sucked poorly, and had wet coats. Lambs improved with nursing and provision of warmth, but none with clinical signs at birth survived beyond 5 days after birth. At necropsy, the kidneys were bilaterally small with fine intra-cortical cysts and distinct cortical and medullary zones. An inherited dominant trait with complete penetrance is suspected.

Renal tubular dysplasia has been diagnosed in Japanese Black cattle (Wagyu) with renal failure, poor growth, and long hooves. Calves were undersized at birth and had repeated episodes of diarrhea during the neonatal period. They began to show signs of growth retardation from 2 to 5 months of age but had a normal appetite. Clinicopathologic findings included azotemia, increased serum phosphorus concentrations, and oliguria. At necropsy, the main lesion was dysplasia of the proximal tubule epithelial cells, with secondary interstitial fibrosis with a reduction in the numbers of glomeruli and tubules in older cattle. An autosomal recessive mode of inheritance has been determined associated with a deletion of the paracellin-1 gene on chromosome 1, which has been renamed the claudin-16 (CL-16) gene. Bovine CL-16 deficiency is classified as type 1 or type 2 depending on the site of the gene mutation. The CL-16 gene encodes a protein that is part of the tight junction of renal epithelial cells that restricts diffusion of solutes through the paracellular pathway. Deletion of the CL-16 gene is considered to be the cause for the renal tubular dysplasia, and a DNA-specific test for this mutation has been developed. Heterozygotes are usually clinically normal and have normal renal function, although one report indicated that some heterozygotes have histologic renal lesions. Renal dysplasia with nephrosclerosis appears to be a different condition in cattle and has been reported in six calves with poor growth rates aged 3 to 6 months. Renal dysplasia has also
been diagnosed in Japanese Black cattle that are of normal gene type, suggesting that although the renal lesions may be associated with a homozygous deletion of the CL-16 gene, there may be accompanying defects that have not been characterized.

REFERENCES

renal lipofuscinosis of cattle

Dark brown or black discolored kidneys (“black kidneys”) have been reported as incidental findings in slaughter cattle for more than 100 years, and has been termed renal lipofuscinosis of Danish cattle. A pigment with characteristics similar to those lipofuscin is present in secondary liposomes in epithelial cells of the proximal tubules. Cases occurred only in Holstein cattle or the Red Danish Dairy Breed and mainly in animals aged 3 years or older. The prevalences of the abnormality were 0.3–0.4% and 1.3–2.5%, respectively in Holstein and Red Danish Dairy breeds. Affected animals produce slightly less milk than similarly aged animals without renal lipofuscinosis. Epidemiologic, genealogic, and genotype analyses indicate an autosomal recessive inheritance on chromosome 17, with incomplete penetrance of the genotype in Danish Holsteins.

Equine Renal Cortical Tubular Ectasia

A 16-year-old Thoroughbred pregnant mare with hemoabdomen, laminitis, and unilateral epistaxis was examined. Her physical condition deteriorated rapidly and the horse was euthanized. A ruptured ovarian artery was found to be the cause of the hemoabdomen, and variably sized, firm, light brown nodular cortical masses that did not extend past the ureter. Definite diagnosis requires excretory urography or endoscopy; visualization of the ureteral openings during endoscopy can be assisted by IV administration of phenolsulfonphthalein (0.01 mg/kg BW) or indigo carmine (0.25 mg/kg BW) to impart a red or blue color, respectively, to the urine being produced. Surgical treatment involving ureterovesical anastomosis or unilateral nephrectomy has been successful. Unilateral and bilateral ureteral defects have been reported in newborn foals. The clinical presentation is similar to rupture of the urinary bladder, but ureteral defects may be more common in filly foals than in colts.

Diseases of the Ureters, Bladder, and Urethra

ECTOPIC URETER AND URETERAL DEFECTS

Ectopic ureter has been recorded in cattle and horses. The condition may be unilateral or bilateral with urinary incontinence present since birth as the major clinical manifestation. Reported neurogenic causes of urinary incontinence in horses include cauda equina neuritis, herpesvirus-1 myelitis, Sudan grass toxicosis, sorghum poisoning, trauma, and neoplasia. Nonneurogenic causes of urinary incontinence in horses include ectopic ureter, cystitis, urolithiasis, hypoprostogenism, and abnormal vaginal conformation.

The ectopic ureter opens into the urethral tract at a place other than the bladder such as the cervix, urethra, or vagina. The condition is often complicated by ascending infections, hydronephrosis, and dilatation of the ureter. Definite diagnosis requires excretory urography or endoscopy; visualization of the ureteral openings during endoscopy can be assisted by a red or blue color, respectively, to the urine being produced. Surgical treatment involving ureterovesical anastomosis or unilateral nephrectomy has been successful.

PARALYSIS OF THE BLADDER AND OVERFLOW INCONTINENCE

Paralysis of the bladder is uncommon in large animals. It usually occurs as a result of neurologic diseases affecting the lumbarosacral spinal cord such as equine herpes myelopathy and cauda equina syndrome, and particularly ascending spinal meningitis in lambs after tail docking. In all species, compression of the lumbar spinal cord by neoplasia (lymphosarcoma and melanoma) or infected tissue (vertebral osteomyelitis) can cause paralysis of the bladder. Excessive tension on the tail, such as by application of tail ropes or use of the tail for restraint in cattle, can injure the cauda equina and result in bladder paralysis. In horses, spinal cord degeneration following consumption of sorghum can lead to bladder paralysis and posterior ataxia. Iatrogenic bladder paralysis occurs in horses in which there has been epidural injection of an excessive quantity of alcohol. Equine protozoal myelonecephalitis and equine polyneuritis can cause signs of cauda equina dysfunction in horses. In some horses, idiopathic bladder paralysis and overflow incontinence may occur sporadically in the absence of other neurologic or systemic signs. When the bladder is markedly distended from a urinary tract obstruction, it may take several days after removal of the obstruction before normal bladder tone returns.

When bladder paralysis arises from spinal cord disease, other upper or lower motor neuron signs are usually present. Bladder involvement is indicated by incontinence with constant or intermittent dribbling of urine. Urine flow is often increased during exercise. The bladder is enlarged on examination per rectum, and urine can be easily expressed by manual compression. In horses, chronic distension of the atomic or hypotonic bladder leads to accumulation of a sludge of calcium carbonate crystals called sabulous urolithiasis. Urine stasis produces ideal conditions for bacterial growth, and cystitis is a common sequel. Treatment is supportive and aimed at relieving bladder distension by regular catheterization and lavage. During catheterization, care must be taken to avoid introducing infection. Manual or pharmacologically induced emptying of the bladder is incomplete so there is a constant risk of cystitis. Pharmacologic enhancement of bladder emptying can sometimes be achieved by administration of parasympathomimetic agents such as bethanechol (parasympathetic stimulation via the pelvic nerve stimulates detrusor contraction; 0.2 to 0.4 mg/kg every 6 to 8 hours, orally) and sympatholytics such as prazosin and phenoxybenzamine (sympathetic stimulation via the hypogastric nerve causes detrusor relaxation and internal sphincter contraction), the administration of antimicrobial agents as a prophylaxis against the development of cystitis is advisable. The prognosis for paralysis associated with spinal cord disease depends on the prognosis for the primary disease. Paralysis in the absence of spinal cord disease has a poor prognosis.

Cattle ingesting Cistus salvifolius, a shrub found in the Mediterranean region, had urinary retention as the primary clinical sign. Cattle had decreased appetites and rumen motility, weight loss, and persistent elevation of the tail head and difficulty in urination. A greatly distended urinary bladder was always detected on palpation per rectum. The mortality rate in advanced cases was high, and affected animals have severe cystitis, pyelonephritis, and a marked increase in bladder wall thickness. No evidence of neurologic injury was present, and it is likely that urine retention was secondary to severe cystitis and swelling of the bladder wall that prevented normal urination.
**EVERSION OF THE BLADDER**

Bladder eversion through the urethra into the vagina and through the vulva occurs very rarely in mares and cows, and is most common immediately after parturition. Eversion is secondary to severe straining in the periparturient period, an increase in intraabdominal pressure, and the presence of a short wide urethra in mares or concomitant hypocalcemia in cows. Bladder eversion observed immediately after parturition must be differentiated from uterine prolapse. There is a report of bladder eversion in a nonpregnant mare secondary to chronic cystitis.\(^1\) Treatment is administration of an epidural or sedation, aseptic cleaning of the perineal region and exposed tissue, examination of the prolapsed tissue to ensure lac erations or full thickness necrotic sections are not present, application of sterile lube to assist movement of tissues, and gentle retroperitoneal mobilization. Umbilical evagination of the bladder has been reported in a neonatal filly. The bladder prolapsed through the umbilicus such that the mucosa of the bladder was outside (bladder eversion). Correction is surgical.

**REFERENCE**

**PATENT URACHUS**

Failure of the urachus to close at birth is most common in foals and is very rare in other species. Patent urachus occurs as three syndromes in foals: congenital and present at birth; acquired and secondary to urachal infection or inflammation; or secondary to severe systemic illness, usually sepsis. The urachus is part of the umbilicus during fetal development and drains urine into the allantoic fluid during intrauterine life; after birth, a patent urachus will therefore manifest as urine leaking from the umbilicus. The urine flow varies from a continuous stream during micturition to constant or intermittent dribbling, or a continuous moistening of the umbilical stalk. Healthy foals with congenital patent urachus heal in several days, and no specific treatment is required. Formerly, cauterization with phenol or silver nitrate was practiced, but this treatment has the theoretical potential to induce necrosis and increases susceptibility to infection.

Foals with patent urachus secondary to umbilical disease usually have an enlarged umbilicus, and some have a purulent discharge. Foals that have patent urachus secondary to other umbilical disease might require surgical correction, although most respond to a 7- to 14-day course of antimicrobials. Foals with patent urachus secondary to systemic disease, usually sepsis, should have their other disease treated aggressively and the urachus allowed to close spontaneously, which it usually does. Ultrasonographic examination of the umbilicus of all foals with patent urachus is essential to determine the extent of disease and presence of intraabdominal disease. As with all sick foals, the immune status of foals with patent urachus secondary to umbilical or systemic disease should be determined by measurement of serum IgG concentration, and foals with low serum IgG concentration should receive a blood or plasma transfusion. Cystitis is an occasional sequel to patent urachus, but omphalitis and urachal abscess may also develop as complications. Patent urachus is rarely diagnosed in neonatal ruminants but has been recorded in a lamb. Urachal abscess is discussed as a subgroup of umbilical abscess in Chapter 19. When the infection is localized in the urachus, there are usually signs of cystitis, especially increased frequency of urination.

**RUPTURE OF THE BLADDER (UROPERITONEUM)**

Rupture of the bladder is most common in castrated male ruminants as a sequel to obstruction of the urethra by calculi. Rare cases are recorded in cows as a sequel to a difficult parturition, in mares after normal parturition, possibly because of compression of a full bladder during foaling, and in a gelding caused by penile and preputial squamous cell carcinoma.\(^1\) In cattle, abnormal fetal position during prolonged dystocia is suspected to obstruct the urethra and decrease the bladder pressure. Subsequent manipulation within the pelvic canal during correction of the dystocia is suspected to lead to rupture of a distended bladder. Occasionally, the urachal remnant can rupture spontaneously in adult cattle, resulting in uroperitoneum. The urachal remnant may be identified using transrectal ultrasonography and a 7.5-MHz transducer.\(^2\) Uroperitoneum in foals is discussed in the next section.

After the bladder ruptures, uroperitoneum results in a series of abnormalities that arise from failure of the excretory process combined with solute and fluid redistribution between the peritoneal fluid and extracellular fluid. The peritoneal membrane serves as a semipermeable membrane through which low molecular weight solutes readily pass. High molecular weight compounds also diffuse across the peritoneal membrane but at a much slower rate. Urine is usually hypotonic, especially in animals whose water intake is decreased by uremia. Osmotic pressure from hypertonic urine promotes movement of extracellular water into the peritoneal cavity. This movement, combined with reduced intake, results in clinical dehydration. Urine usually has a lower concentration of sodium and chloride and higher concentrations of urea, creatinine, potassium, and phosphate than plasma. Diffusion along these concentration gradients across the peritoneal membrane results in a general pattern of azotemia with hypotension, hypochloremia, hyperkalemia, and hyperphosphatemia. There are minor differences between species in these general biochemical changes. In particular, the blood concentration of urea rises much more slowly in ruminants than in horses, and hyperkalemia is not as common in ruminants as in horses because excessive potassium can be excreted in the saliva and therefore eliminated in the feces.

Bladder rupture leads to gradual development of ascites from uroperitoneum, ruminal stasis, constipation, and depression. In cattle, uremia may take 1 to 2 weeks to develop to the point in which euthanasia is necessary. The degree of uremia between individual patients can be highly variable. With therapy, the survival rate of steers in one study was 49%. The best predictor of survival among clinical pathology tests was the serum phosphate concentration; all animals with levels greater than 9.0 mg/dL (2.9 mmol/L) died. In mature horses, clinical signs of depression, anorexia, colic, abdominal distention, and uremia develop within 1 to 2 days following rupture.

In cases of ascites or when urinary tract obstruction is evident, it is important in considering treatment and prognosis to determine whether the bladder has ruptured. The urea and creatinine concentrations in plasma or serum can be compared with the values in the peritoneal fluid. The ratio of urea in peritoneal fluid to that in serum is a good guide in the early stages, but after 40 hours the ratio of the peritoneal to serum creatinine greater than 2:1 is diagnostic of uroperitoneum. Treatment is surgical with a goal of bladder repair. To avoid the costs of laparotomy in feedlot animals, a urethrostomy is created or an indwelling catheter is placed and the rupture is allowed to repair itself.

**REFERENCES**

**UROPERITONEUM IN FOALS**

**ETOLOGY**

Uroperitoneum, the accumulation of urine in the peritoneal cavity, occurs in foals as a result of a variety of situations:

- Congenital (i.e., present at birth) rupture of the bladder
- Bladder rupture associated with sepsis
- Rupture of the urachus, often secondary to sepsis
- Avulsion of the bladder from its urachal attachment, presumably as a result of trauma or strenuous exercise
- Rarely, as embryologic failure of the halves of the bladder to unite (schistocystitis)
- Ureteral defects

The etiology of congenital rupture is unclear, but its association with birth, markedly greater prevalence in colts, and the traumatic
nature of the lesion suggest that it occurs during birth as a result of compression of a distended bladder. Intraabdominal pressures of the mare during parturition are large, and these compressive forces are experienced by the foal during phase 2 of parturition. Compression of a distended bladder can cause rupture. The greater prevalence in colts is speculated to be a result of the greater resistance to bladder emptying conferred by the longer urethra of male foals.

Rupture of the bladder occurs as a distinct entity in septic foals. The underlying reason for bladder rupture is unclear but is usually related to infection, inflammation, and necrosis of the lower urinary tract. This cause of uroperitoneum in foals is increasingly recognized as the most common, especially among hospitalized foals.

Rupture of the urachus occurs in septic foals. It is probably of similar etiology to rupture of the bladder in septic foals. The urachus of affected foals almost always has infection, inflammation, and necrosis evident on histologic examination.

Avulsion of the bladder from its urachal attachments is presumed to occur as a result of trauma, such as might occur with vigorous exercise. The possibility also exists that there is an underlying defect in affected foals, such as urachitis or omphalitis.

Embryologic failure of the halves of the bladder to unite during organogenesis has been reported anecdotally and in case reports, although adequate documentation of its occurrence is lacking. This defect would be a true congenital anomaly, arising during gestation. Ureteral defects are an uncommon cause of uroperitoneum in foals. The defects appear to be congenital and more common in fillies. Both ureters can be affected.

The relative frequency of these diseases is that approximately 20% of foals with uroperitoneum do so because of urachal rupture, approximately 30% because of rupture of the dorsal bladder wall, 18% because of rupture of the ventral bladder wall, and the remainder because of multiple defects involving combinations of the urachus and dorsal and ventral bladder. One report of rupture of the urethra and bladder exists in a colt foal.

Uroperitoneum also occurs rarely in calves as a consequence of umbilical infection.

EPIDEMIOLOGY
The epidemiology of uroperitoneum is not well documented. The incidence in foals appears to be approximately 0.2%, although this estimate is based on a study conducted 50 years ago. The prevalence in hospitalized foals is 2.5%. Male foals are at greater risk than are females for congenital rupture; more than 80% of foals with this disease are colts. In contrast, there is no sex predilection for development of uroperitoneum in foals with sepsis. The age at diagnosis ranges from 2 to more than 60 days, with most cases recognized within the first 2 weeks of life. The average age at diagnosis is approximately 4 to 5 days, although the age at presentation depends on the underlying cause. Foals with congenital rupture of the bladder or ureteral defects are usually recognized at about 3 to 5 days of age, whereas foals with uroperitoneum secondary to sepsis are usually older (5–9 days of age, but up to 60 days). The prognosis for survival for foals with uroperitoneum depends on the underlying cause and availability of appropriate treatment. Foals with congenital rupture of the bladder that are recognized and treated in a timely fashion have an excellent prognosis (>80%) for survival, whereas those with uroperitoneum secondary to sepsis have a more guarded prognosis (50%–60%) because of the sepsis.

PATHOPHYSIOLOGY
The pathophysiology of uroperitoneum is that of postrenal azotemia. Regardless of the underlying cause of the uroperitoneum, accumulation of urine within the peritoneal cavity results in substantial electrolyte, acid-base, and cardiovascular effects in affected foals. The basic principle is that affected foals are unable to excrete metabolic waste products that are normally excreted in the urine, and are unable to maintain water and electrolyte balance. Young foals derive almost all of their nutritional needs, including water, from mare’s milk. Mare’s milk has a low sodium concentration (approximately 12 mEq/L) and a higher potassium concentration (25 mEq/L) compared with serum and a dry matter content of 11%. Therefore foals ingest a diet that contains a large quantity of water and potassium but little sodium. Consequently, the urine of foals contains little sodium (7 mEq/L) and has a low osmolality (100 mOsmol/kg). Leakage of urine into the peritoneum, a semipermeable membrane, results in considerable fluid and electrolyte shifts. Partial equilibration of water and electrolytes across the peritoneal membrane results from diffusion of water from the peritoneum with resultant dilution of serum and reductions in serum sodium and chloride concentrations. The low concentration of sodium in urine favors diffusion of sodium from the blood into the peritoneal fluid, resulting in a reduction in intravascular sodium content and a consequent reduction in effective circulating volume. Excretion of relatively large quantities of potassium in urine and accumulation of potassium-rich fluid in the peritoneum allows diffusion of potassium into the blood and an increase in plasma potassium concentration.

The peritoneal membrane is permeable to creatinine and urea, as evidenced by the efficacy of peritoneal lavage in the treatment of renal failure in a variety of species, including horses. Consequently, serum creatinine and urea concentrations are higher in foals with uroperitoneum than in unaffected foals. However, equilibration of concentrations of these compounds is not complete and peritoneal fluid concentrations of urea, creatinine, and potassium are higher than those in serum.

Foals with uroperitoneum have compromised circulatory function because of reduced effective circulating plasma (blood) volume, despite having an increase in total body water content. Circulatory function is further impaired by a combination of hyperkalemia, abdominal distension, and accumulation of fluid in the pleural space, resulting in foals with uroperitoneum that have signs of mild to moderate circulatory compromise. Hyperkalemia and acidosis associated with uroperitoneum predispose affected foals to development of malignant cardiac rhythm disturbances, including ventricular tachycardia and fibrillation. This abnormal cardiac rhythm is a common cause of death of affected foals.

CLINICAL SIGNS
Clinical signs in foals with uroperitoneum depend in part on the underlying disease. Foals with congenital rupture or mild sepsis have progressive signs of lethargy, decreased appetite, mild abdominal discomfort, and abdominal distension. These signs usually first become apparent at 2 to 4 days of age. These foals do not typically have a fever. As the disease progresses and the amount of urine accumulated in the peritoneum increases, foals have progressive distension of the abdomen and make frequent attempts to urinate. Foals that attempt to urinate ventrally have a narrow-based stance. This should be contrasted with foals with tenesmus, which characteristically have a narrow-based stance (all four limbs being under the body) and arch their back. Affected foals sometimes produce small quantities of urine, but usually there is lack of urination. Abdominal distension is most apparent when the foal is standing. In moderate to severe cases, there is a readily appreciable fluid wave on ballottement of the abdomen. As abdominal distension increases, the foal’s tidal volume is impaired and breathing becomes rapid and shallow. The extremities become cool as cardiovascular function is impaired.

Ventral edema and preputial swelling occur in some foals. Foals with urachal rupture close to or within the abdominal wall or in the subcutaneous tissues will have subcutaneous accumulation of urine (which can be mistaken for ventral edema).

Foals with uroperitoneum secondary to sepsis usually have signs of sepsis as the initial and predominant sign of disease. These signs can range from mild fever and enlargement of the umbilical structures to septic shock and its attendant abnormalities. Initial signs of uroperitoneum in these foals are easily overlooked. As the disease
develops, these foals have progressive abdominal distension. Signs of cardiovascular dysfunction can be incorrectly attributed to worsening of sepsis. It is important when treating septic foals to maintain a high index of suspicion and constant vigilance for development of uroperitoneum.

Infusion of contrast agents, such as methylene blue or fluorescein, into the bladder with subsequent detection of these compounds in the peritoneal fluid has been used to diagnose uroperitoneum. However, use of this method of diagnosis is now obsolete except in those instances in which ultrasonographic examination of the foal is not possible.

### Imaging

**Ultrasonographic** examination of the abdomen of foals has simplified detection of uroperitoneum in foals and is the preferred imaging modality for the detection of excessive peritoneal fluid in foals. The ultrasound examination is best performed with a 5-MHz sector scan probe, with more detailed examination of the umbilical structures performed using a 7-MHz linear or sector scan probe. However, diagnosis of the presence of excessive peritoneal fluid can be achieved using a 7-MHz linear sector scan probe, such as is routinely used for examination of the mare’s reproductive tract. The examination is performed transcutaneously. Ultrasonography reveals the presence of an excessive quantity of fluid that is minimally echogenic. Intestine, mesentery, and omentum are readily visualized floating in this fluid. The presence of a large quantity of minimally echogenic fluid in the peritoneum of foals is very specific (effectively 100%) for uroperitoneum. The procedure is also sensitive, especially if performed repeatedly to detect changes in the amount of fluid, especially when the initial examination is equivocal. The umbilical structures should be examined closely and the urachus tracked to the bladder. Frequently a defect in the urachus or umbilicus is identified. The thorax of affected foals should also be examined, because foals with large quantities of urine in the peritoneum often have a substantial accumulation of pleural fluid. This can be important when considering anesthesia in these foals.

**Radiographic** examination of foals with suspected uroperitoneum is rarely performed because of the utility of ultrasonographic examination in this disease. Plain abdominal radiography is of limited usefulness in the detection of uroperitoneum or localizing the source of urine. Positive contrast cystography using a 10% solution of iohexol or similar water-soluble contrast agent administered into the bladder through a Foley catheter can be useful in detection of leaks, especially small leaks that cannot be visualized on ultrasonographic examination. Care should be taken to ensure that the bladder is sufficiently distended to ensure that any leak is visualized. Use of barium contrast medium, or negative-contrast cystography (infusion of air into the bladder), are contraindicated. IV pyelography is of very limited usefulness in the detection of ureteral defects because of the difficulty in localizing the site of the leak.

**Electrocardiographic** examination can reveal cardiac arrest, atrioventricular block, presumed intraventricular block, ventricular premature complexes, ventricular tachycardia, and ventricular fibrillation. These abnormalities are most likely to occur in foals that are hyperkalemic at the time of induction of anesthesia.

### CLINICAL PATHOLOGY

Foals with uncomplicated uroperitoneum have hyponatremia, hypochloremia, hyperbicarbonatemia (metabolic acidosis), acidemia, hyperkalemia, and azotemia. Severely affected foals can be profoundly hyponatremic (<110 mEq/L) and hyperkalemic (>7.0 mEq/L). Serum or plasma creatinine and urea nitrogen concentrations are elevated. When interpreting SUN concentrations in foals, it should be kept in mind that the urea concentration in normal foals is much lower than in adults.

Diagnosis based on serum electrolyte abnormalities is confounded in hospitalized foals that are being treated with IV fluids. Administration of fluids prevents the development of hyponatremia and hypochloremia in septic foals that develop uroperitoneum during the course of their disease. However, fluid administration does not prevent the increases in serum creatinine or urea nitrogen concentration.

Hematologic abnormalities reflect any underlying sepsis. Analysis of peritoneal fluid reveals that it has a low specific gravity (<1.010), low total protein concentration (<2.5 g/dL; 25 g/L), and low white cell count (<1000 cells/µL, 1 × 10³ cells/L). Peritoneal fluid can have a urinous odor, but this is not a reliable diagnostic sign. Peritoneal fluid from foals with uroperitoneum has elevated concentrations of creatinine (usually twice that in a contemporaneous serum sample), urea nitrogen (twice that of serum), and potassium. Microscopic examination of the fluid can reveal calcium carbonate crystals, the presence of which is diagnostic for urine.

### NECROPSY FINDINGS

Necropsy examination confirms the presence of uroperitoneum and the structural defect allowing leakage of urine into the abdomen. The defect can have signs of healing, which can make it readily confused with a malformation, because affected foals can survive for days after the rupture occurs, which is sufficient time for partial healing of the defect.

### DIFFERENTIAL DIAGNOSIS

**Ultrasonographic** demonstration of an excessive quantity of poorly echogenic fluid in the abdomen of a foal that is passing little if any urine and that has hyponatremia and hyperkalemia is diagnostic of uroabdomen. Confirmation of the diagnosis can be achieved by measurement of creatinine concentration in the peritoneal fluid. Ultrasonographic examination greatly facilitates the diagnosis.

The principal differential diagnoses for azotemia in foals are uroperitoneum and renal disease. **Primary renal disease** in foals can cause hyponatremia, hyperkalemia, and azotemia, but there is no accumulation of fluid in the peritoneum. Additionally, in primary renal disease there are abnormalities in urine composition (presence of blood, protein, leukocytes, and casts). Hyponatremia and hyperkalemia can occur in foals with enterocolitis, but the other clinical signs are diagnostic of this disease. **Addison’s disease** (mineralocorticoid deficiency) does occur in foals but is rare, and there is no accumulation of fluid in the abdomen.

### TREATMENT

Definitive treatment of uroperitoneum in foals is surgical repair of the defect. However, there is no need for surgery on an emergency basis. Instead, care should be taken to correct life-threatening electrolyte and fluid abnormalities before the foal is subjected to anesthesia. Principles of medical treatment are prevention of potentially lethal cardiac arrhythmia; correction of electrolyte, fluid, and acid-base abnormalities; and relief of abdominal distension.

Potentially life-threatening electrolyte abnormalities, especially hyperkalemia, should be corrected urgently and before any attempted surgical correction of the anatomic defect.

Correction of fluid and electrolyte abnormalities is best achieved by draining the abdomen and ensuring continued voiding of urine while administering isotonic fluids intravenously. Because the foal has normal kidney function, draining urine from the abdomen allows the foal to restore normal serum electrolyte concentrations and fluid balance provided it is allowed to nurse and/or is administered parenteral fluids.

Peritoneal drainage is achieved by placement of a catheter into the abdomen. It should be placed so it remains in place until the electrolyte abnormalities have been corrected and the foal is a suitable candidate for surgical repair of the anatomic defect. An ideal catheter is a Foley balloon-tipped catheter placed into the abdomen through a small (5-mm) incision in the skin and external abdominal wall. The catheter should be placed in the inguinal region and to one side of the linear alba to avoid injury and contamination of a future surgical site and to
minimize the chances of the catheter being plugged by omentum. The catheter is inserted under local anesthesia, and the balloon is inflated to secure the catheter in the abdomen. The catheter can be further secured by a suture. Sedation or tranquilization should be avoided in foals at risk of cardiac or respiratory distress because of the electrolyte abnormalities. Urine should be allowed to drain from the catheter into a closed collection system that minimizes the chances of ascending infection of the peritoneum.

Hyperkalemia is usually readily corrected by peritoneal drainage and administration of potassium-free fluid, such as 0.9% sodium chloride. Serum potassium concentration declines quickly when effective peritoneal drainage is obtained, and serum potassium concentrations can normalize in 8 to 12 hours. If emergency management of hyperkalemia is required, administration of 5% dextrose either alone or, if hyponatremia is also present, in 0.9% sodium chloride, is effective in reducing serum potassium concentration. Sodium bicarbonate (1–3 mEq/kg BW, IV) will also decrease serum potassium concentration. Calcium gluconate antagonizes the effect of hyperkalemia on cardiac function and is useful in the treatment of hyperkalemic arrhythmias. The serum potassium concentration should be lower than 5.5 mEq/L before the foal is anesthetized. Mare's milk, which is rich in potassium, should be withheld until the serum potassium concentration is below the required level.

Hyponatremia is resolved by drainage of the peritoneum and administration of 0.9% to 1.8% sodium chloride intravenously. Serum sodium concentration, especially if markedly low, should be corrected slowly to prevent the development of hyponatremic encephalopathy. Serum sodium concentrations should be increased by approximately 1 mEq/L/h.

Affected foals should be administered broad-spectrum antibiotics because of the risk of peritonitis and because many foals with uroperitoneum have sepsis. The immune status of young foals should be examined by measurement of serum IgG concentration and, if it is less than 800 mg/dL (8 g/L), the foal should receive 20 to 40 mL/kg of plasma.

Correction of the defect in the bladder, urachus, or urethra is surgical. Non-surgical management has been described in a foal in which a Foley catheter was inserted in the bladder and left in place for 5 days. The bladder was constantly drained of urine and this allowed the tear to heal. This technique offers an alternative to surgical repair of bladder rupture. However, surgical repair is definitive and is the recommended method of treatment.

Subcutaneous rupture of the urachus can similarly be treated by placement of a Foley catheter through the patent urachus and into the bladder. The defect in the urachus is then allowed to heal and the catheter is removed in 3 to 6 days.

PREVENTION AND CONTROL
There are no recognized means of preventing or controlling this disease. Minimizing the risk of foals developing septic disease is expected to reduce the incidence of uroperitoneum secondary to sepsis.

REFERENCE

CYSTITIS
Inflammation of the bladder is usually associated with bacterial infection and is characterized clinically by frequent, painful urination (pollakuria and dysuria) and the presence of blood (hematuria), inflammatory cells, and bacteria in the urine.

ETIOLOGY
Cystitis occurs sporadically as a result of the introduction of infection into the bladder when trauma to the bladder has occurred or when there is stagnation of the urine. In farm animals, the common associations are

- Cystic calculus
- Difficult parturition
- Contaminated catheterization
- Late pregnancy
- As a sequel to paralysis of the bladder; a special case of bladder paralysis occurs in horses grazing sudax or Sudan grass and in horses with equine herpesvirus myocarditis or encephalitis.

In the previous cases, the bacterial population is usually mixed but is predominantly E. coli. There is also the accommodation of specific pyelonephritides in cattle and pigs, associated with C. renale and Eubacterium suis, respectively. Many sporadic cases also occur in pigs, especially after farrowing. Common isolates from these are E. coli, Streptococcus, and Pseudomonas spp. C. matruchotti causes encrusted cystitis in horses.

Enzootic hematuria of cattle resembles cystitis.

PATHOGENESIS
Bacteria frequently gain entrance to the bladder but are usually removed by the flushing action of voided urine before they invade the mucosa. Mucosal injury facilitates invasion, but stagnation of urine is the most important predisposing cause. Bacteria usually enter the bladder by ascending the urethra, but descending infection from embolic nephritis may also occur.

CLINICAL FINDINGS
The urethritis that usually accompanies cystitis causes painful sensations and the desire to urinate. Urination occurs frequently and is accompanied by pain and sometimes grunting; the animal remains in the urination posture for some minutes after the flow has ceased, often manifesting additional expulsive efforts. The volume of urine passed on each occasion is usually small. In very acute cases, there may be moderate abdominal pain, as evidenced by treading with the hind-feet, kicking at the belly and swishing with the tail, and a moderate febrile reaction. Acute retention may develop if the urethra becomes blocked with pus or blood, but this is unusual.

Chronic cases show a similar syndrome, but the signs are less marked. Frequent urination and small volume are the characteristic signs. In chronic cases, the bladder wall may feel thickened on rectal examination and, in horses, a calculus may be present. In acute cases, no palpable abnormality may be detected but pain may be evidenced. Endoscopic examination of the bladder of affected horses reveals widespread inflammation of the cystic mucosa and occasionally the presence of a cystic calculus.

CLINICAL PATHOLOGY
Blood and pus in the urine is typical of acute cases, and the urine may have a strong ammonia odor. In less severe cases, the urine may be only turbid, and in chronic cases there may be no abnormality on gross inspection. Microscopic examination of urine sediment will reveal erythrocytes, leukocytes, and desquamated epithelial cells. Quantitative bacterial culture is necessary to confirm the diagnosis and to guide treatment selection.

NECROPSY FINDINGS
Acute cystitis is manifested by hyperemia, hemorrhage, and edema of the mucosa. The urine is cloudy and contains mucus. In subacute and chronic cases, the wall is grossly thickened and the mucosal surface is rough and coarsely granular. Highly vascular papillary projections may have eroded, causing the urine to be bloodstained or contain large clots of blood. In the cystitis associated with Sudan grass, soft masses of calcium carbonate may accumulate in the bladder, and the vaginal wall may be inflamed and coated with the same material.

TREATMENT
Antimicrobial agents are indicated to control the infection, and determination of the antimicrobial susceptibility of the causative bacteria is essential. Relapses are common unless treatment is continued for a minimum of 7 and preferably 14 days. Repeated bacterial culture of urine at least once during and again within 7 to 10 days after completion of treatment should be used to assess the success of therapy. Recurrence of the infection is usually caused by failure to eliminate foci of infection in the accessory glands and in the bladder wall.
Diseases

UROLIITHIASIS IN RUMINANTS

Urolithiasis is common as a subclinical disorder among ruminants raised in management systems where the ration is composed primarily of grain or where animals graze certain types of pasture. In these situations, 40% to 60% of animals may form calculi in their urinary tract. Urolithiasis becomes an important clinical disease of castrated male ruminants when calculi cause urinary tract obstruction and usually obstruction of the urethra. Urethral obstruction is characterized clinically by complete retention of urine, frequent unsuccessful attempts to urinate, and distension of the bladder. Urethral perforation and rupture of the bladder can be sequelae. Mortality is high in cases of urethral obstruction, and treatment is surgical. As a result, prevention is important to limit losses from urolithiasis.

ETIOLOGY

Urinary calculi, or uroliths, form when inorganic and organic urinary solutes are precipitated out of solution. The precipitates occur as crystals or as amorphous “deposits.” Calculi form over a long period by a gradual accumulation of precipitate around a nidus. An organic matrix is an integral part of most types of calculi. Several factors affect the rate of urolith formation, including conditions that affect the concentration of specific solutes in urine, the ease with which solutes are precipitated out of solution, the provision of a nidus, and the tendency to concretion of precipitates. These are presented in the following section. Factors that contribute to the clinical syndrome of obstructive urolithiasis are dealt with separately.

EPIDEMIOLOGY

Species Affected

Urolithiasis occurs in all ruminant species but is of greatest economic importance in feeder steers and wethers (castrated lambs) fed heavy concentrate rations and animals on range pasture in particular problem areas. These range areas are associated with the presence of pasture plants containing large quantities of oxalate, estrogens, or silica. When cattle graze pasture containing plants with high levels of silica, uroliths occur in animals of all ages and sexes. The prevalence of uroliths is about the same in cows, heifers, bulls, and steers grazing on the same pasture, and they may even occur in newborn calves. Females and bulls usually pass the calculi, and obstructive urolithiasis is primarily a problem in castrated male animals.

Obstructive urolithiasis is the most common urinary tract disease in breeding rams and goats. There are three main groups of factors that contribute to urolithiasis:

- Those that favor the development of a nidus about which precipitation and concretion can occur
- Those that facilitate precipitation of solutes on to the nidus
- Those that favor concretion by cementing precipitated salts to the developing calculus

Nidus Formation

A nidus favors the deposition of crystals about itself. It may be a group of desquamated epithelial cells or necrotic tissue that may be formed as a result in occasional cases from local infection in the urinary tract. When large numbers of animals are affected, it is probable that some other factor, such as a deficiency of vitamin A or the administration of estrogens, is the cause of excessive epithelial desquamation. When stilbestrol was used as a growth promoter, mortality rates of 20% from obstructive urolithiasis were recorded in wethers receiving stilbestrol implants compared with no mortalities in a control group. Diets low in vitamin A have been suspected as a cause of urolithiasis, but vitamin A deficiency does not appear to be a major causative factor.

Precipitation of Solutes

Urine is a highly saturated solution containing a large number of solutes, many of them in higher concentrations than their individual solubilities permit in a simple solution. Urinary stone formation is currently attributed to supersaturation, crystal growth, and aggregation, with supersaturation and the urinary concentration of promoters and inhibitors playing dominant roles in stone formation. Several factors may explain why solutes remain in solution. Probably the most important factor in preventing precipitation is the presence of protective colloids that convert urine into a gel. These colloids are efficient up to a point, but their capacity to maintain the solution may be overcome by abnormalities in one or more of a number of other factors. Even in normal animals, crystals of a number of solutes may be present in the urine intermittently and urine must be considered to be an unstable solution. The physical characteristics of urine, the amount of solute presented to the kidney for excretion, and the balance between water and solute in urine all influence the ease of calculus formation. In most cases, these factors can also be influenced by management practices.

The pH of urine affects the solubility of some solutes, with mixed phosphate and carbonate calculi more readily formed in an alkaline than an acid medium. More important, the urine pH in ruminants is dependent on the urinary strong ion difference, with urine pH increasing with higher urine concentrations of potassium, sodium, magnesium, and calcium (with the effect of potassium predominating). Likewise, urine pH decreases in ruminants with higher urine concentrations of chloride and sulfate. The high urine potassium concentration in herbivores is the main reason that they have an alkaline urine.

Ammonium chloride or phosphoric acid added to the rations of steers increases the acidity of the urine and reduces the incidence of calculi. The mechanism is uncertain but is probably related to the effect of pH on the stability of the urinary colloids or the effect of diuresis. In contrast, variations in pH between 1 and 8 have little influence on the solubility of silicic acid, the form of silica excreted in the urine of ruminants. As a result, dietary supplementation with ammonium chloride does not consistently prevent the formation of siliceous calculi.

The amount of solute presented to the kidney for excretion is influenced by the diet. Some pasture plants can contain up to 6% silica. Although ruminants grazing on these plants absorb only a small portion of the ingested silica, the kidney is the major route of excretion of absorbed silicic acid. The urine of these animals often becomes supersaturated with silicic acid, which promotes the polymerization or precipitation of the silicic acid and calculus formation.

The prognosis in chronic cases is poor because of the difficulty of completely eradicating the infection and the common secondary involvement of the kidney. Free access to water should be permitted at all times to ensure a free flow of urine.

Differential Diagnosis

The clinical and laboratory findings of cystitis resemble those of pyelonephritis and cystic urolithiasis.

- Pyelonephritis is commonly accompanied by bladder involvement and differentiation depends on whether there are lesions in the kidney. This may be determined by rectal examination but in many cases it is not possible to make a firm decision. Provided the causative bacteria can be identified, this is probably not of major importance as the treatment will be the same in either case. However, the prognosis in pyelonephritis is less favorable than in cystitis. Thickening of the bladder wall, which may suggest a diagnosis of cystitis, occurs also in enzootic hematuria and in poisoning by the yellow-wood tree (Terminalia oblongata) in cattle and by sorghum in horses.
- The presence of calculi in the bladder can usually be detected by rectal examination, by ultrasonographic examination, by endoscopic examination in female ruminants and in both sexes of smaller animals.
- Urethral obstruction may also cause frequent attempts at urination, but the urine flow is greatly restricted, usually only drops are voided and the distended bladder can be felt on rectal examination.

...
Feeding sodium chloride prevents the formation of silica calculi by reducing the concentration of silicic acid in the urine and maintaining it below the saturation concentration. An excessive intake of minerals may occur from highly mineralized artesian water, or from diets containing high concentrations, particularly of phosphates in heavy-concentrate diets. Sheep with a high dietary intake of phosphorus have an increased concentration of phosphorus in their urine and an increased development of calculi. In cattle, sediment begins to appear in urine when concentrations reach 1.5% of the BW, and urolithiasis formation begins when concentrations have been fed for 2 months at the rate of 2.5% of the animal’s BW.

Diets high in magnesium such as some calf milk replacers have been frequently associated with an increasing incidence of obstructive urolithiasis. Supplemental calcium in the diet helps prevent calculus formation when phosphate or magnesium intake is high.

Ingestion of plants with a high oxalic acid content can be a risk factor for formation of calcium carbonate calculi in sheep. Although dietary excesses contribute to certain types of urolithiasis, calculus formation can rarely be recreated experimentally by simple overfeeding. The process of formation of urinary calculi is more complex than a simple dietary excess. However, recognition of associations between diet and some types of urolithiasis has been useful in developing preventive strategies.

Feeding practices can influence the function of the kidney and may contribute to calculus formation. In sheep fed grain in a few large meals, there is a marked reduction in urine volume and a marked increase in urine concentration and calcium excretion at the time of feeding. These short-term changes in urine composition may be factors in the development of uroliths.

The concentration of urine is an important determinant of the concentration of individual solutes in the urine. Although it is difficult to induce urolithiasis by restricting access to water, concentrated urine is a risk factor for calculus formation. Animals can be forced to produce concentrated urine because of lack of easy access to water, a particular problem in pastured animals; lack of familiarity with water delivery systems; and poor quality of available water. Water deprivation can be exacerbated by heavy fluid loss by sweating in hot, arid climates.

Factors Favoring Concretion
Most calculi, and siliceous calculi in particular, are composed of organic matter as well as minerals. This organic component is mucoprotein, particularly its mucopolysaccharide fraction. It acts as a cementing agent and favors the formation of calculi when precipitates are present. The mucoprotein content of urine of feeder steers and lambs is increased by heavy concentrate–low roughage rations, by feeding pelleted rations, even more so by implantation with diethylstilbestrol and, combined with a high dietary intake of phosphate, may be an important cause of urolithiasis in this class of livestock. These high levels of mucoprotein in urine may be the result of a rapid turnover of supporting tissues in animals that are making rapid gains in weight.

Miscellaneous Factors in the Development of Urolithiasis
Stasis of urine favors precipitation of solutes, probably by virtue of the infection that commonly follows, providing cellular material for a nidus. Certain feeds, including cottonseed meal, rice straw, and milo sorghum, are credited with causing more urolithiasis than other feeds. Alfalfa is in an indeterminate position: by some observers it is thought to cause the formation of calculi, by others it is thought to be a valuable aid in preventing their formation. Pelleting appears to increase calculus formation if the ration already has this tendency.

Attempts to produce urolithiasis experimentally by varying any of the previous factors are usually unsuccessful, and natural cases most probably occur as a result of the interaction of several factors. In feedlots a combination of high mineral feeding and a high level of mucoprotein in the urine associated with rapid growth are probably the important factors in most instances. In range animals a high intake of mineralized water, or oxalate or silica in plants, are most commonly associated with a high incidence of urinary calculi, but again other predisposing factors, including deprivation or excessive loss of water, may contribute to the development of the disease. Limited water intake at weaning and in very cold weather may also be a contributory factor.

Composition of Calculi
The chemical composition of urethral calculi varies and appears to depend largely on the dietary intake of individual elements. In semiarid areas such as the great plains of North America and parts of Australia, the dominant pasture grasses have a high content of silica. Cattle and sheep grazing these pastures have a high prevalence of siliceous calculi. Calculi containing calcium carbonate are more common in animals on clover-rich pasture or when oxalate-containing plants abound. Calcium, ammonium, and magnesium carbonate are also common constituents of calculi in cattle and sheep at pasture.

Cattle, sheep, and goats eating a high grain diet in feedlots usually have calculi composed of struvite (magnesium ammonium phosphate, \( \text{NH}_4\text{MgPO}_4\cdot6\text{H}_2\text{O} \)). Cattle, water buffalo, and Boer goats in China fed grain, cottonseed meal, or rice straw as part of their diet may also have crystals present in their urine composed of magnesium potassium phosphate (\( \text{KMgPO}_4\cdot6\text{H}_2\text{O} \)), but these crystals do not appear to precipitate to form calculi. High concentrations of magnesium in feedlot rations also cause a high prevalence of struvite calculi in lambs and goats. Experimental feeding of a ration with high magnesium content increases the prevalence of struvite urolithiasis in goats and calcium apatite urolithiasis in calves. Oxalate calculi are extremely rare in ruminants but have been observed in goats and induced experimentally in feedlot cattle. Xanthine calculi in sheep are recorded in some areas in New Zealand where pasture is poor.

Estrogenic subterranean clover can cause urinary tract obstruction in wethers in a number of ways. Soft, moist, yellow calculi containing 2-benzocoumarins, isoflavones and indigotin–indirubin, have been observed. Calculi or uniformly sediments of benzocoumarins (urolithins) and 4′-O-methylequol, either singly or in various combinations with equol, formononetin, biochanin A, indigotin, and indirubin, also occur. Obstruction is promoted by estrogenic stimulation of squamous metaplasia of the urethral epithelium, accessory sex glandular enlargement, and mucous secretion. Pastures containing these plants are also reputed to cause urinary obstruction by calculi consisting of calcium carbonate. Feedlot lambs receiving a supplement of stilbestrol (1 mg/kg of feed or 2 mg per lamb daily) developed urethral obstruction thought to be caused primarily by plugs of mucoprotein. The accessory sex glands were also enlarged.

Risk Factors for Obstructive Urolithiasis
The risk factors important in the formation of urinary calculi are also important in the development of obstructive urolithiasis.

The size of individual calculi and the amount of calculus material are both important in the development of urethral obstruction. Often the obstruction is caused by one stone, although an aggregation of many small struvite calculi often causes obstruction in sheep fed high-concentrate rations.

Once calculi form, the most important factor contributing to the occurrence of obstruction is the diameter of the urethra. Wethers (castrated lambs) and steers (castrated cattle) are most commonly affected because of the relatively small diameter of the urethra in these animals. Castration significantly impacts the diameter of the urethra in steers. When the urethral diameter of late castrates (6 months old) was compared with early castrates (2 months old), it was found to be 8% larger and would be able to expel a calculus that was 13% larger than a calculus passed by early castrates. Bulls can usually pass calculi that are 44% larger than those that could be passed by an early castrated steer.
Occurrence

Urethral obstruction may occur at any site but is most common at the distal sigmoid flexure in steers near the insertion of the retractor penis muscle, and in the vermiform appendage, distal to the sigmoid flexure, at the distal sigmoid flexure, or subischially in wethers or rams; these are all sites where the urethra narrows. Urolithiasis is as common in females as in males, but obstruction rarely if ever occurs because of the shortness and large diameter of the urethra. Repeated attacks of obstructive urolithiasis are not uncommon in wethers and steers and at necropsy up to 200 calculi may be found in various parts of the tract of one animal. However, generally, a single calculus causes obstruction in cattle, whereas multiple calculi are common in sheep.

In North America, obstructive urolithiasis caused by siliceous calculi is most common in beef feeder cattle during the fall and winter months. The calves are weaned at 6 to 8 months and moved from pasture to a feedlot in which they are fed roughage and grain. The incidence of obstructive urolithiasis is highest during the early part of the feeding period and during cold weather, when the consumption of water may be decreased.

Although the occurrence of obstructive urolithiasis is usually sporadic, with cases occurring at irregular intervals in a group of animals, outbreaks may occur, affecting a large number of animals in a short time. In outbreaks it is probable that factors are present that favor the development of calculi, as well as the development of obstruction. For example, multiple cases of obstructive urolithiasis can occur in lambs within a few weeks of introducing a concentrated ration. Obstructive urolithiasis increases in occurrence with age but has occurred in lambs as young as 1 month of age.

Pathogenesis

Urinary calculi are commonly observed at necropsy in normal animals and in many appear to cause little or no harm. Calculi may be present in the kidneys, ureters, bladder, and urethra. In a few animals, pyelonephritis, cystitis, and urethral obstruction may occur. Obstruction of one ureter may cause unilateral hydronephrosis, with compensation by the contralateral kidney. The major clinical manifestation of urolithiasis is urethral obstruction, particularly in wethers and steers. This difference between urolithiasis and obstructive urolithiasis is an important one. Simple urolithiasis has relatively little importance, but obstructive urolithiasis is a fatal disease unless the obstruction is relieved. Rupture of the urethra or bladder occurs within 2 to 3 days if the obstruction is not relieved and the animal dies of uremia or secondary bacterial infection. Rupture of the bladder is more likely to occur with a spherical, smooth calculus that causes complete obstruction of the urethra. Rupture of the urethra is more common with irregularly shaped stones that cause partial obstruction and pressure necrosis of the urethral wall.

Clinical Findings

Calculi in the renal pelvis or ureters are not usually diagnosed ante-mortem, although obstruction of a ureter may be detectable on rectal examination, especially if it is accompanied by hydronephrosis. Occasionally the exit from the renal pelvis is blocked and the acute distension that results may cause acute pain, accompanied by stiffness of the gait and pain on pressure over the loins. Calculi in the bladder may cause cystitis and are manifested by signs of that disease.

Obstruction of the Urethra by a Calculus

This is a common occurrence in steers and wethers and causes a characteristic syndrome of abdominal pain with kicking at the belly, treading with the hindfeet, and swishing of the tail. Repeated twitching of the penis, sufficient to shake the prepuce, is often observed, and the animal may make strenuous efforts to urinate, accompanied by straining, grunting, and grating of the teeth, but these result in the passage of only a few drops of bloodstained urine. A heavy precipitate of crystals is often visible on the preputial hairs or on the inside of the thighs (Fig. 13-8). Some animals with urethral obstruction will have a dry prepuce because of the absence of urination, although this sign is not specific for urolithiasis.

The passage of a flexible catheter up the urethra, after relaxing the penis by lumbar or epidural anesthesia, by pudendal nerve block or by administering an ataractic drug, may make it possible to locate the sites of obstructions that are anterior to the sigmoid flexure. However, catheterization of the urethra from the glans penis to the bladder is almost impossible in cattle and ruminants because of the urethral diverticulum and its valve. A precurved coronary catheter has been used to catheterize the bladder of calves and goats but requires fluoroscopic guidance.

Cattle with incomplete obstruction (“dribblers”) will pass small amounts of bloodstained urine frequently. Occasionally a small stream of urine will be voided followed by a complete blockage. This confuses the diagnosis. In these animals the calculus is triangular in shape and allows small amounts of urine to move past the obstruction at irregular intervals. However, these instances are rare.

The entire length of the penis must be palpated for evidence of a painful swelling from the preputial orifice to the scrotum, above the scrotum to locate the sigmoid flexure, and proximally up the perineum as far as possible.

In rams, bucks, and wethers the urethral process of the exteriorized penis must be examined for enlargement and the presence of multiple calculi. Extrusion of the penis is difficult in prepubertal sheep and goats because of the presence of an attachment from the prepuce to the glans penis; loss of this attachment is mediated by testosterone and is usually complete by the onset of puberty, although separation may not occur in castrated animals. Penile extrusion is facilitated by xylazine sedation and positioning the animals with lumbosacral flexion. Abnormal urethral processes should be amputated, and in many animals grit is detected during urethral transection.

Fig. 13-8 Extensive precipitation of crystals on the preputial hairs of a steer with obstructive urolithiasis.
On rectal examination, when the size of the animal is appropriate, the urethra and bladder are palpably distended and the urethra is painful and pulsates on manipulation. In rams with obstructive urolithiasis, sudden depression, inappetence, stamping the feet, tail swishing, kicking at the abdomen, bruxism, and anuria or the passage of only a few drops of urine are common. Clinical examination must include inspection of the ventral abdomen for edema, inspection and palpation of the preputial orifice for crystals, palpation of the penis in the area of the sigmoid flexure, and inspection and palpation of the urethral process (vermiform appendage) of the exteriorized penis.

Rupture of Urethra or Bladder
If the obstruction is not relieved, urethral rupture or bladder rupture usually occurs within 48 hours. With urethral rupture, the urine leaks into the connective tissue of the ventral abdominal wall and prepuce and causes an obvious fluid swelling, which may spread as far as the thorax (Fig. 13-9). This results in a severe cellulitis and toxemia. The skin over the swollen area may slough, permitting drainage, and the course is rather more protracted in these cases. When the bladder ruptures, there is an immediate relief from discomfort but anorexia and depression develop as uremia develops. Two types of bladder rupture have been described: multiple pinpoint perforations in areas of necrosis or discrete tears in the bladder wall. The site of leakage is almost always on the dorsal aspect of the bladder. Complete urethral obstruction therefore results in urethral rupture or bladder rupture and never both in the same animal because pressure is released once rupture occurs.

A fluid wave is detectable on tactile percussion, and the abdomen soon becomes distended. The animal may continue in this state for as long as 2 to 3 days before death occurs. Fibrin deposition around the dorsal surface of the bladder may be palpated per rectum in steers. In rare cases death occurs soon after rupture of the bladder as a result of severe internal hemorrhage.

In rare cases calculi may form in the prepuce of steers. The calculi are top shaped and, by acting as floating valves, cause obstruction of the preputial orifice, distention of the prepuce, and infiltration of the abdominal wall with urine. These cases may be mistaken for cases of urethral perforation.

Clinical Pathology
Urinalysis
Laboratory examinations may be useful in the diagnosis of the disease in its early stages when the calculi are present in the kidney or bladder. The urine usually contains erythrocytes and epithelial cells and a higher than normal number of crystals, which are sometimes accompanied by larger aggregations described as sand or sabulous deposit. Bacteria may also be present if secondary invasion of the traumatic cystitis and pyelonephritis has occurred.

Serum Biochemistry
SUN and creatinine concentrations will be increased before either urethral or bladder rupture occurs and will increase even further afterward. Rupture of the bladder will result in uroabdomen. Because urine has a much lower sodium and chloride concentration and higher osmolality than plasma, equilibration of electrolytes and free water into the abdomen of the ruminant will always result in hyponatremia, hypochloremia, hyperphosphatemia, and hypoosmolality in serum, with the magnitude of the changes reflecting the volume of urine in the abdomen. Hypermagnesemia appears to be a common finding in weaned lambs with urolithiasis, although few studies have reported changes in plasma magnesium concentrations in affected animals. Similar changes in serum biochemistry are present in steers with ruptured urethras, with the magnitude of the changes being smaller than in steers with ruptured bladders. Interestingly, steers with ruptured bladder or urethra typically have serum potassium concentrations within the normal range; this result most probably reflects the combined effects of increased salivary potassium loss in the face of hypokalemia. A minority of ruminants with urolithiasis will have hyperkalemia. Prolonged duration of urolithiasis usually results in hypophosphatemia in goats, presumably from increased phosphorus secretion by the salivary glands.

Abdominocentesis and Needle Aspirate of Subcutaneous Tissue
Abdominocentesis is necessary to detect uropertoneum after rupture of the bladder or needle aspiration from the subcutaneous swelling associated with urethral rupture. However, it is often difficult to identify the fluid obtained from the peritoneal cavity or the subcutaneous tissues as urine other than by appearance and smell or by biochemical examination. Generally, in uropertoneum, substantial quantities of fluid can be easily obtained by abdominocentesis. Warming the fluid may facilitate detection of the urine odor, although this is a subjective and poorly sensitive diagnostic test.

Ultrasonography
Ultrasonography is an extremely useful aid for the diagnosis of obstructive urolithiasis in rams and bucks, with a 10- to 15-MHz linear probe used to assess the urethra for dilatation proximal to the obstruction or rupture at the site of obstruction and a 5-MHz microconvex or linear probe used to evaluate the bladder and kidneys. All parts of the urinary tract must be examined for urinary calculi. The kidneys are examined from the paralumbar fossa and the bladder and urethra transrectally. The kidneys are examined for enlargement, and the renal pelves, medullary pyramids, and urethra are examined for dilatation. The size of the bladder should be noted and its contents examined. Distended bladders can reach 20 cm in diameter in adult rams, wethers, and bucks, and ultrasonographically appear as an anechoic (black) area surrounded by a bright white (hyperechoic) line. The bladder diameter should be measured in two dimensions at right angles to each other because the bladder shape changes with

Fig. 13-9 Holstein-Friesian steer with obstructive urolithiasis, urethral rupture, and urine collecting ventrally to the site of rupture. (Photograph graciously provided by Dr. Bruce L. Hull, United States.)
animal movement. A ruptured bladder does not always empty completely. Fibrin tags may be visualized ultrasonographically in animals with uroabdomen or on the dorsal surface of the bladder, which is the usual site for rupture. In rams with obstructive urolithiasis, the urethra and bladder are markedly dilated. Because of severe cystitis, the contents of the bladder appear as multiple, tiny, uniformly distributed echoes. The renal pelves are commonly dilated, and in experimentally induced urethral ligation in male goats, ultrasonographically determined renal dimensions increased after 24 hours of obstruction.

**Radiography**

Plain radiography is very helpful in small ruminants in which radiopaque calculi (calcium carbonate, calcium oxalate, and silica) are common. Plain radiography helps to identify the best method for surgical correction and confirm resolution of the obstruction, but it is not effective in small ruminants with stрувite calculi because the stones are radiolucent and very small in diameter. Contrast radiography using excretory urography, retrograde urethrogramy, cystourethrogramy, and normograde cystourethrogramy via tube cystotomy have also been used because of concerns that the rumen and abdominal viscera (and wool in sheep) obscures the bladder in plain radiographs.

**NECROPSY FINDINGS**

Calculi may be found in the renal pelvis or bladder of normal animals or of those dying of other diseases. In the renal pelvis they may cause no abnormality, although in occasional cases there is accompanying pyelonephritis. Unilateral ureteral obstruction is usually accompanied by dilatation of the ureter and hydronephrosis. Bilateral obstruction causes fatal uremia. Calculi in the bladder are usually accompanied by varying degrees of chronic cystitis. The urethra or urethral process may be obstructed by one or more stones or may be impacted for a number of centimeters with a fine sabulous deposit.

When rupture of the urethra has occurred, the urethra is eroded at the site of obstruction, and extensive cellulitis and accumulation of urine are present in the ventral abdominal wall. When the bladder has ruptured the peritoneal cavity is distended with urine and there is mild to moderate chemical peritonitis. In areas where urolithiasis is a problem, it is an advantage to determine the chemical composition of the calculi.

**Differential Diagnosis**

**Obstruction of the urethra in ruminant animals is almost always caused by a calculus and is characterized clinically by anuria or dribbling, swishing of the tail, abdominal pain with kicking at the abdomen or stamping the feet, and a progressively worsening condition. Nonobstructive urolithiasis may be confused with pyelonephritis or cystitis, and differentiation may be possible only by rectal examination in the case of vesical calculi or by radiographic examination in smaller animals. Subsequent development of hydronephrosis may enable a diagnosis to be made in cattle. Ultrasonographic examination is extremely useful in sheep and goats. A rectal examination, if possible, may reveal tension of the bladder and dilatation and pulsation of the urethra if the bladder has not ruptured. In adults, rupture of the bladder is usually the result of obstructive urolithiasis, although other occasional causes of urethral obstruction are observed.

**Rupture of the urethra in cattle** is characterized by diffuse swelling of the subcutaneous tissues of the ventral body wall, and the skin is usually cooler than normal. It must be differentiated from other causes of swelling of the ventral abdominal wall, including abscesses and herniation of abdominal wall, which can be determined by close physical examination and needle aspiration.

**Dilatation of the urethral recess** in young cattle is characterized by a midline perineal swelling and may resemble pulsation of the perineal urethra in obstructive urolithiasis. The urethral recess arises from the junction of the pelvic and spongy parts of the urethra at the level of the ischial arch. A fold of urethral mucosa proximal to the recess acts as a valve to prevent the retrograde flow of urine into the pelvic urethra. An abnormally large urethral recess has been described in a calf. When there is dilatation of the urethral recess, during urination the proximal urethra pulses and the swelling may enlarge slightly. There is no urethral obstruction, and urine flows passively from the penis for several minutes after the urethral pulsation ceases. The dilatation can be radiographed using contrast media.

**TREATMENT**

The treatment of obstructive urolithiasis has traditionally been primarily surgical, including urethral process amputation (rams, wethers, bucks, llamas, and alpacas), prepubic and perineal urethrostomy, laser lithotripsy, tube cystotomy, and bladder marsupialization. Cattle or lambs with obstructive urolithiasis that are removed from the feedlot feeding period and close to being marketed can be slaughtered for salvage if the result of an ante-mortem inspection is satisfactory. Animals in the early stages of obstruction before urethral or bladder rupture will usually pass inspection at an abattoir. The presence of uremia warrants failure to pass inspection. Recent studies suggest reasonable treatment response to medical treatment of bucks with urolithiasis.
In early stages of the disease or in cases of incomplete obstruction, treatment with smooth muscle relaxants such as phentethazine derivatives (acepromazine 0.7 mg/kg of BW) has been tried to relax the urethral muscle and permit passage of the obstructing calculus; however, treatment efficacy is unknown. Animals treated medically should be observed closely to ensure that urination occurs and that obstruction does not recur. However, field observations indicate that these relaxants are ineffective, and it is difficult to believe that smooth muscle relaxants could be efficacious given that the urethral and periurethral tissue contains very little smooth muscle. Slight sedation induced by acepromazine (0.02 mg/kg IV every 4–6 hours) is of unknown benefit, and if used the sedation should not prevent the animal from standing when approached. A more rational treatment includes parenteral NSAIDs or infiltration of local anesthetic around the origin of the retractor penis muscles or a pudendal nerve block; this theoretically relaxes the retractor penis muscle and straightens the sigmoid flexure, creating a wider and straighter urethral passageway.

Retrograde hydropulsion is only occasionally successful, although it is frequently used as part of the initial treatment. This technique involves catheterization of the urethral orifice with a suitably sized urinary catheter and intermittent injection of 0.9% NaCl containing 2% lidocaine into the urethra in an attempt to flush out the calculi. Frequently, a gritty feeling is detected during this procedure, and one usually is left with the impression that the procedure is creating additional urethral trauma that may contribute to urethral stricture. The addition of lidocaine is thought to decrease urethral spasm but its efficacy and safety are unknown. Retrograde hydropulsion may also pack small crystals more tightly into the urethra. Cystotomy and normograde hydropulsion appear to have a higher success rate than retrograde hydropulsion.

**Surgical treatment includes perineal urethrostomy** to relieve bladder pressure and for the removal of calculi. This is a salvage procedure, and treated animals can be sent to slaughter for salvage when they have recovered sufficiently to pass antemortem inspection. In a series of 85 cases of surgical treatment of urethral obstruction in cattle, only 35% of animals recovered satisfactorily. In small ruminants, which invariably have multiple calculi, amputation of the urethral process may restore urine flow but usually provides only temporary relief, and the long-term prognosis in sheep and goats is poor because there is a high rate of recurrence of obstruction with stricture formation at the urethrostomy site. A recent surgical modification suggests that urethral stricture formation can be decreased in goats with transection of the penile body attachments from the pelvis and careful apposition of the urethra to the skin. If perineal urethrostomy is unsuccessful, **tube cystotomy** is indicated. Urethroscope and **laser lithotripsy** have successfully dissolved uroliths in a small number of small ruminants and one steer, but the technique is expensive and not widely available. **Prepubic urethrostomy** has been performed in a small number of small ruminants that have undergone stricture formation following perineal urethrostomy, whereas **urinary bladder marsupialization** by laparotomy or using a laparoscopy-assisted surgical technique offers an alternative surgical method for correction. There is one report of erection failure in a male goat as a sequela to obstructive urolithiasis; erection failure was attributed to vascular occlusion of the corpus cavernosum penis. Surgical correction of urethral dilatation associated with the urethral recess in cattle has been described.

**PREVENTION**

A number of agents and management procedures have been recommended in the prevention of urolithiasis in feeder lambs and steers. First, and probably most important, the diet should contain an adequate balance of calcium and phosphorus to avoid precipitation of excess phosphorus in the urine. This is the major difficulty in controlling urolithiasis in feedlot ruminants, because their diets are grain rich (and therefore phosphorus rich). The ration should have a Ca:P ratio of 1.2:1, but higher calcium inputs (1.5–2.0:1) have been recommended, as have formulation of low oxalate and silica diets and low-magnesium diets. Every practical effort must be used to increase and maintain water intake in feeder steers that have just been moved into a feedlot situation. The addition of salt at the level of 4% of the total ration of feeder calves has been shown experimentally to have this effect on both steers and lambs. Under practical conditions, salt is usually fed at a concentration of 3% to 5%, higher concentrations causing lack of appetite. It is thought that supplementary feeding with sodium chloride helps to prevent urolithiasis by decreasing the rate of deposition of magnesium and phosphate around the nidus of a calculus, but it is possible that salt-related diuresis may also play an important role. Feeding of pelleted rations may predispose to the development of phosphate calculi (such as struvite or apatite) by reducing the salivary secretion of phosphorus.

The control of siliceous calculi in cattle has been described. The feeding of alfalfa hay is considered to increase urine flow and lower the incidence of urolithiasis but the important reason may be that it contains considerably less silica. As in feedlot animals, water intake can be promoted by supplementing the ration with salt. For yearling (300 kg) steers the daily consumption of 50 g of salt does not prevent the formation of siliceous calculi; at a 200-g daily intake the occurrence of calculi is significantly reduced, and at 300-g daily calculus formation is almost eliminated. For calves on native range, providing supplements ("creep feeds") containing up to 12% salt is effective in eliminating siliceous calculi. This effect is caused by the physical diluting effect of increased water intake promoted by salt supplementation. If the calves consume sufficient quantities of salt to increase the water intake above 200 g/kg BW per day, the formation of siliceous calculi will be completely suppressed. Because siliceous calculi form in the last 60 days before weaning, it is recommended that calves on range be started on creep feed without salt well before weaning and, once calves are established on the supplement, the salt concentration should be gradually increased to 12%. It is usually necessary to increase the salt gradually to this level over a period of several weeks and incorporate it in pellets to facilitate mixing. An alkaline urine (pH >7.0) favors the formation of phosphate-based stones (struvite and apatite) and calcium carbonate-based stones. Struvite crystallization is reported to occur at urine pH >7.2, and dissolution is reported to occur at urine pH <6.5. Feeding an agent that decreases urine pH to a target range of 6.0 to 6.5 will therefore protect against phosphate and calcium carbonate-based stones. The feeding of ammonium chloride (at 0.5%–2.0% of dry matter intake, approximately 45 g/day to steers, 10 g daily to sheep, and 0.4–0.5 g/kg BW each day to male goats) may prevent urolithiasis caused by struvite or calcium carbonate, but the magnitude of urine acidification achieved varies markedly depending on the acidogenic nature of the diet. The safety of long-term feeding of these diets has not been well documented. A potentially practical method to prevent urolithiasis in goats is to feed a dietary cation anion difference (DCAD) of 0 mEq/kg dry matter, where DCAD = [Na+] + [K] – [Cl] – [S] with constituents measured in milliequivalents per kilogram of feed on a dry matter basis. Depending on the aggressiveness of the dosage of ammonium chloride and acidogenicity of the DCAD diet formulation, urine pH decreases over 2 to 5 days before stabilizing. Urine pH should always be closely monitored when adding ammonium chloride to the ration, because clinically relevant acidemia, metabolic acidosis, depression, and inappetence can result from overzealous administration rates, and bone demineralization can theoretically occur with sustained feeding because aciduria promotes hypercalciuria. For range animals, ammonium chloride can be incorporated in a protein supplement and fed at about two-thirds of the earlier dosage. An acidic urine (pH <7.0) favors the formation of silicate stones, so ammonium chloride manipulation...
of urine pH is not indicated in animals at risk of developing siliceous calculi. However, ammonium chloride may prevent the formation of silica calculi in sheep, which may have been caused by the urine-diluting effects of additional chloride intake.

When urolithiasis is caused by pasture exposure, females can be used to graze the dangerous pastures because they are not as susceptible to developing urinary tract obstruction. In areas where the oxalate content of the pasture is high, wethers and steers should be permitted only limited access to pasture dominated by herbaceous plants. Adequate water supplies should be available, and highly saline waters should be regarded with suspicion. Sheep on lush pasture commonly drink little if any water apparently because they obtain sufficient in the feed. Although the importance of vitamin A in the production of the disease has been decreed in recent years an adequate intake should be ensured, especially during drought periods and when animals are fed grain rations in feedlots. Deferment of castration, by permitting greater urethral dilatation, may reduce the incidence of obstructive urolithiasis, but the improvement is unlikely to be significant.

**REFERENCES**

**UROLITHIASIS IN HORSES**

Urolithiasis occurs sporadically in horses. The prevalence is low at about 0.04% to 0.7% of all horse accessions or diagnoses. Animals from about 5 to 15 years of age and older are most often affected, and 76% are males (27% intact and 49% geldings) and 24% are females. The uroliths are most commonly in the bladder (cystic), although they also occur in the renal pelvis, ureters, and urethra. In most cases, there is a single discrete yellowish stone, but a sandy sludge accumulates in cases of paralysis of the bladder. Almost all equine uroliths are composed of calcium carbonate (CaCO₃) in the form of calcite, which is the most stable hexagonal crystal form, although other CaCO₃ forms such as vaterite (a metastable hexagonal crystal form) and aragonite (an orthorhombic form) have been identified that may be more gray-white in color. The factors that contribute to urolith formation in horses are not understood. Urine from healthy adult horses is characterized by a substantial quantity of mucoprotein, a high concentration of minerals, considerable insoluble sabulous material, and alkalinity. Equine urine is normally supersaturated with calcium carbonate, and if it is normal for crystals of calcium carbonate to be present, this is related in some manner with the occurrence of calcium carbonate uroliths in horses. Nephrolithiasis may arise as a sequel to degenerative or inflammatory processes in the kidney in which inflammatory debris serves as a nidus for calculus formation.

**The clinical findings** of urolithiasis in the horse include:

- **Stranguria** (straining to urinate)
- Polakiuria (frequent passage of small amounts of urine), hematuria, and dysuria (difficult urination)
- Incontinence resulting in urine scalding of the perineum in females or of the medial aspect of the hindlimbs in males
- Painful urination with hematuria associated with cystitis
- Weight loss, particularly in horses with nephroliths and chronic renal failure
- Uroabdomen is horses with rupture of the bladder, or less frequently, kidney or ureter
- Bacterial infection of urine is common, usually caused by *E. coli*, *Staphylococcus* spp., and *Streptococcus* spp.

The bladder wall may be thickened and large calculi in the bladder may be palpable per rectum, just as the hand enters the rectum. Calculi are usually spheroid and have an irregular surface. Large calculi may be observed using transrectal ultrasonography and cystoscopy. Calculi may also be palpated in the ureters, per rectum, or enlarged ureters may be present.

In **males**, urethral calculi may present with signs of complete or partial obstruction that may be confused with colic of gastrointestinal origin. Horses with urethral obstructions make frequent attempts to urinate but pass only small amounts of blood-tinged urine. Unless rupture has occurred, the bladder is grossly enlarged. The calculus can be located by palpation of the penile urethra and by passage of a lead wire or catheter. If a catheter or lead wire is passed, care should be taken to prevent damage to the urethral mucosa. Bladder rupture leads to uroperitoneum but, if the rupture occurs at the neck of the bladder, urine may accumulate retroperitoneally and produce a large, diffuse, fluid swelling that is palpable per rectum. When rupture occurs, acute signs disappear and are replaced by depression, immobility, and pain on palpation of the abdominal wall. The heart rate rises rapidly, and the temperature falls to below normal.

Urinalysis reveals evidence of erythrocytes, leukocytes, protein, amorphous debris, and calcium carbonate crystals.

Renal calculi are frequently bilateral and affected animals have often progressed to chronic renal failure by the time of diagnosis without having displayed signs of urinary tract obstruction. A history of chronic weight loss and colic in a horse with renal failure indicates the possible presence of renal calculi. Treatment is supportive as for all cases of chronic renal failure.

**Treatment** for cystic calculi is surgical removal of all calculi and correction of any defect in the bladder. Recurrence of cystic and urethral calculi is common in the horse, which may be related to the failure to remove all calculi. Perineal urethrostomy has been used for removal of cystic calculi in a gelding. Urethral calculi in males are removed through the external urethral orifice or by urethrotomy at the site of obstruction. Some cystic calculi can be removed with the aid of electrohydraulic lithotripsy, laser lithotripsy under endoscopic visualization, or surgery. Extracorporeal shock wave lithotripsy does not appear to have been used in the horse. In large mares with bladder calculi less than 10 cm in diameter, it is possible to remove the calculi manually by passing a very small well-lubricated gloved hand through the urethra into the bladder and retrieving the calculus after administration of epidural analgesia and sedation. Simultaneous palpation per rectum can assist in bringing the calculus to the neck of the bladder. There is one report of laparoscopic removal of a large bladder urolith in a standing gelding. Percutaneous nephrostomy of the right kidney under ultrasonic guidance has been used for short-term diversion of urine in a horse with ureteral calculi.

Control measures typically focus on dietary modifications including decreasing calcium intake, but there appears to be an absence of studies documenting efficacy in control. Water intake should be facilitated and high calcium content feeds, such as alfalfa and clover hay, should be avoided. Ammonium chloride, at 200 mg/kg BW orally twice daily and decreased at biweekly intervals until a dosage of 20 to 60 mg/kg BW is reached, is recommended to maintain the urine pH below 7.0. Urine pH needs to be frequently monitored during supplementation with oral ammonium chloride because of the variability in individual response. Ascorbic acid (1–2 g/kg daily) administered orally is reported to acidify equine urine, but recommended dose rates vary widely and studies documenting treatment efficacy in urolithiasis appear to be lacking.
URETHRAL DEFECTS

An anomalous vas deferens caused a chronic partial urethral obstruction in a 2-year-old Limousin bull, resulting in bilateral hydronephrosis, pyelonephritis of the left kidney, and bilateral ureteral dilatation. There are two reports of a ruptured urinary bladder in neonatal calves apparently caused by a congenital urethral obstruction that was corrected by passing a urethral catheter. Congenital urethral obstruction with subsequent hydronephrosis and uropertoneum is reported in a lamb.

Urethral atresia is recorded rarely in calves and is manifested by failure to pass urine and distention of the patent proximal portion of the urethra.

Imperfect closure of the external male urethra in a series of newborn lambs (hypspadias) is recorded with other neonatal defects including atresia ani and diaphragmatic hernia. No genetic influence was suspected, and the cause was unidentified.

Continuous urethral spasm has been reported in a Standardbred mare with a 3-year history of stranguria and pollakiuria.1

BOVINE ENZOOTIC HEMATURIA

ETIOLOGY

Chronic ptaquiloside poisoning caused by the ingestion of \textit{Pteridium aquilinum} (primarily), but also \textit{Pteridium} spp., \textit{Cheilanthes sieberi}, or \textit{Onychium contiguum} is associated with enzootic hematuria in cattle. In the past, the genus was commonly treated as having only one species, \textit{P. aquilinum}, but more recently the genus is being subdivided into approximately 10 species. A high incidence of vesicular carcinomas, similar to the bladder lesions of enzootic hematuria in cattle, has also been recorded in sheep grazing bracken for long periods.

EPIDEMIOLOGY

Enzootic hematuria is an area problem on all continents where bracken grows. Bracken fern is a very common plant worldwide and the only higher order plant known to cause cancer in animals when ingested. There is a strong association between BPV-2 and chronic bracken fern ingestion in cattle with naturally acquired and experimentally induced bladder cancer. The overall prevalence of cancer can reach 10% in endemic areas, such as Sao Miguel Island in the Azores, and the disease may be associated with heavy losses in areas where bracken is a common plant.2 The disease is usually fatal. Cattle over 3 years of age are most often affected, and the disease has also been recorded in sheep and water buffalo exposed to infested pastures for periods exceeding 2 years. The disease occurs mainly on poor, neglected, or recently opened up land and tends to disappear as soil fertility and land management improves. It is not closely associated with a particular soil type, although it is recorded most commonly on lighter soils. The ptaquiloside content of bracken varies considerably between geographic locations, and there is good correlation between its

REFERENCES

concentration and neoplasia in rats fed bracken from those areas.

PATHOGENESIS
BPV-2 infects the bladder mucosa, producing a latent infection. Chemical carcinogens and immunosuppressants from bracken fern act in a synergistic manner with BPV-2, resulting in neoplastic disease.\(^2,3\) Ptaquiloside from bracken is excreted in the urine and converts to an aglycone dienone intermediate at high urine pH and this substance is the ultimate carcinogen, explaining the location of tumor formation in the bladder. It has been suggested that the dienone reacts with DNA, ultimate carcinogen, explaining the location of tumor formation in the bladder. Chemical carcinogens convert to an aglycone dienone intermediate and initiating carcinogenesis. BPV-2 appears to undergo major changes on cancer development through expression of a viral oncoprotein called E5 and modifying telomerase activity.\(^4,5\) Changes on cancer development through expression of a viral oncoprotein called E5 (E5 oncoprotein) is expressed in tumors and can be detected using PCR.

NECROPSY FINDINGS
All tissues of the carcass are pale, and the animal is usually emaciated. The urinary bladder contains blood clots or bloodstained urine. The presence of premalignant hemangiomas in the submucosa of the urinary bladder is typical of the disease. A range of other neoplasms may be present, including malignant hemangiosarcoma, hemangioendotheliomas (tumors that are histologically intermediate in appearance between hemangioma and hemangiosarcoma), transitional cell carcinoma, adenoma, fibroma, and papilloma.\(^2,3,4\) The malignant types may have invaded the deeper structures of the bladder and have metastasized to the lumbaroartic lymph node (the regional lymph node)\(^1\) or lungs. Tumors expressing p53 mutations appear to be more aggressive.\(^7\) The neoplastic changes in the bladder are accompanied by inflammatory changes of the mucosa and submucosa, including proliferative changes of mucosal epithelium, lymphocytic infiltrates, congestion, edema, and hemorrhage. In some cases, lesions are seen in the ureters and renal pelvis. The severity of the blood loss is not necessarily related to the size or extent of the lesions, and animals may bleed to death when only small localized lesions are present.

DIFFERENTIAL DIAGNOSIS
Diagnosis confirmation is by signs in animals grazing fern-infested pasture and preferably by histopathology of bladder lesions. The differential list includes:
- Cystitis
- Pylonephritis
Both are usually accompanied by fever, frequent urination, and the presence of pus and debris in the urine. Bacteriologic examination of the urine will reveal the presence of infection.

TREATMENT
Primary
No treatment should be attempted and affected animals should be disposed of at the first opportunity.

Supportive
Blood transfusion may be justified in severe cases and hematocrit mixture should be provided in other cases.

CONTROL
A general improvement in nutrition is often followed by a decrease in the number of animals affected. A specific recommendation is to apply gypsum (225–335 kg/hectare) to the pasture as a fertilizer, which is a measure reputed to delay the onset of the disease. Bracken eradication is difficult and should not be undertaken without the advice of the local weed control officer.

Diseases of the Prepuce and Vulvovaginal Area

ENZOOTIC POSTHITIS (PIZZLE ROT, SHEATH ROT, BALANOPPOSTHITIS) AND VULVOVAGINITIS (SCABBY ULCER)

SYNOPSIS
Etiology Multifactorial; organisms that produce urease, usually Corynebacterium renale, produce lesions only in certain...
ETIOLOGY
The etiology of these diseases is multifactorial. High urea concentrations in urine, associated with high protein in pasture, result in cytotoxic levels of ammonia when the urea is split by urease-producing organisms present in the prepuce and vagina. Estrogens in pasture, causing swelling and congestion of the prepuce, may predispose to disease. Most often the organism is \textit{C. renale}, but outbreaks of posthitis in sheep associated with other urease-producing organisms (e.g., \textit{R. equi} and \textit{C. hoofnani}) have been described.

\textit{Mycoplasma mycoides} LC has also been incriminated as a cause of posthitis and vulvovaginitis in sheep.

EPIDEMIOLOGY
The disease is reported primarily from Australia, South Africa, and South America but occurs in all countries with large pastoral sheep industries.

Host Occurrence
Sheep
In Australia, enzootic posthitis occurs most often in Merino sheep, particularly \textit{wethers} over 3 years of age and young rams, but in a severe outbreak young wethers and old rams may also be affected. An ulcerative vulvitis often occurs in ewes in the same flocks in which posthitis occurs in wethers and is thought to be a venereal extension of that disease. The disease also occurs in \textit{goats}.

Cattle
Posthitis is uncommon in bulls but is reported to occur at high rates and to be economically important in South America.

There appears to be no counterpart to ovine vulvitis in cows.

Source of Infection and Transmission
The causative organism can be recovered from lesions and from the clinically normal prepuce of most sheep. It is also present in the lesions of vulvitis in ewes and posthitis in bulls and Angora goat wethers.

Flies are considered to be probable mechanical vectors, and contact with infected soil and herbage is a likely method of spread. Infection at dipping or shearing seems not to be important. Transmission to ewes appears to occur venereally from infected rams. Although the natural disease in cattle is usually benign, they may act as reservoirs of infection for sheep on the same farm.

Host and Environmental Risk Factors
Diet and season are the major risk factors. Enzootic posthitis occurs most extensively on lush, improved pasture with a high legume content and reaches its highest incidence in the autumn in summer rainfall areas and in the spring where the major rainfall is in winter. In these circumstances it can occur in epizootic proportions in wethers. The incidence in affected flocks may be as high as 40%, and in some areas the disease is so common that it is not possible to maintain flocks of wethers.

Factors of lesser importance are continued wetness of the area around the prepuce caused by removal of preputial hairs at shearing; a high-calci um, low-phosphorus diet; and the ingestion of large quantities of alkaline water.

The high incidence in castrates and young rams is probably related to the close adherence of the preputial and penile skins, which separate in mature animals, and to a lesser understood influence of testosterone.

Experimental Reproduction
Implantation of the organism on a scarified prepuce in the presence of urine is capable of causing the external ulceration that is characteristic of the disease.

Economic Importance
Many deaths occur because of uremia and secondary bacterial infections and all affected sheep show a severe setback in growth rate and wool production. Young rams that are affected are incapable of mating.

PATHOGENESIS
The organism is capable of hydrolyzing urea with the production of ammonia. It is thought the initial lesion in the wether (the external lesion) is caused by the cytotoxic effect of ammonia, produced from urea in the urine by the causative bacteria. This lesion may remain in a static condition for a long period but, when there is a high urea content of the urine associated with a high-protein diet, and continued wetting of the wool around the prepuce, the lesion proceeds to invade the interior of the prepuce, producing the “internal lesion.” A similar pathogenesis is postulated for vulvar lesions.

CLINICAL FINDINGS
The primary lesion starts as a pustule, which breaks and forms a soft scab. Small scabs are found on the skin dorsal to the preputial orifice (external lesion) and around the external orifice on the nonhaired part of the prepuce. These may persist for long periods without the appearance of any clinical signs. The scab is adherent and tenacious. When extension to the interior of the prepuce occurs (internal lesion), there is extensive ulceration and scabbing of the preputial opening, and a hard core can be palpated extending 1 to 2 inches into the prepuce. With pressure, a semisolid core of purulent material can be extruded from the preputial orifice. Affected sheep may show restlessness, kicking at the belly, and dribbling urine as in urethral obstruction. The area is often infested by blowfly maggots. In rams, the development of pus and fibrous tissue adhesions may interfere with urination and protrusion of the penis and cause permanent impairment of function.

Some deaths occur from obstructive uremia, toxemia, and septicemia. During an outbreak many sheep may be affected without showing clinical signs and are detected only when they are subjected to a physical examination. Others recover spontaneously when feed conditions deteriorate.

In ewes the lesions are confined to the lips of the vulva and consist of pustules, ulcers, and scabs. These extend minimally into the vagina. Their presence may distort the vulva, and the ewe may urinate onto the wool with a consequent increased susceptibility to fly strike.

In bulls, lesions are similar to the external lesions, which occur in wethers but rarely there may be invasion of the interior of the prepuce. The external lesions occur at any point around the urethral orifice and may encircle it. Their severity varies from local excoriation to marked ulceration with exudation and edema. There is a tendency for the lesions to persist for several months without treatment and with highly alkaline urine.

CLINICAL PATHOLOGY
Isolation of the causative diphtheroid bacterium may be necessary if there is doubt as to the identity of the disease.

NECROPSY AND DIAGNOSTIC CONFIRMATION
Necropsy is not required, and the diagnosis is clinical.
TREATMENT

The principal measures are restriction of the diet to reduce the urea content of the urine, removal of the wool around the prepuce or vulva to reduce the risk of fly strike, segregation of affected sheep and disinfection of the preputial area, and surgical treatment of severe cases.

Sheep can be removed onto dry pasture and their feed intake restricted to that required for subsistence only. They should be inspected at regular intervals, the wool should be shorn from around the prepuce, and affected animals should be treated individually. Weekly application of a 10% copper sulfate ointment is recommended for external lesions; when the interior of the prepuce is involved, it should be irrigated twice weekly with a 5% solution of copper sulfate, cetrimide (20% in alcohol or water with or without 0.25% acid fuchsin), or 90% alcohol.

Penicillin topically, or oxytetracycline or penicillin parenterally, may assist recovery.

In severe cases the only satisfactory treatment is surgical, and surgical treatment is necessary if the prepuce is obstructed. The recommended procedure is to open the ventral sheath by inserting one blade of a pair of scissors into the external preputial orifice and cutting the prepuce back as far as the end of the urethral process; extension beyond this leads to trauma of the penis. Badly affected rams should be disposed of as they are unlikely to be of value for breeding.

CONTROL

Subcutaneous implantation with a mix of testosterone esters is highly effective as a preventive, but testosterone propionate is no longer permitted for use in sheep that will be used for human food. Testosterone enanthate is available in some jurisdictions. A single injection of 75 mg is used for prevention and 150 mg for treatment. It is most economical to use preventive treatments coincident with the periods of maximum incidence, the flush of pasture growth in spring and autumn, but timing will vary from district to district.

Alternative control procedures investigated include running male lambs as cryptorchids, called short scrotum lambs, in which the testes are pushed into the inguinal canal and a rubber ring is applied to remove the scrotum. Another is to run male lambs as hemicastrates. The prevalence of posthitis is significantly reduced in Merino short scrotum lambs and hemicastrates. There is an increase in live weight, with no increase in fleece weight, but there are obvious masculine characteristics such as horn growth.

adequate neurologic examination on an ataxic belligerent beef cow that is still able to walk and attack the examiner. An aggressive, paretic bull in broad sunlight can be a daunting subject if one wants to examine the pupillary light reflex; ophthalmoscopic examination of the fundus of the eye in a convulsing steer in a feedlot pen can be an exasperating task. Thus at one end of the spectrum is the clinical examination of pigs affected with nervous system disease, which is limited to an elementary clinical examination and necropsy examination. At the other end, neurologic examination of the horse with nervous system disease is very advanced. The global occurrence of bovine spongiform encephalopathy (BSE) has highlighted the importance of accurate clinical diagnosis in adult cattle with neurologic abnormalities. Discrete lesions of the central nervous system (CNS) resulting in well-defined neurologic signs are not common in agricultural animals. Many diseases are characterized by diffuse neurologic lesions associated with bacteria, viruses, toxins, nutritional disorders, and embryologic defects, and the clinical findings of each disease are similar. Rather than attempting to localize lesions in the nervous system, large-animal practitioners more commonly devote much of their time to attempting to identify whether an animal has diffuse brain edema or increased intracranial pressure, as in polioencephalomalacia (PEM); whether it has clinical signs of asymmetric brainstem dysfunction and depression of the reticular activating system, as in listeriosis; or whether the dysfunction is at the neuromuscular level, as in hypomagnesemic tetany.

Radiographic examination, including myelography, is not used routinely as a diagnostic aid in large-animal practice. The
collection of cerebrospinal fluid (CSF) from the different species and ages of large animal without causing damage to the animal or contaminating the sample with blood is a technique that few large-animal veterinarians have mastered. However, the collection of CSF from the lumbosacral cistern is not difficult if the animals are adequately restrained, and the information obtained from analysis of CSF can be very useful in the differential diagnosis of diseases of the brain and spinal cord. Referral veterinary centers are now providing detailed neurologic examinations of horses with nervous system disease, and the clinical and pathologic experience has expanded the knowledge base of large-animal clinical neurology.

In spite of the difficulties, the large-animal practitioner has an obligation to make the best diagnosis possible using the diagnostic aids available. The principles of large-animal neurology are presented in this chapter, and the major objective is to recognize the common diseases of the nervous system by correlating the clinical findings with the location and nature of the lesion.

**Accurate neuroanatomical localization of the lesion(s)** remains the fundamental requirement for creating a differential diagnosis list and diagnostic and treatment plan.

A disease such as rabies has major public health implications, and it is important for the veterinarian to be able to recognize the disease as early as possible and to minimize human contact. It is also important to be able to recognize treatable diseases of the nervous system, such as polioencephalomalacia (PEM), listeriosis, and nervous ketosis, and to differentiate these diseases from untreatable and globally important diseases such as Bovine Spongiform Encephalopathy (BSE).

The non-treatable diseases must also be recognized as such, and slaughter for salvage or euthanasia recommended if necessary. There must be a major emphasis on prognosis because it is inhumane and uneconomic to hospitalize or continue to treat an adult cow or horse with incurable neurologic disease for an indefinite period. If they are recumbent, the animals commonly develop ulcers and other self-inflicted injuries because of repeated attempts to rise. Very few diseases of the nervous system of farm animals are treatable successfully over an extended period of time. This has become particularly important in recent years with the introduction of legislation prohibiting the slaughter of animals that have been treated with antibiotics until after a certain withdrawal period, which may vary from 5 to 30 days. This creates even greater pressure on the clinician to make a rapid, inexpensive, and accurate diagnosis and prognosis.

Because of limitations in the neurologic examination of large animals, there must be much more emphasis on the history and epidemiologic findings. Many of the diseases have epidemiologic characteristics that give the clinician a clue to the possible causes, thus helping to narrow the number of possibilities. For example, viral encephalomyelitis of horses occurs with a peak incidence during the insect season, lead poisoning is most common in calves after they have been turned out on to pasture, and PEM occurs in grain-fed feedlot cattle and sheep.

The functions of the nervous system are directed at the maintenance of the body’s spatial relationship with its environment. These functions are performed by the several divisions of the nervous system including the following:

- **Sensory—motor system**, responsible for the maintenance of normal posture and gait
- **Autonomic nervous system**, controlling the activity of smooth muscle and endocrine glands, and thus the internal environment of the body
- **Largely sensory system of special senses**
- **Psychic system**, which controls the animal’s mental state

The nervous system is essentially a reactive one geared to the reception of internal and external stimuli and their translation into activity and consciousness; it is dependent on the integrity of both the afferent and efferent pathways. This integrative function makes it often difficult to determine in a sick animal whether abnormalities are present in the nervous system; the musculoskeletal system; or acid-base, electrolyte, and energy status. Accordingly, the first step when examining an animal with apparent abnormalities in the nervous system is to determine whether other relevant systems are functioning normally. A decision to implicate the nervous system is often made on the exclusion of other systems.

The nervous system itself is not independent of other organs, and its functional capacity is regulated to a large extent by the function of other systems, particularly the cardiovascular system. Inadequate oxygen delivery caused by cardiovascular disease commonly leads to altered cerebral function because of the dependence of the brain on an adequate oxygen supply.

It is important to distinguish between primary and secondary diseases of the nervous system because both the prognosis and the treatment will differ with the cause. In **secondary disease**, the lesion, at least in its early stages, is more likely to be functional and therefore more responsive to treatment, provided the defect in the primary organ can be corrected. The clinical findings that should arouse suspicion of neurologic disturbance include abnormalities in the three main functions of the system.

**Posture and Gait**

An animal’s ability to maintain a normal posture and to proceed with a normal gait depends largely on the tone of the skeletal muscle but also on the efficiency of the postural reflexes. Abnormalities of posture and gait are among the best indications of nervous system disease because these functions are governed largely by the coordination of nervous activity. Along with contributing to posture and gait, skeletal muscle tone is characteristic in its own right. However, its assessment in animals is subject to great inaccuracy because of our inability to request complete voluntary relaxation by the patient. In humans it is a very valuable index of nervous system efficiency, but in animals it has serious limitations. The most difficult step whenever there is a defect of gait or posture is to decide whether the defect originates in the skeleton, the muscles, or the nervous system.

**Sensory Perceptivity**

Tests of sensory perception in animals can only be objective and never subjective, as they can be in humans, and any test used in animals is based heavily on the integrity of the motor system.

**Mental State**

Depression or enhancement of the psychic state is not difficult to judge, particularly if the animal’s owner is observant and accurate. A helpful method for evaluating mental state is to answer the question: Is the animal responding appropriately for its environment? The difficulty usually lies in deciding whether the abnormality is caused by primary or secondary changes in the brain.

**Principles of Nervous Dysfunction**

Nervous tissue is limited in the ways in which it can respond to noxious influences. Because of its essentially coordinating function, the transmission of impulses along nerve fibers can be enhanced or depressed in varying degrees, with the extreme degree being complete failure of transmission. Because of the structure of the system, in which nerve impulses are passed from neuron to neuron by relays at the nerve cells, there may also be excessive or decreased intrinsic activity of individual cells giving rise to an increase or decrease in nerve impulses discharged by the cells. The end result is the same whether the disturbance is one of conduction or discharge, and these are the only two ways in which disease of the nervous system is manifested. Nervous dysfunction can thus be broadly divided into two forms, depressed activity and exaggerated activity. These can be further subdivided into four common modes of nervous dysfunction; excitation (irritation) signs,
release of inhibition signs, paresis or paralysis caused by tissue damage, and nervous shock.

**MODES OF NERVOUS DYSFUNCTION**

**Excitation (Irritation) Signs**
Increased activity of the reactor organ occurs when there is an increase in the number of nerve impulses received either because of excitation of neurons or because of facilitation of passage of stimuli.

The excitability of nerve cells can be increased by many factors, including stimulant drugs, inflammation, and mild degrees of those influences that in a more severe form may cause depression of excitability. Thus early or mild hypoxia may result in increased excitability, whereas sustained or severe hypoxia will cause depression of function or even death of the nerve cell.

Irritation phenomena may result from many causes, including inflammation of nervous tissue associated with bacteria or viruses, certain nerve poisons, hypoxia, and edema. In those diseases that cause an increase in intracranial pressure, irritation phenomena result from interference with circulation and the development of local anemic hypoxia. The major manifestations of irritation of nervous tissue are tetany, local muscle tremor, and whole-body convulsions in the motor system and hyperesthesia and paresthesia in the sensory system. For the most part the signs produced fluctuate in intensity and may occur periodically as nervous energy is discharged and reaccumulated in the nerve cells.

The area of increased excitability may be local or sufficiently generalized to affect the entire body. Thus a local lesion in the brain may cause signs of excitatory nervous dysfunction in one limb, and a more extensive lesion may cause a complete convolution.

**Release of Inhibition Signs**
Exaggeration of normal nervous system activity occurs when lower nervous centers are released from the inhibitory effects of higher centers. The classic example of a release mechanism is experimental decerebrate rigidity caused by transection of the brainstem between the colliculi of the midbrain. This results in an uninhibited extensor tonus of all the antigravity muscles. The head and neck are extended markedly in a posture of opisthotonus, and all four limbs in the quadruped are extended rigidly. The tonic mechanism or myotatic reflex involving the lower motor neuron has been released from the effects of the descending inhibitory upper motor neuron pathways.

Cerebellar ataxia is another example of inhibitory release. In the absence of cerebellar control, combined limb movements are exaggerated in all modes of action including rate, range, force, and direction. In general, release phenomena are present constantly while the causative lesion operates, whereas excitatory phenomena fluctuate with the building up and exhaustion of energy in the nerve cells.

**Paresis or Paralysis Caused by Tissue Damage**
Depression of activity can result from depression of metabolic activity of nerve cells, and the terminal stage is complete paralysis when nervous tissue is destroyed. Such depression of activity may result from failure of supply of oxygen and other essential nutrients, either directly from their general absence or indirectly because of failure of the local circulation. Infection of the nerve cell itself may cause initial excitation, then depression of function, and finally complete paralysis when the nerve cell dies.

Signs of paralysis are constant and are manifested by muscular paresis or paralysis when the motor system is affected and by hypoaesthesia or anaesthesia when the sensory system is involved. Deprivation of metabolites and impairment of function by actual invasion of nerve cells or by toxic depression of their activity produce temporary, partial depression of function that is completely lost when the neurons are destroyed.

**Nervous Shock**
An acute lesion of the nervous system causes damage to nerve cells in the immediate vicinity of the lesion but there may be, in addition, a temporary cessation of function in parts of the nervous system not directly affected. The loss of function in these areas is temporary and usually persists for only a few hours. Stunnung is an obvious example. Recovery from the flaccid unconsciousness of nervous shock may reveal the presence of permanent residual signs caused by the destruction of nervous tissue.

Determining the type of lesion is difficult because of the limited range of modes of reaction to injury in the nervous system. Irritation signs may be caused by bacterial or virus infection, by pressure, by vascular disturbance or general hypoxia, by poisons, and by hypoglycemia. It is often impossible to determine whether the disturbance is structural or functional. Degenerative lesions produce mainly signs of paresis or paralysis but unless there are signs of local nervous tissue injury, such as facial nerve paralysis, paraplegia, or local tremor, the disturbance may only be definable as a general disturbance of a part of the nervous system. Encephalopathy is an all-embracing diagnosis, but it is often impossible to go beyond it unless other clinical data, including signalment of the animal, epidemiology, and systemic signs, are assessed or special tests, including radiographic examination and examination of the CSF, are undertaken.

Some information can be derived from a study of the sign-time relationship in the development of nervous disease. A lesion that develops suddenly tends to produce maximum disturbance of function, sometimes accompanied by nervous shock. Slowly developing lesions permit a form of compensation in that undamaged pathways and centers may assume some of the functions of the damaged areas. Even in rapidly developing lesions partial recovery may occur in time, but the emphasis is on maximum depression of function at the beginning of the disease. Thus a slowly developing tumor of the spinal cord will have a different pattern of clinical development from that resulting from an acute traumatic lesion of the vertebrae. Another aspect of the rapidity of onset of the lesion is that irritation phenomena are more likely to occur when the onset is rapid and less common when the onset is slow.

**Clinical Manifestations of Diseases of the Nervous System**

The major clinical signs of nervous system dysfunction include the following:
- **Altered mentation**
- **Involuntary movements**
- **Abnormal posture and gait**
- **Paresis or paralysis**
- **Altered sensation**
- **Blindness**
- **Abnormalities of the autonomic nervous system**

**ALTERED MENTATION**

Excitation States
Excitation states include mania, frenzy, and aggressive behavior, which are manifestations of general excitation of the cerebral cortex. The areas of the cortex that govern behavior, intellect, and personality traits in humans are the frontal lobes and temporal cortex. The clinical importance of these areas, which are poorly developed in animals, is not great. The frontal lobes, temporal cortex, and limbic system are highly susceptible to influences such as hypoxia and increased intracranial pressure.

**Mania**
In mania the animal acts in a bizarre way and appears to be unaware of its surroundings. Maniacal actions include licking, chewing of foreign material and sometimes themselves, abnormal voice, constant bellowing, apparent blindness, walking into strange surroundings, drunken gait, and aggressiveness in normally docile animals. A state of delirium cannot be diagnosed in animals, but mental disorientation is an obvious component of mania.

Diseases characterized by mania include the following:
- Encephalitis, e.g., the furious form of rabies, Aujeszky’s disease in cattle (pseudorabies, mad itch)
Frenzy
Frenzy is characterized by violent activity and with little regard for surroundings. The animal’s movements are uncontrolled and dangerous to other animals in the group and to human attendants, and are often accompanied by aggressive physical attacks.

Examples of frenzy in diseases of the nervous system include the following:
- Encephalomyelitides, e.g., Aujezsky’s disease.
- Toxic and metabolic brain disease, e.g., hypomagnesemic tetany of cattle and sheep, poisoning with ammoniated roughage in cattle.

Examples of frenzy in diseases of other body systems include the following:
- Acute pain of colic in horses.
- Extreme cutaneous irritation, e.g., photosensitization in cattle. Apparently reasonless panic, especially in individual horses or groups of cattle, is difficult to differentiate from real mania. A horse taking fright at a botfly or a swarm of bees and a herd of cattle stampeding at night are examples.

Aggressive Behavior
Aggression and a willingness to attack other animals, humans, and inert objects is characteristic of the early stages of rabies and Aujezsky’s disease in cattle, in sows during postparturient hysteria, in the later stages of chronic hypoxia in any species, and in some mares and cows with granulosa-cell tumors of the ovary. The latter are accompanied by signs of masculinization and erratic or continuous estrus. It is often difficult to differentiate between an animal with a genuine change in personality and one that is in pain or is physically handicapped, e.g., pigs and cattle with atlantoaxial arthroses.

Depressive States
Depressive mental states include somnolence, lassitude, narcolepsy/cataplexy, syncope, and coma. They are all manifestations of depression of cerebral cortical function in various degrees and occur as a result of those influences that depress nervous system function generally, as well as those that specifically affect behavior, probably via the limbic system. It is not possible to classify accurately the types of depressive abnormality and relate them to specific causes, but the common occurrences in farm animals are listed next.

Depression Leading to Coma
In all species this may result from the following:
- Encephalomyelitis and encephalomalacia
- Toxic and metabolic diseases of the brain such as uremia, hypoglycemia, hepatic insufficiency, toxemia, septicemia, and most toxins that damage tissues generally
- Hypoxia of the brain, as in peripheral circulatory failure of periparturient hypocalcemia in dairy cows
- Heat stroke
- Specific poisons that cause somnolence, including bromides, amitraz in horses, methyl alcohol, *Filix mas* (male fern), and kikuyu grass

Sycope
The sudden onset of fainting (syncope) may occur as a result of the following:
- Acute circulatory and heart failure leading to acute cerebral hypoxia
- Spontaneous cerebral hemorrhage, a most unlikely event in adult animals
- Traumatic concussion and contusion
- Lightening strike, electrocution

Narcolepsy (Cataplexy)
Affected animals experience episodes of uncontrollable sleep and literally “fall” asleep. The disease is recorded in Shetland ponies and is thought to be inherited in them, in other horses, and in cattle.

Compulsive Walking or Head Pressing
Head-pressing is a syndrome characterized by the animal pushing its head against fixed objects and into a corner of a pen as well as leaning into a stanchion or between fence posts. Head-pressing should be differentiated from compulsive walking, in which affected animals put their heads down and walk slowly while appearing blind. If they walk into an object, they lean forward and indulge in head-pressing; if confined to a stall they will often walk around the pen continuously or head-press into a corner. The syndrome represents a change in behavior pattern caused by an unsatisfied compulsive drive characteristic of a disorder of the limbic system. Causes include the following:
- Toxic and metabolic brain disease, especially PEM and hepatic encephalopathy
- Diseases manifested by increased intracranial pressure
- Encephalomyelitides

Aimless Wandering
A similar but less severe syndrome to compulsive walking is aimless walking, severe mental depression, and apparent blindness with tongue protrusion and continuous chewing movements, although the animal is unable to ingest feed or drink water. Causes include the following:
- Toxic and metabolic diseases of brain, including poisoning by *Helichrysum* sp. and tansy mustard
- Degenerative brain diseases, e.g., nigropallidal encephalomalacia in horses, ceroid lipofuscinosis in sheep, hydrocephalus in the newborn

IN Voluntary Movements
Involuntary movements are caused by involuntary muscle contractions, which include gradations from fasciculations, shivering and tremor, to tetany, seizures, or convulsions. Opisthotonus or “backward tone” is a sustained spasm of the neck and limb muscles resulting in dorsal and caudal extension of the head and neck with rigid extension of the limbs.

Tremor
This is a continuous, repetitive twitching of skeletal muscles that is usually visible and palpable. The muscle units involved may be small and cause only local skin movement, in which case the tremor is described as fasciculations; or the muscle units may be extensive and the movement much coarser and sufficient to move the extremities, eyes, or parts of the trunk. The tremor may become intensified when the animal undertakes some positive action. This is usually indicative of cerebellar involvement and is the counterpart of intention tremor in humans. True tremor is often sufficiently severe to cause incoordination and severe disability in gait. Examples of causes of tremor include the following:
- Diffuse diseases of the cerebrum, cerebellum, and spinal cord
- Degenerative nervous system disease, e.g., hypomyelinogenesis of the newborn as in congenital tremor of pigs and calves, poisoning by *Swainsonia* sp.
- Toxic nervous system disease caused by a large number of poisons, especially poisonous plants and fungi, *Clostridium botulinum* toxin in shaker foal syndrome; metabolic disease such as hyperkalemic periodic paralysis in the horse; early stages of hypocalcemia in the cow (fasciculations of the eyelids and ears).

Tics
Tics are spasmodic twitching movements made at much longer intervals than tremor. The intervals are usually at least several seconds in duration and often much longer. The movements are sufficiently widespread to be easily visible and are caused by muscles that are ordinarily under voluntary control. They are rare in large animals but may occur after traumatic injury to a spinal nerve.

Tetany
Tetanus is a sustained contraction of muscles without tremor. The most common cause is *C. tetani* intoxication following localized infection with the organism. The degree of muscular contraction can be exaggerated by
stimulation of the affected animal, and the limbs are rigid and cannot be passively flexed easily ("lead pipe" rigidity).

**Myoclonus** is a brief, intermittent tetanic contraction of the skeletal muscles that results in the entire body being rigid for several seconds, followed by relaxation. Inherited congenital myoclonus (hereditary neurexial edema) of polled, horned, and crossbred Hereford calves is a typical example. Affected calves are bright and alert and can suck normally, but if they undertake a voluntary movement or are handled their entire body becomes rigid for 10 to 15 seconds.

**Convulsions**

Convulsions, seizures, fits, or ictus are violent muscular contractions affecting part or all of the body and occurring for relatively short periods as a rule, although in the late stages of encephalitis they may recur with such rapidity they give the impression of being continuous.

Convulsions are the result of abnormal electrical discharges in forebrain neurons that reach the somatic and visceral motor areas and initiate spontaneous, paroxysmal, involuntary movements. These cerebral dysrhythmias tend to begin and end abruptly, and they have a finite duration. A typical convulsion may have a prodromal phase or aura that lasts for minutes to hours, during which the animal is oblivious to its environment and seems restless. The beginning of the convulsion may be manifested as a localized partial convulsion of one part of the body that soon spreads to involve the whole body, when the animal usually falls to the ground thrashing rhythmically. Following the convulsion there may be depression and temporary blindness, which may last for several minutes up to a few hours.

The convulsion may be clonic with typical "paddling" (involuntary movement in which repeated muscle spasms alternate with periods of relaxation). Tetanic or tonic convulsions are less common and are manifested by prolonged muscular spasm without intervening periods of relaxation. True tetanic convulsions occur only rarely, chiefly in strychnine poisoning and in tetanus, and in most cases they are a brief introduction to a clonic convulsion.

Convulsions can originate from disturbances anywhere in the prosencephalon, including cerebrum, thalamus, or even the hypothalamus alone. However, the initiating cause may be in the nervous system outside the cranium or in some other system altogether; convulsions are therefore often subdivided into intracranial and extracranial types. Causes are many and include the following.

Intracranial convulsions are caused by:
- Local lesions caused by trauma (concussion, contusion), abscess, tumor, parasitic injury; hemorrhage
- Inherited idiopathic epilepsy
- Extracranial convulsions are caused by brain hypoxia, as in acute circulatory or cardiac failure, and toxic and metabolic diseases of the nervous system, including the following:
  - Hepatic encephalopathy
  - Hypoglycemia (as in newborn piglets and in hyperinsulinism caused by islet cell adenoma of the pancreas as described in a pony)
  - Hypomagnesemia (as in lactation tetany in cows and mares)
  - Inorganic poisons, poisonous plants, and fungi; there are too many to give a complete list, but well-known examples are the chlorinated hydrocarbons, pluronics used in bloat control in cattle, *Clostridium* spp.; intoxications, e.g., *C. perfringens* type D and *C. sordellii*, and subacute fluoraoacetate poisoning
  - Congenital and inherited defects without lesions, e.g., familial convulsions and ataxia in Angus cattle

**Involuntary Spastic Paresis**

Involuntary, intermittent contractions of large muscle masses may result in spasmodic movements of individual limbs or parts of the body. In most, contractions occur when voluntary movement is attempted. Diseases in this category include the following:
- Stringhalt and Australian stringhalt of horses
- Inherited spastic paresis (Elso heel) of cattle
- Inherited periodic spasticity (stall cramp) of cattle
- Inherited congenital myotonia of cattle
- Inherited myotonia of goats

**ABNORMAL POSTURE AND GAIT**

**Posture**

Posture is evaluated with the animal at rest. Abnormal postures may be adopted intermittently by animals in pain, but in diseases of the nervous system the abnormality is usually continuous and repeatable. Deviation of the head and neck from the axial plane or rotation of the head and neck from the horizontal plane (head tilt); drooping of the lips, eyelids, cheeks, and ears; and opisthotonus and orthotonicus are examples, although the latter two are often intermittent because they occur as part of a convulsive seizure. Head pressing and assumption of a dog-sitting posture are further examples. Diseases of the nervous system, including those of the brainstem, cerebellum, all levels of the spinal cord, spinal nerve roots, peripheral nerves, neuromuscular junctions, and muscles. The clinical emphasis is on vestibular disease, cerebellar disease, and spinal cord disease. It is important to emphasize that cerebral lesions do not cause abnormalities in posture and gait.

**Vestibular Disease**

The vestibular system is a special proprioceptive system that assists the animal in maintaining orientation in its environment with respect to gravity. It helps to maintain the position of the eyes, trunk, and limbs in relation to movements and positioning of the head.

From the vestibular nuclei, the vestibulospinal tracts descend ipsilaterally through the length of the spinal cord. These neurons are facilitatory to ipsilateral motor neurons going to extensor muscles of the limbs, are inhibitory to ipsilateral motor flexor muscles, and are inhibitory to contralateral extensor muscles. The principal effect of unilateral stimulation of this system on the limbs is a relative ipsilateral extensor tonus and contralateral flexor tonus, which promote ipsilateral support of the trunk against gravity. Conversely, a unilateral vestibular lesion usually results in ipsilateral flexor and contralateral extensor tonus, forcing the animal toward the side of the lesion.

The nuclei of cranial nerves (CNs) III, IV, and VI, which control eye movement, are connected with the vestibular system by way of a brainstem tract called the medial longitudinal fasciculus. Through this tract, coordinated eye movements occur with changes in positioning of the head. Through these various pathways, the vestibular system coordinates movements of the eye, trunk, and limbs with head movements and maintains equilibrium of the entire body during motion and rest.

Signs of vestibular disease vary depending on whether there is unilateral or bilateral involvement and whether the disease involves peripheral or central components of the system.

The vestibular influence on balance can be affected
- At the inner ear
- Along the vestibular nerve or
- At the vestibular nucleus in the medulla. Unilateral excitation or loss of function can be caused by lesions at any of these points.

General signs of vestibular system dysfunction are staggering, leaning, rolling, circling, drifting sideways when walking and a head tilt, and various changes in eye position such as strabismus and nystagmus. The walking in a circle toward the affected side is accompanied by increased tone in the contralateral limbs, which is most easily observed in the contralateral forelimb. Rotation or tilt of the head occurs, and severely affected animals fall to the affected side.

When the lesion affects the inner ear, as in some cases of otitis media, the affected side is turned down, the animal falls to that side, and there may be facial paralysis on the same side if the lesion is extensive and affects CN VII.
the recumbent position, the affected side is held to the ground, and if these animals are rolled over to the opposite side they quickly roll back to the affected side. When the vestibular nuclei are affected, as in listeriosis, the animal falls to the affected side.

Nystagmus and forced circling are common when there is irritation of the vestibular nucleus or the medial longitudinal fasciculus.

**Causes** of vestibular disease include the following:
- Otitis media interna with involvement of the inner ear
- Focal lesion at the vestibular nucleus, e.g., listeriosis
- Traumatic injury to the vestibular apparatus in the horse caused by fracture of the basisphenoid, basioccipital, and temporal bones; the clinical signs include lack of control of balance, rotation of the head, circling to the affected side, nystagmus, and facial paralysis

**In paradoxical vestibular syndrome** there is also head tilting, but circling in a direction away from the side of the lesion. Deviation of the head and neck must be distinguished from a head tilt. Asymmetric lesions of the forebrain such as a brain abscess, some cases of PEM, verminous larval migration, or head trauma may cause an animal to hold its head and neck turned to one side, but there is no head tilt and the circle is large in diameter. In fact, the presence of a head tilt (deviation of eyes away from a horizontal plane) accompanied by a tight circle provide clinically useful methods of differentiating a cerebral lesion from a vestibular lesion.

**Gait**

Gait is assessed when the animal is moving. Neurologic gait abnormalities have two components, weakness and ataxia. Weakness (paresis) is evident when an animal drags its limbs, has worn hooves, or has a low arc to the swing phase of the stride. When an animal bears weight on a weak limb, the limb often trembles and the animal may even collapse on that limb because of lack of support. While circling, walking on a slope, and walking with the head elevated, an animal frequently will stumble on a weak limb and knuckle over at the fetlock. During manipulation of the limb, the clinician will usually make the subjective observation that the muscle tone is reduced.

**Ataxia**

Ataxia is an unconscious, general proprioceptive deficit causing incoordination when the animal moves. It is manifested as a swaying from side to side of the pelvis, trunk, and sometimes the whole body (truncal sway). Ataxia may also appear as a weaving of the affected limb during the swing phase of the stride. This often results in abducted or adducted foot placement, crossing of the limbs, or stepping on the opposite foot.

**Hypermotria** is an increased range of movement and is seen as an overreaching of the limbs with excessive joint movement. Hypermetria without paresis is characteristic of spino cerebellar and cerebellar disease. It is a decreased range of movement that is characterized by a stiff or spastic movement of the limbs with little flexion of the joints, particularly the carpals and tarsal joints.

**Dysmetria** is a term that includes both hypermetria and hypometria, with goose-stepping being the most common sign. It usually is caused by a lesion in the cerebellum or cerebellar pathway.

In equine degenerative myeloencephalopathy (EDM), there is dysmetria of the hindlimbs and tetraparesis caused by neuronal dystrophy originating in the accessory cuneate nuclei. Severely affected horses lift their feet excessively high and stamp them to the ground.

**Cerebellar Disease**

When cerebellar function is abnormal there is ataxia, which is an incoordination when the animal moves. In general terms, there are defects in the rate, range, and direction of movement. In typical cerebellar diseases, ataxia of the limbs is common and no weakness is evident. In true cerebellar ataxia (e.g., cerebellar hypoplasia), the affected animal stands with the legs wide apart, sways, and has a tendency to fall. Ataxia of the head and neck are characterized by wide, swinging, head excursions; jerky head bobbing; and an intention tremor (nodding) of the head.

The head tremor may be the most obvious sign in mild cases of cerebellar hypoplasia in young foals. The limbs do not move in unison, the movements are grossly exaggerated, muscular strength is usually preserved, and there is a lack of proper placement of the feet (hypermotria and hypometria); falling is common. The fault in placement is the result of poor motor coordination and not related in any way to muscle weakness or proprioceptive deficit. Attempts to proceed to a particular point are usually unsuccessful, and the animal cannot accurately reach its feed or drinking bowl. Examples of cerebellar disease include the following:
- Inherited defects of cerebellar structure or abiotrophy in most breeds of cattle and in Arabian horses
- Congenital cerebellar defects resulting from maternal viral infections such as bovine virus diarrhea (BVD) infection in cattle
- Dysplastic disease of the cerebellum of the horse
- Traumatic injury, e.g., by parasite larvae such as Hypoderma bovis, which have caused unilateral cerebellar ataxia in adult cattle
- Tremorgenic mycotoxicoes and ryegrasses
- Cerebellar degeneration in cattle in Uruguay caused by grazing the perennial shrub Solanum bonariense ("Naranjillo")
- Encephalomyelitis in which other localizing signs also occur

**Spinal Cord Disease**

Ataxia caused by cerebellar dysfunction can be difficult to differentiate from the proprioceptive defects and partial motor paralysis (weakness) that occur in animals with spinal cord lesions, and it is most important that this differentiation is made. Spinal cord disease, causing varying degrees of weakness, and ataxia are common in large animals. The weakness is caused by damage to the upper or lower motor neurons and the proprioceptive deficit by damage to the ascending sensory neurons. With a mild or even moderate cervical spinal cord lesion in an adult cow or horse, signs of ataxia and weakness may be evident in the pelvic limbs only, and it can be difficult to determine whether the thoracic limbs are involved.

Close examination of the gait, posture, and postural reactions in the limbs, together with a search for localizing abnormalities, will often be productive in localizing the lesion. Signs of weakness or ataxia may be elicited by gently pushing the hindquarters to one side or pulling the tail to one side as the animal is walked (the sway response). The normal animal resists these movements or steps briskly to the side as it is pushed or pulled. The weak animal can be easily pulled to one side and may stumble or fall and may also tend to buckle or collapse when strong pressure is applied with the hand over the withers and loin regions. The ataxic animal may sway to one side, be slow to protract a limb, cross its hindlegs, or step on its opposite limb.

It is often difficult to distinguish paresis from ataxia, but in most instances it is unimportant because of the close anatomic relationship of the ascending general proprioceptive and descending upper motor neuron tracts in the white matter of the spinal cord. These same abnormal sway responses can be elicited in the standing animal.

The ataxic animal may abduct the outside pelvic limb too far as it is pushed to one side or moved in a small circle. This may appear as a hypermetric movement similar to a stringhalt action and is assumed to be a sign of a general proprioceptive tract lesion. The pushed or circled animal may keep the head tilted and may even force the animal into a "dog-sitting" posture.

Examples of ataxia caused by spinal cord disease include the following:
- Limited trauma to the spinal cord
- The early stages of a developing compression lesion in the vertebral canal
Degenerative and inflammatory diseases of the nervous system, especially those causing enzootic incoordination in horses and staggers in sheep (both of them dealt with under their respective headings)

Functional diseases in toxic and metabolic diseases of the nervous system in which lesions have not yet been identified and that are caused mainly by poisons, especially plant materials; typical examples are poisoning by the fungi Claviceps paspali, Diploodia spp., Acremonium loli, the grass Phalaris aquatica, the ferns Zamia and Xanthorhhea spp., and herbaceous plants such as Kallstroemia, Vicia, Baccharis, Solanum, Aesculus, and Ficus spp.

Heat stress in lambs

Nutritional deficiency especially of thiamine, occurring naturally in horses poisoned by bran, and experimentally in pigs

Developmental defects including congenital abnormalities and abiotrophic abnormalities that develop sometime after birth; examples are Brown Swiss weavers and Pietrain creeper pigs.

In many of these diseases, incoordination and paresis are a stage in the development of tetraplegia or paraplegia.

**PARESIS AND PARALYSIS**

The motor system comprises the following:

- Pyramidal tracts, which originate in the motor cortex
- Extrapyramidal system, which originates in the corpus striatum, red nucleus, vestibular nucleus, and roof of the midbrain
- Peripheral nerves, which originate in the ventral horn cells

The pyramidal tracts are of minor importance in hoofed animals (ungulates), reaching only to the fourth cervical segment. Accordingly, lesions of the motor cortex in farm animals do not produce any deficit of gait. There is also no paresis, although in an acute lesion weakness may be evident for the first day or two. If the lesion is unilateral, the paresis will be on the contralateral side. This is in marked contradistinction to the severe abnormalities of posture and gait that occur with lesions of the pons, medulla, and spinal cord.

The main motor nuclei in these animals are subcortical and comprise the extrapyramidal system, and most combined movements are controlled by nerve stimuli originating in the tectal nuclei, reticular nuclei, vestibular nuclei, and possibly red nuclei. The pyramidal and extrapyramidal tracts comprise the upper motor neurons, which reach to the ventral horn cells of the spinal cord, whose cells, together with their peripheral axons, form the lower motor neurons. Paralysis is a physiologic result in all cases of motor nerve injury, which if severe enough is expressed clinically. The type of paralysis is often indicative of the site of the lesion.

A lesion of the upper motor neuron causes the following:

- **Spasticity with loss of voluntary movement**
- **Increased tone of limb muscles**
- **Increased spinal reflexes**

The spasticity of an upper motor neuron lesion usually occurs with the affected limb in extension. These are all release phenomena resulting from liberation of spinal reflex arcs from higher control.

A lesion of the lower motor neuron causes:

- **Paresis or paralysis with loss of voluntary movement**
- **Decreased tone of the limb muscles**
- **Absence of spinal reflexes**
- **Wasting of the affected muscle**

Because injuries to specific peripheral nerves are treated surgically, these are dealt with in surgical textbooks and are not repeated here.

A special form of paralysis is the **Schiff-Sherrington syndrome**, which is common in dogs but recorded rarely in large animals. It is caused by acute, severe compressive injury of the thoracolumbar spinal cord and manifested by extensor rigidity or hypertonia of the forelimbs and hypotonic paralysis of the hindlimbs. Neurons located in the lumbar spinal cord are responsible for the tonic inhibition of extensor muscle alpha motor neurons in the cervical intumescence. The cell bodies of these neurons are located in the ventral gray column from L1-L7, with a maximum population from L2-L4. Their axons ascend to the cervical intumescence. Acute severe lesions cranial to these neurons and caudal to the cervical intumescence will suddenly deprive the cervical intumescence neurons of this source of tonic inhibition, resulting in a release of these latter neurons. This results in extensor hypertonia observed in the thoracic limbs, which can function normally in the gait and postural reactions, except for the hypertonia.

The degree of paresis or paralysis needs to be defined. Paralysis is identified as an inability to make purposeful movements. Thus convulsive, uncontrolled movements as they occur in PEM may still fit a description of paralysis. Paresis, or weakness short of paralysis, can be classified into four categories:

- Animals that cannot rise or support themselves if helped up but can make purposeful movements in attempting to rise
- Animals that cannot rise but can support themselves if helped up
- Animals that can rise but are paretic and can move the limbs well and stumble only slightly on walking
- Animals that move with difficulty and have severe incoordination and stumbling.

Probably the most difficult decision in farm animal neurology is whether a patient’s inability to move is because of a nervous or muscular deficit. For example, the horse recumbent because of exertional rhabdomyolysis often resembles a horse with an injured spinal cord. Examples of paresis and paralysis include the following:

- Focal inflammatory, neoplastic, traumatic lesions in the motor pathway. These lesions usually produce an asymmetric nervous deficit.
- Toxic and metabolic diseases of the nervous system in their most severe form, e.g., flaccid paralysis associated with tick bite (Ixodes holocyclus, Ornithodoros sp.), poisoning, botulism, and snakebite. Comparable tetanic paralyses include tetanus, lactation tetany of mares, and hypomagnesemic tetany of cows and calves. In contrast to inflammatory, neoplastic, and traumatic lesions in the motor pathway, toxic and metabolic lesions usually produce a symmetric nervous deficit.

**Neurogenic Muscular Atrophy**

Destruction of the lower motor neurons either within the vertebral canal or peripherally to it causes neurogenic atrophy. Whether or not the atrophy is visible depends on how many neurons and therefore how many muscle fibers are affected.

**ALTERED SENSATION**

Lesions of the sensory system are rarely diagnosed in animals, except for those affecting sight and the vestibular apparatus, because of the impossibility of measuring subjective responses.

Although animals must experience paresthesia, as in Aujeszky’s disease (pseudorabies) in cattle and sheep, the animal’s response of licking or scratching does not make it possible to decide whether the diagnosis should be paresthesia or pruritus. Lesions of the peripheral sensory neurons cause hypersensitivity or decreased sensitivity of the area supplied by the nerve. Lesions of the spinal cord may affect only motor or only sensory fiber tracts or both, or may be unilateral.

Although it is often difficult to decide whether failure to respond to a normally painful stimulus is caused by failure to perceive or inability to respond, certain tests may give valuable information. The test usually used is prickling the skin with a needle, or pinching the skin with a pair of forceps, and observing the reaction. In exceptional circumstances, light stroking may elicit an exaggerated response. The "nibbling" reaction stimulated by stroking the lumbar back of sheep affected with scrapie is a striking example of hypersensitivity.
In every test of sensitivity, it must be remembered that there is considerable variation between animals and in an individual animal from time to time, and much discretion must be exercised when assessing the response. In any animal, there are also cutaneous areas that are more sensitive than others. The face and the cranial cervical region are highly sensitive, the caudal cervical and shoulder regions less so, with sensitivity increasing over the caudal thorax and lumbar region and to a high degree on the perineum. The proximal parts of the limbs are much less sensitive than the distal parts and sensitivity is highest over the digits, particularly on the medial aspect.

**Absence of a response** to the application of a painful stimulus to the limbs (absence of the withdrawal reflex) indicates interruption of the reflex arc; absence of the reflex with persistence of central perception, as demonstrated by groaning or body movement such as looking at the site of stimulus application, indicates interruption of motor pathways and that central perception of pain persists. In the horse, the response can be much more subtle than in other species, and movements of the ears and eyelids are the best indicators of pain perception. Increased sensitivity is described as hyperesthesia, decreased as hypoesthesia, and complete absence of sensitivity is described as anesthesia. Special cutaneous reflexes include the anal reflex, in which spasmodic contraction of the anus occurs when it is touched, and the corneal reflex, in which there is closure of the eyelids on touching the cornea. The (cutaneous trunci) panniculus reflex is valuable in that the sensory pathways, detected by the prick of a pin, enter the cord at spinal cord segments T1-L3, but the motor pathways leave the cord only at spinal cord segments C8, T1, and T2. The quick twitch of the superficial cutaneous muscle along the whole back, which is the positive response (panniculus reflex), is quite unmistakable. Examination of the eye reflexes and hearing are discussed under the section Cranial Nerves (see later).

## BLINDNESS

Blindness is manifested as a clinical abnormality by the animal walking into objects that it should avoid. Vision is a cerebral cortical function and is evaluated using the pupillary light reflex, the menace response, and the ability to navigate around a novel obstacle course.

The **pupillary light reflex** is present at birth in large animals but does not need an intact cerebral cortex. This is the reason why ruminants with thiamine-responsive polioencephalomalacia appear blind but have an intact pupillary light reflex; in contrast, ruminants with lead poisoning and a greater extent of cerebral dysfunction appear blind but have a depressed or absent pupillary light reflex. The pupillary light reflex measures the integrity of the retina, optic nerves and chiasm, and oculomotor and pretectal nuclei in the midbrain, and then to a descending motor pathway that includes the oculomotor nerve, ciliary ganglion, and constrictor pupillae muscle.

The menace or blink response is used to test the integrity of the entire visual pathway (retina, optic nerves, optic chiasm, optic tract, lateral geniculate nucleus, and internal capsule to the visual area in the cerebrum [occipital lobe]). The visual cortex processes the information and relays signals to the motor cortex. The descending motor pathway receives some input from the cerebellum and proceeds from the ipsilateral pons to the contralateral facial nerve nucleus in the medulla oblongata, and then to the facial nerve, and finally the orbicularis oculi muscle. A threatening gesture of the hand (or even better by the index finger in a pointing manner) toward the eye elicits immediate closure of the eyelids. The finger must come close enough to the eye without touching the tactile hairs of the eyelids or creating a wind that can be felt by the animal. Some stoic, depressed, or even excited animals may not respond to a menace reflex with closure of the eyelids; others may keep the eyelids partially or almost closed. It may be necessary to alert the patient to the risk of injury by touching the eyelids first. The menace response is a learned response that is absent in neonates. Most foals have a menace response by 9 days after birth and most calves by 5 to 7 days after birth. Group housing of neonatal calves appeared to facilitate faster learning of the menace response as a result of more visual threats.

The most definitive test is to make the animal walk an obstacle course and place objects in front of it so that it must step over the objects easily. A similar procedure is the only way to test for night blindness (nyctalopia). The area should be dimly lit, but the observer should be able to see the obstructions clearly. A decision that the animal is blind creates a need for examination of the visual pathways.

### Central or Peripheral Blindness

Blindness may be central or peripheral. Animals with forebrain lesions are centrally blind, with depressed menace response in one or both eyes, whereas the pupillary light reflexes are usually intact. In peripheral blindness, such as hypovitaminosis A, the menace reflex is absent, and the pupillary light reflexes are also absent.

Blindness can be caused by lesions along the visual pathway, from the eye to the cerebral cortex:

- **Diseases of the retina** include keratoconjunctivitis, hypopyon, cataract, panophthalmitis, mixed ocular defects inherited in white Shorthorn and Jersey cattle, night blindness in Appaloosa horses, and sporadic cases of blindness caused by idiopathic retinal degenerative disease in cattle.

- **Diseases of the optic nerve and chiasma**, e.g., abscess of pituitary rete mirabile, constriction of optic nerve by diet deficient in vitamin A, tumor of pituitary gland, and injury to the optic nerve, especially in horses after rearing and falling backward. There is a sudden onset of unilateral or bilateral blindness with no ophthalmologic change until 3 to 4 weeks after the injury, when the optic disc becomes paler and less vascular.

- **Metabolic or ischemic lesions of the cerebral cortex** as in PEMS, cerebral edema, and hydrocephaus.

- **Localized infectious or parasitic lesions** caused by abscesses or migrating larvae.

- **Functional blindness** in which there is complete, often temporary, apparent blindness in the absence of any physical lesions is seen. Causes are acetoneemia, pregnancy toxemia, and acute carbohydrate indigestion (hyper d-lactatemia) of ruminants.

- **Specific poisonings** causing blindness include E. mas (male fern), Cheilanthes spp. (rock fern), and rape. Stypandra spp. cause a specific degeneration of the optic nerves. Lead poisoning in cattle can also cause blindness.

### ABNORMALITIES OF THE AUTONOMIC NERVOUS SYSTEM

Lesions affecting the cranial parasympathetic outflow do so by involvement of the oculo-motor, facial, vagus, and glossopharyngeal nerves or their nuclei. The effects produced are discussed in the Cranial Nerves section of Special examination of the Nervous System. In general, the lesions cause abnormality of pupillary constriction, salivation, and involuntary muscular activity in the upper part of the alimentary and respiratory tracts. Lesions of the spinal sympathetic system interfere with normal function of the heart and alimentary tract. For the most part, affections of the autonomic nervous system are of minor importance in farm animals. Central lesions of the hypothalamus can cause abnormalities of heat exchange, manifested as neurogenic hyperthermia or hypothermia and obesity, but they are also of minor importance.

Some manifestations of autonomic disease are important. Autonomic imbalance
is usually described as the physiologic basis for spasmodic colic of horses; grass sickness of horses is characterized by degenerative lesions in the sympathetic ganglia; and involvement of the vagus nerve in traumatic reticuloperitonitis of cattle can lead to impaired fore stamped and abomasal motility as well as the development of vagus indigestion.

Defects of sphincter control and motility of the bladder and rectum may also be of importance in the diagnosis of defects of sacral parasympathetic outflow and the spinal sympathetic system. The sacral segments of the spinal cord are the critical ones, and loss of their function will cause incontinence of urine and loss of rectal tone. The parasympathetic nerve supply to the bladder stimulates the detrusor muscle and relaxes the sphincter; the sympathetic nerve supply has the reverse function. A spinal cord lesion may cause loss of the parasympathetic control and result in urinary retention. Incontinence, if it occurs, does so from overflow. When the sympathetic control is removed, incontinence occurs but the bladder should empty. Similar disturbances of defecation occur. Both micturition and defecation are controlled by medullary and spinal centers, but some measure of control is regained even when the extrinsic nerve supply to the bladder and rectum is completely removed.

**Special Examination of the Nervous System**

Veterinarians commonly include several components of a neurologic examination in a complete clinical examination. Most often a diagnosis and differential diagnosis can be made from consideration of the history and the clinical findings. However, if the diagnosis is uncertain it may be necessary to conduct a complete neurologic examination, which may uncover additional clinical findings necessary to make a diagnosis and give a prognosis.

The accuracy of a clinical diagnosis of neurologic diseases in the horse is high. In a study of 210 horses in which a definitive pathologic diagnosis was confirmed, the overall accuracy of clinical diagnosis for all diseases was 0.95; the accuracy ranged from 0.79 to 1.00, the sensitivity varied from 0.73 to 0.95, and the specificity varied from 0.88 to 1.00 for individual disease categories. Some neurologic diseases are therefore underdiagnosed, whereas others are overdiagnosed. The use of careful and thorough clinical examinations and diagnostic techniques, combined with confirmed pathologic diagnoses, will result in more accurate diagnosis and therapy. Retrospective studies of series of ataxic horses, for example, will add to the body of knowledge and improve diagnosis.

**NEUROLOGIC EXAMINATION**

The primary aim of the neurologic examination is to confirm whether or not a neurologic abnormality exists and to determine the neuroanatomical location of the lesion. A clinicooanatomic diagnosis is necessary before one can develop a list of differential diagnoses and decide whether or not treatment is possible. The format for a precise practical examination procedure that is logical in sequence, easy to remember with practice, and emphasizes the need for an anatomic diagnosis is outlined later. The rationale for the sequence is that the examination starts from a distance to assess posture and mentation and then proceeds to a closer examination that may require placing the animal in stocks or a chute. The examination sequence is therefore suitable for minimally handled beef cattle, dairy cattle, horses, sheep, goats, and New World camels. The results of the neurologic examination should be documented and not left to memory. There are many standard examination forms available that outline each step in the examination and provide for documentation of the results.

**SIGNALMENT AND EPIDEMIOLOGY**

The age, breed, sex, use, and value of the animal are all important considerations in the diagnosis and prognosis of neurologic disease. Some diseases occur more frequently under certain conditions, for example, lead poisoning in nursing beef calves turned out to pasture in the spring of the year. *Histoplasma capsulatum* meningocerebralitis is most common in feedlot cattle from 6 to 10 months of age, and hypovitaminosis A is most common in beef calves 6 to 8 months of age after grazing dry summer pastures. In the horse, there are several clearly defined diseases that affect the spinal cord including cervical stenotic myelopathy, degenerative myeloneuropathalopathy, protozoal myelitis, equine rhinopneumonitis myelopathy, rabies polioencephalomyelitis, and equine motor neuron disease. Some of these diseases have distinguishing epidemiologic characteristics that are useful in diagnosis and differential diagnosis. The neurologic examination of the newborn foal is fraught with hazards because of the different responses elicited from those in adults. The differences relate mostly to the temporary asymmetry of gait and exaggerated responses of reflexes.

**HISTORY**

Special attention should be given to the recording of an accurate history. The questioning of the owner should focus on the primary complaint and when it occurred and how it has changed over time (the sign-time relationship). The duration of signs; the mode of onset, particularly whether acute with later subsidence, or chronic with gradual onset; the progression of involvement; and the description of signs that occur only intermittently should be ascertained. When the disease is a herd problem, the morbidity and mortality rates and the method of spread may indicate an intoxication when all affected animals show signs within a very short period. Diseases associated with infectious agents may have an acute or chronic onset. Neoplastic diseases of the nervous system may begin abruptly but are often slowly progressive. For some diseases, such as epilepsy, consideration of the history may be the only way to make a diagnosis. Traumatic injuries have a sudden onset and then often stabilize or improve.

When obtaining a history of convulsive episodes, an estimate should be made of their duration and frequency. The pattern is also important and may be diagnostic, e.g., in salt poisoning in swine. The occurrence of palor or cyanosis during the convulsion is particularly important in the differentiation of cardiac syncope and a convulsion originating in the nervous system.

**HEAD**

**Behavior**

The owner should be questioned about the animal’s abnormal behavior, which can include bellowing, yawning, licking, mania, convulsions, aggressiveness, head-pressing, wandering, compulsive walking, and head-shaking. Head-shaking may be photic in origin and can be tested by the application of blindfolds, covering the eyes with a face mask, and observing the horse in total darkness outdoors. In one horse, head-shaking ceased with blindfolding or night darkness outdoors, and became less with the use of gray lenses. Outdoor behavior suggested efforts to avoid light.

**Mental Status**

Assessment of mental status is based on the animal’s level of awareness or consciousness. Coma is a state of complete unresponsiveness to noxious stimuli. Other abnormal mental states include stupor, somnolence, deliriousness, lethargy, and depression. Animals may exhibit opisthotonus, either spontaneously or in response to stimulation (Fig. 14-1). Large animals that are recumbent because of spinal cord disease are usually bright and alert unless affected with complications, which may cause fever and anorexia. Mature beef cattle that are recumbent with a spinal cord lesion and not used to being handled may be quite aggressive and apprehensive.

**Head Position and Coordination**

Lesions of the vestibular system often result in a head tilt. Lesions of the cerebrum often result in deviation of the head and neck. In
cerebellar disease, there may be jerky movements of the head, which are exaggerated by increasing voluntary effort. These fine jerky movements of the head are called intention tremors. Animals with severe neck pain will hold their neck in a fixed position and be reluctant to move the head and neck. Head-shaking in horses has been associated with ear mite infestation, otitis externa, CN dysfunction, cervical injury, ocular disease, guttural pouch mycosis, dental periapical osteitis, and vasomotor rhinitis. However, idiopathic head-shaking in the horse is often associated with evidence of nasal irritation, sneezing and snorting, nasal discharge, coughing, and excessive lacrimation.

**Cranial Nerves**

Abnormalities of CN function assist in localizing a lesion near or within the brainstem. Some of the information on CN dysfunction is presented in tabular form (Tables 14-1 through 14-6) in addition to the more detailed examination described here.

**Olfactory Nerve (Cranial Nerve I)**

Tests of smell are unsatisfactory in large animals because of their response to food by sight and sound.

**Optic Nerve (Cranial Nerve II)**

The only tests of visual acuity applicable in animals are testing the eye preservation (menace) reflex (provoking closure of the eyelids and withdrawal of the head by stabbing the finger at the eye) and by making the animal run a contrived obstacle course. Both tests are often difficult to interpret and must be performed in such a way that other senses are not used to determine the presence of the obstacles or threatened injury. In more intelligent species, a good test is to drop some light object, such as a handkerchief or feather, in front of the animal. It should gaze at the object while it is falling and continue to watch it on the ground. The same method can be applied to young ruminants, which demonstrate normal vision by following the examiner’s moving hand at an age so early that they have not yet developed a menace reflex. Ophthalmoscopic examination is an integral part of an examination of the optic nerve.

**Oculomotor Nerve (Cranial Nerve III)**

This nerve supplies the pupilloconstrictor muscles of the iris and all the extrinsic cranial Nerves. Abnormalities of CN function assist in localizing a lesion near or within the brainstem.

</table>
muscles of the eyeball except the dorsal oblique, the lateral rectus, and the retractor muscles. Loss of function of the nerve results in pupillary dilation and defective pupillary constriction when the light intensity is increased, abnormal position (ventrolateral deviation) or defective movement of the eyeballs, and palpebral ptosis.

The pupillary light reflex is best tested by shining a bright point source of light into the eye, which causes constriction of the iris of that eye (direct pupillary reflex). Constriction of the opposite eye (consensual pupillary light reflex) will also occur. The consensual light reflex may be used to localize lesions of the optic pathways.

Examination of the menace reflex (eye preservation reflex to a menace) and the results of the pupillary light reflex can be used to distinguish between blindness caused by a lesion in the cerebral cortex (central blindness) and that caused by lesions in the optic nerve or other peripheral parts of the optic pathways (peripheral blindness).

As examples, in PEM (central blindness) the menace reflex is absent, but the pupillary light reflex is present. In the ocular form of hypovitaminosis A (peripheral blindness) in cattle, the menace reflex is also absent, the pupils are widely dilated, and the pupillary light reflex is absent. In PEM, the optic nerve, oculomotor nucleus, and oculomotor nerve are usually intact but the visual cortex is not; in hypovitaminosis A, the optic nerve is usually degenerate, which interferes with both the menace and pupillary light reflexes.

Testing of ocular movements can be performed by moving the hand about in front of the face. In paralysis of the oculomotor nerve, there may also be deviation from the normal ocular axes and rotation of the eyeball. There will be an absence of the normal horizontal nystagmus reaction with deviation laterally indicates a defect of the eye. Absence of the eye preservation reflex may be caused by facial nerve paralysis or blindness. Facial paralysis is evidenced by ipsilateral drooping of the ear, ptosis of the upper eyelid, drooping of the lips, and pulling of the philtrum to the unaffected side. There may also be drooling of saliva from the commissures of the lips, and in some cases a small amount of feed may remain in the cheeks of the affected side.

The common causes of damage to the eye are fracture of the petrous temporal bone, gullar pouch mycosis, and damage to the peripheral nerve at the mandible. A common accompaniment is injury to the vestibular nerve or center. A diagnosis of central, compared with peripheral, nerve involvement can be made by identifying involvement of adjacent structures in the medulla oblongata. Signs such as depression, weakness, and a head tilt would result, and are frequently present in ruminants and New World camels with listeriosis.

Vestibulocochlear Nerve (Cranial Nerve VIII)

The cochlear part of the vestibulocochlear nerve is not easily tested by simple clinical examination, but failure to respond to sudden sharp sounds, created out of sight and without creating air currents, suggests deafness. The cochlear portion can be tested electronically (the brainstem auditory evoked response, or BAER, test) to diagnose a lesion of the auditory nerve, eliminating the possibility of a central brain lesion. Abnormalities of balance and carriage of the head (rotation around the long axis and not deviation laterally) accompany lesions of the vestibular part of the vestibulocochlear nerve, and nystagmus is usually present.

In severe cases, rotation of the head is extreme, the animal is unable to stand and lies in lateral recumbency; moving to achieve this posture is compulsive and forceful.
POSTURE AND GAIT

The examiner evaluates posture and gait to give a general assessment of brainstem, spinal cord, and peripheral nerve and muscle function. Evaluation of posture and gait consists of determining which limbs are abnormal and looking for evidence of lameness suggesting a musculoskeletal gait abnormality. Weakness and ataxia are the essential components of gait abnormality. Each limb is examined for evidence of these abnormalities. This is done while the animal is standing still, walking, trotting, turning tightly (pivoting), and backing up. To detect subtle asymmetry in the length of the stride, the observer should walk parallel to or behind the animal, step for step. If possible, the gait should also be evaluated while the animal is walking up and down a slope or walking with the head and neck held extended, while blindfolded and while running free in an enclosure.

The best observations are made when the animal is running free, preferably at a fast gait, to avoid abnormalities resulting from being led. Also, slight abnormalities such as a high-stepping gait, slight incoordination of movement, errors of placement of feet, stumbling, and failure to flex joints properly are all better observed in a free animal.

Weakness or paresis is evident when an animal drags its limbs, has worn hooves, or has a low arc to the swing phase of the stride. When an animal bears weight on a weak limb, the limb often trembles and the animal may even collapse on that limb because of lack of support. When circling, walking on a slope, and walking with the head held elevated, an animal frequently will stumble on a weak limb and knuckle over on the fetlock.

The presence of weakness in the limbs of horses or cattle can be determined by pulling the tail while the animal is walking forward. A weak animal is easily pulled to the side and is seen as an overreaching of the limbs, particularly the carpal and tarsal joints. This generally is indicative of increased extensor tone and of a lesion affecting the descending motor or ascending spinocerebellar pathways to that limb. A hypometric gait, particularly in the thoracic limbs, is best seen when the animal is backed up or when it is maneuvered on a slope with the head held elevated. The thoracic limbs may move almost without flexing.

Dysmetria is a term that incorporates both hypermetria and hypometria. Animals with severe cerebellar lesions may have a high-stepping gait but have limited movement of the distal limb joints, especially in thoracic limbs.

The degree of weakness, ataxia, hypometria, and hypermetria should be graded for each limb. The types of gait abnormalities and the degree of weakness reflect various nervous and musculoskeletal lesions. Generally, with focal, particularly compressive, lesions in the cervical spinal cord or brainstem, neurologic signs are one grade more severe in the pelvic limbs than in the thoracic limbs. Thus with a mild, focal, cervical spinal cord lesion, there may be more abnormality in the pelvic limbs with no signs in the thoracic limbs. The anatomic diagnosis in such cases may be a thoracolumbar, cervical, or diffuse spinal cord lesion.

A moderate or severe abnormality in the pelvic limbs, and none in the thoracic limbs, is consistent with a thoracolumbar spinal cord lesion. With a mild and a severe change in the thoracic and the pelvic limb gaits, respectively, one must consider a severe thoracolumbar lesion plus a mild cervical lesion, or a diffuse spinal cord disease.

Weak and ataxic animals frequently will stumble on slopes, and walking with the head held elevated, an animal frequently will stumble on a weak limb and knuckle over on the fetlock. It may also appear as a weaving of the affected limb during the swing phase. This often results in swaying from side to side of the pelvis, trunk, and sometimes the entire body. It may also appear as a weaving of the affected limb during the swing phase. This often results in swaying from side to side of the pelvis, trunk, and sometimes the entire body.
there are varying degrees of ptosis; prolapse of the third eyelid; miosis; enophthalmos; and increased temperature of the face, neck, and shoulder. The syndrome is associated with lesions affecting the descending sympathetic fibers in the white matter of the spinal cord or gray matter in the cranial thoracic segments, thoracocervical sympathetic trunk, cervical vago-sympathetic trunk, or cranial cervical ganglion and its preganglionic and postganglionic fibers.

**Sensory perception from the neck and forelimbs** is assessed using a painful stimulus such as a blunt needle or forceps. The local responses as well as the cerebral responses are noted when the skin over the shoulders and down the limbs is pricked.

**Gait deficits** are evaluated by making the horse or halter-broken ruminant perform a series of movements. Such exercises should include walking and trotting in a straight line, in large circles, in tight circles, backing on a level ground and on a slight slope, walking and trotting over curbs or low obstacles, walking in straight lines and circles, and walking on a slope with the head held elevated. The sway reaction for the thoracic limb is assessed by pushing against the shoulders and forcing the animal first to resist and then to take a step laterally. This can be done while the animal is standing still and walking forward. Pulling the tail and lead rope laterally at the same time will assess the strength on each side of the body. Making the animal turn in a tight circle by pulling the lead rope and tail at the same time will indicate strength; an adult horse should be able to pull the examiner around and should not pivot on a limb or be pulled to the side. Pressing down with the fingers on the withers of a normal animal causes some arching, followed by resistance to the downward pressure. An animal with weakness in the thoracic limbs may not be able to resist this pressure by fixing its vertebral column but will arch its back more than normal and often buckle in the thoracic limbs.

In smaller farm animal species, other postural reactions can be performed. These include wheelbarrowing and the hopping response test. The spinal reflexes are assumed to be intact in animals that are ambulating normally. If a large mature horse, cow, or pig has a gait abnormality, it is very rare to cast the animal to assess the spinal reflexes. However, spinal reflexes are usually examined in calves, sheep, and goats.

A **recumbent animal** that can use its thoracic limbs to sit up in the dog-sitting position may have a lesion caudal to spinal cord segment T2. If a recumbent animal cannot attain a dog-sitting position, the lesion may be in the cervical spinal cord. In lambs aged between 4 and 10 weeks with thoracic vertebral body abscesses extending into the epidural space causing spinal cord compression, the thoracic limbs are normal and the lambs frequently adopt a dog-sitting position and move themselves around using the thoracic limbs only. Lambs with a cervical spinal cord lesion are unable to maintain sternal recumbency and have paresis of all four limbs.

However, mature cattle with the downer cow syndrome secondary to hypocalcemia may be unable to use both the thoracic and pelvic limbs. If only the head, but not the neck, can be raised off the ground, there may be a severe cranial cervical lesion. With a severe caudal cervical lesion, the head and neck can usually be raised off the ground but thoracic limb function is decreased and the animal is unable to maintain sternal recumbency.

**Assessment** of limb function is done by manipulating each limb separately, in its free state, for muscle tone and sensory and motor activity. A limb that has been lain on for some time cannot be properly evaluated because there will be poor tone from the compression. A flaccid limb, with no motor activity, indicates a lower motor lesion to that limb. A severe upper motor neuron lesion to the thoracic limbs causes decreased, or absent, voluntary effort, but there is commonly normal or increased muscle tone in the limbs. This is caused by release of the lower motor neuron, which reflexly maintains normal muscle tone from the calming influence of the descending upper motor neuron pathways.

**The tone of skeletal muscle** may be examined by passively flexing and extending the limbs and moving the neck from side to side and up and down. Increased muscle tone, spasticity, or tetany may be so great that the limb cannot be flexed without considerable effort. If the spastic-extended limb does begin to flex but the resistance remains, this is known as lead-pipe rigidity, which is seen in tetanus. If after beginning to flex an extended spastic limb the resistance suddenly disappears (“clasp-knife release”), then this suggests an upper motor neuron lesion. The laryngeal adductory reflex is of special interest in the examination of ataxic horses. In normal horses, a slap on the saddle region just caudal to the withers causes a flickering adductory movement of the contralateral arytenoid cartilage that is visible by an endoscope. Reflex muscle contraction can be palpated on the dorsolateral surfaces of the larynx. The reflex is absent when there is damage to afferent tracts up the spinal cord, when there is damage to the recurrent laryngeal nerves, and in tense or frightened horses. Elicitation of the reflex is called the **slap test**.

### TRUNK AND HINDLIMBS

If examination of the posture, gait, head, neck, or thoracic limbs reveals evidence of a lesion, then an attempt should be made to explain any further signs found during examination of the trunk and hindlimbs that could have been caused by the lesion. If there are only signs in the trunk and hindlimbs, then the lesion(s) must be either between spinal cord segments T2 and S2 or in the trunk and pelvic limb nerves or muscles. It must be remembered that a subtle neurologic gait in the pelvic limbs may be anywhere between the midsacral spinal cord and the rostral brainstem.

The trunk and hindlimbs are observed and palpated for malformations and asymmetry. Diffuse or localized sweating, the result of epinephrine release and sympathetic denervation, is often present in horses affected with a severe spinal cord injury.

Gentle pricking of the skin over the trunk and over the lateral aspects of the body wall on both sides, including on either side of the thoracolumbar vertebral column, will test-stimulate the cutaneous trunci reflex. The sensory stimulus travels to the spinal cord in thoracolumbar spinal nerves at the level of the site of stimulation. These impulses
are transmitted up the spinal cord to spinal cord segments C8-T1, where the lateral thoracic nerve is stimulated, causing contraction of the cutaneous trunci muscle, which is seen as a flicking of the skin over the trunk. Lesions anywhere along this pathway will result in suppression or absence of this reflex. Caudal to the site of the lesion, degrees of hypalgesia and analgesia have been detected in cases of thoracolumbar spinal cord lesions, especially if they are severe. In mature cattle with fractured thoracolumbar vertebral fractures, the degree of voluntary effort, particularly in the pelvic limbs includes the pelvic limb and the spinal cord segments are L4 and L5. These abnormalities are much more transitory and will likely be resolved within one day. The stretch reflex is elicited by lightly pinning the skin of the pelvis and observing reflex contraction of the anal sphincter and clamping down of the tail. The sensory fibers are contained within the perineal branches of the pudendal nerve (spinal cord segments S1-S3). Contraction of the anal sphincter is mediated by the caudal rectal branch of the pudendal nerve, and tail flexion is mediated by the sacral and coccygeal segments and nerves (spinal cord segments S1-S3). An animal with a flaccid tail and anus, caused by a lower motor neuron lesion, will not have an anal or tail reflex. However, it may still have normal sensation from the anus and tail provided that the sensory nerves and spinal cord and brainstem white matter nociceptive pathways are intact. Observation of defecation and urination movements and postures contributes to knowledge of the state of the cauda equina. Thus, urination in cases of cauda equina is characterized by flaccid paralysis and analgesia of the tail, anus and perineum, rectum, and bladder. There is no paresis or paralysis of the hindlimbs unless lumbosacral segments of the cord are damaged. 

Skin sensations of the pelvic limbs should be assessed independently from reflex activity. The femoral nerve is sensory to the skin of the medial thigh region, the peroneal nerve to the dorsal tarsus and metatarsus, and the tibial nerve to the plantar surface of the metatarsus. 

TINT AND ANUS 

Tail tone is evaluated by lifting the tail and noting the resistance to movement. A flaccid tail, with no voluntary movement, is indicative of a lesion of the sacrococcygeal spinal cord segments, nerves, or muscles. Decreased tone in the tail can be detected with severe spinal cord lesions cranial to the coccygeal segment. 

The perineal reflex is elicited by lightly pinching the skin of the perineum and observing reflex contraction of the anal sphincter and clamping down of the tail. The sensory fibers are contained within the perineal branches of the pudendal nerve (spinal cord segments S1-S3). Contraction of the anal sphincter is mediated by the caudal rectal branch of the pudendal nerve, and tail flexion is mediated by the sacral and coccygeal segments and nerves (spinal cord segments S1-S3). An animal with a flaccid tail and anus, caused by a lower motor neuron lesion, will not have an anal or tail reflex. However, it may still have normal sensation from the anus and tail provided that the sensory nerves and spinal cord and brainstem white matter nociceptive pathways are intact. 

PALPATION OF THE BONY ENCASEMENT OF THE CENTRAL NERVOUS SYSTEM 

Palpable or visible abnormalities of the cranium or spinal column are not commonly encountered in diseases of the nervous system, but the examination should not be neglected. There may be displacement, abnormal configuration, or pain on deep palpation. These abnormalities are much more readily palpable in the vertebral column and if vertebrae are fractured. Abnormal rigidity or flexibility of the vertebral column, such as occurs in atlantooccipital malformations in Arabian horses and cattle, may also be detectable by manipulation.

COLLECTION AND EXAMINATION OF CEREBROSPINAL FLUID

The collection and laboratory analysis of CSF from farm animals with clinical evidence of nervous system disease can provide useful diagnostic and prognostic information. A case series involving 102 cattle highlighted the clinical utility of CSF analysis in the ante-mortem diagnoses of nervous diseases. 

CSF is formed mostly from the choroid plexuses of the lateral, third, and fourth ventricles by the ultrafiltration of plasma and the active transport of selected substances across the blood-brain barrier; such as CSF should be regarded as a modified ultrafiltrate of plasma. A small amount of CSF is formed by the ependymal lining of the ventricular system, the pia arachnoid and meningeal blood vessels, and the central canal of the spinal cord. The rate of CSF turnover is approximately 1% per minute; accordingly, it takes many minutes for systemic electrolyte or acid-base changes (such as an increase in plasma magnesium concentration in hypomagnesemic beef cattle) to result in detectable and clinically relevant changes in CSF concentrations. CSF in the ventricular system flows caudally and diffuses out of the lateral recess in the fourth ventricle to circulate around the brain and spinal cord. The presence of CSF in the subarachnoid space separates the brain and spinal cord from the bony cranium and vertebral column, which reduces trauma to the underlying delicate nervous tissue. CSF flows within the subarachnoid space of leptomeninges, and it is primarily in this location that CSF equilibrates with the extracellular fluid (ECF) compartment of CNS parenchyma. It also helps regulate intracranial pressure, maintains electrolyte and acid-base homeostasis, serves as an intracerebral transport system for neurotransmitters and hormones, and has excretory functions with the removal of products of cerebral metabolism. CSF analysis therefore provides a clinically valuable insight into diseases of the CNS. 

Collection of Cerebrospinal Fluid CSF can be collected from the lumbosacral cistern with sedation (horses) or restraint (ruminants) and the atlantooccipital cistern (cisterna magna) using injectable general anesthesia. For collection it is necessary to puncture the subarachnoid space in either the lumbosacral space or cisterna magna. Although there is no substantial difference between the composition of lumbosacral or cisternal CSF samples unless there is a compressive lesion of the spinal cord, the general policy is to sample as close to the lesion as possible, with the exception that...
atlantooccipital sampling should not be attempted in animals suspected to have increased intracranial pressure. CSF should be collected into a sterile tube and there is no need to add an anticoagulant, even in samples visibly contaminated with blood. Cytology should be performed as soon as possible after collection (ideally within 15 minutes) because the cells rapidly degenerate after collection. The reason for this rapid degeneration appears to be associated with the low oncotic pressure in CSF; the addition of autologous serum to make a 11% serum solution permitted storage of bovine CSF samples for 24 hours at 4°C before cytologic examination was performed with no loss in cell integrity. The addition of serum to CSF in a ratio that provides an approximate final serum solution of approximately 11% should therefore be considered if there is an unavoidable delay before cytologic examination can be performed.

### Collection From the Lumbosacral Cistern

The lumbosacral site is preferred because general anesthesia is not required. CSF can be collected from the lumbosacral cistern with relative ease provided that adequate restraint can be achieved and the anatomic landmarks can be identified. It can be collected from the standing or recumbent animal. If recumbent, the animal should be placed in sternal recumbency with hips flexed and the pelvic limbs extended alongside the abdomen. This widens the lumbosacral space to permit correct placement of the spinal needle. Ultrasonographic guidance has been described but is rarely needed.

The site for collection is the midpoint of the lumbosacral space, which can be identified as the midline depression between the last palpable dorsal lumbar spine (L6 in cattle, goats, and horses; L6 or L7 in sheep and pigs; L7 in New World camelids) and the first palpable sacral dorsal spine (usually S2). In well-conditioned animals, these landmarks cannot always be identified; in which case the site is identified as the midpoint of a line connecting the caudal aspect of the tuber coxae. The site is clipped, surgically prepared, and 1 to 2 mL of local anesthetic is administered subcutaneously. Sterile surgical gloves should be worn. Hypodermic spinal needles with stylets are recommended because ordinary needles commonly plug with tissue. The length and gauge of needle depends on the size of the animal, but at least 15-cm (6-inch) 18-gauge needles are needed for adult horses and cattle. These needles can bend considerably with animal movement, requiring the use of at least an 18-gauge needle; very tall horses may need a 20-cm needle because the depth needed maybe 16 to 18 cm. The following guide is recommended (Table 14-7).

Provided the animal is well restrained and care is exercised in introducing the needle, little difficulty should be encountered. For collection from the lumbosacral space the needle is slowly advanced perpendicularly or up to 15 degrees caudal to perpendicular to the plane of the vertebral column. The needle must be introduced in a perfectly vertical position relative to the plane of the animal’s vertebral column because of the danger of entering one of the lateral blood vessels in the vertebral canal. Changes in tissue resistance can be felt as the needle point passes sequentially through the subcutaneous tissue and interarcuate ligament; then there is a sudden “pop” caused by the loss of resistance as the needle point penetrates the ligamentum flavum into the epidural space. Once the needle point has penetrated the dorsal subarachnoid space, CSF will well up in the needle hub within 2 to 3 seconds. Failure to appreciate the changes in resistance as the needle moves down may result in puncture of the conus medullaris, which may elicit an immediate pain response and some discomfort. Movement of the pelvic limbs may dislodge the needle point, with the risk of causing local trauma and hemorrhage in the leptomeninges, which results in blood in the sample. Repeated CSF taps of the lumbosacral space may make it more difficult to obtain an adequate sample volume because of fibrosis of epidural tissue.

Careful aspiration with a syringe attached to the needle held between the thumb and index finger is usually required to obtain a sample of 2 to 3 mL, which is sufficient for laboratory analysis. This can be facilitated by firmly resting the forearms and wrists on the animal’s back. Failure to obtain fluid is usually caused by incorrect direction of the needle, in which case the bony landmarks of the lumbosacral space (depression) must be rechecked and, with the needle correctly realigned, the procedure repeated. Occasional small rotations of the needle to change the direction of the bevel can be successful in obtaining CSF, particularly in smaller animals.

In animals with a vertebral body abscess and neurologic disease confined to the hindlimbs, CSF may be difficult to obtain from the lumbosacral space because flow is occluded. In these circumstances, if a sample is obtained, the CSF protein may be increased as a result of stagnation of CSF distal to the lesion with exudation or transudation of protein from the lesion (Froin’s syndrome).

### Collection From the Atlantooccipital Cistern (Cisterna Magna)

This site is preferred for intracranial lesions because the fluid is produced in the subarachnoid space and flows caudally down the spinal cord. However, this site is rarely used because of the inherent risk of needle penetration of the brainstem. Xylazine at 0.20 mg/kg body weight (BW) intramuscularly is effective in providing adequate sedation and analgesia for this procedure in cattle. A general anesthetic (such as combined intravenous administration of xylazine and ketamine) is recommended for horses. Ultrasonographic guidance has been described but is rarely needed.

The site is prepared as with the lumbosacral cistern. Ventreflexion of the head and neck of cattle enlarges the space of the cisterna magna and allows easy entry using a stylletted spinal needle inserted at a point created by the transection of the transverse line of the cranial rim of the wing of the atlas and the dorsal midline. The needle is advanced carefully and steadily, and the tip is directed rostrally toward the symphysis of the lower jaw. The needle point goes through the skin, ligamentum nuchae, and leptomeninges. In most mature cattle with a BW over 500 kg, a 20-gauge, 10-cm (4-inch) spinal needle will enter the cisterna magna at 5 to 7 cm after going through the ligamentum nuchae, which provides some increased resistance. A 20-gauge 3.8-cm (1.5-inch) needle can be used in sheep, goats, foals, and neonatal calves. The entrance to the cisterna magna is at a depth of approximately 4 to 6 cm in adult horses and 1.5 to 2.5 cm in neonatal foals. Once at the lower range of the anticipated depth to enter the cisterna magna, the spinal needle is advanced 1 to 2 mm at a time. When the needle point punctures the leptomeninges, the animal may move its head slightly. At that point the needle is advanced only 1 to 2 mm and the styllette is then removed. If the end of the needle is in the cisterna magna, CSF will flow out of the needle freely and the manometer can be attached and the pressure measured.

### Cerebrospinal Fluid Pressure

CSF pressure can be determined by the use of a manometer attached to the spinal needle. Normal CSF pressures of the cisterna magna in cattle and xylazine/ketamine-anesthetized horses range from 5 to 15 cm H₂O (unknown reference point) and 28 ± 4 cm H₂O (referenced to the right atrium), respectively. When the fluid system is properly connected, occlusion of both jugular veins causes a marked rise in CSF pressure; this is called
Queckenstedt's test. This test involves bilateral jugular vein compression, which results in a sudden increase in intracranial subarachnoid pressure that is transmitted to the cranial subarachnoid space. The resultant CSF pressure wave is transmitted to the lumbar area (when obtaining CSF from the lumbosacral space) in the absence of an obstruction in the spinal subarachnoid space, resulting in an increased flow of CSF.

Variations in CSF pressure are not of much use in clinical diagnosis except in hypovitaminosis A, and measurement of CSF pressure is only indicated in animals with signs of cerebral disease (abnormal mentation) that may have cerebral edema. Care is needed in interpreting results because the pressure is greatly affected by voluntary movement such as tenesmus. CSF pressure is increased in a number of diseases, including PEM, bacterial meningitis, and hypovitaminosis A reflecting the presence of increased intracranial pressure. Xylazine given intravenously causes a decrease in intracranial pressure in healthy conscious horses. Intracranial pressure is increased in anesthetized horses when their head is placed lower than their heart because of an increase in the hydrostatic pressure gradient. Epidural pressure of cattle changes in the hydrostatic pressure gradient, horses. Intracranial pressure is increased in intracranial pressure in healthy conscious animals.

Xylazine given intravenously causes a decrease in intracranial pressure in healthy conscious horses. Intracranial pressure is increased in anesthetized horses when their head is placed lower than their heart because of an increase in the hydrostatic pressure gradient. Epidural pressure of cattle changes in the hydrostatic pressure gradient.

In cattle, protein concentrations range from 23 to 60 mg/dL; sodium concentrations from 132 to 144 mmol/L; potassium 2.7 to 3.2 mmol/L; magnesium 1.8 to 2.1 mEq/L; and glucose concentrations 37 to 51 mg/dL. In the horse, the reference values for CSF are similar. Neonatal foals under 3 weeks of age have higher CSF protein concentrations than do adult horses. Glucose concentrations peak in the first 48 hours after birth and then decrease to adult values by the second week of life. Concentrations of sodium and potassium are not affected by age and are similar to values reported for adult horses and ponies. In sheep, protein concentrations range from 12 to 60 mg/dL and glucose concentrations from 38 to 63 mg/dL.

Cytokine concentrations in CSF may have prognostic value, and the cytokine gene expression in nucleated cells in CSF may have clinical utility in the diagnosis of specific nervous diseases. The presence of one or more eosinophils in CSF is extremely unusual and should be assumed to indicate the presence of an aberrant parasite migration or fungal encephalitis. Theoretically, the CSF glucose concentration will be decreased and CSF lactate concentration will be increased in animals with bacterial meningitis because of bacterial metabolism, but these are unreliable signs and usually do not provide additional information to that provided by determination of CSF leukocyte and protein concentrations. Bacteria may also be cultured from the CSF.

The creatine kinase and lactate dehydrogenase activities in CSF have been examined as an aid in the differentiation of some neurologic diseases. However, creatine kinase activity is considered to be unreliable in the horse; contamination of the sample with extraneous muscle tissue results in falsely elevated creatine kinase activity. In contrast, CSF creatine kinase activity >19.5 U/L provided an excellent diagnostic test of nonrecovery in sheep with Listeriosis. Insufficient information is available to evaluate the clinical utility of CSF lactate dehydrogenase activity in large animals.

Blood contamination of CSF can make interpretation difficult. A formula has been developed that "corrects" the CSF values for the degree of blood contamination, based on the red blood cell count (RBC) in CSF (RBC_CS) and blood (RBC_blood), in which the corrected value for substance X in CSF (X_corrected) where X is a concentration or activity is derived from the measured value of X in CSF (X_CS) and blood (X_blood) and applying the following formula:

$$X_{\text{corrected}} = X_{\text{CS}} \times (\frac{\text{RBC}_{\text{CS}}}{\text{RBC}_{\text{blood}}})$$

Calculation of a "corrected" value rarely provides additional insight into the CSF analysis and is not commonly practiced in large animals. Xanthochromia is a slight yellow tinge to CSF that indicates previous erythrocyte lysis or more commonly increased protein concentration. A foamy appearance to the CSF is also suggestive of increased protein concentration.

Protein fractionation of CSF is not routinely performed because it requires sensitive electrophoresis methodology or species-specific radial immunodiffusion assays.Albumin (ALB) concentration in CSF can also be measured using an immunologic technique based on the detection of albumin-antialbumin immune complexes by nephelometry. Calculation of the albumin quotient and IgG index may be informative in specific neurologic diseases. Theoretically, these calculations can differentiate four blood-brain permeability patterns, normal blood-brain barrier permeability (normal albumin quotient and IgG index), intrathecal IgG production with normal blood-brain barrier permeability (normal albumin quotient and increased IgG index), increased blood-brain barrier permeability without intrathecal IgG production (increased albumin quotient and normal IgG index), and increased blood-brain barrier permeability with intrathecal production of IgG (increased albumin quotient and increased IgG index). The albumin quotient is calculated from the albumin concentration in CSF (ALB_CS) and serum (ALB_serum), in which:

$$\text{Albumin Quotient} = (\frac{ALB_{\text{CS}}}{ALB_{\text{serum}}}) \times 100.$$

The normal range for albumin quotient in the adult horse is 0.6 to 2.2 for atlantooccipital CSF samples and 0.7 to 2.5 for lumbosacral CSF samples, but the mean is 0.4 to 0.5 in cattle and adult llamas. Because CSF protein is most often derived by disturbance of the blood-brain barrier and inflammation (resulting in an increased CSF albumin concentration), an increased CSF protein concentration is usually accompanied by an increased albumin quotient.

In animals suspected to have increased immunoglobulin production in the CNS (a rare occurrence, and almost always accompanied by disturbance of the blood-brain barrier), the IgG index can be calculated from the IgG concentration in CSF (IgG_CS) and serum (IgG_serum), and the albumin...
concentration in CSF (ALB<sub>CSF</sub>) and serum (ALB<sub>serum</sub>), in which:

$$\text{IgG Index} = \frac{\text{IgG}_{\text{serum}}}{\text{IgG}_{\text{serum}} / (\text{ALB}_{\text{serum}} / \text{ALB}_{\text{CSF}})}$$

An IgG index of more than 0.3 is suspected to indicate intrathecal IgG production in the adult horse. This formula corrects the CSF IgG concentration for an increased permeability of the blood-brain barrier; therefore, theoretically it provides a more sensitive method for detecting local production of IgG within the CNS. Calculating the albumin quotient and IgG index is expensive and rarely provides additional information to that provided by CSF protein concentration alone, and for this reason is not commonly performed in large animals.

When antigen-specific titers are measured, two modified CSF indices, the Goldman-Witmer coefficient (C-value) and the antibody index (AI), can be calculated to distinguish intrathecal versus passively acquired antibodies in the CSF. The C-value is calculated as

$$C-\text{value} = \frac{(\text{IgG}_{\text{serum}} \times \text{reciprocal serum titer})}{(\text{IgG}_{\text{CSF}} \times \text{reciprocal serum titer})}$$

The AI is calculated as the ratio of the specific antibody quotient to the albumin quotient, in which

$$AI = \frac{(\text{reciprocal CSF titer})}{(\text{reciprocal serum titer})} / \frac{(\text{CSF albumin concentration})}{(\text{serum albumin concentration})}$$

The urine dipstick protein test provides a useful on-farm assessment of CSF protein concentration and is underutilized in clinical practice. Most dipsticks use the following gradations of trace (<25 mg/dL), 1+ (28–75 mg/dL), 2+ (115–240 mg/dL), and 3+ (470–590 mg/dL), and a study of dog CSF samples indicated that all dogs with a urine dipstick protein of 2+ or greater had increased CSF protein concentration. Similar studies do not appear to have been conducted in large animals.

The Pandy test also provides a useful on-farm assessment of CSF protein concentration. The basis for the test is that proteins (globulin and albumin) are precipitated by a saturated solution of phenol in water. The Pandy test uses a 10% solution of carboxylic acid crystals dissolved in water (providing a saturated aqueous solution of phenol); the solution is termed Pandy’s solution. One milliliter of Pandy’s solution is placed in a glass tube and one drop (approximately 0.05 mL) of CSF is carefully layered on top. A turbid appearance at the interface signifies the presence of elevated concentrations of globulin or albumin in the CSF and is regarded as a positive Pandy’s reaction (usually a total protein concentration greater than approximately 50 mg/dL). A variant of the test has the sample thoroughly mixed and the degree of turbidity ranked from 1+ (faint turbidity) to 4+ (dense milk-colored precipitate).

In summary, collection and analysis of CSF from the lumbar spinal region provides a practical, safe, and informative diagnostic tool in conscious large animals with neurologic disease. Analysis of CSF in animals with CNS disease has greater diagnostic value than analysis of the leukon or serum biochemical analysis. Routine assessment of CSF should include total protein concentration (including the semiquantitative Pandy test and urine dipstick measurement), erythrocyte count, leukocyte count, and leukocyte differential count. Other analytical procedures on CSF can be performed in specific diseases related to the nervous system.

EXAMINATION OF THE NERVOUS SYSTEM WITH SERUM BIOCHEMICAL ANALYSIS

Arterial Plasma Ammonia Concentration

In animals suspected of having hepatic encephalopathy, measurement of the arterial plasma ammonia concentration provides a clinically useful diagnostic test and a means of monitoring the response to treatment. In monogastrics, ammonia is produced by bacterial degradation of amines, amino acids, and purines in the gastrointestinal tract, by the action of bacterial and intestinal urease on urea in the gastrointestinal tract, and by the catabolism of glutamine by enterocytes. In ruminants, ammonia is derived predominantly from bacterial metabolism in the rumen and catabolism of amino acids in tissue. Absorbed ammonia is normally converted to urea by the liver and to glutamine by the liver, skeletal muscle, and brain. In the presence of hepatic dysfunction, ammonia is inadequately metabolized, resulting in high plasma ammonia concentrations. Ammonia is a direct neurotoxin that alters inhibitory and excitatory neurotransmission in the brain.

Hyperammonemia can be used as a specific indicator of hepatic dysfunction. Normal values for arterial plasma ammonia concentration are less than 29 μmol/L in adult cattle but may reach higher values in the immediate periparturient period. Arterial values are higher than venous values and are preferred for analysis.

Blood gas analysis and serum electrolyte determination should be routinely undertaken in animals with clinical signs of encephalopathy to rule out metabolic causes of cerebral dysfunction.

EXAMINATION OF THE NERVOUS SYSTEM WITH IMAGING TECHNIQUES

Radiography

Examination of the bony skeleton of the head and vertebral column to detect abnormalities that are affecting the nervous system of large animals is commonly used in referral centers. Conventional diagnostic radiography remains the best method for the initial evaluation of trauma to the brain and spinal cord, but usually the trauma needs to have displaced bone for the lesion to be readily visible on a radiograph. Lesions that can be identified on plain radiographs include fracture, luxated, or subluxated vertebra; intervertebral disk prolapse; discospondylitis; osteomyelitis; and neoplasia. The injection of contrast media into the CSF system (myelography) is used for the detection of spinal cord compression but is not often performed in large animals because spinal cord depression surgery is rarely undertaken and because sensitivity and specificity estimates are low depending on criteria used for interpretation. In cases of peripheral nerve injury the radiograph of the appropriate limb may reveal the presence of a fracture or space-occupying lesion that has caused dysfunction of the peripheral nerve.
Radiography has been used to diagnose lesions of the tympanic bullae in cattle (otitis interna) characterized by thickening of the bulla wall, increased soft tissue opacity within the bulla, and osteolysis of the bulla wall and trabeculations. Radiography is not as sensitive as computed tomography (CT) for the diagnosis of otitis media, however, because CT provides more detailed information regarding the bony structures of the middle ear and is more sensitive and specific than radiography in the diagnosis of otitis media in calves.

**Computed Tomography**

CT of the skull has several advantages over radiography because structures are viewed in cross section without superimposition. The use of contrast agents and development of computer software and technology that permit rapid acquisition times and three-dimensional reconstruction allows a large amount of information to be obtained from a CT examination. Numerous diseases of the head of the horse, including those of the brain and cervical spine, can be diagnosed using this technique, but the limiting factors are the weight of the patient (a custom-designed table is required for adult horses and cattle), accessibility for large animals, and the need for general anesthesia.

CT provides an excellent image of skeletal cranial defects and soft tissue defects that differ considerably from surrounding tissue. CT has been used for the antemortem diagnosis of many conditions in foals, horses, and cattle, including cerebral abscess, porencephaly, meningoencephalocele, pituitary adenoma, cervical stenotic myelopathy, spinal cord rupture, and otitis interna/media, and has been used to guide brain biopsy for in vivo diagnosis of an intracranial mass. CT provides less contrast resolution than magnetic resonance imaging (MRI), but CT provides better spatial resolution (i.e., is more able to differentiate fine anatomic features such as bone trabeculae), is more widely available, and has a shorter scan acquisition time. In a case series of 57 cases, CT was a useful diagnostic test in horses with abnormal mentation or a history of trauma followed by a period of unconsciousness. In contrast, CT did not provide clinically helpful information in horses with seizures.

**Magnetic Resonance Imaging**

MRI scanning uses nuclear magnetic resonance to create cross-sectional images based on the magnetic properties of tissues. In general, MRI provides an excellent image of soft tissue defects and is considered superior to CT for intracranial and intraspinal lesions because MRI provides a high contrast between soft tissues and better anatomic detail. MRI can be performed in standing sedated horses; however, these MRI units (typically 0.25 T) produce low-resolution images that may not have sufficient detail to be diagnostic for many nervous diseases. Higher resolution images are produced by more expensive magnets (typically 1.0–3.0 T) that require the patient be immobile. The limiting factors for MRI use are therefore cost (MRI is more expensive than CT), the weight of the patient, accessibility for large animals, and the need for general anesthesia for higher resolution images (usually MRI has a longer imaging time than CT). Other challenges specific to MRI are that the environment provides considerable challenges for the monitoring of anesthesia and the placement of limbs to minimize postanesthetic myopathy/neuropathy syndrome, particularly in horses.

MRI has been used for the antemortem diagnosis of a number of neurologic conditions in foals and horses, including brain abscess, hydrocephalus, nigropallidal encephalomalacia, cerebellar atrophy, congenital myelopathy, and peripheral nerve sheath tumor (PNST) in the tongue. MRI has also been used to diagnose PEM and cerebellar hypoplasia in calves and PEM, leukoencephalomalacia, and porencephaly and demyelination in sheep and goats. More studies are required documenting the clinical superiority of MRI versus other diagnostic modalities. For instance, MRI can differentiate horses with cervical stenotic myelopathy (CSM) and cervical vertebral stenosis from healthy horses and horses with other causes for ataxia; however, MRI cannot accurately localize the site of cord compression. MRI will be more widely used in the diagnosis of nervous diseases, particularly intracranial and cervical spinal cord disease, as equipment and acquisition costs decrease.

**Ultrasonography**

Ultrasonography of the cricoarytenoideus lateralis muscle has been used as part of the examination of horses with suspected laryngeal hemiplegia and compared with endoscopic findings obtained at rest and during exercise. An 8.4-MHz curvilinear transducer was applied over the larynx and four acoustic windows evaluated. Subjectively assessed increased echogenicity of this muscle had a sensitivity of 94.6% and a specificity of 94.5% for detecting laryngeal hemiplegia. The reported advantages of ultrasonography are that it is widely available, noninvasive, and depicts a real-time view of the tissues.

The supraspinous ligament has been evaluated in horses with and without back pathology using ultrasonography. Linear and sector array transducers (5–10 MHz) were used to obtain longitudinal and cross-sectional views of the supraspinous ligament, and lesions were identified and categorized. All 39 horses studied had at least one site of supraspinous ligament desmitis, and there was no association between desmitis lesions and clinical signs of pain that could be localized to this region.

Ultrasonography has been used to diagnose syringohydromyelia and segmental hypoplasia of the lumbar spinal cord in a 4-day-old Holstein Friesian calf that had been unable to stand since birth. The calf was placed in right lateral recumbency, and lumbosacral flexion was induced to enable widening of ultrasound windows. Diagnostic images of the lumbar spinal cord were obtained in sagittal and transverse orientations at the lumbosacral junction (L6-S1), as well as the proximal lumbar intervertebral junctions up to L2-L3, using a 6- to 10-MHz linear transducer.

An ultrasound imaging technique of the tympanic bullae has been developed for the diagnosis of otitis media in calves. A 7.5-MHz linear probe is applied to the base of the ear without the use of coupling gel and with the calf in a standing position. The probe is applied ventral to the base of the ear and caudal to the mandible. Abnormalities detected included anechoic to hyperechoic content; trabecular lysis; and thinning, deformation, and rupture of the bulla wall. In calves, ultrasonography has also been used to identify the femoral nerve in calves to assist in the diagnosis of spastic paresis cases that involve the quadriiceps muscle (such as in Belgian Blue cattle with a cranially directed hyperextension of the limb) instead of the more common form of spastic paresis that involves the gastrocnemius muscle and a caudally directed hyperextension of the hindlimb. Placement of a 5-MHz curved linear array transducer over the dorsal paravertebral space between the fifth and sixth lumbar transverse processes provided the best view of the femoral nerve and permitted selective blocking of the femoral nerve using 4% procaine solution.
**ENDOSCOPY (RHINOLARYNGOSCOPY)**

Endoscopy (rhinolaryngoscopy) is now a routine technique for the examination of horses with suspected laryngeal hemiplegia, which is a distal axonopathy of the left recurrent laryngeal nerve.

Endoscopic examination of the epideral and subarachnoid space from the atlantooccipital space to the eighth cervical nerve has been performed safely in healthy adult horses. The procedure was performed under general anesthesia. The technique may have clinical utility in the diagnosis of cervical vertebral stenotic myelopathy because physical constraints do not currently permit imaging of the caudal cervical vertebral column by MRI or CT.

Endoscopy has also been used to examine the anatomic structures in the sacrococcygeal area of adult cattle. Cows were restrained and sedated with xylazine (0.03 mg/kg, intravenously). A lidocaine epidural was administered and a flexible endoscope (outside diameter, 2.3 mm) introduced through an introducer set and a small amount of air introduced. The procedure permitted visualization of blood vessels, connective tissue, fat, nerves, and the spinal dura mater.

**OPHTHALMOSCOPY**

Ophthalmoscopy for the examination of the structures of the eye is important in the diagnosis of diseases affecting the optic nerve such as vitamin A deficiency and the optic disc edema (papilledema) associated with diffuse cerebral edema.

**ELECTROMYOGRAPHY**

Electromyographic needle examination is a technique that records the electrical activity generated by single muscle fibers and the summated electrical activity of muscle fibers in individual motor units. The technique involves inserting a recording needle into the muscle of interest and recording the resultant EMG. Typically, animals are unsedated and restrained in stocks or a chute. An abnormal EMG signals include short-duration and low-amplitude motor unit action potentials, which indicate diseased muscle fibers of early or incomplete reinervation after denervation. Other abnormalities include the presence of fibrillation potentials, positive sharp waves, and complex repetitive discharges that occur when the skeletal cell membrane becomes unstable because of denervation or myopathy.

EMG provides a more practical diagnostic test than electroencephalography (EEG) and provides a sensitive indicator of neurologic dysfunction and assists in the neuroanatomic localization of the lesion. It is especially useful for evaluating peripheral nerve injury and diagnosing hyperkalemic periodic paresis in horses and should be helpful in additional studies on calving-associated paralysis and other peripheral nerve injuries in cattle. EMG can discriminate between lower motor neuron and myogenic disorders, and nerve conduction studies can differentiate axonal loss from demyelination. In addition, repetitive stimulation can provide information regarding neuromuscular transmission. Reference values for motor nerve conduction velocity have been developed for calves and, as expected, conduction velocities are related to the nerve fiber diameter.

**Somatosensory evoked potentials** of the trigeminal complex using the infraorbital nerve have been used in horses to assist in the diagnosis of idiopathic head-shaking. An electrical surface stimulus is applied at a set stimulus rate but variable stimulus currents to a focal area of the buccal mucosa. Recording electrodes placed along the sensory pathway of the trigeminal complex detect the presence or absence of sensory nerve action potentials (SNAPs) and nerve conduction velocity. The threshold current required to trigger a SNAP provides clinically useful information about the sensitivity of the anatomic location to stimuli.

EMG has been coupled with transcranial magnetic stimulation to induce magnetic motor evoked potentials in the horse. This provides a useful noninvasive evaluation of cervical spinal cord dysfunction in horses with radiologic abnormalities of the cervical vertebrae by detecting the presence of a neuropathy involving the descending motor tracts. However, EMG does not provide information on upper motor neurons; therefore it is not useful in the clinical evaluation of horses suspected to have hindlimb neurologic deficits caused by cervical spinal cord disease.

**ELECTROENCEPHALOGRAPHY**

EEG has not been used to any significant degree in large animals. It requires sophisticated equipment, a quiet dim environment free from electrical interference, and a quiet patient that has minimal muscular activity. Because of the difficulty in obtaining quality recordings in a conscious large animal, it is preferred that the animal is sedated or anesthetized for the recording, which confounds interpretation of the EEG pattern depending on the anesthetic protocol. Thorough and repeated observations of simultaneously recorded EEG and video may facilitate interpretation of the EEG, but the clinical utility of EEG remains uncertain in large animals exhibiting nervous signs consistent with an intracranial lesion. Therefore EEG has been primarily used in large animals as an antemortem or research tool, and its use will probably remain as a complementary test to other neurologic examinations and diagnostic tests at referral institutions.

Recommendations have been made to standardize EEG techniques for animals; these typically involve meticulous preparation of the recording sites on the scalp, and placement of electrodes over the left and right frontal areas, the left and right occipital areas, and the vertex area, and a reference electrode is placed behind the tip of the nose. The addition of other recording sites increases the ability to localize a focal lesion. Neurologic disease is associated with changes in EEG frequency or amplitude, or both, and frequency changes are a more reliable indicator of disease. In general, focal EEG abnormalities indicate a focal lesion in the cortex, whereas diffuse EEG abnormalities indicate diffuse cortical or subcortical lesions or focal subcortical lesions.

EEG has been used to study epilepsy in goats and cattle, congenital hydranencephaly and hydrocephalus in cattle, scrapie in sheep, thiamine-responsive PEM in cattle, and BSE in cattle. When performed under controlled conditions, EEG has been shown to be a useful diagnostic tool for the early diagnosis of equine intracranial diseases, with adequate sensitivity and specificity.

**ELECTRORETINOGRAPHY**

Flash electroretinography (ERG) is a recording of rod and cone function of the eyes. The animal is sedated (usually with xylazine) and topical 0.5% proparacaine is applied to both eyes to permit the placement of a contact lens electrode on both eyes. Subcutaneous electrodes are then placed at the lateral canthus and midline at the nostrils to provide reference and ground electrodes, respectively. A period of dark adaptation is then implemented, and a standardized flash sequence applied. Decreased B-wave amplitudes during flash ERG have been identified in horses with equine motor neuron disease and attributed to lipofuscin deposits on the retina.

**BRAINSTEM AUDITORY EVOKED POTENTIALS**

The brainstem auditory evoked potential (BAEP) is a recording of the electrical activity of the brainstem following an acoustic stimulation; as such, BAEP can be used to evaluate the integrity of the auditory pathway. The use of the BAEP permits differentiation of cochlear pathology (including otitis media/interna) from retrocochlear pathology (auditory nerve or brainstem).

BAEP is obtained on a sedated patient (xylazine is frequently used) by recording neuroelectrical activity from generators in the auditory pathway immediately following an acoustic click stimulus, and BAEP waveforms for horses and ponies, foals, and calves have been recorded. Such recordings can be useful in evaluating horses suspected...
to have deafness, vestibular disease, brain-stem disease, or temporohyoid osteoarthropy-
athy, as well as calves with otitis media and facial paralysis, and to monitor the response
to treatment.

INTRACRANIAL PRESSURE MEASUREMENT

Intracranial pressure has been measured in neonatal foals, although the clinical utility of
such measurements in foals has not been demonstrated. Increases in intracranial pressure can cause decreases in cerebral perfusion pressure and irreversible injury to the CNS.

The head-down position in the horse increases the hydrostatic pressure gradient between the heart and brain, increasing mean intracranial pressure in isoflurane-anesthetized horses from 31 to 55 mm Hg when placed in the Trendelenburg position to facilitate abdominal surgery. Similar directional changes in intraocular pressure were measured in adult horses sedated with detomidine. Hydrostatic pressure effects on intracranial pressure have also been observed in isoflurane-anesthetized adult cattle. In other words, large animals suspected to have increased intracranial pressure should be encouraged to keep their heads elevated to prevent cerebral edema formation. In addition, head position must be standardized when intracranial pressure is measured.

KINETIC GAIT ANALYSIS

Lameness is common in large animals and usually results in asymmetric gait abnormal-
ities; lameness caused by selected musculoskele-
tal abnormalities is discussed in Chapter 15. Ataxia caused by spinal cord disease also causes gait abnormalities that are usually symmetric and particularly evident in the hindlimbs. Diagnostic differentiation of lameness and neurologic causes of gait abnormalities can be challenging, even to experienced practitioners. Consequently, kinetic gait analysis offers an objective quan-
titative test that may assist in the differen-
tiation of neurologic from musculoskeletal causes for a gait abnormality. Two indices appear to have the greatest clinical utility in identifying the presence of a neurologic gait abnormality: higher lateral force peak and increased variation in vertical force peak in both hindlimbs.

REPRESENTATION

Diffuse or Multifocal Diseases of the Brain and Spinal Cord

There are many different causes of diffuse or multifocal nervous system disease in large domestic animals.

- Infectious causes include bacteria, viruses, fungi, and helminth, arthropod, and protozoan parasites.
- Exogenous substances such as lead, salt, selenium, organophosphate insecticides, feed additives such as urea, poisonous plants, and many other chemicals are common causes.
- Endogenous substances such as products of disease in other body systems or of abnormal metabolism such as bacterial toxins, ammonia, and carbon dioxide can cause abnormalities of the nervous system.
- Metabolic and nutritional causes include ischemia secondary to cardiopulmonary disease; hypoglycemia; hypomagnesemia; copper deficiency in pregnant animals; and hyper β-lactatemia in calves, lambs, and kids with neonatal diarrhea and adult ruminants with grain overload.
- Chronic acidemia associated with diarrhea can cause mental depression and ataxia (whereas experimentally induced acute acidemia does not cause mental depression in neonatal calves).
- Idiopathic diseases account for several diseases of the spinal cord of horses.
- Malformation occurs primarily in the developing fetus and results in congenital nervous system disease, which is usually present at birth. Many different teratogens can cause congenital defects. In some cases of inherited disease, the clinical signs do not manifest until sometime after birth.

Responses of Central Nervous System to Injury

The CNS may respond to injury by morpho-
logic changes that include cerebral edema and brain swelling, inflammation, and demy-
elination. Malformations occur when the CNS is affected during fetal life.

The remainder of this chapter will present the general clinical aspects of the diseases of the nervous system according to anatomic sites and causative agent. The salient features of the etiology, pathogenesis, clinical find-
ings, diagnosis, and treatment of these clin-
onomatoanatomical diseases are described. Cerebral hypoxia, hydrocephalus, cerebral edema, meningitis, encephalitis, myelitis, encephalomalacia, and myelolamacia are common to many diffuse or multifocal diseases of the nervous system and are described here.

CEREBRAL HYPOXIA

Cerebral hypoxia occurs when the supply of oxygen to the brain is reduced for any reason. An acute or chronic syndrome develops depending on the acuteness of the depriva-
tion. Initially there are irritation signs followed terminally by signs of loss of function.

ETIOLOGY

All forms of hypoxia, including anemic, anoxic, histotoxic, and stagnant forms cause some degree of cerebral hypoxia, but signs referable to cerebral dysfunction occur only when the hypoxia is severe. Hypoxia of the brain may be secondary to a general systemic hypoxia or be caused by lesions restricted to the cranial cavity.

Cerebral Hypoxia Secondary to General Hypoxia

- Poisoning by hydrocyanic acid or nitrite
- Acute heart failure in severe copper deficiency in cattle
- Anesthetic accidents
- Terminalia in pneumonia, congestive heart failure
- During or at birth in foals, hypoxic-ischemic encephalopathy in foals (also known as neonatal encephalopathy, perinatal asphyxia, dumpy foal syndrome, or neonatal maladjustment syndrome), or intrapartum hypoxia in calves and lambs caused by prolonged parturition

Cerebral Hypoxia Secondary to Intracranial Lesion

- In increased intracranial pressure
- In brain edema
PATHOGENESIS
The CNS is extremely sensitive to hypoxia, and degeneration occurs if the deprivation is extreme and prolonged for more than a few minutes. The effects of the hypoxia vary with the speed of onset and with the severity. When the onset is sudden, there is usually a transitory period during which excitation phenomena occur, and this is followed by a period of loss of function. If recovery occurs, a second period of excitation usually develops as function returns. In more chronic cases the excitation phase is not observed, and the signs are mainly those of loss of function. These signs include dullness and lethargy when deprivation is moderate and unconsciousness when it is severe. All forms of nervous activity are depressed, but the higher centers are more susceptible than medullary centers and the pattern of development of signs may suggest this.

CLINICAL FINDINGS
Acute and chronic syndromes occur depending on the severity of the hypoxia. Acute cerebral hypoxia is manifested by a sudden onset of signs referable to paralysis of all brain functions, including tetraparesis and unconsciousness. Muscle tremor, beginning about the head and spreading to the trunk and limbs, followed by recumbency, clonic convulsions, and death or recovery after further clonic convulsions is the most common pattern, although affected animals may fall to the ground without premonitory signs. In chronic hypoxia, there is lethargy, dullness, ataxia, weakness, and blindness and in some cases muscle tremor or convulsions. In both acute and chronic hypoxia, the signs of the primary disease will also be evident. Cerebral hypoxia of fetal calves is thought to be a cause of weakness and failure to suck after birth, leading to the eventual death of the calf from starvation. Such hypoxia can occur during the birth process, especially if it is difficult or delayed, or during late pregnancy.

CLINICAL PATHOLOGY AND NECROPSY FINDINGS
There is no distinctive clinical pathology or characteristic necropsy lesion other than those of the primary disease.

DIFFERENTIAL DIAGNOSIS
Clinically there is little to differentiate cerebral hypoxia from hypoglycemia or polioencephalomalacia in which similar signs occur. Irritation and paralytic signs follow one another in many poisonings including lead and arsenic and in most diffuse diseases of the brain including encephalitis and encephalomalacia. The differential diagnosis of cerebral hypoxia depends on the detection of the cause of the hypoxia.

TREATMENT
An increase in oxygen delivery is essential and can usually only be provided by removing the causative agent. A respiratory stimulant (the most effective is doxapram, 2 mg/kg BW, intravenously) may be advantageous in acute cases, and artificial respiration may be necessary and effective.

INCREASED INTRACRANIAL PRESSURE, CEREBRAL EDEMA, AND BRAIN SWELLING
Diffuse cerebral edema and brain swelling usually occur acutely and cause a general increase in intracranial pressure. Cerebral edema is rarely a primary disease, but is commonly an accompaniment of other diseases. Cerebral edema is often a transient phenomenon and may be fatal, but complete recovery or recovery with residual nervous signs also occurs. It is manifested clinically by blindness, opisthotonus, muscle tremor, paralysis, and clonic convulsions.

ETIOLOGY
Diffuse cerebral edema and brain swelling may be vasogenic, when there is increased permeability of capillary endothelium, and cytotoxic when all the elements of brain tissue, glia, neurons, and endothelial cells undergo swelling. Causes include the following.

Vasogenic Edema
- Brain abscess, neoplasm, hemorrhage, lead encephalopathy, purulent meningitis
- Minor edema after most traumatic injuries, in many encephalitides and many poisonings, including propylene glycol in the horse; probably contributes to the pathogenesis
- Accidental intracarotid injection of promazine in horses
- Leukoencephalomalacia in horses caused by fumonisin consumption
- Septicemia in neonatal foals

Cytotoxic Edema
- Hypoxia
- PEM of ruminants (thiamine deficiency or sulfur toxicity)
- Salt poisoning of swine

Interstitial Edema
- Hydrocephalus

PATHOGENESIS
Cerebral Edema and Brain Swelling
This disease is potentially life-threatening because of the limited ability for accommodation of increased volume within the confines of the dura and the cranium. CNS parenchyma does not possess a lymphatic system, and the interstitial space between cells, especially in the gray matter, is much narrower than in other tissues. When CNS edema develops, of necessity it largely accumulates within cells, although interstitial fluid will form if cells lyse or if the edema is severe.

Cerebral edema usually occurs to some degree in all pathologic states, whether degenerative or inflammatory or traumatic or neoplastic. Edema around chronic, focal lesions such as abscesses, parasitic cysts, and primary or metastatic tumors in white matter often produce marked swelling. Cerebral hemispheric swelling compresses the underlying brainstem, flattening the rostral colliculi and distorting the aqueduct. As the swollen brain expands and fills the confines of the calvaria, some regions are prone to herniation. If this occurs, the accompanying blood vessels are likely to become occluded, which may result in hemorrhage or infarction. Commonly with brain swelling the caudal lobe of the cerebellar vermis protrudes as a flattened lip over the medulla oblongata toward the foramen magnum.

In vasogenic edema the primary insult is to the wall of cerebral capillaries, allowing the escape of plasma fluid and proteins under the hydrostatic pressure of the circulation. The inciting vascular injury may be brain or spinal cord trauma, vasculitis, a neoplasm, or a cerebrovascular accident. Vasogenic edema affects predominantly the white matter, in which fluid accumulates within the cytoplasm of astrocytes and spreads in the interstitial spaces. Vasogenic edema moves over very long distances and from one hemisphere to the other via the corpus callosum. A chronic epidural abscess involving the frontal lobe can produce sufficient brain swelling from vasogenic edema to induce herniation of the occipital cortex beneath the tentorium cerebelli.

Cytotoxic edema results from an injury to a glial cell that disturbs osmoregulation of that cell by depletion of energy stores and failure of energy-dependent ionic pumps. This leads to cell swelling with fluid and differs from edema in other tissues in which fluid accumulation is interstitial. Cytotoxic edema reflects a specific cellular insult and may result from ischemia or hypoxia, nutritional deficiency, an intoxication, or an inherited metabolic abnormality. Brain swelling from cytotoxic edema is less dramatic than that seen in vasogenic edema. It may affect just the gray matter, just the white matter, or both.

The ECF volume in vasogenic edema is increased by the edema fluid, which is a plasma filtrate containing plasma protein. In cytotoxic edema it is the cellular elements themselves that increase in size. In hypoxia this is because of failure of the adenosine triphosphate (ATP)-dependent sodium pump within the cells. As a result sodium accumulates within the cells and water follows to maintain osmotic equilibrium. In PEM and salt poisoning, the edema of the
brain is primary. In salt poisoning in pigs there is an increase in concentration of cations in brain tissue with a sudden passage of water into the brain to maintain osmotic equilibrium. The cause of the edema in PEM of ruminants, associated with a thiamine inadequacy, is unknown. When promazine is injected accidentally into the carotid artery of the horse, it produces a vasogenic edema and infarction generally, but especially in the thalamus and corpora quadrigemina on the injected side. The vasogenic edema surrounding an abscess is localized and is not evident in the white matter.

Cerebral edema and cerebellar herniation have been described in neonatal foals admitted to an intensive care unit for treatment. All foals had septicemia. It was suggested that hypoglycemia, hypoxia, or the alterations in cerebral blood flow associated with septicemia might have initiated injury to cell membranes, resulting in vascular damage and subsequent edema. It is hypothesized that cerebellar herniation occurs in neonatal foals with sepsis because of the inelastic nature of the dural folds and the anatomic rigidity of the neonatal equine skull. This is in contrast to the human infant, in whom cerebral edema occurs in bacterial meningitis but cerebral or cerebellar herniation is not normally a feature. The relatively small brain of the newborn foal is only 1% of total body mass compared with the human infant, which is 12% and in which the brain is enclosed within a large but relatively thin calvarium with sutures that, in the preterm infant at least, can be separated by excess internal pressure.

An increase in intracranial pressure occurs suddenly and, as in hydrocephalus, there is a resulting ischemic anoxia of the brain caused by compression of blood vessels and impairment of blood supply. This may not be the only factor that interferes with cerebral activity in PEM and salt poisoning. The clinical syndrome produced by the rapid rise in intracranial pressure is manifested by involuntary movements such as tremor and convulsions followed by signs of weakness. If the compression of the brain is severe enough and of sufficient duration, ischemic necrosis of the superficial layers of the cortical gray matter may occur, resulting in permanent nervous defects in those animals that recover. Opisthotonus and nystagmus are commonly observed and are probably caused by the partial herniation of the cerebellum into the foramen magnum.

**CLINICAL FINDINGS**

Although the rise of intracranial pressure in diffuse edema of the brain is usually more acute than in hydrocephalus, the development of clinical signs takes place over a period of 12 to 24 hours and nervous shock does not occur. There is central blindness, and periodic attacks of abnormality occur in which opisthotonus, nystagmus, muscle tremor, and convulsions are prominent.

In the intervening periods, the animal is dull, depressed, and blind, and optic disc edema may be present. The involuntary signs of tremor, convulsions, and opisthotonus are usually not extreme, but this varies with the rapidity of onset of the edema. Because of the involvement of the brain stem, in severe cases muscle weakness appears, the animal becomes ataxic, goes down and is unable to rise, and the early signs persist. Clonic convulsions occur terminally, and animals that survive may have residual defects of mentality and vision.

**CLINICAL PATHOLOGY**

Clinicopathologic observations will depend on the specific disease causing the edema.

**NECROPSY FINDINGS**

Microscopically the gyri are flattened and the cerebellum is partially herniated into the foramen magnum with consequent distortion of its caudal aspect. The brain has a soft, swollen appearance and tends to sag over the edges of the cranium when the top has been removed. Caudal portions of the occipital lobes herniate ventral to the tentorium cerebelli.

**DIFFERENTIAL DIAGNOSIS**

Diffuse brain edema causes a syndrome not unlike that of encephalitis, although there are fewer irritation phenomena. Differentiation from encephalomalacia and vitamin A deficiency may be difficult if the history does not give a clue to the cause of the disease. Metabolic diseases, particularly pregnancy toxemia, hypomagnesemic tetany of calves, and lactation tetany, resemble it closely, as do some cases of acute ruminal impaction. In the history of each of these diseases, there are distinguishing features that aid in making a tentative diagnosis. Some of the poisonings, particularly lead, organic mercurial and arsenicals, and enterotoxemia associated with Clostridium perfringens type D produce similar nervous signs, and gut edema of swine may be mistaken for diffuse cerebral edema.

**TREATMENT**

Decompression of the brain is desirable in acute edema. The treatment will depend in part on the cause; the edema associated with PEM will respond to early treatment with thiamine. In general terms, edema of the brain responds to parenteral treatment with hypertonic solutions (mannitol and hypertonic sodium chloride are most often used) and corticosteroids (specifically dexamethasone). Hypertonic solutions are most applicable to cytotoxic edema and corticosteroids to vasogenic edema. This is in addition to treatment for the primary cause of the disease.

Hypertonic solutions open the blood-brain barrier by shrinking endothelial cells and widening the tight junctions. The magnitude of the opening is dependent on the type of hypertonic solution (mannitol and hypertonic saline are used most frequently with mannitol as the first choice treatment) and the achieved plasma concentration. The magnitude of the opening is also dependent on age, with neonates having a “leakier” blood-brain barrier than adults. This supports clinical observations that mannitol treatment appears to be more successful in treating neonates suspected to have cerebral edema than adults. The preferred treatment is mannitol given as a 20% solution in a series of bolus intravenous infusions of 0.25 to 1 g/kg BW every 4 to 6 hours. The suggested dose rate has been derived from those recommended for humans and dogs but is very expensive. There are dangers with mannitol: it should not be repeated often, it must not be given to an animal in shock, and it should be given intravenously slowly. A recent meta-analysis suggested that hypertonic saline (1.5–23.5% NaCl at 10–30 mL/kg BW total dose) may be as effective as 20% mannitol in the treatment of cerebral edema, with 7.5% NaCl as the most commonly used osmality.

Dexamethasone administration (1 mg/kg BW intravenously every 24 hours) is no longer recommended for the treatment of cerebral edema in human infants,1 and its efficacy in large animals with cerebral edema is uncertain. Dexamethasone is thought to decrease cerebral edema and CSF production and inhibit tumor-induced angiogenesis in patients with intracranial tumors. Hypertonic glucose given intravenously is not recommended because an initial temporary decompression is followed after a 4- to 6-hour interval by a return to pretreatment CSF pressure when the glucose is metabolized.

Diuretics usually produce tissue dehydration too slowly to be of much value in acute cases, but they may be of value as an adjunct to hypertonic solutions or in early or chronic cases. The removal of CSF from the cisterna magna in an attempt to provide relief may cause complications. In some cases the removal of 25 to 75 mL of CSF provides some temporary relief, but the condition becomes worse later because portions of the swollen brain herniate into the foramen magnum. There is no published information available on how much CSF can be safely removed; therefore recommendations cannot be made.

**REFERENCES**

HYDROCEPHALUS

Obstructive hydrocephalus may be congenital or acquired and is manifested in both cases by a syndrome referable to a general increase in intracranial pressure. Irritation signs of mania, head-pressing, muscle tremor, and convulsions occur when the onset is rapid, and signs of paralysis including dullness, blindness, and muscular weakness are present when the increased pressure develops slowly.

ETIOLOGY

Obstructive hydrocephalus may be congenital or acquired, but in both instances it is caused by defective drainage or absorption of CSF. In the congenital disease, there is an embryologic defect in the drainage canals and foramina between the individual ventricles or between the ventricles and the subarachnoid space, or in the absorptive mechanism, the arachnoid villi.

Congenital Hydrocephalus

Causes include the following:
- Alone, with lateral narrowing of the mesencephalon
- Inherited defects of Hereford, Holstein, Ayrshire, and Jersey cattle
- Inherited combined defects with chondrodysplasia, or in white Shorthorn cattle combined with hydrocephalus, microphthalmia, and retinal dysplasia
- Virus infections of the fetus suggest themselves as possible causes of embryologic defects in the drainage system, but there are no verified examples of this; the cavitation of brain tissue and subsequent accumulation of fluid, hydranencephaly, which occurs after infection with bluetongue virus in lambs, and Akabane virus in calves, is compensatory, not obstructive
- Vitamin A deficiency may contribute
- Other occurrences, sometimes at high levels of prevalence, but without known cause

Acquired Hydrocephalus

Causes include the following:
- Hypovitaminosis A in young growing calves causing impaired absorption of fluid by the arachnoid villi
- Cholesteatoma in choroid plexuses of the lateral ventricles in the horse; these may produce an acute, transient hydrocephalus on a number of occasions before the tumor reaches sufficient size to cause permanent obstruction
- Other tumor or chronic inflammatory lesion obstructing drainage from the lateral ventricles

PATHOGENESIS

Increased intracranial pressure in the fetus and before the syndesmoses of the skull have fused causes hydrocephalus with enlargement of the cranium. After fusion of the suture lines the skull acts as a rigid container, and an increase in the volume of its contents increases intracranial pressure. Although the increase in volume of the contents may be caused by the development of a local lesion such as an abscess, tumor, hematoma or cestode cyst, which interferes with drainage of the CSF, the more common lesion is a congenital defect of CSF drainage.

Clinical and pathologic hydrocephalus has been produced experimentally in animals by creating granulomatous meningitis. The clinical signs included depression, stiffness of gait, recumbency, and opisthotonus with paddling convulsions. The general effects in all cases are the same, the only difference is that local lesions may produce localizing signs as well as signs of increased intracranial pressure. These latter signs are caused by compression atrophy of nervous tissue and ischemic anoxia caused by compression of blood vessels and impairment of blood supply to the brain.

In congenital hydrocephalus the signs observed are usually those of paralysis of function, whereas acquired hydrocephalus, being more acute, is usually manifested first by irritation phenomena followed by signs of paralysis. Edema of the optic papilla is a sign of increased intracranial pressure and may be detected using an ophthalmoscope. Bradycardia occurs inconstantly and cannot be considered to be diagnostic.

CLINICAL FINDINGS

In acquired hydrocephalus there is, in most cases, a gradual onset of general paresis. Initially there is depression, disinclination to move, central blindness, an expressionless stare, and a lack of precision in acquired movements. A stage of somnolence follows and is most marked in horses. The animal stands with half-closed eyes, lowered head, and a vacant expression and often leans against or supports itself on some solid object. Chewing is slow, intermittent, and incomplete, and animals are often observed standing with food hanging from their mouths. The reaction to cutaneous stimulation is reduced, and abnormal postures are frequently adopted. Frequent stumbling, faulty placement of the feet, and incoordination are evidenced when the animal moves, and circling may occur in some cases. Bradycardia and cardiac arrhythmia have been observed.

Although the emphasis is on depression and paresis, signs of brain irritation may occur, particularly in the early stages. These signs often occur in isolated episodes during which a wild expression, charging, head-pressing, circling, tremor, and convulsions appear. These episodes may be separated by quite long intervals, sometimes of several weeks’ duration. In vitamin A deficiency in calves, blindness and papilledema are the early signs and an acute convulsive stage occurs terminally.

Congenitally affected animals are usually alive at birth but are unable to stand and most die within 48 hours. The cranium is sometimes domed, the eyes protrude, and nystagmus is often evident (Fig. 14-2). Meningocele is an infrequent accompaniment.

CLINICAL PATHOLOGY

Examination of the composition and pressure of the CSF will be of value. The fluid is usually normal biochemically and cytologically but the pressure is increased. A marked increase in serum muscle enzyme activity has been observed in calves with congenital hydrocephalus, caused probably to an accompanying muscular dystrophy. Convulsions, if they occur, may contribute to this increase.

NECROPSY FINDINGS

On necropsy the cranium may be enlarged and soft in congenital hydrocephalus. The ventricles are distended with CSF under pressure and the overlying cerebral tissue is thinned if the pressure has been present for some time.
MENINGITIS

Inflammation of the meninges occurs most commonly as a complication of a preexisting disease. Meningitis is usually associated with a bacterial infection and is manifested clinically by fever, cutaneous hyperesthesia, and rigidity of muscles. Although meningitis may affect the spinal cord or brain specifically, it commonly affects both and is dealt with here as a single entity. Meningoencephalitis is common in neonatal farm animals. Primary bacterial meningitis is extremely rare in adult farm animals, with the exception of listeriosis and *H. somni* (formerly *Haemophilus somnus*) infection, although the latter is more a vasculitis than a primary meningitis. The possibility of immunodeficiency should be considered in adult horses with bacterial meningitis. Compared with adults, bacterial meningitis is more common in neonates because their immune system is immature, the blood-brain barrier is incomplete, and umbilical infections are common, providing a nidus of infection.

ETIOLOGY

Most significant meningitides are bacterial, although most viral encephalitides have some meningitic component.

Cattle
- Viral diseases including bovine malignant catarrh, sporadic bovine encephalomyelitis
- Bacterial diseases including listeriosis, *H. somni*, chronic lesions elsewhere in the body possibly associated with meningitis in adult animals; rarely tuberculosis
- Facial paralysis syndrome of calves in the Franklin district of New Zealand

Sheep
- Melioidosis, *S. aureus* (tick pyemia) in newborn lambs
- *Pasteurella multocida* in lambs
- *Mannheimia (Pasteurella) haemolytica* in lambs

Horses

Pigs
- Glasser’s disease, erysipelas, salmonellosis; *S. suis* type 2 in weaned and feeder pigs
- Coliform and streptococcal septicemias are probably the most common causes of meningitis in neonatal farm animals. The infection may originate from omphalophlebitis, bacteremia, or bacterial translocation across the gastrointestinal tract in neonates less than 24 hours of age or with enteritis. Septicemia occurs in all species, especially calves, and may be accompanied by polyarthritis, endocarditis, and hypopyon. The causative bacteria are usually a mixed flora.
- Hematogenous infection occurs from other sites also. In neonatal animals, some of the common infections include the following:
  - *Calf*: *Escherichia coli*; the disease is most common in calves under several days of age and can occur in less than 24 hours after birth; failure of transfer of immunoglobulins is a common contributing factor
  - *Piglet*: *S. zooepidemicus*, *S. suis* type 1
  - *Lamb*: *S. zooepidemicus*

PATHOGENESIS
