The most common presentation of acute bacterial sinusitis is persistent rhinorrhea, nasal congestion, and cough, especially at night. Symptoms should be persistent and not improving for more than 10 days to distinguish sinusitis from a URI. Less common symptoms include halitosis, headache, and facial swelling and tenderness. Alternate presentations of acute bacterial sinusitis include high fever and purulent nasal discharge for at least 3 days or a biphasic illness where a patient has typical URI symptoms for up to a week but then worsens with increasing respiratory symptoms and new or recurrent fever.

Chronic sinusitis includes upper respiratory symptoms for more than 30 days, often accompanied by sore throat and/or headache. Fever is rare.

LABORATORY AND IMAGING STUDIES

Culture of the nasal mucosa is not useful. Sinus aspirate culture is the most accurate method of determining etiology but is not practical or necessary in immunocompetent patients.

Routine imaging is not recommended in uncomplicated infections. Plain x-ray, computed tomography (CT), and magnetic resonance imaging (MRI) may reveal sinus clouding, mucosal thickening, or air-fluid levels in the sinuses. However, abnormal radiographic findings do not differentiate infection from allergic disease and often show abnormalities in the sinuses of children with a simple viral URI. Conversely, normal imaging can have a high negative predictive value for bacterial sinusitis. Bony erosion may be seen on imaging studies in immunocompromised hosts.

TREATMENT

Amoxicillin for 10–14 days can be used as first-line therapy of uncomplicated sinusitis in children. Broadening therapy to amoxicillin-clavulanate is appropriate if there is no clinical response to amoxicillin within 2–3 days, if risk factors for resistant organisms are present (antibiotic treatment in the preceding 1–3 months, daycare attendance), if there is chronic sinusitis, or if any amount of eye swelling is present.

COMPLICATIONS AND PROGNOSIS

Complications of bacterial sinusitis include orbital cellulitis, epidural or subdural empyema, brain abscess, dural sinus thrombosis, osteomyelitis of the frontal sinus (**Pott puffy tumor**), and meningitis. These all should be managed with sinus drainage and broad-spectrum parenteral antibiotics. Sinusitis also may exacerbate bronchoconstriction in patients with asthma.

Orbital (postseptal) cellulitis is a serious complication of sinusitis that follows bacterial spread into the orbit through the wall of the infected sinus. It typically begins as ethmoid sinusitis and spreads through the **lamina papyracea**, a thin, bony plate that separates the medial orbit and the ethmoid sinus. Orbital involvement can lead to subperiosteal abscess, cavernous sinus thrombosis, and vision loss. Clinical manifestations of orbital cellulitis include a swollen edematous eye, eye pain, proptosis, chemosis, and limitations and pain with extraocular muscle motion, diplopia, and reduced visual acuity. Infection of the orbit must be differentiated from that of the preseptal (anterior to the palpebral fascia) or periorbital space. **Preseptal (periorbital) cellulitis** is common in young children; these patients do not have proptosis or ophthalmoplegia. Preseptal cellulitis may be associated with a skin lesion or trauma and usually is caused by *S. aureus* or group A streptococcus.

The diagnosis of orbital cellulitis is confirmed by a CT scan of the orbit, which helps determine the extent of orbital infection and the need for surgical drainage. Therapy for orbital cellulitis involves broad-spectrum parenteral antibiotics, such as vancomycin or clindamycin with ceftriaxone. Preseptal cellulitis may be treated with oral antibiotics in children with mild disease.

PREVENTION

The best means of prevention is good handwashing to minimize acquisition of URIs and management of allergic rhinitis.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 105

Otitis Media

ETIOLOGY

Otitis media (OM) is a suppurative infection of the middle ear cavity. Bacteria gain access to the middle ear when the normal patency of the eustachian tube is blocked by upper airway infection or hypertrophied adenoids. Air trapped in the middle ear is resorbed, creating negative pressure in this cavity and facilitating reflux of nasopharyngeal bacteria.

Bacteria are the most common pathogens in OM, most frequently as a co-infection with viruses. Viruses can be the sole pathogen in OM, but this is less common (<20%). The common bacterial pathogens are *Streptococcus pneumoniae*, nontypable *Haemophilus influenzae*, *Moraxella catarrhalis*, and,

less frequently, group A streptococcus. *S. pneumoniae* that is **relatively resistant** to penicillin (minimal inhibitory concentration 2–8 µg/mL) or **highly resistant** to penicillin (minimal inhibitory concentration ≥ 8 µg/mL) is isolated with increasing frequency from young children, particularly those who attend day care or have recently received antibiotics.

EPIDEMIOLOGY

Diseases of the middle ear account for approximately one third of office visits to pediatricians. The peak incidence of acute otitis media (AOM) is between 6 and 15 months of life. By the third birthday, 80% of children will have experienced at least one episode of symptomatic or asymptomatic OM. OM is more common in younger children, children exposed to young children, and those with a positive family history. In most of the United States, OM is a seasonal disease with a distinct peak in late winter/early spring, which corresponds to the rhinovirus, respiratory syncytial virus, and influenza seasons.

Approximately 10% of children in the general population have **recurrent OM**, as defined by the presence of three or more AOM episodes in the preceding 6 months or four or more episodes in the preceding 12 months. Craniofacial anomalies (cleft palate) and immunodeficiencies often are associated with recurrent OM, although most children with recurrent AOM are otherwise healthy.

CLINICAL MANIFESTATIONS

In infants, the most frequent symptoms of AOM are nonspecific and include fever, irritability, and poor feeding. In older children and adolescents, AOM usually is associated with fever and **otalgia** (acute ear pain). AOM also may present with **otorrhea** (ear drainage) after spontaneous rupture of the tympanic membrane. Signs of a common cold, which predisposes to AOM, are often present (see [Chapter 102](#)). A bulging tympanic membrane, air fluid level, or visualization of purulent material by otoscopy are reliable signs of infection ([Table 105.1](#)).

Examination of the ears is essential for diagnosis and should be part of the physical examination of any child with fever. The hallmark of OM is the presence of effusion in the middle ear

TABLE 105.1 Definition of Acute Otitis Media

A diagnosis of acute otitis media (AOM) requires:
History of acute onset of signs and symptoms
Presence of middle ear effusion
Signs and symptoms of middle ear inflammation
The definition of AOM includes all of the following:
Recent, usually abrupt, onset of signs and symptoms of middle ear inflammation and middle ear effusion
The presence of middle ear effusion that is indicated by any of the following:
Bulging of the tympanic membrane (TM)
Limited or absent mobility of the TM
Air-fluid level behind the TM
Abnormal TM color (white, yellow, amber)
Otorrhea
Signs or symptoms of middle ear inflammation as indicated by either:
Distinct erythema of the TM
Distinct otalgia (discomfort clearly referable to the ear that results in interference with or precludes normal activity or sleep)

cavity (see [Table 105.1](#)). The presence of an effusion does not confirm the presence of a bacterial OM, but it does define the need for appropriate diagnosis and therapy.

Pneumatic otoscopy, using an attachment to an otoscope, allows evaluation of ventilation of the middle ear and is a standard for clinical diagnosis. The tympanic membrane of the normal, air-filled middle ear has much greater compliance than if the middle ear is fluid filled. With AOM, the tympanic membrane is often characterized by **hyperemia**, or red color rather than the normal pearly gray color, but may appear pink, white, or yellow depending on the degree of bulging ([Fig. 105.1](#)). The light reflex is lost, and the middle ear structures are obscured and difficult to distinguish.

FIGURE 105.1 Acute otitis media. (A) This is the classic picture—an erythematous, opaque, bulging tympanic membrane. The light reflex is reduced, and the landmarks are partially obscured. Mobility is markedly reduced. (B) In this acutely febrile child who complained of otalgia, the presence of both air and fluid formed bubbles separated by grayish-yellow menisci. Even though the drum was not injected, this finding, combined with fever and otalgia, is consistent with acute infection. (C) In this child, the tympanic membrane was injected at the periphery, and a yellow purulent effusion caused the inferior portion to bulge outward. Mobility was markedly reduced. (From Yellon RF, Chi DH. *Otolaryngology*. In: Zitelli BJ, McIntire SC, Nowalk AJ, eds. *Atlas of Pediatric Physical Diagnosis*. 7th ed. Philadelphia: Saunders; 2018:868-915 [fig. 24.24].)

There should be poor or absent mobility to negative and positive pressure; this is a necessary finding for the diagnosis of OM. A hole in the tympanic membrane or purulent drainage confirms perforation. Occasionally, bullae are present on the lateral aspect of the tympanic membrane, which characteristically are associated with severe ear pain.

LABORATORY AND IMAGING STUDIES

Routine laboratory studies are not useful in the evaluation of OM. **Tympanometry** provides objective acoustic measurements of the tympanic membrane–middle ear system by reflection or absorption of sound energy from the external ear duct as pressure in the duct is varied. Measurements of the resulting **tympanogram** correlate well with the presence or absence of middle ear effusion.

Instruments using **acoustic reflectometry** are available for office use. Use of reflectometry as a screening test for AOM should be followed by examination with pneumatic otoscopy when abnormal reflectometry is identified.

Bacteria recovered from the nasopharynx do not correlate with bacteria isolated by tympanocentesis. Tympanocentesis and middle ear exudate culture are not always necessary, but they are required for accurate identification of bacterial pathogens and may be useful in neonates, immunocompromised patients, and patients not responding to therapy.

DIFFERENTIAL DIAGNOSIS

The major difficulty is differentiation of AOM from **OM with effusion (OME)**, which also is referred to as **chronic OM**. AOM is accompanied by signs of acute illness, such as fever, pain, and upper respiratory tract inflammation. OME is the presence of effusion without any of the other signs and symptoms. OME may occur either as the sequela of AOM or eustachian tube dysfunction secondary to an upper respiratory tract infection. It may also predispose to the development of AOM. Because OME is not an acute infectious process, it is important to be able to differentiate between OME and AOM accurately to prevent overprescribing of antibiotics.

TREATMENT

Recommendations for treatment are based on age, certainty of diagnosis, and severity of illness (Table 105.2). The recommended first-line therapy for most children meeting criteria

for antibiotic therapy is amoxicillin (80–90 mg/kg/day in two divided doses). Some children with mild illness or uncertain diagnosis may be observed if appropriate follow-up within 48–72 hours can be arranged with initiation of antibiotic therapy if symptoms do not self-resolve (see Table 105.2). The failure of initial therapy with amoxicillin at 3 days suggests infection with β -lactamase-producing *H. influenzae*, *M. catarrhalis*, or resistant *S. pneumoniae*. Recommended next-step treatments include high-dose amoxicillin-clavulanate (amoxicillin 80–90 mg/kg/day), cefdinir, or ceftriaxone (50 mg/kg intramuscularly in daily doses for 3 days). Intramuscular ceftriaxone is especially appropriate for children with vomiting that precludes oral treatment. Tympanocentesis may be required for patients who are difficult to treat or who do not respond to therapy. Acetaminophen and ibuprofen are recommended for fever or pain. Decongestants or antihistamines are not effective.

COMPLICATIONS AND PROGNOSIS

The complications of OM are tympanic membrane perforation, chronic effusion, chronic otorrhea, hearing loss, cholesteatoma (masslike keratinized epithelial growth), facial palsy, petrositis, intracranial extension (brain abscess, subdural empyema, or venous thrombosis), and mastoiditis. **Acute mastoiditis** is a suppurative complication of OM with inflammation and potential destruction of the mastoid air spaces. The disease progresses from a periostitis to an osteitis with mastoid abscess formation. Posterior auricular tenderness, swelling, and erythema, in addition to the signs of OM, are present. The pinna is displaced downward and outward. Computed tomography scan of the mastoid reveals clouding of the air cells, demineralization, or bone destruction. Treatment includes systemic antibiotics and drainage if the disease has progressed to abscess formation.

OME is the most frequent sequela of AOM and occurs most frequently in the first 2 years of life (up to 30–50% of children with AOM). **Persistent middle ear effusion** may last for many weeks or months in some children but usually resolves by 3 months following infection. Evaluating young children for this condition is an important part of all well-child examinations because, although not an infectious process, it is associated with hearing loss.

Conductive hearing loss should be assumed to be present with persistent middle ear effusion; the loss is mild to moderate and often is transient or fluctuating. In children at developmental

AOM, Acute otitis media.

risk or with frequent episodes of recurrent AOM, 3 months of persistent effusion with significant bilateral hearing loss is a reasonable indicator of need for intervention with insertion of pressure equalization tubes (tympanostomy tubes).

PREVENTION

Parents should be encouraged to continue exclusive breast-feeding as long as possible and should be cautioned about the risks of *bottle-propping* and of children taking a bottle to bed. The home should be a smoke-free environment, and pacifier use should be limited.

The conjugate *S. pneumoniae* vaccine reduces pneumococcal OM caused by vaccine serotypes by 50%, all pneumococcal OM by 33%, and all OM by 6–10%. Annual immunization against influenza virus may be helpful in high-risk children.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 106

Otitis Externa

ETIOLOGY

Otitis externa, also known as **swimmer's ear**, is defined by inflammation and exudate in the external auditory canal in the absence of other disorders, such as otitis media or mastoiditis. The most common bacterial pathogens are *Pseudomonas aeruginosa*, especially in association with swimming in pools or lakes, and *Staphylococcus aureus*. Otitis externa develops in approximately 20% of children with **tympanostomy tubes**, associated with *S. aureus*, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, *Proteus*, *Klebsiella*, and, occasionally, anaerobes. Coagulase-negative staphylococci and *Corynebacterium* are isolated frequently from cultures of the external canal but represent normal flora. **Malignant otitis externa** is caused by *P. aeruginosa* in immunocompromised persons and adults with diabetes.

EPIDEMIOLOGY

Otitis externa cases peak in summer, in contrast to otitis media, which occurs primarily in colder seasons in association with viral upper respiratory tract infections. Cleaning of the auditory canal, swimming, and, in particular, diving disrupt the integrity of the cutaneous lining of the ear canal and local defenses, such as cerumen, predisposing to otitis externa.

CLINICAL MANIFESTATIONS

Pain, tenderness, and aural discharge are the characteristic clinical findings of otitis externa. Fever is notably absent. Hearing is typically normal, but conductive hearing loss may be present if edema of the canal is severe. Tenderness with movement of the pinna, especially the tragus, and with chewing is particularly characteristic, which are symptoms notably

absent in otitis media. Inspection usually reveals that the lining of the auditory canal is inflamed with mild to severe erythema and edema. Scant to copious discharge from the auditory canal may obscure the tympanic membrane. The most common symptoms of **malignant otitis externa** are similar, but facial nerve palsy, vertigo, and/or sensorineural hearing loss may also occur. The most common physical findings are swelling and granulation tissue in the canal, usually with a discharge from the external auditory canal.

LABORATORY AND IMAGING STUDIES

The diagnosis of uncomplicated otitis externa usually is established solely on the basis of the clinical symptoms and physical examination findings without the need for additional laboratory or microbiologic evaluation. Cultures are required to identify the etiologic agent and the antimicrobial susceptibility.

DIFFERENTIAL DIAGNOSIS

Otitis media with tympanic perforation and discharge into the auditory canal may be confused with otitis externa. Pain on movement of the pinnae or tragus, typical of otitis externa, is absent. Local and systemic signs of **mastoiditis** (Chapter 105) indicate a process more extensive than otitis externa. Malignancies or cholesteatoma presenting in the auditory canal are rare in children but may present with discharge, unusual pain, or hearing loss.

TREATMENT

Topical antimicrobial/corticosteroid otic preparations (such as ofloxacin, ciprofloxacin with hydrocortisone or dexamethasone, and polymyxin B-neosporin-hydrocortisone) are sufficient in most cases of otitis externa. These preparations are equally effective and are active against *S. aureus* and most gram-negative bacteria, including *P. aeruginosa*. Use of aminoglycosides such as neomycin should be avoided in cases of tympanic membrane rupture due to their ototoxicity. **Tympanostomy tube otorrhea** is best treated with quinolone otic drugs, which are considered less likely to be ototoxic.

Treatment with topical otic analgesics and cerumenolytics is usually unnecessary. It is important with any topical therapy to remove purulent discharge from the external auditory canal with a swab or with suction to permit instillation of the solution. Excess water should be removed after bathing, and the ear canal dried using a hairdryer. The predisposing activity, such as swimming or diving, should be avoided until the inflammation has resolved.

Fungi such as *Aspergillus*, *Candida*, and dermatophytes are occasionally isolated from the external ear. It may be difficult to determine whether they represent normal flora or are the cause of inflammation. In most cases, local therapy and restoration of normal pH as recommended for bacterial otitis externa are sufficient.

Malignant otitis externa is treated by parenteral antimicrobials with activity against *P. aeruginosa*, such as an extended-spectrum penicillin (piperacillin-tazobactam), a cephalosporin with activity against *P. aeruginosa* (ceftazidime, cefepime), or a fluoroquinolone (ciprofloxacin).

COMPLICATIONS AND PROGNOSIS

Acute otitis externa usually resolves promptly without complications within 1–2 days of initiating treatment. Persistent pain, especially if severe or if accompanied by other symptoms (e.g., fever), should prompt re-evaluation for other conditions.

Complications of malignant otitis externa include invasion of the bones at the base of the skull, which may cause cranial nerve palsies. A mortality of 15–20% occurs in adults with malignant otitis media. Relapses within the first year after treatment are common.

PREVENTION

Overly vigorous cleaning of an asymptomatic auditory canal should be avoided. Drying the auditory canals with acetic acid (2%) or diluted isopropyl alcohol (rubbing alcohol) after swimming may be used prophylactically to help prevent the maceration that facilitates bacterial invasion. There is no role for prophylactic otic antibiotics.

PEARLS FOR PRACTITIONERS

See Infectious Diseases: Pearls for Practitioners at the end of this section.

CHAPTER 107

Croup (Laryngotracheobronchitis)

ETIOLOGY AND EPIDEMIOLOGY

Croup, or laryngotracheobronchitis, is the most common infection of the middle respiratory tract. The most common causes of croup are parainfluenza viruses (types 1, 2, and 3), respiratory syncytial virus (RSV), influenza, and adenovirus. Laryngotracheal airway inflammation disproportionately affects children because a small decrease in diameter secondary to mucosal edema and inflammation exponentially increases airway resistance and the work of breathing. During inspiration, the walls of the subglottic space are drawn together, aggravating the obstruction and producing the **stridor** characteristic of croup. Croup is most common in children 6 months to 3 years of age, with a peak in fall and early winter. It typically follows a common cold. Symptomatic re-infection is common, yet re-infections are usually mild. In adolescents, it manifests as laryngitis.

CLINICAL MANIFESTATIONS

The manifestations of croup are a harsh cough described as **barking** or **brassy**, hoarseness, inspiratory stridor, low-grade fever, and respiratory distress. **Stridor** is a harsh, high-pitched respiratory sound produced by turbulent airflow. It is usually inspiratory, but it may be biphasic and is a sign of upper airway obstruction. Signs of upper airway obstruction, such as labored breathing, cyanosis, and marked suprasternal, intercostal, and subcostal retractions, may be evident on examination (see Chapter 135). Wheezing may be present if there is associated lower airway involvement. Symptoms of croup are characteristically worse at night and are exacerbated with crying or agitation.

LABORATORY AND IMAGING STUDIES

Croup is a clinical diagnosis and does not require routine radiology or laboratory studies. If obtained, anteroposterior radiographs of the neck often show the diagnostic subglottic narrowing of croup known as the **steeple sign** (Fig. 107.1). Leukocytosis is uncommon and suggests epiglottitis or bacterial tracheitis. Many rapid tests (using polymerase chain reaction [PCR]) are available for parainfluenza viruses, RSV, and other less common viral causes of croup, such as influenza and adenoviruses.

DIFFERENTIAL DIAGNOSIS

The infectious differential diagnosis includes epiglottitis, bacterial tracheitis, and parapharyngeal abscess. Noninfectious causes of stridor include mechanical and anatomic causes (foreign body aspiration, laryngomalacia, subglottic stenosis, hemangioma, vascular ring, vocal cord paralysis). Stridor in infants younger than 4 months of age, positional stridor, or persistence of symptoms for longer than 1 week indicates an increased probability of another lesion and the need for imaging and direct laryngoscopy (see Chapter 135).

Epiglottitis is a medical emergency because of the risk of sudden airway obstruction. Following the introduction of the *Haemophilus influenzae* type b vaccine, this illness is rare and usually caused by group A streptococcus or *Staphylococcus aureus* or *H. influenzae* type b in unimmunized patients. Patients typically prefer sitting, often with the head held forward, the mouth open, and the jaw thrust forward (**sniffing position**), and they may appear distressed and toxic. Lateral radiograph reveals thickened and bulging epiglottis (**thumb sign**) and swelling of the aryepiglottic folds. The diagnosis is confirmed by direct observation of the inflamed and swollen

FIGURE 107.1 Croup (laryngotracheobronchitis). Radiograph of the airway and chest of a patient with croup, demonstrating the typical subglottic narrowing ("steeple sign"). (From Rodrigues KK, Roosevelt GE. Acute inflammatory upper airway obstruction [croup, epiglottitis, laryngitis, and bacterial tracheitis]. In: Kliegman RM, St. Geme III JW, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia: Elsevier; 2020 [fig. 412-1].)

supraglottic structures and swollen, cherry red epiglottis. Direct observation of the larynx should only be performed in the operating room with an anesthesiologist and a competent surgeon prepared to place an endotracheal tube or perform a tracheostomy if needed. Epiglottitis requires antibiotic therapy and endotracheal intubation to maintain the airway. Both onset and clinical recovery are rapid, and most children can be extubated safely within 48–72 hours.

Bacterial tracheitis is a rare but serious superinfection of the trachea that may follow viral croup and is most commonly caused by *S. aureus*. Patients may be toxic appearing, and intubation may be required. **Spasmodic croup** describes sudden onset of croup symptoms, usually at night, but without a significant upper respiratory tract prodrome. These episodes may be recurrent and severe but usually are of short duration. Spasmodic croup has a milder course than viral croup and responds to relatively simple therapies, such as exposure to cool or humidified air. The etiology is not well understood and may be allergic.

TREATMENT

Oral or intramuscular dexamethasone for children with viral croup reduces symptoms and the need for hospitalization and shortens hospital stays. Dexamethasone (0.6 mg/kg) may be given once intramuscularly or orally. Alternatively, prednisolone (2 mg/kg/day) may be given orally for 3 days. For significant airway compromise, administration of aerosolized racemic (D- and L-) epinephrine reduces subglottic edema by adrenergic vasoconstriction, temporarily producing marked clinical improvement. The peak effect is within 10–30 minutes and fades within 60–90 minutes. A rebound effect may occur, with worsening of symptoms as the effect of the drug dissipates. Aerosol treatment may need to be repeated every 20 minutes in severe cases.

Children should be kept as calm as possible to minimize forceful inspiration. One useful calming method is for a child with croup to sit on the parent's lap. Sedatives should be used cautiously and in the intensive care unit only.

Hospitalization is often required for children with cyanosis or stridor at rest. Children receiving aerosol treatment should be hospitalized or observed for at least 2–3 hours because of the risk of rebound airway obstruction. Decreased symptoms may indicate improvement or fatigue and impending respiratory failure.

COMPLICATIONS AND PROGNOSIS

The most common complication of croup is viral pneumonia, which occurs in 1–2% of children. Parainfluenza virus pneumonia and secondary bacterial pneumonia are more common in immunocompromised patients. Bacterial tracheitis may also be a complication of croup.

The prognosis for croup is excellent. Illness usually lasts approximately 5 days. As children grow, they become less susceptible to the airway effects of viral infections of the middle respiratory tract.

PREVENTION

There are no licensed vaccines for parainfluenza, RSV, or adenovirus. Annual influenza vaccine is recommended for children over 6 months of age.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 108

Pertussis

ETIOLOGY

Pertussis (**whooping cough**) is caused by *Bordetella pertussis*, a gram-negative pleomorphic bacillus with fastidious growth requirements. *B. pertussis* infects only humans and is transmitted person to person by coughing.

EPIDEMIOLOGY

The typical incubation period is 7–10 days but can range between 5 and 21 days. Patients are most contagious during the first 2 weeks of cough. The annual rate of pertussis was approximately 100–200 cases per 100,000 population in the pre-vaccination era; worldwide, there continue to be an estimated 20 million cases of pertussis and 200,000 childhood deaths annually. In the United States, the incidence of pertussis decreased after the introduction of vaccine, but it has increased steadily since the 1980s, with more than 15,000 cases reported in 2019. Pertussis incidence peaks among those less than 6 months of age—infants too young to be completely immunized and most likely to have severe complications—ranging from 40 to 160 cases per 100,000 population in the United States. Infection in late childhood and adolescence is likely due to a combination of waning immunity from previous vaccines, underimmunization, exposure to infected family members, and improved diagnostics. Epidemics can occur in fully immunized patients because vaccine-induced immunity wanes.

CLINICAL MANIFESTATIONS

Classic pertussis is seen in children between 1 and 10 years old. The progression of the disease is divided into catarrhal, paroxysmal, and convalescent stages. The **catarrhal stage** is marked by nonspecific signs (increased nasal secretions and low-grade fever) lasting 1–2 weeks. The **paroxysmal stage** is the most distinctive stage of pertussis and lasts 2–4 weeks. Coughing occurs in **paroxysms** during expiration, causing young children to lose their breath. This pattern of coughing is needed to dislodge plugs of necrotic bronchial epithelial tissues and thick mucus. The forceful inhalation against a narrowed glottis that follows this paroxysm of cough produces the characteristic **whoop**. Posttussive emesis is common. The **convalescent stage** is marked by gradual resolution of symptoms over 1–2 weeks. Coughing becomes less severe, and the paroxysms and whoops slowly disappear. Although the disease typically lasts 6–8 weeks, residual cough may persist for months, especially with physical stress or respiratory irritants.

Infants may not display the classic findings, and the first sign in the neonate may be apnea. Young infants are unlikely to have the classic whoop, more likely to have central nervous

system damage as a result of hypoxia, and more likely to have secondary bacterial pneumonia. Adolescents and adults with pertussis usually present with a prolonged bronchitic illness with persistent, nonproductive cough that often begins as a nonspecific upper respiratory tract infection. In general, adolescents and adults do not have a whoop with the cough, although they may have severe paroxysms.

LABORATORY AND IMAGING STUDIES

The diagnosis depends on isolation of *B. pertussis* or detection of its nucleic acids. Culture on specialized media is usually performed during the early phases of illness on specimens from nasopharyngeal swabs or aspirates, but this can be difficult to accomplish given the organism's fastidious nature. Polymerase chain reaction is available in many clinical laboratories. False-positive results can occur. Direct fluorescent antibody staining is not recommended. Serologic tests are not useful for diagnosing acute infection but can be confirmatory in the convalescent phase of illness, though there are no commercial kits approved by the U.S. Food and Drug Administration.

Lymphocytosis is present in 75–85% of infants and young children but is not diagnostic. The white blood cell count may increase from 20,000/mm³ to more than 50,000/mm³, consisting primarily of mature lymphocytes. Physical examination and radiographic signs of segmental lung atelectasis may develop during pertussis, especially during the paroxysmal stage. Perihilar infiltrates are common and are similar to those seen in viral pneumonia.

DIFFERENTIAL DIAGNOSIS

For a young child with classic pertussis, the diagnosis based on the pattern of illness is quite accurate. The paroxysmal stage is the most distinctive part of the syndrome. Other causes of pertussis-like prolonged cough illnesses include *Bordetella parapertussis* and *Bordetella holmesii*—which cause a similar but milder illness and are not prevented by *B. pertussis* vaccination—*Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, adenoviruses, and respiratory syncytial virus.

TREATMENT

Macrolide antibiotics (azithromycin, clarithromycin, or erythromycin) are recommended for treatment. Azithromycin is preferred in neonates due to the association between erythromycin treatment and the development of pyloric stenosis. Treatment during the catarrhal phase eradicates nasopharyngeal carriage of organisms within 3–4 days and may lessen symptom severity. Treatment in the paroxysmal stage does not alter the course of illness but decreases the potential for spread to others. Trimethoprim-sulfamethoxazole is an alternative therapy among children older than 2 months, although studies of its use for this indication are limited.

COMPLICATIONS AND PROGNOSIS

Major complications are most common among infants and young children and include hypoxia, apnea, pneumonia, seizures, encephalopathy, malnutrition, and death. The most frequent complication is pneumonia caused by *B. pertussis*

itself or resulting from secondary bacterial infection with *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*. Atelectasis may develop secondary to mucus plugs. The force of the paroxysm may produce pneumomediastinum, pneumothorax, or interstitial or subcutaneous emphysema; epistaxis; hernias; and retinal and subconjunctival hemorrhages. Otitis media and sinusitis may occur.

Most children recover normal pulmonary function with complete healing of the respiratory epithelium. Most permanent disability is a result of encephalopathy.

PREVENTION

Active immunity is induced with acellular pertussis components given as a vaccine in combination with the tetanus and diphtheria toxoids (DTaP). The acellular pertussis vaccines contain two to five antigens of *B. pertussis*, including pertussis toxin, pertactin, filamentous hemagglutinin, and fimbrial agglutinogens FIM-2 and FIM-3. DTaP vaccine is recommended at 2, 4, 6, and 15–18 months, with a booster at 4–6 years, and has an efficacy of 70–90%. A single booster dose of Tdap vaccine is recommended at 11–12 years or once for all adults. A booster dose of Tdap vaccine is recommended for pregnant women with each pregnancy, preferably in the third trimester, to provide higher levels of antibodies to the infant via transplacental transfer.

Macrolides are effective in preventing secondary cases in contacts exposed to pertussis. Underimmunized close contacts under 7 years of age should receive a booster dose of DTaP (unless a booster dose has been given within the preceding 3 years), whereas those 7–10 years of age should receive Tdap. All close contacts should receive prophylactic antibiotics for 5 days (azithromycin) or 7–14 days (clarithromycin or erythromycin, duration based on age).

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 109

Bronchiolitis

ETIOLOGY

Bronchiolitis is a disease of small bronchioles with increased mucus production and occasional bronchospasm, sometimes leading to airway obstruction. It is commonly caused by a viral lower respiratory tract infection. Bronchiolitis is most commonly seen in infants and young children, with most severe cases occurring among infants; it is potentially life threatening.

Respiratory syncytial virus (RSV) is a primary cause of bronchiolitis, followed in frequency by human metapneumovirus, parainfluenza viruses, influenza viruses, adenoviruses, rhinoviruses, coronaviruses, and, infrequently, *Mycoplasma pneumoniae*. Viral bronchiolitis is extremely contagious and is spread by contact with infected respiratory

secretions. Although coughing produces aerosols, hand carriage of contaminated secretions is the most frequent mode of transmission.

EPIDEMIOLOGY

Bronchiolitis is a leading cause of hospitalization of infants. Bronchiolitis occurs almost exclusively during the first 2 years of life, with a peak age at 2–6 months. Many healthy children with bronchiolitis can be managed as outpatients; however, premature infants and children with chronic lung disease of prematurity, hemodynamically significant congenital heart disease, neuromuscular weakness, or immunodeficiency are at increased risk of severe, potentially fatal disease. Children acquire infection after exposure to infected family members, who typically have symptoms of an upper respiratory tract infection, or from infected children in day care. In the United States, annual peaks are usually in the late winter months from December through March.

CLINICAL MANIFESTATIONS

Bronchiolitis caused by RSV typically has an incubation period of 4–6 days. Bronchiolitis classically presents as a progressive respiratory illness similar to the common cold in its early phase, with cough and rhinorrhea. It progresses over 3–7 days to noisy, raspy breathing and audible wheezing. There is usually a low-grade fever accompanied by irritability, which may reflect the increased work of breathing. In contrast to the classic progression of disease, young infants infected with RSV may not have a prodrome and may have apnea as the first sign of infection.

Physical signs of bronchiolar obstruction include prolongation of the expiratory phase of breathing, nasal flaring, intercostal retractions, suprasternal retractions, and air trapping with hyperexpansion of the lungs. During the wheezing phase, percussion of the chest usually reveals only hyperresonance, but auscultation usually reveals diffuse wheezes and crackles throughout the breathing cycle. With more severe disease, grunting and cyanosis may be present.

LABORATORY AND IMAGING STUDIES

Routine laboratory tests are not required to confirm the diagnosis. It is important to assess oxygenation in severe cases of bronchiolitis. **Pulse oximetry** is adequate for monitoring oxygen saturation. Frequent, regular assessments and cardiorespiratory monitoring of infants are necessary because respiratory failure may develop precipitously in very tired infants even though blood gas values taken before rapid decompensation are reassuring.

Rapid viral diagnosis of nasopharyngeal secretions performed by polymerase chain reactions for RSV, human metapneumovirus, parainfluenza viruses, influenza viruses, coronaviruses, and adenoviruses are sensitive tests to confirm the infection. Identifying the viral agent is helpful for cohorting children with the same infection but is not necessary to make the diagnosis of bronchiolitis.

Chest radiographs are not always necessary but frequently show signs of lung hyperinflation, including increased lung lucency and flattened or depressed diaphragms. Areas of increased density may represent either viral pneumonia or localized atelectasis.

DIFFERENTIAL DIAGNOSIS

The major difficulty in the diagnosis of bronchiolitis is to differentiate other diseases associated with wheezing. It may be difficult to differentiate asthma from bronchiolitis by physical examination, but age of presentation, presence of fever, and absence of personal or family history of asthma are the major differential factors. Bronchiolitis occurs primarily in the first year of life and is accompanied by fever, whereas asthma usually presents in older children with previous wheezing episodes and is typically unaccompanied by fever unless a respiratory tract infection is the trigger for the asthma exacerbation.

Wheezing may also be due to an airway foreign body, congenital airway obstructive lesion, cystic fibrosis, exacerbation of chronic lung disease, viral or bacterial pneumonia, and other lower respiratory tract diseases (see Chapter 78). **Cardiogenic asthma**, which can be confused with bronchiolitis in infants, is wheezing associated with pulmonary congestion secondary to left-sided heart failure. Wheezing associated with gastroesophageal reflux is likely to be chronic or recurrent, and the patient may have a history of frequent emesis. Cystic fibrosis is associated with poor growth, chronic diarrhea, and a positive family history. A focal area on radiography that remains inflated despite changes in position suggests **foreign body aspiration**.

TREATMENT

Bronchiolitis treatment consists of supportive therapy, including respiratory monitoring, control of fever, hydration, upper airway suctioning, and, if needed, oxygen administration. Indications for hospitalization include moderate to marked respiratory distress, hypoxemia, apnea, inability to tolerate oral feeding, and lack of appropriate care available at home. Hospitalization of high-risk children with bronchiolitis should be considered. Among hospitalized infants, supplemental oxygen by nasal cannula is often necessary, but intubation and ventilatory assistance for respiratory failure or apnea are required in less than 10% of these infants. Bronchodilators, corticosteroids, chest physiotherapy, and hypertonic saline are seldom effective and are not generally recommended. Likewise, antibiotics should be avoided unless there is strong suspicion for concomitant bacterial infection.

COMPLICATIONS AND PROGNOSIS

Most hospitalized children show marked improvement in 2–5 days with supportive treatment alone. The course of the wheezing phase varies, however. Tachypnea and hypoxia may progress to respiratory failure requiring assisted ventilation. Apnea is a major concern for very young infants with bronchiolitis.

Most cases of bronchiolitis resolve completely, although minor abnormalities of pulmonary function and bronchial hyperreactivity may persist for several years. Recurrence is common but tends to be mild and should be assessed and treated similarly to the first episode. The incidence of asthma seems to be higher in children hospitalized for bronchiolitis as infants, but it is unclear whether this is causal or whether children prone to asthma are more likely to be hospitalized with bronchiolitis. There is a 1–2% mortality rate, highest among infants with pre-existing cardiopulmonary or immunologic impairment.

PREVENTION

Monthly injections of **palivizumab**, an RSV-specific monoclonal antibody, initiated just before the onset of the RSV season confers some protection from severe RSV disease. Palivizumab is indicated for infants with prematurity (born before 29 weeks, 0 days gestation), chronic lung disease of prematurity, and those with hemodynamically significant cyanotic and acyanotic congenital heart disease in the first year of life, and, rarely, in the second year of life. Immunization with influenza vaccine is recommended for all children older than 6 months and may prevent influenza-associated disease.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 110

Pneumonia

ETIOLOGY

Pneumonia is an infection of the lower respiratory tract that involves the airways and parenchyma, with consolidation of the alveolar spaces. The term **lower respiratory tract infection** is often used to encompass bronchitis, bronchiolitis (see Chapter 109), pneumonia, or any combination of the three. **Pneumonitis** is a general term for lung inflammation that may or may not be associated with consolidation. **Lobar pneumonia** describes pneumonia localized to one or more lobes of the lung. **Atypical pneumonia** describes patterns typically more diffuse or interstitial than lobar pneumonia. **Bronchopneumonia** refers to inflammation of the lung that is centered in the bronchioles and leads to the production of a mucopurulent exudate that obstructs some of these small airways and causes patchy consolidation of the adjacent lobules. **Interstitial pneumonitis** refers to inflammation of the interstitium, which is composed of the walls of the alveoli, the alveolar sacs and ducts, and the bronchioles. Interstitial pneumonitis is characteristic of acute viral infections but may also be a chronic inflammatory or fibrosing process (childhood interstitial lung diseases).

Defects in host defenses increase the risk of pneumonia. Lower airways and secretions are generally considered sterile as a result of a multifactorial system. Airway contaminants are caught in the mucus secreted by the goblet cells. Cilia on epithelial surfaces, composing the ciliary elevator system, beat synchronously to move particles upward toward central airways and into the throat, where they are swallowed or expectorated. Polymorphonuclear neutrophils from the blood and tissue macrophages ingest and kill microorganisms. IgA secreted into the upper airway fluid protects against invasive infections and facilitates viral neutralization.

Infectious agents that commonly cause community-acquired pneumonia vary by age (Table 110.1). *Streptococcus pneumoniae* is the most common bacterial cause of pneumonia (particularly **lobar pneumonia**) and occurs in children of any age outside the neonatal period. Other common

causes include respiratory syncytial virus (RSV) in infants (see Chapter 109), other respiratory viruses (parainfluenza viruses, influenza viruses, human metapneumovirus, adenoviruses) in children younger than 5 years old, and *Mycoplasma pneumoniae* in children older than age 5 years. *M. pneumoniae* and *Chlamydia pneumoniae* are principal causes of **atypical pneumonia**.

Chlamydia trachomatis and, less commonly, *Mycoplasma hominis*, *Ureaplasma urealyticum*, and cytomegalovirus (CMV) cause a similar respiratory syndrome in infants 2 weeks to 3 months of age, with subacute onset of an **afebrile pneumonia**; cough and hyperinflation are the predominant signs. These infections are difficult to diagnose and distinguish from each other. In adults these organisms are carried primarily as part of the genital mucosal flora. Women who harbor these agents may transmit them perinatally to newborns.

Additional agents occasionally cause pneumonia. **Severe acute respiratory syndrome (SARS)** is due to SARS-associated coronavirus (SARS-CoV) or SARS-CoV-2, the cause of the coronavirus infectious disease (COVID-19) pandemic. SARS-CoV-2 is an emerging pathogen but appears to cause less mortality in children than in adults; in addition to respiratory disease, it is also associated with a postinfectious multisystem inflammatory syndrome similar but not the same as Kawasaki disease (Chapter 88). SARS-CoV-2 is a highly contagious, airborne (cough, sneeze, talking, breathing) virus that presents within a broad spectrum of symptoms. Many patients are asymptomatic (but contagious) or have mild to moderate symptoms that do not require hospitalization. A minority develop a severe or critical illness.

Avian influenza (bird flu) is a highly contagious viral disease of poultry and other birds caused by **influenza A (H5N1)**. There were outbreaks among humans in Southeast Asia in 1997 and 2003–2004, with high mortality rates. A novel influenza A (H1N1) of swine origin began circulating in 2009. Other etiologic agents to consider, based on specific exposure history, include *Staphylococcus aureus* and *Streptococcus pyogenes* (especially after influenza infection), *Mycobacterium tuberculosis*, *Francisella tularensis*, *Brucella* spp., *Coxiella burnetii*, *Chlamydia psittaci*, *Legionella pneumophila*, hantavirus, *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, and oral flora or gram-negative bacilli (after aspiration).

Causes of pneumonia in immunocompromised persons include gram-negative enteric bacteria, mycobacteria (*M. avium* complex), fungi (aspergillosis), viruses (CMV), and *Pneumocystis jirovecii* (formerly *carinii*). Pneumonia in patients with cystic fibrosis is usually caused by *S. aureus* in infancy and *Pseudomonas aeruginosa* or *Burkholderia cepacia* in older patients.

EPIDEMIOLOGY

Immunizations have markedly reduced the incidence of pneumonia caused by pertussis, diphtheria, measles, *Haemophilus influenzae* type b, and *S. pneumoniae*. Where used, bacille Calmette-Guérin (BCG) immunization for tuberculosis has also had some impact. Pneumonia is the single largest contributor of childhood mortality worldwide, killing an estimated 1 million children under 5 years of age annually. Risk factors for lower respiratory tract infections include exposure to infected persons, gastroesophageal reflux, neurologic

*Severe pneumonia, from *Streptococcus pneumoniae*, *Staphylococcus aureus*, group A streptococcus, *Haemophilus influenzae*, or *Mycoplasma pneumoniae* requiring admission to an intensive care unit. Antipseudomonal agents should be added if *Pseudomonas* is suspected.

[†]Oral administration.

[‡]Intravenous administration for inpatients except for the macrolides (erythromycin, azithromycin, and clarithromycin), which are given orally.

[§]*Haemophilus influenzae* type b infection is uncommon with universal H. influenzae type b immunization. Pandemic viruses vary from influenza to coronaviruses (location and year dependent).

^{||}Fluoroquinolones are contraindicated for children younger than 18 years of age and pregnant or lactating women. Tetracyclines are not recommended for children younger than 9 years. MRSA, Methicillin-resistant *Staphylococcus aureus*.

impairment (aspiration), immunocompromised states, anatomic abnormalities of the respiratory tract, residence in residential care facilities, and hospitalization, especially in an intensive care unit.

CLINICAL MANIFESTATIONS

Age is a determinant in the clinical manifestations of pneumonia. Neonates may have fever or hypoxia only, with subtle or absent physical examination findings (see Chapter 65). With a young infant, apnea may be the first sign of pneumonia. Fever, chills, tachypnea, cough, malaise, pleuritic chest pain, retractions, and apprehension—because of difficulty breathing or shortness of breath—are common in older infants and children. Dominant features of the pulmonary symptoms of COVID-19 include cough, fever, dyspnea, and myalgias. Other common features include abdominal pain and diarrhea, headache, sore throat, as well as loss of taste or smell sensations. Severe involvement includes worsening dyspnea, hypoxia, and greater than 50% lung infiltrates on imaging. Critical illness includes respiratory failure requiring mechanical ventilation or extracorporeal membrane oxygenation (ECMO) and multiorgan system dysfunction (myocarditis, hypercoagulability, acute kidney injury).

Physical examination findings cannot reliably distinguish viral and bacterial pneumonias, but complete physical examination may help identify other foci of disease or associated findings to suggest an etiology.

Viral pneumonias are generally associated more often with cough, wheezing, or stridor; fever is less prominent than with bacterial pneumonia. Mucosal congestion and upper airway inflammation suggest a viral infection. Bacterial pneumonias are typically associated with higher fever, chills, cough, dyspnea, and auscultatory findings of lung consolidation. Atypical pneumonia in young infants is characterized by tachypnea, cough, and crackles on auscultation. Concomitant conjunctivitis may be present in infants with chlamydial pneumonia. Other signs of respiratory distress include nasal flaring, intercostal and subcostal retractions, and grunting.

Asymmetry or shallow breathing may be due to splinting from pain. Hyperexpansion, common in asthma but also frequently accompanying viral lower respiratory infections, may cause a low diaphragm seen on a chest x-ray. Poor diaphragmatic excursion may indicate hyperexpanded lungs or an inability for expansion due to a large consolidation or effusion. Dullness to percussion may be due to lobar or segmental infiltrates or pleural fluid. Auscultation may be normal in early or very focal pneumonia, but the presence of localized crackles, rhonchi, and wheezes may help one detect and locate pneumonia. Distant breath sounds may indicate a large, poorly ventilated area of consolidation or pleural fluid.

LABORATORY AND IMAGING STUDIES

Bacterial flora of the upper respiratory tract does not accurately reflect flora present in lower respiratory tract infections, and high-quality sputum is rarely obtainable from children. In otherwise healthy children without life-threatening disease, invasive procedures to obtain lower respiratory tissue or secretions are seldom indicated. Serologic

tests are not useful for the most common causes of bacterial pneumonia.

The white blood cell (WBC) count with viral pneumonias is often normal or mildly elevated, with a predominance of lymphocytes, whereas with bacterial pneumonias, the WBC count can be elevated ($>15,000\text{--}20,000/\text{mm}^3$) and with a predominance of neutrophils. Mild eosinophilia is characteristic of infant *C. trachomatis* pneumonia. Blood cultures should be performed on moderately to severely ill, hospitalized children to attempt to diagnose a bacterial cause of pneumonia. Blood cultures identify a bacterial respiratory pathogen in approximately 5–10% of children hospitalized for pneumonia (and 10–20% of those with pneumonia with empyema or large effusion). Urinary antigen tests are especially useful for *L. pneumophila* (Legionnaires disease).

Viral respiratory pathogens can be diagnosed using polymerase chain reaction (PCR) or rapid viral antigen detection. *M. pneumoniae* can be confirmed by *Mycoplasma* PCR. CMV pneumonitis can be diagnosed with PCR from bronchoalveolar lavage fluid. The diagnosis of *M. tuberculosis* is established by the tuberculin skin test, serum interferon- γ release assay, or analysis of sputum or gastric aspirates by culture, antigen detection, or PCR.

The need to establish an etiologic diagnosis of pneumonia is greater in immunocompromised patients, patients with recurrent pneumonia, or those with pneumonia unresponsive to empirical therapy. For these patients, bronchoscopy with bronchoalveolar lavage and brush mucosal biopsy, needle aspiration of the lung, and open lung biopsy are methods of obtaining material for microbiologic diagnosis.

When there is a pleural **effusion or empyema**, a thoracentesis to obtain pleural fluid can be diagnostic and therapeutic. Evaluation differentiates between empyema and a sterile parapneumonic effusion caused by irritation of the pleura contiguous with the pneumonia. Gram stain, bacterial culture, or broad-range bacterial PCR may lead to microbiologic diagnosis. The pleural fluid can also be cultured for mycobacteria and fungi. Removal of grossly purulent pleural fluid reduces the patient's toxicity and associated discomfort and may facilitate more rapid recovery. Drainage of large pleural accumulations also improves pulmonary mechanics and gas exchange by increasing the ability of the lung to expand.

Frontal and lateral radiographs are required to localize disease and adequately visualize retrocardiac infiltrates; they are recommended for diagnosis among hospitalized children but are not necessary to confirm the diagnosis in well-appearing outpatients. Although there are characteristic radiographic findings of pneumonia, radiography alone cannot provide a definitive microbiologic diagnosis. Bacterial pneumonia characteristically shows lobar consolidation or a round pneumonia, with pleural effusion in 10–30% of cases (Fig. 110.1). Viral pneumonia characteristically shows diffuse, streaky infiltrates of bronchopneumonia (Fig. 110.2) and hyperinflation. Atypical pneumonia, as with *M. pneumoniae* and *C. pneumoniae*, shows increased interstitial markings or bronchopneumonia. Chest radiographs may be normal in early pneumonia, with infiltrates appearing during treatment as hydration is restored. Hilar lymphadenopathy is uncommon with bacterial pneumonia but may be a sign of tuberculosis, endemic mycoses, autoimmune conditions, or an underlying malignant neoplasm. Decubitus views or

FIGURE 110.1 Acute lobar pneumonia of the right lower lobe in a 14-year-old boy with fever and cough. (A) Posteroanterior and (B) lateral chest radiographs demonstrate right-lower-lobe airspace consolidation, which obliterates the silhouette of the right heart border. (From Kelly MS, Sandora TJ. Community-acquired pneumonia. In: Kliegman RM, St. Geme III JW, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia: Elsevier; 2020 [fig. 428.3].)

FIGURE 110.2 Diffuse respiratory syncytial virus pneumonia in a 6-month-old infant with tachypnea and fever. Anteroposterior chest radiograph shows bilateral, perihilar, peribronchial thickening and fine airspace disease with hyperinflation. (From Kelly MS, Sandora TJ. Community-acquired pneumonia. In: Kliegman RM, St. Geme III JW, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia: Elsevier; 2020 [fig. 428.2A].)

ultrasound should be used to assess the size of pleural effusions and whether they are freely mobile. Computed tomography (CT) is used to evaluate serious disease, lung abscesses, bronchiectasis, and effusion characteristics. Unusual etiologies or recurrent pneumonias require special considerations (Table 110.2). Lung abscesses, pneumatoceles, and empyema may require surgical management.

DIFFERENTIAL DIAGNOSIS

Pneumonia must be differentiated from other acute pulmonary diseases, including allergic hypersensitivity pneumonitis, e-cigarette or vaping product use-associated lung injury

(EVALI), asthma, and cystic fibrosis; cardiac diseases, such as pulmonary edema caused by heart failure; and autoimmune diseases, such as certain vasculitides and systemic lupus erythematosus. Radiographically, pneumonia must be differentiated from lung trauma and contusion, hemorrhage, foreign body aspiration, and sympathetic effusion due to subdiaphragmatic inflammation.

TREATMENT

Therapy for pneumonia includes supportive and specific treatment and depends on the degree of illness, complications, and knowledge of the infectious agent likely causing the pneumonia. Most cases of pneumonia in healthy children can be managed on an outpatient basis. However, children with hypoxemia, inability to maintain adequate hydration, or moderate to severe respiratory distress should be hospitalized. Hospitalization should be considered in infants under 6 months with suspected bacterial pneumonia, those in whom there is a concern for a pathogen with increased virulence (e.g., methicillin-resistant *S. aureus* [MRSA]), or when concern exists about a family's ability to care for the child and to assess symptom progression.

Because viruses cause many community-acquired pneumonias in young children, not all children require empiric antibiotic treatment for pneumonia. Recommended therapies in those without recent antibiotic exposure are listed in Table 110.1. Exceptional situations include lack of response to empirical therapy, unusually severe presentations, nosocomial pneumonia, and immunocompromised children susceptible to infections with opportunistic pathogens (Table 110.3). Presumed pneumococcal pneumonia can be treated with high-dose ampicillin therapy. Ceftriaxone and/or vancomycin can be used if the isolate shows high-level resistance and the patient is severely ill. For infants 2–18 weeks old with afebrile pneumonia most likely caused by *C. trachomatis*, a macrolide is the recommended treatment. Oseltamivir or zanamivir

should be used if influenza is identified or suspected, ideally within 48 hours of symptom onset.

Severe or critical COVID-19 is treated with oxygen, dexamethasone, remdesivir, mechanical ventilation, and ECMO.

COMPLICATIONS AND PROGNOSIS

Bacterial pneumonias frequently cause inflammatory fluid to collect in the adjacent pleural space, causing a **parapneumonic effusion** or, if grossly purulent, an **empyema**. Small effusions may not require any special therapy. Large effusions may restrict breathing and require drainage. Air dissection within lung tissue results in a **pneumatocele**. Scarring of the airways and lung tissue may leave dilated bronchi, resulting in **bronchiectasis** and increased risk for recurrent infection.

Pneumonia that causes necrosis of lung tissue may evolve into a **lung abscess**. Lung abscess is an uncommon problem in children and is usually caused by aspiration, infection behind an obstructed bronchus, or certain virulent organisms. Anaerobic bacteria usually predominate, along with various streptococci, *Escherichia coli*, *Klebsiella pneumoniae*, *P. aeruginosa*, and *S. aureus*. Chest radiograph or CT scan reveals a cavitary lesion, often with an air-fluid level, surrounded by parenchymal inflammation. If the cavity communicates with the bronchi, organisms may be isolated from sputum. Diagnostic bronchoscopy may be indicated to exclude a foreign body and obtain microbiologic specimens. Lung abscesses usually respond to appropriate antimicrobial therapy with clindamycin or ampicillin-sulbactam.

Most children recover from pneumonia rapidly and completely, although radiographic abnormalities may persist for 6–8 weeks. In a few children, symptoms may last longer than 1 month or may be recurrent. In such cases, the possibility of underlying disease must be investigated further, such as with the tuberculin skin test, sweat chloride determination for cystic fibrosis, serum immunoglobulin (Ig) and IgG subclass determinations, bronchoscopy to identify anatomic abnormalities or foreign body, and barium swallow for gastroesophageal reflux.

Severe adenovirus pneumonia may result in **bronchiolitis obliterans**, a subacute inflammatory process in which the small airways are replaced by scar tissue, resulting in a reduction in lung volume and lung compliance. **Unilateral hyperlucent lung**, or **Swyer-James syndrome**, is a focal sequela of severe necrotizing pneumonia in which all or part of a lung has increased translucency radiographically; it has been linked to adenovirus type 21.

PREVENTION

Annual influenza vaccine is recommended for all children over 6 months of age (see Chapter 94). Trivalent or quadrivalent, inactivated influenza vaccines are licensed for use beginning at 6 months of age; live-attenuated vaccine can be used for persons 2–49 years of age. Universal childhood vaccination with conjugate vaccines for *H. influenzae* type b and *S. pneumoniae* has greatly diminished the incidence of these pneumonias. RSV infections can be prevented by use of palivizumab in some high-risk patients (see Chapter 109). Prevention of COVID-19 includes the use of face masks, physical distancing, avoiding contact with infected patients, and contact isolation. As of mid-2021, three SARS-CoV-2 vaccines are available under emergency use authorization in the United States and are recommended for all children age 12 and older, with studies under way to evaluate safety and efficacy in younger children. Visit the CDC website for updated information (<https://www.cdc.gov/vaccines/covid-19/index.html>).

Reducing the duration of mechanical ventilation and administering antibiotics judiciously reduces the incidence of ventilator-associated pneumonias. The head of the bed should be raised to 30–45 degrees for intubated patients to minimize risk of aspiration, and all suctioning equipment and saline should be sterile. Handwashing before and after every patient contact and use of gloves for invasive procedures are important measures to prevent nosocomial transmission of infections. Hospital staff with respiratory illnesses or who are carriers of certain organisms, such as MRSA, should comply with infection control policies to prevent transfer of organisms to patients. Treating sources of aerosols, such as air coolers, can prevent *L. pneumoniae*.

TABLE 110.3 Antimicrobial Therapy for Pneumonia Caused by Specific Pathogens*

PATHOGEN	RECOMMENDED TREATMENT	ALTERNATIVE TREATMENT
<i>Streptococcus pneumoniae</i> with MIC for penicillin ≤ 2.0 $\mu\text{g/mL}$	Ampicillin or penicillin IV; amoxicillin PO	Ceftriaxone, clindamycin, or vancomycin IV; cefuroxime, cefpodoxime, levofloxacin, [†] or linezolid PO
<i>S. pneumoniae</i> with MIC for penicillin ≥ 4.0 $\mu\text{g/mL}$	Ceftriaxone IV; levofloxacin [†] or linezolid PO	Ampicillin, levofloxacin, [†] clindamycin, or vancomycin IV; clindamycin PO
Group A streptococcus	Penicillin or ampicillin IV; amoxicillin or penicillin PO	Ceftriaxone, clindamycin, or vancomycin IV; clindamycin PO
Group B streptococcus	Penicillin or ampicillin IV; amoxicillin or penicillin PO	Ceftriaxone, clindamycin, or vancomycin IV; clindamycin PO
<i>Haemophilus influenzae</i>	Ampicillin IV or amoxicillin PO if β -lactamase negative; ceftriaxone IV or amoxicillin-clavulanate PO if β -lactamase positive	Ciprofloxacin [†] or levofloxacin [†] IV; cefdinir, cefixime, or cefpodoxime PO
<i>Mycoplasma pneumoniae</i> , <i>Chlamydia pneumoniae</i> , or <i>Chlamydia trachomatis</i>	Azithromycin IV or PO	Erythromycin or levofloxacin IV; clarithromycin, erythromycin, doxycycline, [†] or a fluoroquinolone [†] PO
<i>Staphylococcus aureus</i> , methicillin susceptible (MSSA)	Cefazolin, oxacillin, or nafcillin IV; cephalexin PO	Clindamycin or vancomycin IV; clindamycin PO

Gram-negative aerobic bacilli (except <i>P. aeruginosa</i>)	Ceftriaxone with or without an aminoglycoside IV; amoxicillin-clavulanate, cefdinir, or cefixime PO	Piperacillin-tazobactam plus an aminoglycoside [‡] ; fluoroquinolone [†] PO
<i>P. aeruginosa</i>	Ceftazidime IV with or without an aminoglycoside [‡] ; ciprofloxacin [†] if susceptible PO	Piperacillin-tazobactam IV with or without an aminoglycoside [‡]
Herpes simplex virus	Acyclovir IV	

*Oral outpatient therapy may be used for mild illness. Intravenous inpatient therapy should be used for moderate to severe illness.

[†]Appropriate respiratory fluoroquinolones include moxifloxacin, gatifloxacin, levofloxacin, and gemifloxacin. Fluoroquinolones are contraindicated for children younger than 18 years of age and pregnant or lactating women. Tetracyclines are not recommended for children younger than 9 years.

[‡]Aminoglycoside dosing should be guided by serum antibiotic concentrations after a steady state has been reached.

IV, Intravenous; MIC, minimum inhibitory concentration; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *Staphylococcus aureus*; PO, per os (orally); TMP-SMX, trimethoprim-sulfamethoxazole.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 111

Infective Endocarditis

ETIOLOGY

Infective endocarditis (IE) is an infection on the endothelial surface of the heart, including the heart valves. The management of infections on the endothelial surfaces of blood vessels (**endovascular infections**) is very similar. Turbulent flow from congenital heart disease or an indwelling central venous catheter can result in endothelial damage. Fibrin and platelets gather at the site, forming a thrombus. In the setting of transient bacteremia, this lesion can become infected and can result in a **vegetation**, which usually occurs on a valve leaflet and is composed of microorganisms trapped in a fibrin mesh that extends into the bloodstream.

Many microorganisms have been reported to cause endocarditis, although there are only a few common causes in children (Table 111.1). Viridans group streptococci (*S. mutans*, *S. sanguinis*, others) are the principal cause in children with congenital heart diseases without previous surgery. *Staphylococcus aureus* and coagulase-negative staphylococci (CONS) are important causes of endocarditis, especially following cardiac surgery and in the presence of prosthetic cardiac and endovascular materials. Gram-negative endocarditis is rare. *Candida* species can cause fungal endocarditis, especially in premature infants with central venous catheters and/or receiving parenteral nutrition.

EPIDEMIOLOGY

Rheumatic heart disease used to be a major risk factor for IE but has become much less common. Patients at highest risk for IE include those with prosthetic cardiac valves and children who have cyanotic congenital heart disease, either with or without repair. The risk in these patients is increased after dental and oral procedures or procedures of the respiratory, genitourinary, or gastrointestinal tracts. Use of central vascular catheters is a significant risk factor for native valve endocarditis. Approximately 8–10% of IE in children occurs without

structural heart disease (normal native valve) or other obvious risk factors. *S. aureus* is the most likely infective organism in these cases.

CLINICAL MANIFESTATIONS

The most common early symptoms of IE are nonspecific and include fever, malaise, and weight loss. Tachycardia and a new or changed heart murmur are common findings. The subtle and nonspecific findings underscore the need to obtain blood cultures if endocarditis is suspected, especially for children with congenital heart disease and for unexplained illness after dental or surgical procedures. Endocarditis is often a subacute, slowly progressive process, but it can also present acutely with high fevers and a sepsis-like picture. Heart failure, splenomegaly, petechiae, glomerulonephritis, and embolic phenomena (Osler nodes, Roth spots, Janeway lesions, and splinter hemorrhages) may be present. In neonates, the signs and symptoms of IE may be especially subtle and variable, including feeding issues, respiratory distress, and hypotension, in addition to changes in the cardiac exam.

LABORATORY STUDIES AND IMAGING

The key to diagnosis is confirming continuous bacteremia or fungemia by culturing the blood. Multiple blood cultures should be obtained before initiating antibiotic therapy. For optimal sensitivity, adequate volumes of blood should be obtained: 1–3 mL for infants and young children and at

least 5–7 mL for older children. If volumes are not adequate, emphasis should be placed on obtaining aerobic blood cultures, as anaerobic organisms rarely cause IE. If possible, in patients who are not critically ill, empirical antibiotic therapy should be held until at least three sets of blood cultures (from different venipuncture sites) are obtained. Patients who have recently been treated with antibiotics or who are currently receiving antibiotics should have additional serial cultures performed. Despite adequate blood culture techniques, the microbiologic diagnosis is not confirmed in 5–15% of cases, known as **culture-negative endocarditis**.

The agent in culture-negative endocarditis may be identified by antibody testing and examination of the valve tissue (following surgery) by polymerase chain reaction (PCR) for bacterial (16S) or fungal (18S) ribosomal RNA.

Erythrocyte sedimentation rate and C-reactive protein are often elevated. Leukocytosis, anemia, and hematuria are common laboratory findings.

Echocardiography should be performed in all cases where IE is suspected. It can be used to visualize vegetations and assess valvular regurgitation and conduit flow. Transesophageal echocardiography (TEE) is more sensitive than transthoracic echocardiography (TTE) for adolescents and adults and for patients with prosthetic valves, but it is often unnecessary in children.

DIFFERENTIAL DIAGNOSIS

IE must be differentiated from other causes of bacteremia and other cardiac conditions. The modified **Duke criteria** can be used to assist in the diagnosis of IE (Table 111.2). Noninfectious causes of endocardial vegetations must be excluded, such as sterile clots or lupus. Prolonged bacteremia can be caused by infectious endothelial foci outside of the heart, often associated with congenital vascular malformations, vascular trauma, an infected venous thrombosis, or previous vascular surgery.

TREATMENT

Severely ill patients must be stabilized with supportive therapies for cardiac failure, pulmonary edema, and low cardiac output (see Chapter 145). Empirical antibiotic therapy may be started for acutely ill patients after blood cultures are obtained. With subacute disease, awaiting results of blood cultures to confirm the diagnosis is recommended to direct therapy according to the susceptibility of the isolate. Because antibiotics must reach the organisms by passive diffusion through the fibrin mesh, high doses of bactericidal antibiotics are required for an extended period of treatment (4–6 weeks). Exact duration of therapy varies depending on the presence of prosthetic material and the causative organism. *Staphylococcus aureus* bacteremia can be persistent, and if associated with an indwelling catheter it requires line removal in most cases. Surgery is indicated if medical treatment is unsuccessful, if bacteremia is persistent, or if the pathogen is unusual or difficult to treat (e.g., fungal endocarditis). Surgical intervention may also be required with the presence of a valve annulus or myocardial abscess, rupture of a valve leaflet, valvular insufficiency with acute or refractory heart failure, recurrent serious embolic complications, or refractory prosthetic valve disease (Table 111.3).

TABLE 111.2 Modified Duke Criteria for Infective Endocarditis		
DEFINITE ENDOCARDITIS	POSSIBLE ENDOCARDITIS	REJECTED ENDOCARDITIS
2 major criteria 1 major and ≥ 3 minor criteria 5 minor criteria	1 major and 1–2 minor criteria 3–4 minor criteria	0 major and 1–2 minor criteria 1 major and 0 minor criteria
MAJOR CRITERIA		
<p>A. Supportive Laboratory Evidence Typical microorganism for infective endocarditis from two separate blood cultures: <i>Viridans streptococci</i>, <i>Staphylococcus aureus</i>, <i>Streptococcus bovis</i> HACEK group (<i>Haemophilus</i> spp., <i>Actinobacillus actinomycetemcomitans</i>, <i>Cardiobacterium hominis</i>, <i>Eikenella</i> spp., and <i>Kingella kingae</i>) or community-acquired enterococci, in the absence of a primary focus Single positive blood culture for <i>Coxiella burnetii</i> or phase I antibody titer $>1:800$</p> <p>B. Evidence of Endocardial Involvement Echocardiogram supportive of infective endocarditis Definition of positive findings: oscillating intracardiac mass, on valve or supporting structures, or in the path of regurgitant jets, or on implanted material, in the absence of an alternative anatomic explanation or myocardial abscess or new partial dehiscence of prosthetic valve New valvular regurgitation (increase or change in pre-existing murmur not sufficient)</p>		
MINOR CRITERIA		
<p>A. Predisposing heart condition or intravenous drug use B. Fever $\geq 38^{\circ}\text{C}$ (100.4°F) C. Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhage, Janeway lesions D. Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor E. Positive blood culture not meeting major criterion as noted previously (excluding single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis) or serologic evidence of active infection with organism consistent with infective endocarditis</p>		

From El-Dalati S, Cronin D, Shea M, et al *Clinical practice update on infectious endocarditis*. Am J Med. 2020;133:44-49 (table 1).

COMPLICATIONS AND PROGNOSIS

The major complications of IE are direct damage to cardiac tissue and function and distant complications secondary to **septic emboli** from vegetations. Damage to cardiac valves may cause regurgitation, defects in valve leaflets, abscess of the valve ring, or myocardial abscess. Cardiac function can decline, resulting in heart failure. These complications should be monitored by physical examination and echocardiography. Septic emboli can result in pneumonia, osteomyelitis, and abscesses in the brain, kidneys, and spleen.

The prognosis of IE varies depending on causative organism and underlying cardiac condition. Cardiovascular infections with gram-negative bacilli and fungi have the poorest prognosis.

PREVENTION

Good oral hygiene should be emphasized in all patients at risk for IE. In certain high-risk patients (unrepaired cyanotic heart disease, previous IE, prosthetic cardiac valve, repaired

TABLE 111.3 2015 American Heart Association Recommendation for Surgical Management of Left-Sided Native Valve Endocarditis	
<ol style="list-style-type: none"> 1. Early surgery (during initial hospitalization and before completion of a full course of antibiotics) is indicated in patients with IE who present with valve dysfunction resulting in symptoms or signs of heart failure. 2. Early surgery should be considered particularly in patients with IE caused by fungal or highly resistant organisms (e.g., vancomycin-resistant <i>Enterococcus</i>, multidrug-resistant gram-negative bacilli). 3. Early surgery is indicated in patients with IE complicated by heart block, annular or aortic abscess, or destructive penetrating lesions. 4. Early surgery is indicated for evidence of persistent infection (manifested by persistent bacteremia or fever lasting >5–7 days and provided that other sites of infection and fever have been excluded) after the start of appropriate antimicrobial therapy. 5. Early surgery is reasonable in patients who present with recurrent emboli and persistent or enlarging vegetations despite appropriate antibiotic therapy. 6. Early surgery is reasonable in patients with severe valve regurgitation and mobile vegetations >10 mm. 7. Early surgery may be considered in patients with mobile vegetations >10 mm, particularly when involving the anterior leaflet of the mitral valve and associated with other relative indications for surgery. 	

IE, Infective endocarditis.

congenital heart disease with residual defects, cardiac transplantation), prophylactic antibiotics may be considered before certain dental and other invasive procedures of the respiratory tract and/or infected skin or muscle.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 112

Acute Gastroenteritis

ETIOLOGY AND EPIDEMIOLOGY

Acute gastroenteritis refers to a clinical syndrome of diarrhea (more than three stool episodes in 24 hours) with or without vomiting that usually lasts for several days. In general, diarrhea is caused by a variety of infectious or inflammatory processes in the intestine that directly affect enterocyte secretory and absorptive functions. Gastroenteritis or enteritis has many infectious causes, including viruses, bacteria, and parasites (Table 112.1). Based on pathogenesis, diarrhea can be classified as invasive or inflammatory, or it can be classified as secretory, producing either bloody stools with abdominal cramping and fever or large quantities of watery stool without other symptoms (Table 112.2).

Infectious diarrhea is a leading cause of morbidity and mortality in children around the world. Rates of disease and death vary with age and access to health care, clean water,

TABLE 112.1 Common Pathogenic Organisms Causing Diarrhea and Their Virulence Mechanisms	
ORGANISMS	PATHOGENIC MECHANISM(S)
VIRUSES	
Rotaviruses	Damage to microvilli
Caliciviruses (noroviruses)	Mucosal lesion
Astroviruses	Mucosal lesion
Enteric adenoviruses (serotypes 40 and 41)	Mucosal lesion
BACTERIA	
<i>Campylobacter jejuni</i>	Invasion, enterotoxin
<i>Clostridium difficile</i>	Cytotoxin, enterotoxin
<i>Escherichia coli</i>	
Enteropathogenic (EPEC)	Adherence, effacement
Enterotoxigenic (ETEC) (traveler's diarrhea)	Enterotoxins (heat stable or heat labile)
Enteroinvasive (EIEC)	Invasion of mucosa
Enterohemorrhagic (EHEC) (includes O157:H7 causing HUS)	Adherence, effacement, cytotoxin
Enterococcal (EAEC)	Adherence, mucosal damage
<i>Salmonella</i>	Invasion, enterotoxin
<i>Shigella</i>	Invasion, enterotoxin, cytotoxin
<i>Vibrio cholerae</i>	Enterotoxin
<i>Vibrio parahaemolyticus</i>	Invasion, cytotoxin
<i>Yersinia enterocolitica</i>	Invasion, enterotoxin
PARASITES	
<i>Entamoeba histolytica</i>	Invasion, enzyme and cytotoxin production; cyst resistant to physical destruction
<i>Giardia lamblia</i>	Adheres to mucosa; cyst resistant to physical destruction
Spore-forming intestinal protozoa	Adherence, inflammation
<i>Cryptosporidium parvum</i>	
<i>Isospora belli</i>	
<i>Cyclospora cayatanensis</i>	
Microsporidia (<i>Enterocytozoon bieneusi</i> , <i>Encephalitozoon intestinalis</i>)	

HUS, Hemolytic uremic syndrome.

and sanitation. Gastrointestinal infections are generally acquired via fecal-oral transmission or through ingestion of contaminated food or water. The patient's immune status and environmental exposures (i.e., food, water, travel, antibiotics, child care) help guide the differential diagnosis in the presence of acute gastrointestinal symptoms. Traveler's diarrhea occurs frequently, especially within the first 1–2 weeks of arrival to endemic areas. Epidemiology varies with destination, but in

general children are at risk for the same illnesses that affect adult travelers.

Viral gastroenteritis is the most common cause of diarrhea in children globally. These illnesses may be associated with vomiting as well as diarrhea, have incubation periods of hours to days, and are usually self-limited illnesses lasting 3–7 days. **Rotavirus** is the most frequent cause of diarrhea in young children during the winter months. Primary infection with rotavirus may cause moderate to severe disease in infancy but is less severe later in life. Globally, the rotavirus vaccine has resulted in significant reductions in the incidence of acute gastroenteritis and hospitalizations due to rotavirus. **Norovirus** occurs in people of all ages, year-round, and is the most common cause of outbreaks of acute gastroenteritis because it is highly contagious. Other viral causes of acute gastroenteritis include astroviruses, sapovirus, and enteric adenoviruses (serotypes 40 and 41).

Food-borne and water-borne diseases are important causes of acute gastroenteritis both for individual and public health reasons. In the United States, common bacterial food-borne causes include nontyphoidal *Salmonella*, *Campylobacter*, *Shigella*, *Escherichia coli* O157:H7, *Yersinia*, and *Listeria monocytogenes*. Food-borne diarrhea can also result from ingestion of preformed enterotoxins produced by bacteria, such as *Staphylococcus aureus* and *Bacillus cereus*, which multiply in contaminated foods, and nonbacterial toxins such as from fish, shellfish, and mushrooms. After a short incubation period, vomiting and cramps are prominent symptoms, and diarrhea may or may not be present. Heavy metals that leach into canned food or drinks causing gastric irritation and emetic syndromes may mimic symptoms of acute infectious enteritis.

Nontyphoidal Salmonella produces diarrhea by invading the intestinal mucosa. The organisms are transmitted through contact with infected animals (chickens, iguanas, other reptiles, turtles) or from contaminated food products, such as dairy products, eggs, and poultry. A large inoculum of organisms is required for disease because *Salmonella* is killed by gastric acidity. The incubation period for gastroenteritis ranges from 6–72 hours but is usually less than 24 hours.

Shigella dysenteriae may cause disease by producing **Shiga toxin**. The incubation period is 1–7 days. Infected adults may shed organisms for up to 1 month. Infection is spread by person-to-person contact or by the ingestion of contaminated food with 10–100 organisms. The colon is selectively affected. High fever and febrile seizures may occur in addition to diarrhea.

Only certain strains of *E. coli* produce diarrhea. Strains associated with enteritis are classified by the mechanism of diarrhea. Enterotoxigenic (ETEC) strains produce **heat-labile (cholera-like)** and/or **heat-stable enterotoxin** and adhere to the epithelial cells in the small intestine and produce disease by liberating toxins that induce intestinal secretion and limit absorption. ETEC is a frequent cause of **traveler's diarrhea**. Enterohemorrhagic (EHEC) or Shiga toxin-producing (STEC) strains, especially the *E. coli* O157:H7 strain, produce a **Shiga-like toxin** that is responsible for a hemorrhagic colitis and most cases of diarrhea associated with **hemolytic uremic syndrome (HUS)**, which presents with microangiopathic hemolytic anemia, thrombocytopenia, and renal failure (see Chapter 164). STEC is associated with contaminated food, including unpasteurized fruit juices and especially undercooked beef, and can present with

TABLE 112.2 Mechanisms of Infectious Diarrhea

PRIMARY MECHANISM	DEFECT	STOOL EXAMINATION	EXAMPLES	COMMENTS
Secretory	Decreased absorption, increased secretion: electrolyte transport	Watery, normal osmolality	Cholera, toxigenic <i>Escherichia coli</i> (EPEC, ETEC); carcinoid, <i>Clostridium difficile</i> , cryptosporidiosis (in AIDS)	Persists during fasting; bile salt malabsorption also may increase intestinal water secretion; no stool leukocytes
Mucosal invasion	Inflammation, decreased mucosal surface area and/or colonic reabsorption, increased motility	Blood and increased WBCs in stool	Celiac disease, <i>Salmonella</i> infection, shigellosis, amebiasis, yersiniosis, <i>Campylobacter</i> infection	Dysentery (blood, mucus, and WBCs)

WBCs, White blood cells; infection may also contribute to increased motility.

Adapted from Maqbool A, Liacouras CA. Major symptoms and signs of digestive tract disorders. In: Kliegman RM, St Geme III JW, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia: Elsevier; 2020 (table 332.10).

nonbloody diarrhea that then becomes bloody. Enteroinvasive *E. coli* (EIEC) invades the colonic mucosa, producing widespread mucosal damage with acute inflammation similar to *Shigella*. EIEC diarrhea is usually watery and is often associated with fever. Enteropathogenic (EPEC) strains cause mild watery diarrhea but can cause severe dehydration in young children in resource-poor countries in sporadic or epidemic patterns.

Campylobacter jejuni is spread by person-to-person contact and by contaminated water and food, especially poultry, raw milk, and cheese. The organism invades the mucosa of the jejunum, ileum, and colon. *Yersinia enterocolitica* is transmitted by pets and contaminated food, especially chitterlings. Infants and young children characteristically have a diarrheal disease, whereas older children usually have acute lesions of the terminal ileum or acute mesenteric lymphadenitis mimicking appendicitis or Crohn disease. Postinfectious arthritis, rash, and spondylopathy may develop.

Clostridium difficile causes diarrhea and/or colitis and is usually associated with prior antibiotic exposure. The organism produces spores that spread from person to person and also as fomites on surfaces. Infection is generally hospital acquired, but community acquisition of infection is increasingly reported. Diagnosis is made by detection of toxin in the stool. Infants younger than 12 months should not be tested for *C. difficile* as they are frequently asymptotically colonized with the organism in their stool, possibly due to a lack of the receptor required for infection. Of note, patients on antibiotics often experience diarrhea related to alterations in their intestinal flora that are unrelated to *C. difficile* infection.

Important enteric parasites found in North America include *Giardia lamblia*, *Cryptosporidium parvum*, and *Entamoeba histolytica* (amebiasis). **Amebiasis** occurs in warmer climates, whereas giardiasis is endemic throughout the United States and is common among infants in daycare centers. *G. lamblia* is transmitted through ingestion of cysts, either from contact with an infected individual or from food or water contaminated with infected feces. The organism adheres to the microvilli of the duodenal and jejunal epithelium. Insidious onset of progressive anorexia, nausea, gaseousness, abdominal distention, watery diarrhea, secondary lactose intolerance, and weight loss is characteristic of giardiasis. *Cryptosporidium* causes mild, watery diarrhea in immunocompetent persons that resolves without treatment.

It can produce severe, prolonged diarrhea in persons with AIDS (see Chapter 125). *E. histolytica* infects the colon; amebae may pass through the bowel wall and invade the liver, lung, and brain. Diarrhea is of acute onset, is bloody, and contains leukocytes.

CLINICAL MANIFESTATIONS

Gastroenteritis may be accompanied by systemic findings, such as fever, lethargy, myalgias, and abdominal pain. **Viral diarrhea** is characterized by watery stools with no blood or mucus. Vomiting may be present, and dehydration may be prominent, especially in infants and younger children. Fever, when present, is low grade.

Dysentery is enteritis involving the colon and rectum, with blood and mucus, possibly foul-smelling stools, and fever. *Shigella* is the prototypical cause of dysentery, which must be differentiated from infection with EIEC, EHEC, *E. histolytica* (**amebic dysentery**), *C. jejuni*, *Y. enterocolitica*, and nontyphoidal *Salmonella*. Gastrointestinal bleeding and blood loss may be significant.

A chief consideration in the management of a child with diarrhea is assessing the degree of dehydration as evident from clinical signs and symptoms, ongoing losses, and daily requirements (see Chapter 33). The degree of dehydration dictates the urgency of the situation and the volume of fluid needed for rehydration. Mild to moderate dehydration can usually be treated with oral rehydration; severe dehydration usually requires intravenous rehydration and may even require admission to an intensive care unit.

LABORATORY AND IMAGING STUDIES

Initial laboratory evaluation of moderate to severe diarrhea includes electrolytes, blood urea nitrogen, creatinine, and urinalysis for specific gravity as an indicator of hydration. Stool specimens can be examined for mucus, blood, and leukocytes, which indicate colitis in response to bacteria that diffusely invade the colonic mucosa. Patients infected with Shiga toxin-producing *E. coli* and *E. histolytica* generally have minimal fecal leukocytes.

Polymerase chain reaction (PCR)—also called the nucleic acid amplification test (NAAT)—assays may be used

if the diagnosis will alter management. Multiplex PCR panels for gastroenteritis have replaced bacterial stool cultures. Stool evaluation for parasitic agents should be considered for acute dysenteric illness, especially in travelers returning from endemic areas, and in protracted cases of diarrhea in which no bacterial agent is identified. The diagnosis of *E. histolytica* is based on identification of the organism in the stool. Serologic tests are useful for diagnosis of extraintestinal amebiasis, including amebic hepatic abscess. Giardiasis can be diagnosed by identifying trophozoites or cysts in stool, but this may require three specimens. More specific and sensitive fecal immunoassays and NAATs are the diagnostic tests of choice.

Positive blood cultures are uncommon with bacterial enteritis except for *Salmonella* and *E. coli* enteritis in very young infants. In typhoid fever, blood cultures are more likely to be positive than stool cultures.

DIFFERENTIAL DIAGNOSIS

Diarrhea can be caused by infection, toxins, gastrointestinal allergy (including allergy to milk or soy proteins), malabsorption defects, inflammatory bowel disease, celiac disease, or any injury to enterocytes. Acute enteritis may mimic other diseases, such as intussusception and acute appendicitis, which are best identified by diagnostic imaging. Many noninfectious causes of diarrhea produce chronic diarrhea, with persistence for more than 14 days. Persistent or chronic symptoms may require tests for malabsorption or invasive studies, including endoscopy and small bowel biopsy.

TREATMENT

Most infectious causes of diarrhea in children are self-limited. Antibiotics are not generally useful and may be a risk factor in the development of HUS when *E. coli* O157:H7 is present. Management of viral and most bacterial causes of diarrhea is primarily supportive and consists of correcting dehydration and ongoing fluid and electrolyte deficits.

Hyponatremia is common; hypernatremia is less common. Metabolic acidosis results from losses of bicarbonate in stool, lactic acidosis results from shock, and phosphate retention results from transient prerenal-renal insufficiency. Therapy for severe fluid and electrolyte losses involves intravenous hydration. Less severe degrees of dehydration (<10%) in the absence of excessive vomiting or shock may be managed with oral rehydration solutions containing glucose and electrolytes. *Ondansetron* may be administered to reduce emesis when this is persistent.

Antibiotic therapy may be necessary for high-risk patients or those with severe disease or bacteremia. Antibiotic treatment of *Shigella* may reduce the duration of symptoms and decrease transmission of infection. Azithromycin is first-line oral therapy for children; ciprofloxacin and third-generation cephalosporins may also be used. Many *Shigella sonnei* isolates, the predominant strain affecting children, are resistant to amoxicillin and trimethoprim-sulfamethoxazole. Fluoroquinolone resistance in *Salmonella* and many other gram-negative organisms is increasing in many parts of the world. *Salmonella* is treated with antibiotics in children less than 3 months of age due to risk of bacteremia and extraintestinal infection.

Treatment of traveler's diarrhea is generally supportive, although antibiotics can be indicated in instances of bloody

diarrhea or a febrile illness, in which case azithromycin is a recommended choice for children. Due to lack of consistent access to health care in many areas, providing a prescription to a family in advance of travel to a high-risk area such as in Asia, Africa, or South America may be considered.

Treatment of *C. difficile* (pseudomembranous colitis) includes discontinuation of the inciting antibiotic and administration of oral metronidazole, fidaxomicin, or vancomycin. *E. histolytica* dysentery is treated with metronidazole followed by a luminal agent, such as iodoquinol. The treatment of *G. lamblia* is metronidazole, tinidazole, or nitazoxanide.

COMPLICATIONS AND PROGNOSIS

The major complication of gastroenteritis is dehydration and hypovolemic shock. Seizures may occur with high fever, especially with *Shigella*. Intestinal abscesses can form with *Shigella*, *Yersinia*, and *Salmonella* infections, leading to intestinal perforation, a life-threatening complication. Severe vomiting associated with gastroenteritis can cause esophageal tears or aspiration pneumonia.

Deaths resulting from diarrhea reflect the principal problem of disruption of fluid and electrolyte homeostasis, which can lead to dehydration, electrolyte imbalance, hemodynamic instability, and shock. Diarrheal diseases cause approximately 10% of childhood deaths worldwide.

PREVENTION

The most important means of preventing childhood diarrhea is the provision of clean, uncontaminated water and proper hygiene in growing, collecting, and preparing foods. Good hygienic measures, especially appropriate handwashing with soap and water, are the best means of controlling person-to-person spread of most organisms causing gastroenteritis. Poultry products should be considered potentially contaminated with *Salmonella* and should be handled and cooked appropriately. Families should also be aware of the risk of acquiring salmonellosis from household reptile pets and should practice thorough handwashing after handling the animals or their cages. Children under 5 years of age and immunocompromised persons should avoid contact with reptiles.

Immunization against rotavirus infection is recommended for all children beginning at 6 weeks of age, with the first dose by 15 weeks and the last dose by 8 months of age (see Chapter 94). Two typhoid vaccines are licensed in the United States: an oral live-attenuated vaccine (Ty21a) for children 6 years of age and older and a capsular polysaccharide vaccine (ViCPS) for intramuscular administration for children 2 years of age and older. These are recommended for travelers to endemic areas of developing countries or for household contacts of *S. typhi* chronic carriers.

The risk for traveler's diarrhea, caused primarily by ETEC, may be minimized by avoiding uncooked food and untreated drinking water. Symptomatic self-treatment for mild diarrhea with an **oral rehydration solution** is recommended, while self-treatment of moderate diarrhea and fever with azithromycin can be considered for children. Prompt medical evaluation is indicated for disease persisting more than 3 days, bloody stools, fever above 102°F (38.9°C) or chills, persistent vomiting, or moderate to severe dehydration.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 113

Viral Hepatitis

ETIOLOGY

Acute hepatitis, or liver inflammation, can be the result of a number of infectious and noninfectious etiologies. Among infectious causes of hepatitis, viruses play an important role. The six primary hepatotropic viruses, hepatitis A to G, differ in their virologic characteristics, transmission, severity, likelihood of persistence, and subsequent risk of causing hepatocellular carcinoma (Table 113.1). The cause of 10–15% of cases of acute hepatitis is unknown.

EPIDEMIOLOGY

Hepatitis A virus (HAV) is the most common cause of acute viral hepatitis and is spread by fecal-oral transmission. HAV

is common in children globally, especially in areas of poor sanitation. Among U.S. children, infection due to HAV was often associated with childcare settings; however, rates have decreased since the introduction of routine vaccination. Hepatitis B virus (HBV), hepatitis C virus (HCV), and hepatitis D virus (HDV) infections can result in chronic hepatitis, or a chronic carrier state, which facilitates spread. HDV, also known as the **delta agent**, is a defective virus that requires HBV for spread and causes either coinfection with HBV or superinfection in chronic carriers of hepatitis B surface antigen (HBsAg). Routine vaccination has also been effective in reducing the rates of HBV infection, especially in children.

The major risk factors for HBV and HCV are injectable drug use, frequent exposure to blood products, unprotected sexual exposure, and perinatal transmission from maternal infection. Hepatitis E virus (HEV) infection occurs following travel to endemic areas (South Asia) outside of the United States. Hepatitis G virus (HGV) is prevalent in HIV-infected persons. HBV and HCV cause chronic infection, which may lead to cirrhosis and hepatocellular carcinoma and represents a persistent risk of transmission.

CLINICAL MANIFESTATIONS

Asymptomatic or mild, nonspecific illness without icterus is common with HAV, HBV, and HCV, especially in young

TABLE 113.1 Characteristics of Agents Causing Acute Viral Hepatitis

FEATURE	HAV	HBV	HCV	HDV	HEV	HGV

dsDNA, Double-stranded DNA; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; HGV, hepatitis G virus; PCR, polymerase chain reaction; RIBA, recombinant immunoblot assay; RT-PCR, reverse transcriptase–polymerase chain reaction; ssDNA/ssRNA, single-stranded DNA/RNA; TTV, transfusion-transmitted virus.

children. When present, symptoms of acute infection include malaise, nausea, vomiting and diarrhea, followed by jaundice, and are difficult to distinguish between these viruses. Fulminant HAV infection is rare, and chronic infection does not occur. In acute HBV infection the likelihood of symptoms increases with age, ranging from 1% of infants younger than 12 months to 30–50% of people older than 5 years. In HBV infection, the **preicteric phase**, which lasts approximately 1 week, is characterized by headache, anorexia, malaise, abdominal discomfort, nausea, and vomiting; it usually precedes the onset of clinically detectable disease. Extrahepatic manifestations such as arthralgia, arthritis, rash, thrombocytopenia, glomerulonephritis, or papular acrodermatitis (**Gianotti-Crosti syndrome**) can occur early in the illness. Jaundice and tender hepatomegaly occur later and characterize the **icteric phase**. Prodromal symptoms, particularly in children, may abate during the icteric phase. Hepatic enzymes may increase 15- to 20-fold. Resolution of the hyperbilirubinemia and normalization of the transaminases may take 6–8 weeks.

LABORATORY AND IMAGING STUDIES

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels are elevated and generally reflect the degree of parenchymal inflammation. Alkaline phosphatase and total and direct (conjugated) bilirubin levels indicate the degree of cholestasis, which results from hepatocellular and bile duct damage. The prothrombin time is a good predictor of severe hepatocellular injury and progression to fulminant hepatic failure (see [Chapter 130](#)).

The diagnosis of viral hepatitis is confirmed by serologic testing (see [Table 113.1](#); [Fig. 113.1](#)). The presence of immunoglobulin M (IgM)-specific antibody to HAV with low or absent IgG antibody is presumptive evidence of acute HAV infection.

The presence of HBsAg signifies acute or chronic infection with HBV. Antigenemia appears early in the illness and is usually transient but is characteristic of chronic infection. Maternal HBsAg status should always be determined when HBV infection is diagnosed in children younger than 1 year of age because of the likelihood of vertical transmission. Hepatitis B early antigen (HBeAg) appears in the serum with acute HBV. The continued presence of HBsAg and HBeAg in the absence of antibody to e antigen (anti-HBe) indicates high risk of transmissibility that is associated with ongoing viral replication. Clearance of HBsAg from the serum precedes a variable **window period**, followed by the emergence of the antibody to surface antigen (anti-HBs), which indicates development of lifelong immunity and is also a marker of immunization. Antibody to core antigen (anti-HBc) is a useful marker for recognizing HBV infection during the window phase (when HBsAg has disappeared but before the appearance of anti-HBs). Anti-HBe is useful in predicting a low degree of infectivity during the carrier state.

Seroconversion after HCV infection may occur 6 months after infection. A positive result of HCV enzyme-linked immunosorbent assay (ELISA) should be confirmed with the more specific recombinant immunoblot assay, which detects antibodies to multiple HCV antigens. Detection of HCV RNA by polymerase chain reaction (PCR) is a sensitive marker for active infection, and results may be positive just 3 days after inoculation.

FIGURE 113.1 Clinical course and laboratory findings associated with hepatitis A, hepatitis B, and hepatitis C. ALT, Alanine aminotransferase; HAV, hepatitis A virus; anti-HB_c, antibody to hepatitis B core antigen; HBeAg, hepatitis B early antigen; anti-HBe, antibody to hepatitis B early antigen; HBsAg, hepatitis B surface antigen; anti-HBs, antibody to hepatitis B surface antigen; HCV, hepatitis C virus; PCR, polymerase chain reaction.

DIFFERENTIAL DIAGNOSIS

Many other viruses may cause hepatitis as a component of systemic infection, including Epstein-Barr virus, cytomegalovirus, varicella-zoster virus, herpes simplex virus, parvovirus, and adenoviruses. Bacterial sepsis can also cause hepatic inflammation and dysfunction. Patients with cholecystitis, cholangitis, and choledocholithiasis may present with acute symptoms and jaundice. Other causes of acute liver disease in childhood include drugs (isoniazid, phenytoin, valproic acid, carbamazepine, oral contraceptives, acetaminophen), parenteral nutrition, toxins (ethanol, poisonous mushroom), Wilson disease, metabolic disease (galactosemia, tyrosinemia, mitochondrial disorders), α_1 -antitrypsin deficiency, tumor, shock, anoxia, autoimmune hepatitis, hemophagocytic syndromes, and graft-versus-host disease (see [Chapter 130](#)).

TREATMENT

The treatment of acute hepatitis is largely supportive and involves rest, hydration, and adequate nutrition. Hospitalization is indicated for children with severe vomiting and dehydration, a prolonged prothrombin time, or signs of hepatic encephalopathy. When the diagnosis of viral hepatitis is established, attention should be directed toward preventing its spread to close contacts. For HAV, hygienic measures include hand-washing and careful disposal of excreta, contaminated diapers or clothing, needles, and other blood-contaminated items.

The treatment of chronic HBV and HCV infections includes the use of direct-acting antivirals; nucleotide and nucleoside analogues (HBV), or protease and polymerase inhibitors (HCV). The decision to treat is based on the patient's age, viral genotype, and stage of viral infection.

COMPLICATIONS AND PROGNOSIS

Most cases of acute viral hepatitis resolve without specific therapy, with less than 0.1% of cases progressing to fulminant hepatic necrosis. HAV and HEV cause acute infection only. HBV, HCV, and HDV may persist as chronic infection, with chronic inflammation, fibrosis, and cirrhosis and the associated risk of hepatocellular carcinoma.

From 5–10% of adults with HBV develop persistent infection, defined by persistence of HBsAg in the blood for more than 6 months, compared with 90% of children who acquire HBV by perinatal transmission. Chronic HBsAg carriers are usually HBeAg negative and have no clinical, biochemical, or serologic evidence of active hepatitis unless there is superinfection with HDV. Approximately 10–15% of HBsAg carriers eventually clear HBsAg.

Approximately 85% of persons infected with HCV remain chronically infected, which is characterized by fluctuating transaminase levels (see [Fig. 113.1](#)). There is poor correlation of symptoms with ongoing liver damage. Approximately 20% of persons with chronic infection develop cirrhosis, and approximately 25% of those develop hepatocellular carcinoma. HIV infection and ethanol use increase the risk of HCV progression.

PREVENTION

Good hygienic practices significantly reduce the risk of fecal-oral transmission of HAV. HAV vaccine is recommended for

routine immunization of all children beginning at 12 months. Unvaccinated household and sexual contacts of persons with HAV should receive postexposure prophylaxis as soon as possible and within 2 weeks of the last exposure. A single dose of HAV vaccine at the age-appropriate dose is preferred for persons 12 months to 40 years of age. Immunoglobulin (0.1 mL/kg) given intramuscularly (IGIM) is preferred for children under 12 months of age, persons over 40 years of age, and immunocompromised persons. For pre-exposure prophylaxis, unvaccinated travelers to endemic regions who are 12 months of age or older should receive a single dose of HAV vaccine administered at any time before departure. Older adults, immunocompromised people, or those with chronic liver disease or other chronic medical conditions who are traveling to an endemic area in less than 2 weeks time should receive IGIM along with the HAV vaccine dose to optimize protection. Infants younger than 12 months traveling to an endemic area should also receive IGIM as they are too young to receive the HAV vaccine.

HBV vaccine is recommended for routine immunization of all infants beginning at birth and for all children and adolescents through 18 years of age who have not been immunized previously (see [Fig. 94.1](#)). It is also recommended as a pre-exposure vaccination for older children and adults at increased risk of sexual, percutaneous, or mucosal exposure to HBV as well as those with chronic liver disease, HIV, and travelers to areas of endemic HBV infection. Routine prenatal screening for HBsAg is recommended for all pregnant women in the United States. Infants born to HBsAg-positive mothers should receive HBV vaccine and hepatitis B immunoglobulin (HBIG; 0.5 mL) within 12 hours of birth, with subsequent vaccine doses at 1 and 6 months of age followed by testing for HBsAg and anti-HBs at 9–15 months of age. Infants born to mothers whose HBsAg status is unknown should receive vaccine within 12 hours of birth. If maternal testing is positive for HBsAg, the infant should receive HBIG as soon as possible (no later than 1 week of age). The combination of HBIG and vaccination is 99% effective in preventing vertical transmission of HBV. Vaccination alone without HBIG may prevent 75% of cases of perinatal HBV transmission and approximately 95% of cases of symptomatic childhood HBV infection.

Postexposure prophylaxis of unvaccinated persons using HBIG and vaccine is recommended following needle-stick injuries with blood from an HBsAg-positive patient and for sexual or needle-sharing contacts or victims of sexual abuse by an HBsAg-positive person. The screening of blood donors significantly reduces the risk of blood-borne transmission.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 114

Urinary Tract Infection

ETIOLOGY

Urinary tract infections (UTIs) include **cystitis** (infection localized to the bladder), **pyelonephritis** (infection of

the renal parenchyma, calyces, and renal pelvis), and **renal abscess**, which may be intrarenal or perinephric. The urinary tract and urine are normally sterile. *Escherichia coli*, ascending from bowel (perineum) flora, accounts for 85% of first infections. Other bacteria commonly causing infection include *Klebsiella*, *Proteus*, *Enterococcus*, *Pseudomonas*, and *Enterobacter*. *Staphylococcus saprophyticus* is associated with UTI in some children and accounts for 15% or more of UTIs in adolescent girls. *Staphylococcus aureus* is an uncommon cause of UTI and usually represents bacteremic seeding of the urinary tract.

EPIDEMIOLOGY

Approximately 3% of girls and 1% of boys have a UTI during their prepubertal years with the highest incidence in the first year of life. It is only during the first year of life that the incidence of UTIs in males exceeds that in females; during this period uncircumcised boys are at 10-fold greater risk of developing a UTI compared to circumcised boys. After 12 months of age, UTI in healthy children usually is seen in girls.

A short urethra predisposes girls to UTIs. Obstruction to urine flow and urinary stasis is the major risk factor and may result from anatomic abnormalities, nephrolithiasis, renal tumor, indwelling urinary catheter, ureteropelvic junction obstruction, megaureter, extrinsic compression, and pregnancy. Severe vesicoureteral reflux, whether primary or secondary to urinary tract obstruction, predisposes to chronic infection and renal scarring. Scarring may also develop in the absence of reflux. Constipation or withholding urine also increases the risk of UTI.

CLINICAL MANIFESTATIONS

The symptoms and signs of UTI vary markedly with age. Few have high positive predictive value in neonates, with failure to thrive, feeding problems, and fever as the most consistent symptoms. Infants 1 month to 2 years of age may present with feeding problems, failure to thrive, diarrhea, vomiting, or unexplained fever. The symptoms may masquerade as gastrointestinal illness, with colic, irritability, and crying periods. At 2 years of age, children begin to show the classic signs of UTI, such as urgency, dysuria, frequency, and abdominal or back pain. *The presence of UTI should be suspected in all infants and young children with unexplained fever and in patients of all ages with fever and congenital anomalies of the urinary tract.*

LABORATORY AND IMAGING STUDIES

The diagnosis of UTI in infants and young children requires the presence of both pyuria and at least 50,000 CFU/mL of a single pathogenic organism. For older children and adolescents, more than 100,000 CFU/mL indicates infection. It is appropriate to obtain urine cultures by midstream, clean-catch technique for older children and adolescents, whereas transurethral catheterization or suprapubic bladder aspiration is the appropriate method for younger children and infants. Perineal bags for urine collection are prone to contamination and are not recommended for urine collection for culture.

If there is uncertainty about diagnosis of UTI in a younger child or infant, urine can be collected by the most convenient method for urinalysis, and if suggestive of infection, collect urine by catheterization prior to starting antibiotics.

Urinalysis showing **pyuria** (leukocyturia of >10 white blood cells [WBCs]/mm³) suggests infection but is also consistent with urethritis, vaginitis, nephrolithiasis, glomerulonephritis, and interstitial nephritis. Other urinalysis findings suggestive of infection include any bacteria per high-powered field in the unstained uncentrifuged urinary sediment, positive urinary leukocyte esterase test, and positive urinary nitrite test. Combined testing for leukocyte esterase, nitrite, and microscopic bacteria has almost 100% sensitivity for detecting UTI by positivity of one or more of the three tests. The negative predictive value of a urinalysis is about 100% if all three tests are negative and may obviate the need for culture except in neonates, where urinalysis results are less reliable predictors of infection.

Ultrasonography of the bladder and kidneys is recommended for infants and non-toilet-trained children with first-time febrile UTIs to exclude structural abnormalities or detect hydronephrosis. Voiding cystourethrogram (VCUG) is indicated if the ultrasound is abnormal (hydronephrosis, scarring, or other findings suggesting obstruction or congenital abnormality). Vesicoureteral reflux is the most common abnormality found and is ranked from grade I (ureter only) to grade V (complete gross dilation of the ureter and obliteration of caliceal and pelvic anatomy) (see [Chapter 167](#)). A technetium-99m dimercaptosuccinic acid (DMSA) scan can identify acute pyelonephritis and is most useful to define renal scarring as a late effect of UTI.

DIFFERENTIAL DIAGNOSIS

The diagnosis of a UTI is confirmed by a positive urine culture, but this does not distinguish between upper and lower tract infection. Localization of a UTI is important because pyelonephritis is associated more frequently with bacteremia and anatomic abnormalities than is uncomplicated cystitis. The clinical manifestations of UTI do not reliably distinguish the site of infection in neonates, infants, and toddlers. Fever and abdominal pain may occur with either lower or upper UTI, although high fever, vomiting, costovertebral tenderness, leukocytosis on complete blood count (CBC), and bacteremia each suggest upper tract involvement.

The manifestations of UTI overlap with signs of sepsis seen in young children and with enteritis, appendicitis, mesenteric lymphadenitis, and pneumonia in older children. Dysuria may indicate pinworm infection, hypersensitivity to soaps or detergents, vaginitis, or sexual abuse and infection.

TREATMENT

Therapy should be initiated for symptomatic children and for all children with a urine culture confirming UTI. For infants and children who do not appear ill but have a positive urine culture, oral antibiotic therapy should be initiated. For all young infants and any child with suspected UTI who appears toxic, appears dehydrated, or is unable to retain oral fluids, initial antibiotic therapy should be administered parenterally.

Neonates with UTI are treated initially with parenteral antibiotics because UTIs in this age group are assumed to occur from hematogenous spread regardless of blood culture results. Often, if there is rapid clinical improvement and initial blood cultures are negative, patients can eventually be transitioned to enteral antibiotics to complete a 14-day total course of therapy. Older children with febrile UTI are treated for 7–14 days of enteral antibiotics or a combination of parenteral followed by enteral antibiotic therapy. Initial treatment with parenteral antibiotics in this age group is determined by clinical status. Parenteral antibiotics should be continued until there is clinical improvement (typically 24–48 hours), defined as resolution of fever and improved oral intake. Empirical antibiotic therapy should be guided by the local antimicrobial susceptibility patterns and the results of the patient's prior urine cultures because of increasing problems related to antimicrobial resistance. Definitive antibiotic therapy should be guided by the patient's urine culture results. Commonly used empirical parenteral antibiotics include cefazolin, ceftriaxone, or ampicillin plus gentamicin. Oral regimens include cephalixin, amoxicillin plus clavulanic acid, trimethoprim-sulfamethoxazole, or fluoroquinolones (older children only). Infants and children who do not show the expected clinical response within 2–3 days of starting antimicrobial therapy should be re-evaluated, have another urine specimen obtained for culture, and undergo imaging promptly to evaluate for renal abscess.

The degree of toxicity, dehydration, and ability to retain oral intake of fluids should be assessed carefully. Restoring or maintaining adequate hydration, including correction of electrolyte abnormalities that are often associated with vomiting or poor oral intake, is important.

COMPLICATIONS AND PROGNOSIS

Bacteremia occurs in approximately 5% of patients with pyelonephritis and is more likely in infants than in older children. Focal renal abscesses are an uncommon complication. Parents should be counseled to follow up for evaluation for subsequent fevers to determine the possibility of a recurrence of UTI. If a recurrent UTI is diagnosed, further imaging studies (VCUG) are indicated, if not already performed, to evaluate the possibility of vesicoureteral reflux (see [Chapter 167](#)).

PREVENTION

Primary prevention is achieved by promoting good perineal hygiene and managing underlying risk factors for UTI, such as chronic constipation, encopresis, and daytime and nighttime urinary incontinence. There is evidence that antibiotic prophylaxis may prevent more severe symptomatic recurrent infections, although the effect is small and is associated with the development of resistant organisms. The impact of secondary prophylaxis to prevent renal scarring is unknown. Acidification of the urine with cranberry juice is not recommended as the sole means of preventing UTI in children at high risk.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 115

Vulvovaginitis

ETIOLOGY

Vulvovaginitis, which is inflammation of the vulva or vagina or both, is the most common gynecologic problem in prepubertal girls. Poor hygienic practices, close proximity of the vagina to the rectum, and low levels of estrogen predispose prepubertal girls to vulvovaginal irritation. Low levels of estrogen result in thin, atrophic vaginal epithelium that is susceptible to bacterial invasion. At puberty, estrogen increases, and the pH of the vagina becomes more acidic. Vulvovaginitis can be due to non-specific and specific causes. **Nonspecific vaginitis** results from overgrowth of normal aerobic vaginal flora that is associated with poor hygiene. There are several specific causes of vulvovaginitis (Table 115.1), including sexually transmitted infections such as *Trichomonas vaginalis* and herpes simplex virus (see Chapter 116). **Bacterial vaginosis** is the most common cause of vaginitis in postpubertal females and represents disruption of the normal vaginal flora with reduction in *Lactobacillus* and overgrowth of organisms including *Gardnerella vaginalis*, *Bacteroides*, *Mobiluncus*, and *Peptostreptococcus*.

EPIDEMIOLOGY

Nonspecific vaginitis is the most common cause of vulvovaginitis in prepubertal females. *G. vaginalis* is often present as part of the normal vaginal flora in prepubertal females, and its role as a cause of vaginitis in this age group is uncommon. *Candida* is much less common in prepubertal girls than in postpubertal females.

CLINICAL MANIFESTATIONS

The primary symptoms of vulvovaginitis are vaginal discharge, erythema, foul smell, dysuria, and pruritus. Characteristics of specific etiologies are outlined in Table 115.1.

LABORATORY AND IMAGING STUDIES

Wet mount microscopic examination, prepared by mixing vaginal secretions with normal saline solution, and culture may be used to confirm a specific diagnosis (see Table 115.1). **Clue cells** are vaginal epithelial cells that are covered with *G. vaginalis* and have a granular appearance (Fig. 115.1). Vaginal cultures for *G. vaginalis* are not useful. *Candida* may be identified by KOH stain or by culture.

DIFFERENTIAL DIAGNOSIS

Noninfectious causes of vulvovaginitis include physical agents (foreign body, sand), chemical agents (bubble bath, soap, detergent), and vulvar skin disease (atopic dermatitis, seborrhea, psoriasis). Physiologic vaginal discharge or **physiologic leukorrhea** of desquamated vaginal cells and mucus occurs normally in females soon after birth, with discharge lasting about 1 week, and appears again at 6–12 months before menarche. The discharge is minimal, clear, and thin without pruritus or inflammation. No treatment is necessary.

TABLE 115.1 Characteristics of Vulvovaginitis

ETIOLOGY CONDITION/ DISORDER	PRESENTATION	DIAGNOSIS	TREATMENT
Physiologic vaginal discharge (physiologic leukorrhea)	Minimal, clear, thin discharge without pruritus or inflammation; occurs soon after birth and again at 6–12 mo before menarche	No pathogenic organisms on culture	Reassurance
Nonspecific vaginitis	Vaginal discharge, dysuria, pruritus; fecal soiling of underwear	Evidence of poor hygiene; no pathogenic organisms on culture	Improved hygiene, sitz baths 2–3 times/day
Bacterial vaginosis	Often asymptomatic; possible thin vaginal discharge with a “fishy” odor	≥3 of the following criteria: (1) thin, homogeneous vaginal discharge; (2) vaginal pH >4.5; (3) a fishy odor of volatile amines on the addition of a drop of 10% potassium hydroxide to a drop of vaginal discharge (the “whiff test”); and (4) the presence of clue cells on a saline wet mount of vaginal discharge	Metronidazole, clindamycin
Candidiasis	Pruritus, dysuria, white “cottage cheese” vaginal discharge that is usually not malodorous	<i>Candida</i> on KOH preparation of vaginal discharge	Topical antifungal (e.g., butoconazole, clotrimazole, miconazole, nystatin) Single oral dose fluconazole
Enterobiasis (pinworms)	Perineal pruritus (nocturnal); gastrointestinal symptoms; variable vulvovaginal contamination from feces; often recurrent symptoms	Adult worms in stool or eggs on perianal skin (“Scotch tape test”)	Pyrantel pamoate, mebendazole, or albendazole
Molluscum contagiosum	Vulvar lesions, nodules with central umbilication; white core of curdlike material	Clinical appearance; isolation of poxvirus	Generally self-limited; dermal curettage of umbilicated area
<i>Phthirus pubis</i> infection (pediculosis pubis)	Pruritus, excoriation, sky-blue macules; inner thigh or lower abdomen	Nits on hair shafts, lice on skin or clothing	1% permethrin
<i>Sarcoptes scabiei</i> infection (scabies)	Nocturnal pruritus, pruritic vesicles, pustules in runs	Mites; ova, black dots of feces (microscopic)	5% permethrin
<i>Shigella</i> infection	Bloody vaginal discharge; fever, malaise, fecal contamination, diarrhea; blood and mucus in stool, abdominal cramps	Stools: white blood cells and red blood cells, NAAT positive for <i>Shigella</i>	TMP-SMX, azithromycin, or oral third-generation cephalosporin
<i>Staphylococcus</i> , <i>Streptococcus</i> infection	Vaginal discharge, possibly bloody; hyperemic vulvar mucosa; spread from primary lesion	Isolation of causative organism on bacterial culture	First-generation cephalosporin or dicloxacillin; penicillin or amoxicillin for group A streptococcus infection
Foreign body	Foul-smelling vaginal discharge, sometimes bloody	Foreign body on physical examination	Removal of foreign body

KOH, Potassium hydroxide; NAAT, nucleic acid amplification test; TMP-SMX, trimethoprim-sulfamethoxazole.

TREATMENT

The treatment of vulvovaginitis depends on the etiology (see Table 115.1). Treatment of nonspecific vaginitis focuses on improving perineal hygiene. Douching or vaginal irrigation is not beneficial and is not recommended.

COMPLICATIONS AND PROGNOSIS

Complications of nonspecific vulvovaginitis are rare, and prognosis is excellent. Bacterial vaginosis is associated with birth complications such as chorioamnionitis and preterm

labor, but evidence regarding treatment of bacterial vaginosis to prevent these complications is conflicting.

PREVENTION

There are no recognized prophylactic measures for bacterial vaginosis or nonspecific vaginitis other than maintaining good perineal hygiene. Females should wear cotton underwear and limit time spent in tights, leggings, and wet swimsuits. Douching is not protective and reduces normal vaginal flora, which are protective against pathogenic organisms.

FIGURE 115.1 A film of coccobacilli covers squamous cells in a cervical cytology sample. This aspect is commonly referred to as “clue cells” and is associated with bacterial vaginosis (Papanicolaou stain, $\times 100$). (From Tambouret R. Gynecologic infections. In: Kradin RL, ed. *Diagnostic Pathology of Infectious Diseases*. Philadelphia: Elsevier; 2010.)

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 116

Sexually Transmitted Infections

Adolescents have the highest rates of sexually transmitted infections (STIs). Compared with adults, sexually active adolescents are more likely to believe they will not contract an STI, more likely to come into contact with an infected sexual partner, less likely to receive health care when an STI develops, and less likely to be compliant with treatment for an STI.

Although numerous organisms cause STIs, the diseases can be grouped by their characteristic clinical presentations. **Urethritis** and **endocervicitis** (Table 116.1) are characteristic of *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Note that 70% of new genital chlamydial infections occur in adolescents aged 15–24 years, and most infections are asymptomatic. **Genital ulcers** (Table 116.2) are characteristic of syphilis (*Treponema pallidum*), genital herpes simplex virus (HSV) infections, chancroid (*Haemophilus ducreyi*), lymphogranuloma venereum (LGV; *C. trachomatis*), and granuloma inguinale, also known as *donovanosis* (*Klebsiella granulomatis*). **Vaginal discharge** (Table 116.3) is a symptom of trichomoniasis (*Trichomonas vaginalis*) and is part of the spectrum of vulvovaginitis (see Chapter 115), which is not always associated with sexual activity. Human papillomavirus (HPV) causes **condylomata acuminata**, or **genital warts** (Table 116.4), and is the major risk factor for cervical, vulvar, and vaginal cancers.

STIs are associated with significant physiologic and psychologic morbidity. Early diagnosis and treatment are important for preventing medical complications and infertility. All STIs are preventable; primary prevention of STIs should be a

goal of all health care providers for adolescents. Diagnosis of an STI necessitates evaluation or treatment for concomitant STIs and notification and treatment of sexual partners; some STIs are reportable to state health departments.

Many infections that are not traditionally considered STIs are sexually transmissible, including those caused by HIV, human T-cell leukemia viruses types I and II, cytomegalovirus, Epstein-Barr virus, human herpes virus (HHV-6, HHV-7), hepatitis B virus, molluscum contagiosum virus, and *Sarcoptes scabiei*. The presence of any STI suggests behavior that increases risk for HIV (see Chapter 125), and HIV counseling and testing should be provided to all adolescents with STIs. Acquisition of gonorrhea, chlamydia, syphilis, genital HSV, and trichomoniasis in prepubertal children beyond the neonatal period indicates sexual contact and signifies the need to investigate for possible sexual abuse (see Chapter 22); diagnosis of STIs in infants can represent abuse or perinatal acquisition. The association of sexual abuse with vulvovaginitis and genital HPV infection, which may result from skin or genital HPV types, is less certain.

PELVIC INFLAMMATORY DISEASE

Direct extension of *N. gonorrhoeae* and/or *C. trachomatis* to the endometrium, fallopian tubes, and peritoneum causes **pelvic inflammatory disease (PID)**. Complications of PID include tubo-ovarian abscess, perihepatitis (**Fitz-Hugh-Curtis syndrome**, an inflammation of the liver capsule), and infertility. The differential diagnosis of PID includes ectopic pregnancy, septic abortion, ovarian cyst torsion or rupture, urinary tract infection, appendicitis, mesenteric lymphadenitis, and inflammatory bowel disease. Pelvic ultrasound may detect thickened adnexal structures and is the imaging study of choice to exclude other possible diagnoses. Minimum clinical criteria for diagnosis of PID are pelvic or lower abdominal tenderness with uterine, adnexal, or cervical motion tenderness. Additional criteria that support the diagnosis are fever, mucopurulent cervical discharge or cervical friability, presence of abundant numbers of white blood cells (WBCs) on saline microscopy of vaginal fluid, elevated inflammatory markers, and documented infection with *N. gonorrhoeae* or *C. trachomatis*. Adolescents should be hospitalized for treatment if there is uncertainty about the diagnosis, pregnancy, no clinical response to oral therapy within 72 hours, inability to adhere to or tolerate oral therapy, tubo-ovarian abscess, or severe illness with high fever, nausea, and vomiting. The recommended parenteral treatment for hospitalized patients is intravenous (IV) cefotetan or cefoxitin plus doxycycline (oral [PO] or IV). The recommended ambulatory treatment of PID is ceftriaxone (500 mg) in a single intramuscular (IM) dose, plus doxycycline (100 mg PO twice a day) for 14 days, with or without metronidazole (500 mg PO twice a day) for 14 days. Follow-up examination should be performed within 72 hours.

GONORRHEA (NEISSERIA GONORRHOEAE)

N. gonorrhoeae, a gram-negative coccus, is often seen microscopically as diplococci. Gonorrhea is a common STI among adolescents. The highest incidence in the United States is in 15- to 24-year-olds, and incidence rates differ by race and gender, with more cases in males than in females. The organism causes infection at the site of acquisition, which

TABLE 116.1 Features of Sexually Transmitted Infections Caused by *Chlamydia trachomatis* and *Neisseria gonorrhoeae*

FEATURE	C. TRACHOMATIS	N. GONORRHOEAE
Incubation period	7–21 days	2–7 days
Possible presentations	Conjunctivitis (including neonatal conjunctivitis), pneumonia, urethritis, cervicitis, proctitis, epididymitis, perihepatitis, lymphogranuloma venereum, reactive arthritis (arthritis, urethritis, and bilateral conjunctivitis)	Pharyngitis, conjunctivitis (including neonatal conjunctivitis), urethritis, cervicitis, proctitis, epididymitis, perihepatitis, disseminated disease (arthritis, dermatitis, endocarditis, meningitis)
SIGNS/SYMPTOMS OF COMMON SYNDROMES		
Urethritis	<i>Female</i> Dysuria, frequency >10PMNs/hpf <i>Male</i> Penile discharge >10PMNs/hpf	
Mucopurulent cervicitis	Cervical erythema, friability, with thick creamy discharge >10PMNs/hpf Mild cervical tenderness Gram-negative intracellular diplococci	Cervical edema, erythema, or friability with purulent or mucopurulent discharge >10PMNs/hpf Mild cervical tenderness Gram-negative diplococci
Pelvic inflammatory disease	Onset of symptoms within 7 days menstrual cycle Lower abdominal pain Adnexal tenderness, mass (5–50%) Pain on cervical motion (>95%) Fever (35%) Vaginal discharge (55%) Mucopurulent cervical discharge (80%) Menstrual irregularities (variable) Nausea, vomiting (variable) Weakness, syncope, dizziness (variable) Perihepatitis (5%)	
Diagnostic tests	NAAT, culture	NAAT, culture
Treatment	Ceftriaxone <i>plus</i> doxycycline or ceftriaxone <i>plus</i> doxycycline <i>plus</i> metronidazole If PID: cefotetan or cefoxitin <i>plus</i> doxycycline	

*Co-infection is common, and clinical presentations have significant overlap.

hpf, High-power field; NAAT, nucleic acid amplification test; PID, pelvic inflammatory disease; PMNs, polymorphonuclear cells.

commonly results in mucopurulent cervicitis and urethritis (see Table 116.1), but infection of the rectum and pharynx can also occur. **Disseminated gonococcal infections** can occur with hematogenous spread and results in petechial or pustular acral skin lesions, asymmetric polyarthralgia, tenosynovitis or oligoarticular septic arthritis, and, occasionally, endocarditis or meningitis. Perinatal transmission of maternal infection can lead to neonatal sepsis (see Chapter 65), meningitis (see Chapter 100), and ophthalmia neonatorum (see Chapter 119).

Gonococcal infection is diagnosed by either culture of endocervical (females) or urethral (males) swab specimens or nucleic acid amplification tests (NAATs) of endocervical swabs, vaginal swabs, urethral swabs, throat specimens, and urine. Culture should be performed in cases of possible

treatment failure to allow for antimicrobial susceptibility testing. In cases of suspected sexual abuse, culture is the preferred diagnostic method due to concerns regarding NAAT false-positive results from cross reaction with nongonococcal *Neisseria* species.

Increasing rates of resistance to fluoroquinolones limit treatment options. A single IM dose of ceftriaxone (500 mg for patients 45–150 kg and 1 g for patients >150 kg) is recommended for uncomplicated gonococcal infections of the cervix, urethra, and rectum. If chlamydial infection has not been ruled out, empirical treatment for *C. trachomatis* with doxycycline should also be given. For patients with disseminated gonococcal infections, hospitalization is warranted; gonorrhea culture and antimicrobial susceptibility testing should be performed to guide therapy in these cases.

TABLE 116.2 Features of Sexually Transmitted Infections Characterized by Genital Ulcers

	SYPHILIS	GENITAL HERPES	CHANCROID	GRANULOMA INGUINALE (DONOVANOSIS)
Agent	<i>Treponema pallidum</i>	HSV-1, HSV-2	<i>Haemophilus ducreyi</i>	<i>Klebsiella granulomatis</i>
Incubation	10–90 days	2–14 days	1–10 days	8–80 days
Systemic findings	Primary syphilis: uncommon Secondary syphilis: fever, rash, malaise, anorexia, arthralgia, lymphadenopathy	Headache, fever, malaise, myalgia (40–70%)	None	Local spread only
Inguinal lymphadenopathy	Late, bilateral, nontender, no suppuration	Early, bilateral, tender, no suppuration	Early, rapid, tender, and unilateral; suppuration likely (bubo)	Lymphatic obstruction
Primary lesion	Papule	Vesicle	Papule to pustule	Subcutaneous nodule
ULCER CHARACTERISTICS				
Number	Usually 1	Multiple	<3	>1, may coalesce
Edges	Distinct	Reddened, ragged	Sharply demarcated, serpiginous borders	Rolled, distinct
Depth	Shallow	Shallow	Shallow	Raised
Base	Red, smooth	Red, smooth	Necrotic	Beefy red, clean
Secretion	Serous	Serous	Purulent	None
Induration	Firm	None	None	Firm
Pain	None	Usual	Often	None
Diagnosis				
Serology	MHA-TP or FTA-ABS; VDRL or RPR	Seroconversion (primary infection only)	None	None
Isolation	No in vitro test; rabbit testes inoculation	Culture	Swab of ulcer on selective medium, node aspirates usually sterile	None
Microscopic	Dark-field examination	PCR or fluorescent antibody staining	Gram-negative coccobacilli	Staining of ulcer biopsy material for Donovan bodies
Treatment	<i>Early (primary, secondary and early latent):</i> benzathine penicillin G (2.4 million U IM) once	Acyclovir or famciclovir or valacyclovir	Aspirate or excise fluctuant nodes	Doxycycline or azithromycin
	<i>Late latent (>1 yr duration):</i> benzathine penicillin G (2.4 million U IM) weekly × 3 doses		Incision and drainage of buboes >5 cm Azithromycin or ceftriaxone or ciprofloxacin or erythromycin	

FTA-ABS, Fluorescent treponemal antibody–absorption; HSV, herpes simplex virus; IM, intramuscular; MHA-TP, microhemagglutination assay–*Treponema pallidum*; PCR, polymerase chain reaction; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratory.

CHLAMYDIA (*CHLAMYDIA TRACHOMATIS*)

Chlamydiae are obligate intracellular bacteria with a biphasic life cycle, existing as relatively inert elementary bodies in their extracellular form and as reticulate bodies when phagocytosed and replicating within a phagosome. Reticulate bodies divide by binary fission and, after 48–72 hours, reorganize into elementary bodies that are released from the cell. Chlamydia infects nonciliated squamocolumnar cells and the transitional epithelial cells that line the mucosa of the urethra, cervix, rectum, and conjunctiva. The incidence of chlamydial infections

is highest among persons younger than 25 years, and annual screening is recommended for all sexually active females in this age group.

There are at least 18 *C. trachomatis* serovars. Serovars A through C cause trachoma, an ocular infection eventually leading to blindness from extensive local scarring; serovars B and D through K cause urethritis, cervicitis, PID, inclusion conjunctivitis in newborns, and infant pneumonia; serovars L1–3 cause LGV, an infrequent STI characterized by an ulcerative genital lesion followed by unilateral, painful inguinal lymphadenitis.

TABLE 116.3 Features of Sexually Transmitted Infections Characterized by Vaginal Discharge

FEATURE	PHYSIOLOGIC LEUKORRHEA (NORMAL)	TRICHOMONIASIS	BACTERIAL VAGINOSIS
Agent	Normal flora	<i>Trichomonas vaginalis</i>	Reduction in <i>Lactobacillus</i> and overgrowth organisms including <i>Gardnerella vaginalis</i> , <i>Bacteroides</i> , <i>Mobiluncus</i> , and <i>Peptostreptococcus</i>
Incubation	—	5–28 days	Not necessarily sexually transmitted
Predominant Symptoms			
Pruritus	None	Mild to moderate	None to mild
Discharge	Minimal	Moderate to severe	Mild to moderate
Pain	None	Mild	Uncommon
Vulvar inflammation	None	Common	Uncommon
Characteristics of Discharge			
Amount	Small	Profuse	Moderate
Color	Clear, milky	Yellow-green or gray	Gray
Consistency	Flocculent	Frothy	Homogeneous
Viscosity	Thin	Thin	Thin
Foul odor	None	Possible	Yes
Odor with KOH	None	Possible	Characteristic fishy odor (amine)
pH	<4.5	>5.0	>4.5
Diagnosis			
Saline drop	Squamous and few WBCs	WBC; motile flagellates, slightly larger than WBCs	Squamous cells studded with bacteria (“clue cells”) and WBCs
Gram stain	Gram-positive and gram-negative rods and cocci	<i>Trichomonas</i>	Predominance of gram-negative rods and cocci with paucity of gram-positive rods
Culture	Mixed flora with <i>Lactobacillus</i> predominant	Culture generally not indicated; antibody and nucleic acid tests available	Culture not useful
Treatment	Reassurance	Metronidazole or tinidazole	Metronidazole or clindamycin

KOH, Potassium hydroxide; WBCs, white blood cells.

Chlamydia is the most frequently diagnosed bacterial STI in adolescents and accounts for most cases of **nongonococcal urethritis and cervicitis** (see Table 116.1). There is a 2.5:1 female:male ratio. Males often have dysuria and mucopurulent discharge, although asymptomatic infection also occurs. Females are more often asymptomatic or may have minimal symptoms, including dysuria, mild abdominal pain, or vaginal discharge. Prepubertal females may have vaginitis. At least 30% of persons with gonococcal cervicitis, urethritis, proctitis, or epididymitis have *C. trachomatis* co-infection.

Chlamydia infection is usually diagnosed by NAAT detection of vaginal, cervical, urethral, and early-morning first-voided urine specimens. Amplification tests have supplanted less sensitive culture and enzyme-linked immunosorbent assay (ELISA) tests. NAAT can be used for vaginal and urine specimens from females in the evaluation of sexual abuse.

Recommended treatment for *C. trachomatis* infection is oral doxycycline 100 mg twice daily for 7 days; azithromycin and levofloxacin are alternatives. Individuals should be advised to avoid unprotected intercourse until all their sexual partners have been tested and treated. Tests of cure are not recommended unless therapeutic adherence is in question, symptoms persist, or reinfection is suspected.

SYPHILIS (*TREPONEMA PALLIDUM*)

Syphilis is caused by *T. pallidum*, a long, slender, coiled spirochete. It cannot be cultivated routinely in vitro but can be observed by dark-field microscopy. Untreated infection progresses through several clinical stages (see Table 116.2). **Primary syphilis** is manifested as a single, painless genital ulcer, or **chancre**, usually on the genitalia, that appears approximately 3 weeks after inoculation and spontaneously

TABLE 116.4 Features of Sexually Transmitted Infections Characterized by Nonulcerative External Genital Symptoms

FEATURE	GENITAL WARTS	VULVOVAGINAL CANDIDIASIS	PEDICULOSIS PUBIS (CRABS)
Agent	Human papillomavirus	<i>Candida albicans</i>	<i>Phthirus pubis</i>
Incubation/transmission	Variable	Uncommon sexual transmission	5–10 days for eggs to hatch
Presenting complaints	Genital warts are seen or felt	Vulvar itching or discharge	Pubic itching; live organisms may be seen; sexual partner has “crabs”
Signs	Firm, gray-to-pink, single or multiple, fimbriated, painless excrescences on vulva, introitus, vagina, cervix, penis, perineum, anus	Inflammation of vulva, with thick, white, “cottage cheese” discharge, pH <4.5; friable mucosa that easily bleeds	Eggs (nits) at base of pubic hairs, lice may be visible; excoriated, red skin secondary to infestation
Clinical associations	Cervical neoplasia, dysplasia	Oral contraceptives, diabetes, antibiotics	—
Diagnosis	Clinical appearance; most infections asymptomatic; acetowhite changes on colposcopy; enlarged cells with perinuclear halo and hyperchromatic nuclei	KOH (10%): pseudohyphae; Gram stain: gram-positive pseudohyphae; Nickerson or Sabouraud medium for culture	History and clinical appearance
Treatment	<i>Patient-applied therapies:</i> podofilox solution or gel or imiquimod cream	<i>Intravaginal agents:</i> butoconazole or clotrimazole or miconazole or nystatin <i>Oral agent:</i> fluconazole	Permethrin 1% cream or pyrethrin with piperonyl butoxide
	<i>Provider-applied therapies:</i> cryotherapy with liquid nitrogen or cryoprobe or topical podophyllin resin or trichloroacetic acid or bichloroacetic acid or surgical removal		

KOH, Potassium hydroxide.

heals in a few weeks. **Secondary syphilis** follows 4–8 weeks later and is manifested as fever, generalized lymphadenopathy, and a disseminated maculopapular rash that is also present on the palms and soles. Plaquelike skin lesions, **condylomata lata**, and mucous membrane lesions occur, particularly in moist areas around the vulva and anus, and are infectious. Secondary syphilis resolves spontaneously within 3–12 weeks. **Tertiary syphilis** is a slowly progressive disease involving the cardiovascular, neurologic, and musculoskeletal systems that manifests 15–30 years after initial infection. **Latent syphilis** is an asymptomatic infection detected by serologic testing. Early latent syphilis indicates acquisition within the preceding year; all other cases of latent syphilis are designated as either late latent syphilis or latent syphilis of unknown duration. Infection can be passed from pregnant females to infect their infants, resulting in **congenital syphilis** (see Chapter 66).

The diagnosis of syphilis is based on serologic testing. There are different types of serologic tests for syphilis, and both are required to make a diagnosis: **nontreponemal antibody tests:** the **Venereal Disease Research Laboratory (VDRL)** test, the **rapid plasma reagin (RPR)** test; **specific treponemal antibody tests:** the **microhemagglutination assay–*T. pallidum* (MHA-TP)**, the **fluorescent treponemal antibody-absorption (FTA-ABS)** test, various enzyme immunoassays (EIAs), and chemiluminescence immunoassays. The syphilis screening algorithm starts with a screening nontreponemal antibody test followed by a specific treponemal antibody test.

Screening with nontreponemal antibody tests indicates a presumptive diagnosis but needs to be confirmed by one of the specific treponemal tests to exclude false-positive results. The nontreponemal antibody test titer can then help guide management, as it increases with increasing duration of infection and decreases in response to therapy. Some laboratories have instituted a “reverse-sequence screening” approach to diagnose syphilis that starts with a specific treponemal test followed by a confirmatory nontreponemal test if the specific treponemal test is positive. The Centers for Disease Control and Prevention (CDC) and the U.S. Preventative Services Task Force (USPSTF) do not currently recommend this “reverse-sequence screening” approach as it can be associated with high rates of false-positive tests, particularly in low-prevalence populations. A nonquantitative VDRL test can be performed on cerebrospinal fluid but is insensitive. Rheumatic disease and other infectious diseases may cause false-positive VDRL results. Dark-field examination of chancres, mucous membranes, or cutaneous lesions may reveal motile organisms.

The treatment of choice for all stages of syphilis is parenteral penicillin G. Primary syphilis, secondary syphilis, and early latent syphilis are treated with a single IM dose of benzathine penicillin G. Tertiary, late latent, and latent syphilis of unknown duration are treated with three doses at 1-week intervals. Neurosyphilis is treated with IV aqueous crystalline penicillin G for 10–14 days. A systemic, febrile **Jarisch-Herxheimer reaction** can occur within the first 24 hours of penicillin initiation in patients being treated for syphilis.

HERPES SIMPLEX VIRUS INFECTION

HSV-1 and HSV-2 are large, double-stranded DNA viruses of the herpesvirus family with a linear genome contained within an icosahedral capsid. There is significant DNA homology between types 1 and 2. The virus initially infects mucosal surfaces and enters cutaneous neurons, where it migrates along the axons to sensory ganglia. As viral replication occurs in the ganglia, infectious virus moves along the axon to infect and destroy epithelial cells. Infection may disseminate to other organs in immunocompromised patients. Virus latency is maintained in the ganglia where it undergoes periodic reactivation and replication triggered by undefined events. Although either virus can be found in any site, HSV-1 more commonly occurs in the central nervous system, eyes, and mouth, whereas HSV-2 more commonly involves the genitalia. Reinfection can occur with exposure to the other type or even a second strain of the same type.

Primary genital herpes is characterized by multiple painful, grouped vesicles or ulcerative and crusted external genital lesions on an erythematous base (see Table 116.2). In females, the cervix may also be involved. Symptoms may include fever, regional lymphadenopathy, discharge, and dysuria. Primary illness lasts 10–20 days. Asymptomatic primary infection also occurs. **Secondary, recurrent, or reactivation eruptions** are not as dramatic and are not associated with systemic symptoms. In primary infection, viral shedding lasts an average of 11 days, and the entire course from vesicle and ulcer onset resolves over 20 days. In recurrent disease, virus shedding lasts for an average of 4 days, and the course resolves over 9–10 days. Many persons experience four to six recurrences per year. Some primary and many recurrent episodes are asymptomatic.

Viral cultures and polymerase chain reaction (PCR) are the preferred methods of diagnosis; culture typically shows cytopathic effect in 1–3 days and seldom takes longer than 5 days. PCR assays have increased sensitivity over culture. Viral shedding is intermittent after primary infection, so both culture and PCR can fail to detect latent infection. Serologic testing is useful for primary infection only (to show seroconversion between acute and convalescent sera), and positive serologies persist lifelong. Titers are not helpful in guiding management of recurrences.

Oral acyclovir, famciclovir, and valacyclovir are effective treatments in reducing the severity and duration of symptoms in primary cases and may reduce recurrences. Once-daily suppressive therapy reduces the frequency of genital herpes recurrences by more than 75%, and lesions tend to be mild when they do occur. Local hygiene and sitz baths may relieve discomfort. The use of condoms provides some protection against sexual transmission of HSV.

TRICHOMONIASIS (TRICHOMONAS VAGINALIS)

Trichomoniasis is caused by the protozoan *T. vaginalis* and often is associated with other STIs, such as gonorrhea and *Chlamydia*. Infection is asymptomatic in as many as 70–85% of infected persons. Symptomatic males can have urethritis. Symptomatic females have vaginitis, with thin, malodorous, frothy yellow-green discharge, vulvar irritation, and cervical “strawberry hemorrhages” (see Table 116.3). Diagnosis is based on visualization of motile, flagellated protozoans in

the urine or in a saline wet mount, which has a sensitivity of only 60–70% among symptomatic women. *T. vaginalis*-specific NAAT is available for testing vaginal, endocervical, and urine samples and is highly sensitive (95–100%) and specific (95–100%). Rapid point-of-care testing has become available in recent years, with a turnaround time of approximately 10 minutes. Treatment with oral metronidazole or tinidazole in a single dose is recommended for adolescents and adults; sexual partners should also be treated to prevent reinfection.

GENITAL WARTS (HUMAN PAPILLOMAVIRUSES)

HPV, the cause of genital warts (**condylomata acuminata**), is the most common STI in the United States, with the highest prevalence rates among 15- to 24-year-olds. Most HPV infections are asymptomatic or subclinical (90%) and self-resolve within 2 years. HPV types 6 and 11 cause 90% of genital warts and are nononcogenic. HPV types 16 and 18 are associated with 70% of cases of cervical cancer. HPV types 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, and 68 are also oncogenic. Three HPV vaccines are licensed for use in the United States: a quadrivalent vaccine (types 6, 11, 16, and 18), a bivalent vaccine (types 16 and 18), and a 9-valent vaccine (types 6, 11, 16, 18, 31, 33, 45, 52, and 58), though only the 9-valent vaccine is currently available in the United States. Vaccination is recommended for all adolescents at age 11–12 years; it is important that children are vaccinated before becoming sexually active because the rate of HPV acquisition is high shortly after the onset of sexual activity.

Genital warts can occur on the squamous epithelium or mucous membranes of the genital and perineal structures of females and males (see Table 116.4). Genital warts are usually multiple, firm, gray-to-pink excrescences. Untreated genital warts may remain unchanged, increase in size or number, or resolve spontaneously. Warts can become tender if macerated or secondarily infected. The diagnosis is usually established by appearance without biopsy. The differential diagnosis includes condylomata lata (secondary syphilis) and tumors.

The goal of treatment is removal of symptomatic warts to induce wart-free periods. Treatment modalities involve destruction of infected epithelium; patient-applied therapies include podofilox, sinecatechins, or imiquimod; and provider-applied therapies include cryotherapy with liquid nitrogen or cryoprobe and trichloroacetic acid or bichloroacetic acid. An alternative is surgical removal. Intralesional interferon and laser surgery have also been effective. Factors that may influence selection of treatment include wart number, size, anatomic sites, wart morphology, patient preference, treatment cost, convenience, adverse effects, and provider experience. Recurrences after treatment are common and are frequently asymptomatic.

PUBIC LICE (PHTHIRUS PUBIS)

Pubic lice, or pediculosis pubis, are caused by infestation with *Phthirus pubis*, the **pubic crab louse**. The louse is predominantly sexually transmitted and lives out its life cycle on pubic hair, where it causes characteristic, intense pruritus (see Table 116.4). Diagnosis can be made clinically; lice are visible to the naked eye. Erythematous papules and **egg cases (nits)** are not

seen before puberty. Treatment consists of education regarding personal and environmental hygiene and the application of an appropriate pediculicide, such as permethrin 1% cream or pyrethrins with piperonyl butoxide. Bedding and clothing should be decontaminated (machine washed and machine dried using the heat cycle or dry cleaned) or removed from body contact for at least 72 hours. Fumigation of living areas is not necessary.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 117

Osteomyelitis

ETIOLOGY

Acute hematogenous osteomyelitis is the most common manifestation of osteomyelitis in children and evolves secondary to bacteremia. **Subacute osteomyelitis** may follow local inoculation by penetrating trauma and is not associated with systemic symptoms; **chronic osteomyelitis** results from an untreated or inadequately treated (usually subacute) osteomyelitis.

In children beyond the newborn period and without hemoglobinopathies, bone infections occur almost exclusively in the metaphyses of long bones due to sluggish blood flow through tortuous vascular loops unique to this site. Preceding nonpenetrating trauma is often reported and may lead to local bone injury that predisposes to infection. Bone infections in children with sickle cell disease occur in the diaphyseal portion of

the long bones, probably as a consequence of antecedent focal infarction. In children younger than 12–18 months of age, capillaries perforate the epiphyseal growth plate, permitting spread of infection across the epiphysis and leading to suppurative arthritis, whereas in older children, infection is contained in the metaphysis because these vessels no longer cross the epiphyseal plate (Fig. 117.1).

Staphylococcus aureus is responsible for more than 80% of acute skeletal infections in which an organism can be identified. Other common causes include group A streptococcus and *Streptococcus pneumoniae*. *Neisseria meningitidis*, *Mycobacterium tuberculosis*, *Bartonella henselae*, and *Actinomyces* spp. anaerobes are less common causes. Group B streptococcus and enteric gram-negatives are other major causes in neonates. Sickle cell disease and other hemoglobinopathies predispose to osteomyelitis caused by *Salmonella* and *S. aureus*. *Pasteurella multocida* osteomyelitis may follow cat or dog bites. The use of polymerase chain reaction (PCR) testing reveals that a significant proportion of **culture-negative osteomyelitis** is due to *Kingella kingae*, particularly in children under 5 years of age. Conjugate vaccine has greatly reduced the incidence of *Haemophilus influenzae* type b infections.

Subacute focal bone infections caused by *Pseudomonas aeruginosa* and *S. aureus* usually occur in ambulatory persons who sustain **puncture wounds** of the foot. *Pseudomonas chondritis* is strongly associated with puncture wounds through sneakers, which harbor *Pseudomonas* in the foam insole. *S. aureus* is the most common cause of chronic osteomyelitis. **Chronic recurrent multifocal osteomyelitis** (also known as **chronic nonbacterial osteomyelitis**) is an autoinflammatory noninfectious syndrome characterized by recurrent episodes of fever, bone pain, and radiographic findings of osteomyelitis. Bones uncommonly involved in acute hematogenous osteomyelitis—such as the clavicle, scapula, or small bones of the hands or feet—are often affected. Pathogens are not identified

FIGURE 117.1 (A) Major structures of the bone of an infant before maturation of the epiphyseal growth plate. Note the transphyseal vessel, which connects the vascular supply of the epiphysis and metaphysis, facilitating spread of osteomyelitis between these two areas. (B) Major structures of the bone of a child. Joint capsule A inserts below the epiphyseal growth plate, as in the hip, elbow, ankle, and shoulder. Rupture of a metaphyseal osteomyelitis abscess in these bones is likely to produce the pyarthrosis of suppurative arthritis. Joint capsule B inserts at the epiphyseal growth plate, as in other tubular bones. Rupture of a metaphyseal abscess in these bones is likely to lead to a subperiosteal abscess but seldom to an associated pyarthrosis. (From Gutman LT. Acute, subacute, and chronic osteomyelitis and pyogenic arthritis in children. *Curr Probl Pediatr*. 1985;15:1–72.)

on culture, and histopathology demonstrates plasmacytic infiltrates.

EPIDEMIOLOGY

Osteomyelitis may occur at any age but is most common in children 3–12 years of age; it affects males twice as frequently as females. Osteomyelitis from penetrating trauma or peripheral vascular disease is more common in adults.

CLINICAL MANIFESTATIONS

The most common presenting complaints are focal pain, exquisite point tenderness over the bone, warmth, erythema, and swelling. Fever, anorexia, irritability, and lethargy may accompany the focal findings. Weight bearing and active and passive motion of the affected extremity are decreased, mimicking paralysis (**pseudoparalysis**). Muscle spasm may make the extremity difficult to examine. The adjacent joint space may be involved in young children, suggested by pain with minimal joint range of motion (see [Chapter 118](#)).

Usually only one bone is involved. The femur, tibia, or humerus is affected in approximately two thirds of patients. Approximately 15% of cases involve the bones of the hands or feet, and 10% involve the pelvis. Vertebral osteomyelitis is notable for an insidious onset, vague symptoms, backache, occasional spinal cord compression, and, usually, little associated fever or systemic toxicity. Patients with osteomyelitis of the pelvis may present with fever, limp, and vague abdominal, hip, groin, or thigh pain. **Pyomyositis** of pelvic muscles may mimic osteomyelitis.

LABORATORY AND IMAGING STUDIES

The presence of leukocytosis is inconsistent. Blood cultures are important but are negative in more than half of cases. Elevated acute-phase reactants, erythrocyte sedimentation rate (ESR), procalcitonin, and C-reactive protein (CRP) are

sensitive but nonspecific findings. Serial determinations of inflammatory markers are helpful in monitoring the course of the illness and response to treatment. Direct subperiosteal or metaphyseal needle aspiration can definitively establish the diagnosis. Identification of bacteria in aspirated material by Gram stain can establish the diagnosis within hours of clinical presentation.

Plain radiographs can demonstrate soft tissue swelling such as the **loss of the periosteal fat line** within the first 3 days of symptoms, but bony lesions such as **periosteal elevation** and **bone destruction** are absent until after 10–14 days of symptoms. **Brodie abscess** is a subacute intraosseous abscess that does not drain into the subperiosteal space and is classically located in the distal tibia. **Sequestra**, portions of avascular bone that have separated from adjacent bone, frequently are covered with a thickened sheath, or **involucrum**, both of which are hallmarks of chronic osteomyelitis.

Magnetic resonance imaging (MRI) is sensitive to the inflammatory marrow changes even during the earliest stages of osteomyelitis and is the diagnostic study of choice ([Fig. 117.2](#)). Whole body rapid short tau inversion recovery (STIR) MRI is useful for identifying multifocal disease.

DIFFERENTIAL DIAGNOSIS

Osteomyelitis must be differentiated from infectious arthritis (see [Chapter 118](#)), cellulitis, pyomyositis, fasciitis, bursitis, diskitis, trauma, juvenile idiopathic arthritis, bone cysts, histiocytosis, and malignancy.

TREATMENT

Initial antibiotic therapy for osteomyelitis is based on the likely organism for the age of the child, Gram stain of bone aspirate, and associated diseases ([Table 117.1](#)). Initial therapy includes an antibiotic that targets *S. aureus* and *Kingella*, such

FIGURE 117.2 Acute osteomyelitis of the distal femur in a 5-year-old boy. (A) T2-weighted fat-saturated axial magnetic resonance imaging (MRI) shows a large subperiosteal abscess (arrows) at the posterior femur. Increased signal is seen within the bone, along with adjacent soft tissue edema. (B) T1-weighted fat-saturated post-gadolinium sagittal MRI demonstrates the longitudinal extent of the same subperiosteal abscess and its enhancing wall (arrows). (From Kan JH, Meyers AB, Azouz EM. Musculoskeletal infections. In: Coley BD, ed. *Caffey's Pediatric Diagnostic Imaging*. 13th ed. Philadelphia: Saunders; 2019 [fig. 137.13].)

TABLE 117.1 Recommended Antibiotic Therapy for Osteomyelitis in Children

COMMON PATHOGEN	RECOMMENDED TREATMENT*
ACUTE HEMATOGENOUS OSTEOMYELITIS	
<i>Staphylococcus aureus</i>	
Methicillin-sensitive	Nafcillin (or oxacillin) or cefazolin
Methicillin-resistant	Clindamycin or trimethoprim-sulfamethoxazole or vancomycin or linezolid
<i>Streptococcus pyogenes</i> (group A streptococci)	Ampicillin/amoxicillin
<i>Streptococcus pneumoniae</i>	Ampicillin/amoxicillin or ceftriaxone or vancomycin
SUBACUTE FOCAL OSTEOMYELITIS	
<i>Pseudomonas aeruginosa</i>	Ceftazidime or piperacillin-tazobactam or ciprofloxacin
<i>Kingella kingae</i>	Penicillin (ampicillin) or cephalosporin (first, second, or third generation)

*Optimal specific therapy is based on susceptibilities of the organism that is isolated.

as cefazolin. Clindamycin or vancomycin should be used if methicillin-resistant *S. aureus* is suspected based on patient factors or local *S. aureus* epidemiology. For patients with sickle cell disease, initial therapy should include an antibiotic with activity against *Salmonella* and *S. pneumoniae*.

Response to intravenous (IV) antibiotics usually occurs within 48 hours. Lack of improvement after 48 hours indicates that surgical drainage may be necessary or that an unusual pathogen may be present. Surgical drainage is indicated for presence of extensive, severe, chronic, or atypical disease; presence of abscess; hip joint involvement; or **sequestrum** or spinal cord compression. Antibiotics are administered for a minimum 3–4 weeks. After initial inpatient treatment and adequate clinical response, including decreases in inflammatory markers, transition to home therapy with oral (for most patients) or IV antibiotics (for those with complicated disease) is standard. Home IV antibiotics are associated with increased adverse event rates and need for unscheduled medical visits.

COMPLICATIONS AND PROGNOSIS

Complications of acute osteomyelitis are uncommon and usually arise because of inadequate or delayed therapy or concomitant bacteremia. Vascular insufficiency, which affects delivery of antibiotics, and trauma are associated with higher rates of complications.

Hematogenous osteomyelitis has an excellent prognosis if treated promptly and if surgical drainage is performed when appropriate. The poorest outcomes are in neonates and in infants with involvement of the hip or shoulder joints (see Chapter 118). Approximately 2–4% of acute infections recur

despite adequate therapy, and approximately 25% of these fail to respond to extensive surgical debridement and prolonged antimicrobial therapy, ultimately resulting in bone loss, sinus tract formation, or amputation (although rare). Sequelae related to skeletal growth disturbance are most common with neonatal osteomyelitis or if the growth plate has been extensively disrupted.

PREVENTION

There are no effective means of preventing hematogenous *S. aureus* osteomyelitis. Universal immunization of infants with conjugate *H. influenzae* type b vaccine has practically eliminated serious bacterial infections from this organism, including bone and joint infections.

Children with puncture wounds to the foot should receive prompt irrigation, cleansing, debridement, removal of any visible foreign body or debris, and tetanus prophylaxis. The value of oral prophylactic antibiotics for preventing osteomyelitis after penetrating injury is uncertain.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 118

Infectious Arthritis

ETIOLOGY

Infectious arthritis (**suppurative** or **septic arthritis**) is a serious bacterial infection of the joint space resulting from hematogenous bacterial dissemination. Infectious arthritis less often results from contiguous spread of infection from surrounding soft tissues or direct inoculation into the joint (penetrating trauma). Spread of osteomyelitis into the joint space is more common in children under 18 months of age and occurs via organisms passing through transphyseal vessels to the epiphysis (see Fig. 117.1A). The bacteria causing infectious arthritis are similar to those causing osteomyelitis (Table 118.1). Lyme disease may also cause arthritis (see Chapter 122).

The arthritis of **disseminated gonococcal infections** includes both reactive and suppurative forms in early and late gonococcal disease, respectively. With untreated genital infection, gonococcemia may occur with fever and a polyarticular, symmetric arthritis and rash, known as the **arthritis-dermatitis syndrome**. Bacterial cultures of the synovium are sterile at this stage, despite a relatively high prevalence of bacteremia. Monoarticular arthritis of large, weight-bearing joints develops days to weeks later. Cultures of affected synovial fluid at this stage often yield the pathogen.

Reactive arthritis is immune-mediated synovial inflammation that follows a bacterial or viral infection, especially with *Chlamydia trachomatis*, *Yersinia*, and other enteric infections. Reactive arthritis of the hip joints in children 3–6 years of age is known as **toxic** or **transient synovitis** (see Chapter 200).

TABLE 118.1 Pathogenic Organisms Causing Arthritis in Children	
COMMON	UNCOMMON
YOUNG INFANT (<2 MO)	
Group B streptococci	<i>Neisseria gonorrhoeae</i>
<i>Staphylococcus aureus</i>	<i>Candida</i>
<i>Escherichia coli</i>	
<i>Klebsiella pneumoniae</i>	
OLDER INFANTS AND CHILDREN (2 MO TO MATURITY)	
<i>S. aureus</i>	Anaerobic bacteria
<i>Streptococcus pneumoniae</i>	<i>Pseudomonas aeruginosa</i>
Group A streptococci	<i>Enterobacteriaceae</i>
<i>Kingella kingae</i>	<i>Haemophilus influenzae</i> type b*
<i>N. gonorrhoeae</i>	<i>Mycobacterium tuberculosis</i>
<i>Borrelia burgdorferi</i> (Lyme disease)	
REACTIVE ARTHRITIS	
<i>Yersinia enterocolitica</i>	
<i>Campylobacter jejuni</i>	
<i>Shigella flexneri</i>	
<i>Chlamydia trachomatis</i>	
Salmonella	
Group A streptococci	
<i>Neisseria meningitidis</i>	
<i>Coccidioides immitis</i>	
Rubella virus	

*The incidence of invasive infections caused by *Haemophilus influenzae* type b has diminished greatly with universal childhood Hib vaccination.

EPIDEMIOLOGY

Infectious arthritis occurs most commonly in children younger than 5 years of age and adolescents.

CLINICAL MANIFESTATIONS

The typical features of suppurative arthritis include monoarticular involvement with erythema, warmth, swelling, and tenderness over the affected joint with a palpable effusion and markedly decreased range of movement secondary to pain. The onset may be sudden or insidious with symptoms noted only when the joint is moved, such as during a diaper change, or if parents become aware of decreased voluntary movement of a joint or limb. Toddlers may exhibit a limp or refuse to walk. In septic arthritis of the hip, the lower limb may be preferentially held in external rotation and flexion to minimize pain from pressure on the joint capsule. Similarly, the knee and elbow joints are usually held in flexion. The joints of the lower extremity are most often involved: knees (40%), hips (20%), and ankles (14%).

Small joints, such as those of the hand, are usually involved after penetrating trauma or closed fist injuries.

Minor genital tract symptoms that have been ignored may precede development of the early arthritis-dermatitis syndrome associated with disseminated gonococcal infection. A history of febrile illness antedating the development of monoarticular arthritis characterizes late gonococcal arthritis.

Reactive arthritis is typically symmetric and polyarticular, and it usually involves the large joints, especially the hips. Patients may have had a preceding episode of gastroenteritis or urethritis. Urethritis may appear with the arthritis.

LABORATORY AND IMAGING STUDIES

Leukocytosis and an elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are common. Arthrocentesis is important to distinguish among the causes of arthritis (Table 118.2). Adolescents with acute infectious arthritis should have urethral, cervical, rectal, and pharyngeal examinations and cultures or nucleic acid amplification tests performed for *Neisseria gonorrhoeae*.

Either blood or joint cultures are positive in approximately 50% of cases. Joint fluid that exhibits the characteristics of pyogenic infection may not reveal bacterial pathogens, even in the absence of preceding antibiotic therapy because of the bacteriostatic effects of synovial fluid. Gram stain should be performed and is often informative even if the cultures are negative. PCR testing for *Kingella* is useful in culture-negative samples.

Ultrasound is especially helpful for identifying joint effusions and is the initial diagnostic procedure of choice for evaluating suppurative infections of the hip. Plain radiographs typically add little information to the physical findings. Radiographs may show joint capsule swelling, a widened joint space, and displacement of adjacent normal fat lines. Magnetic resonance imaging is helpful to confirm the diagnosis and exclude concurrent bone infection or deep abscesses.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of infectious arthritis in infants, children, and adolescents includes other infectious diseases, autoimmune disorders, rheumatic fever, malignancy, and trauma.

Suppurative arthritis must be distinguished from Lyme disease, osteomyelitis, suppurative bursitis, fasciitis, myositis, cellulitis, and soft tissue abscesses. Psoas muscle abscess often presents with fever and pain on hip flexion and rotation. Juvenile idiopathic arthritis, Kawasaki syndrome, Henoch-Schönlein purpura (IgA vasculitis), other rheumatic disorders, and Crohn disease must be differentiated from infectious arthritis. In most of these diseases, the presence of symmetric or multiple joint involvement often excludes infectious arthritis. **Suppurative bursitis** with *Staphylococcus aureus* occurs most often in older males and is usually a consequence of trauma or, less commonly, a complication of bacteremia.

TREATMENT

Initial antibiotic therapy for infectious arthritis is based on the likely organism for the age of the child and the Gram stain of joint fluid. Suppurative arthritis of the hip joint, especially, or shoulder joint necessitates prompt surgical drainage. With insertion of the joint capsule below the epiphysis in these

TABLE 118.2 Synovial Fluid Findings in Various Joint Diseases

CONDITION	APPEARANCE	WBC COUNT (mm ³ /L)	PMNS (%)	MUCIN CLOT	SYNOVIAL FLUID–BLOOD GLUCOSE DIFFERENCE (mg/dL)	COMMENTS
Normal	Clear, yellow	0–200 (200)*	<10	Good	No difference	—
Trauma	Clear, turbid, or hemorrhagic	50–4,000 (600)	<30	Good	No difference	Common in hemophilia
Systemic lupus erythematosus	Clear or slightly turbid	0–9,000 (3,000)	<20	Good to fair	No difference	LE cell positive, complement decreased
Juvenile idiopathic arthritis, reactive arthritis, inflammatory bowel disease	Turbid	250–80,000 (19,000)	>70	Poor	30	Decreased complement
Infectious pyogenic infection	Turbid	10,000–250,000 (80,000)	>90	Poor	50–90	Positive culture result, positive Gram stain
Tuberculosis	Turbid	2,500–100,000 (20,000)	>60	Poor	40–70	Positive results on culture, PPD or interferon- γ release assay testing, and acid-fast stain
Lyme arthritis	Turbid	500–100,000 (20,000)	>60	Poor	70	History of tick bite or erythema migrans and appropriate travel risk factors

*Average in parentheses.

LE, Lupus erythematosus; PMN, polymorphonuclear cell; PPD, purified protein derivative; WBC, white blood cell.

TABLE 118.3 Recommended Antibiotic Therapy for Infectious Arthritis in Children

AGE GROUP	COMMON PATHOGENS	RECOMMENDED TREATMENT*
Infants (<2 mo of age)	Group B streptococci	Ampicillin plus aminoglycoside
	<i>Escherichia coli</i>	Ceftazidime or ceftriaxone with or without aminoglycoside
	<i>Klebsiella pneumoniae</i>	Ceftazidime or ceftriaxone with or without aminoglycoside
Older infants and children	<i>Staphylococcus aureus</i>	Nafcillin (or oxacillin or cefazolin), or clindamycin or vancomycin
	<i>S. aureus</i>	Nafcillin (or oxacillin or cefazolin), or clindamycin or vancomycin
	<i>Streptococcus pneumoniae</i>	Ampicillin or ceftriaxone or vancomycin
	Group A streptococci	Penicillin G
	<i>Kingella kingae</i>	Amoxicillin or ampicillin
	<i>Haemophilus influenzae</i> type b [†]	Ampicillin or ceftriaxone
	<i>Neisseria gonorrhoeae</i> : disseminated gonococcal infection	Ceftriaxone

*Use the narrowest-spectrum agent available based on organism's susceptibilities.

[†]The incidence of invasive infections caused by *Haemophilus influenzae* type b has diminished greatly with universal childhood *Haemophilus influenzae* type b vaccination.

ball-and-socket joints, increased pressure in the joint space can adversely affect the vascular supply to the head of the femur or humerus, leading to avascular necrosis. Infections of the knee may be treated with repeated arthrocenteses in addition to appropriate parenteral antibiotics.

Several antimicrobial agents provide adequate antibiotic levels in joint spaces (Table 118.3). Initial therapy for neonates should include antibiotics such as cefazolin with clindamycin for activity against *S. aureus*, group B streptococcus, and aerobic gram-negative rods. Initial therapy for children 3 months to 5 years old should include antibiotics with activity against *S. aureus*. Addition of appropriate antibiotics should be considered if the child is unimmunized against *Haemophilus influenzae* type b (Hib). Confirmed methicillin-susceptible *S. aureus* infections are best treated with cefazolin, nafcillin, or oxacillin initially; methicillin-resistant *S. aureus* infections are best treated with clindamycin if susceptible or vancomycin otherwise.

The duration of therapy depends on clinical resolution of fever and pain and decline of the ESR and CRP. Infection with virulent organisms, such as *S. aureus*, usually necessitates treatment for at least 21 days, although shorter courses of 10–14 days have been used in some circumstances. Treatment may be transitioned to oral antibiotics if adherence can be ensured. Oral agents with excellent activity against *S. aureus* that are often used to complete therapy include cephalexin, clindamycin, amoxicillin-clavulanate, dicloxacillin, and ciprofloxacin, though due to concerns about ciprofloxacin's side effects it should not be first-line treatment.

COMPLICATIONS AND PROGNOSIS

The prognosis for the common forms of infectious arthritis encountered in infants and children is excellent. The major complications of neonatal, childhood, and gonococcal arthritis

are loss of joint function resulting from damage to the articular surface. The highest incidence of these complications occurs with hip and shoulder infections, presumably resulting from avascular necrosis. The high incidence of concurrent suppurative arthritis with adjacent osteomyelitis in neonates places the epiphyseal growth plate at high risk for growth abnormalities. Neonates with osteomyelitis have an approximately 40–50% likelihood of growth disturbances with loss of longitudinal bone growth and ultimate limb shortening.

PREVENTION

There are no effective means of preventing hematogenous *S. aureus* arthritis. Universal immunization of infants with conjugate Hib vaccine has practically eliminated serious bacterial infections from this organism, including bone and joint infections.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 119

Ocular Infections

ETIOLOGY

Acute conjunctivitis is usually a viral or bacterial infection of the eye characterized by a rapid onset of symptoms that persist for a few days. Nontypable *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis* account for approximately two thirds of bacterial causes (Table 119.1). Other causes include *Neisseria gonorrhoeae* and *Pseudomonas aeruginosa*; the latter is associated with extended-wear soft contact lenses. *Bartonella henselae* can cause a granulomatous conjunctivitis associated with preauricular lymphadenopathy or **Parinaud oculoglandular syndrome**. Viral conjunctivitis most commonly is caused by adenoviruses, which cause **epidemic keratoconjunctivitis**, and less frequently by coxsackieviruses and other enteroviruses. **Keratitis**, or inflammation of the cornea, is not commonly associated with conjunctivitis but occurs with *N. gonorrhoeae*, herpes simplex virus (HSV), and adenovirus infections.

Neonatal conjunctivitis, or **ophthalmia neonatorum**, is purulent conjunctivitis during the first month of life, usually acquired during birth. The common causes of neonatal conjunctivitis, in order of decreasing prevalence, are chemical conjunctivitis secondary to silver nitrate gonococcal prophylaxis, *Chlamydia trachomatis*, common bacterial causes of conjunctivitis, *Escherichia coli*, other gram-negative enteric bacilli, HSV, and *N. gonorrhoeae*.

EPIDEMIOLOGY

Conjunctivitis is common in young children, especially if they come in contact with other children with conjunctivitis. Predisposing factors for bacterial infection include nasolacrimal duct obstruction, sinus disease, ear infection, and allergic

TABLE 119.1 Manifestations of Acute Conjunctivitis in Children

FEATURE	CLINICAL CHARACTERISTICS	
	BACTERIAL	VIRAL
Common pathogens	<i>Haemophilus influenzae</i> (usually nontypable)	Adenoviruses types 8, 19
	<i>Streptococcus pneumoniae</i>	Enteroviruses
	<i>Moraxella catarrhalis</i>	Herpes simplex virus
Incubation	24–72 hr	1–14 days
SYMPTOMS		
Photophobia	Mild	Moderate to severe
Blurred vision	Common with discharge	If keratitis is present
Foreign body sensation	Unusual	Yes
SIGNS		
Discharge	Purulent discharge	Mucoid/serous discharge
Palpebral reaction	Papillary response	Follicular response
Preauricular lymph node	Unusual for acute (<10%)	More common (20%)
Chemosis	Moderate	Mild
Hemorrhagic conjunctivae	Occasionally with pneumococcus or <i>Haemophilus</i> sp.	Frequent with enteroviruses
Treatment (topical)	Polymyxin B–trimethoprim or sulfacetamide 5% or erythromycin or moxifloxacin or gatifloxacin	Adenovirus: self-limited Herpes simplex virus: trifluridine 1% solution or ganciclovir 0.15% gel or acyclovir; ophthalmologic consultation
End of contagious period	24 hr after start of effective treatment	7 days after onset of symptoms

disease when children rub their eyes frequently. Conjunctivitis occurs in 1–12% of neonates. Approximately 50% of infants born vaginally to infected mothers have neonatal acquisition of *C. trachomatis*, with which the risk of chlamydial conjunctivitis (**inclusion conjunctivitis**) is 25–50%.

CLINICAL MANIFESTATIONS

Symptoms of ocular infection include redness, discharge, matted eyelids, and mild photophobia. Physical examination findings include chemosis, injection of the conjunctiva, and edema of the eyelids. Corneal involvement suggests gonococcal or herpetic infection. Herpetic corneal lesions appear

TABLE 119.2 Clinical Manifestations and Treatment of Neonatal Conjunctivitis

ETIOLOGIC AGENT	CASES (%)	DISCHARGE AND EXTERNAL EXAMINATION	TYPICAL AGE AT ONSET	DIAGNOSIS	ASSOCIATED MANIFESTATIONS	TREATMENT
Chemical: silver nitrate	Variable (1%), depending on use of silver nitrate	Watery discharge	1–3 days	No organisms on smear or culture	None	None
<i>Chlamydia trachomatis</i> (inclusion conjunctivitis)	2–40	Scant discharge; mild swelling; hyperemia; follicular response; late corneal staining	4–19 days	Test of discharge with a DIF test or PCR assay	May presage <i>C. trachomatis</i> pneumonia (at 3 wk to 3 mo of age)	Erythromycin (oral)
Bacterial: <i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Pseudomonas</i> , <i>E. coli</i>	30–50	Purulent moderate discharge; mild lid and conjunctival swelling; corneal involvement with risk for perforation	2–7 days	Gram stain; culture on blood agar		Topical therapy
<i>Neisseria gonorrhoeae</i>	<1	Copious, purulent discharge; swelling of lids and conjunctivae; corneal involvement common; risk for perforation and corneal scar	1–7 days	Gram stain (gram-negative intracellular diplococci); culture on chocolate agar. Culture other sites including blood and CSF	May be associated with severe disseminated gonococcal infection	Ceftriaxone Hospitalize patient
HSV	<1	Clear or serosanguineous discharge; lid swelling; keratitis with cloudy cornea; dendrite formation	3 days to 3 wk	Viral culture; DIF test, PCR assay	May be associated with disseminated perinatal HSV infection	Acyclovir (intravenous)

CSF, Cerebrospinal fluid; DIF, direct immunofluorescence; HSV, herpes simplex virus; PCR, polymerase chain reaction.

as dendritic or ameboid ulcers or, more commonly, in recurrent infection, as a deep keratitis. Unilateral conjunctivitis with ipsilateral otitis media is often caused by nontypable *H. influenzae*.

The timing and manifestations of neonatal conjunctivitis are helpful in identifying the cause (Table 119.2). *N. gonorrhoeae* causes severe conjunctivitis with profuse purulent discharge. Chlamydial conjunctivitis usually occurs in the second week of life but may appear 3 days to 6 weeks after delivery. There is mild to moderate inflammation with purulent discharge issuing from one or both eyes.

LABORATORY AND IMAGING STUDIES

Cultures are not routinely obtained because bacterial conjunctivitis is usually self-limited or responds quickly to topical antibiotic treatment. If gonococcal conjunctivitis is suspected, especially in neonates, Gram stain and culture must be obtained. In these infants, blood and other sites of infection (such as cerebrospinal fluid) should also be cultured. Additional testing for *Chlamydia*, HIV, and syphilis should be performed on the mother and infant as necessary.

DIFFERENTIAL DIAGNOSIS

Distinguishing bacterial from viral conjunctivitis by presentation and appearance is difficult (see Table 119.1). Vesicular lid lesions, if present, suggest HSV. **Hyperpurulent conjunctivitis** characterized by reaccumulation of purulent discharge

within minutes is characteristic of *N. gonorrhoeae* infection. The differential diagnosis is delineated in Table 119.3.

Blepharitis is associated with staphylococcal infections, seborrhea, and meibomian gland dysfunction. The child complains of photophobia, burning, irritation, and a foreign body sensation that causes the child to rub the eyes. Eyelid hygiene with an **eyelid scrub** routine is the initial step in treatment.

Hordeola are acute suppurative nodular inflammatory lesions of the eyelids associated with pain and redness. **External hordeola** or **styes** occur on the anterior eyelid, in the Zeis glands, or in the lash follicles and usually are caused by staphylococci. **Internal hordeola** occur in the meibomian glands and may be infected with staphylococci or may be sterile. If the meibomian gland becomes obstructed, the gland secretions accumulate, and a **chalazion** develops. Hordeola usually respond spontaneously to local treatment measures but may recur.

Dacryocystitis is an infection or inflammation of the lacrimal sac, which is usually obstructed, and is commonly caused by *Staphylococcus aureus* or coagulase-negative staphylococci. A mucopurulent discharge can be expressed with gentle pressure on the nasolacrimal sac. Treatment usually requires probing of the nasolacrimal system to establish communication.

Endophthalmitis is an emergent, sight-threatening infection that usually follows trauma, surgery, or hematogenous spread from a distant focus. Causative organisms include coagulase-negative staphylococci, *S. aureus*, *S. pneumoniae*, *Bacillus cereus*, and *Candida albicans*. Examination is difficult because of severe blepharospasm and extreme photophobia. A

TABLE 119.3 Differential Diagnosis of Ocular Infections			
CONDITION	ETIOLOGIC AGENTS	SIGNS AND SYMPTOMS	TREATMENT
Bacterial conjunctivitis	<i>Haemophilus influenzae</i> , <i>Haemophilus aegyptius</i> , <i>Streptococcus pneumoniae</i> , <i>Neisseria gonorrhoeae</i>	Mucopurulent unilateral or bilateral discharge, normal vision, photophobia, conjunctival injection and edema (chemosis); gritty sensation	Topical antibiotics, parenteral ceftriaxone for gonococcus
Viral conjunctivitis	Adenovirus, echovirus, coxsackievirus	Same as for bacterial infection; may be hemorrhagic, unilateral	Self-limited
Neonatal conjunctivitis	<i>Chlamydia trachomatis</i> , gonococcus, chemical (silver nitrate), <i>Staphylococcus aureus</i>	Palpebral conjunctival follicle or papillae; same as for bacterial infection	Ceftriaxone for gonococcus and oral erythromycin for <i>C. trachomatis</i>
Allergic conjunctivitis	Seasonal pollens or allergen exposure	Itching, incidence of bilateral chemosis (edema) greater than that of erythema, tarsal papillae	Antihistamines, steroids, cromolyn
Keratitis	Herpes simplex, adenovirus, <i>S. pneumoniae</i> , <i>S. aureus</i> , <i>Pseudomonas</i> , <i>Acanthamoeba</i> , chemicals	Severe pain, corneal swelling, clouding, limbus erythema, hypopyon, cataracts; contact lens history with amebic infection	Specific antibiotics for bacterial/fungal infections; keratoplasty, acyclovir for herpes
Endophthalmitis	<i>S. aureus</i> , <i>S. pneumoniae</i> , <i>Candida albicans</i> , associated surgery or trauma	Acute onset, pain, loss of vision, swelling, chemosis, redness; hypopyon and vitreous haze	Specific antibiotics for bacterial/fungal infections
Anterior uveitis (iritis)	JIA, reactive arthritis, sarcoidosis, Behçet disease, inflammatory bowel disease	Unilateral/bilateral; erythema, ciliary flush, irregular pupil, iris adhesions; pain, photophobia, small pupil, poor vision	Topical steroids, plus therapy for primary disease
Posterior uveitis (choroiditis)	Toxoplasmosis, histoplasmosis, <i>Toxocara canis</i>	No signs of erythema, decreased vision	Specific therapy for pathogen
Episcleritis/scleritis	Idiopathic autoimmune disease (e.g., SLE, Henoch-Schönlein purpura)	Localized pain, intense erythema, unilateral; blood vessels bigger than in conjunctivitis; scleritis may cause globe perforation	Episcleritis is self-limiting; topical steroids for fast relief
Foreign body	Occupational or other exposure	Unilateral, red, gritty feeling; visible or microscopic size	Irrigation, removal; check for ulceration
Blepharitis	<i>S. aureus</i> , <i>Staphylococcus epidermidis</i> , seborrheic, blocked lacrimal duct; rarely molluscum contagiosum, <i>Phthirus pubis</i> , <i>Pediculus capitis</i>	Bilateral, irritation, itching, hyperemia, crusting, affecting lid margins	Topical antibiotics, warm compresses
Dacryocystitis	Obstructed lacrimal sac: <i>S. aureus</i> , <i>H. influenzae</i> , <i>S. pneumoniae</i>	Pain, tenderness, erythema, and exudate in areas of lacrimal sac (inferomedial to inner canthus); tearing (epiphora); possible orbital cellulitis	Systemic, topical antibiotics; surgical drainage
Dacryoadenitis	<i>S. aureus</i> , <i>S. pneumoniae</i> , CMV, measles, EBV, enteroviruses; trauma, sarcoidosis, leukemia	Pain, tenderness, edema, erythema over gland area (upper temporal lid); fever, leukocytosis	Systemic antibiotics; drainage of orbital abscesses
Orbital cellulitis (postseptal cellulitis)	Paranasal sinusitis: <i>H. influenzae</i> , <i>S. aureus</i> , <i>S. pneumoniae</i> , other streptococci Trauma: <i>S. aureus</i> Fungi: <i>Aspergillus</i> , <i>Mucor</i> if immunodeficient	Rhinorrhea, chemosis, vision loss, painful extraocular motion, proptosis, ophthalmoplegia, fever, lid edema, leukocytosis	Systemic antibiotics; drainage of orbital abscesses
Periorbital cellulitis (preseptal cellulitis)	Trauma: <i>S. aureus</i> , other streptococci Bacteremia: pneumococcus, streptococci, <i>H. influenzae</i>	Cutaneous erythema, warmth, normal vision, minimal involvement of orbit; fever, leukocytosis, toxic appearance	Systemic antibiotics

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; JIA, juvenile idiopathic arthritis; SLE, systemic lupus erythematosus.

hypopyon and haze in the anterior chamber may be visible on examination.

TREATMENT

The lids should be treated as needed with warm compresses to remove accumulated discharge. Acute bacterial conjunctivitis is frequently self-limited, but topical antibiotics hasten resolution. Antibiotics are instilled between the eyelids four times a day until the discharge and chemosis subside. Recommended treatment includes topical trimethoprim-polymyxin B solution, sulfacetamide 5% solution, or erythromycin ointment (see Table 119.1). Ciprofloxacin solution should be restricted to corneal infections and resistant gram-negative infections in hospitalized patients. Gonococcal conjunctivitis in adolescents and adults is treated with a single intramuscular (IM) dose of ceftriaxone (1 g).

The treatment of **ophthalmia neonatorum** depends on the cause (see Table 119.2). Gonococcal ophthalmia neonatorum is treated with a single dose of ceftriaxone (25–50 mg/kg intravenous [IV] or IM; maximum dose 250 mg). These infants should be hospitalized. Antibiotic treatment also is recommended for infants born to mothers with untreated gonorrhea. Chlamydial conjunctivitis is treated with oral erythromycin for 14 days, partly to reduce the risk of subsequent chlamydial pneumonia.

COMPLICATIONS AND PROGNOSIS

The prognosis for bacterial and viral conjunctivitis is excellent. The major complication is keratitis, which can lead to ulcerations and perforation, and is uncommon except with *N. gonorrhoeae* and HSV infections. Chlamydial conjunctivitis may progress in infants to chlamydial pneumonia, which typically develops from 2–18 weeks of age (see Chapter 110).

PREVENTION

Careful handwashing is important to prevent spread of conjunctivitis. Bacterial conjunctivitis is considered contagious for 24 hours after initiating effective treatment. Children may return to school, but treatment measures must be continued until there is complete clinical resolution.

All newborns, whether delivered vaginally or by cesarean section, should receive prophylaxis for gonococcal ophthalmia neonatorum as soon as possible after delivery. A single application of erythromycin 0.5% ointment is used most often. Alternative methods include tetracycline 1% ointment and silver nitrate 1% solution. These are equally effective in preventing gonococcal ophthalmia, but silver nitrate usually causes a chemical conjunctivitis. Neither silver nitrate solution nor tetracycline ophthalmic ointment is manufactured in the United States currently. Erythromycin ointment does not prevent chlamydial ophthalmia.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 120

Infection in the
Immunocompromised Person

See also Section 13 (Immunology).

ETIOLOGY

Many diseases or their treatments adversely affect the immune system, including primary immunodeficiencies, HIV infection and AIDS, cancer, stem cell and organ transplantation, and immunosuppressive drugs used to treat cancer, autoimmune diseases, and transplant patients. These patients are at significant risk of life-threatening infections from invasive bacterial or fungal flora of the oropharynx, skin, and gastrointestinal tract; acquisition of exogenous infection from infected persons or the environment; and reactivation of latent infections until their immune function recovers (Table 120.1).

The infections seen in immunocompromised persons can often be predicted by which component of the immune system is abnormal. Episodes of fever and **neutropenia**, defined as an **absolute neutrophil count (ANC)** of less than $500/\text{mm}^3$, are especially common in cancer and transplant patients and increase the risk for bacterial and fungal infections. The use of **corticosteroids** and potent immunosuppressive drugs that impair the activation of T lymphocytes increases the risk for pathogens normally controlled by T-cell-mediated responses, such as *Pneumocystis jirovecii* and *Toxoplasma gondii*, as well as intracellular pathogens, such as *Salmonella*, *Listeria*, and *Mycobacterium*. Lymphopenia also increases the risk of viral infections, either due to primary acquisition or reactivation of latent infection.

Immunocompromised patients also have increased risk for bacterial infection due to the presence of central indwelling catheters. Organisms most commonly isolated in this case include coagulase-negative staphylococci, *S. aureus*, gram-negative bacteria, *Enterococcus*, and *Candida* (see Chapter 121).

Fungal pathogens account for approximately 10% of all infections associated with childhood cancer. *Candida* species are the most common cause of all fungal infections, with *Aspergillus* being the second most common pathogen. Other risk factors for fungal infections include oropharyngeal and gastrointestinal mucositis facilitating systemic fungal invasion, presence of long-term indwelling intravascular catheters, parenteral nutrition, hyperglycemia, extreme prematurity, and broad-spectrum antibacterial therapy that promotes fungal colonization as a precursor to infection.

Infection with *T. gondii* represents reactivation of quiescent infection facilitated by cancer-associated or therapy-associated cellular immunodeficiency. *P. jirovecii* primarily causes pneumonitis in patients with leukemia, lymphoma, HIV, or those on long-term corticosteroids and can occasionally cause extrapulmonary disease (sinusitis, otitis media).

Viral opportunistic infections in patients with cancer usually represent symptomatic reactivation from latency facilitated by cancer or therapy-associated cellular

TABLE 120.1 Immunodeficiencies and Associated Prevalent Pathogens

From Blijlevens NMA, van der Velden WJFM. Infections in the immunocompromised host: general principles. In: Mandell GL, Bennett JE, Dolin R, eds. Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases. 9th ed. Philadelphia: Elsevier; 2020:3617 (table 305.1).

immunodeficiency. Herpes simplex virus (HSV) can cause severe and prolonged mucocutaneous infection or disseminated disease. Cytomegalovirus (CMV) can also cause focal or systemic disease in immunocompromised persons, especially in transplant patients. Manifestations of CMV disease include retinitis, hepatitis, pneumonitis, esophagitis, encephalitis, and colitis. Reactivation of Epstein-Barr virus (EBV) is associated with **posttransplant lymphoproliferative disorder (PTLD)**. Varicella-zoster virus (VZV) can cause serious primary infection in susceptible persons, sometimes with accompanying encephalitis, hepatitis, or pneumonitis. VZV can also reactivate as shingles during chemotherapy and may cause disseminated infection.

EPIDEMIOLOGY

Chemotherapeutic agents target rapidly dividing cells, especially myeloproliferative cells, which causes myelosuppression. Children receiving allogeneic stem cell (bone marrow) transplants are at greater risk for infection than children receiving autologous transplants. Prolonged time to hematologic engraftment is a significant risk factor for infection in these patients (Fig. 120.1). Foreign bodies (shunts, central venous catheters) and mucositis interfere with cutaneous barriers against infection and, together with neutropenia and/or lymphopenia, increase the risk of bacterial or fungal infections. Multiple antimicrobial exposures put these patients at risk for resistant bacterial, fungal, and viral infections.

The relative rate of some infections in patients with cancer is 10–15%. The most frequently infected sites, in descending

order, are the respiratory tract (lung, sinuses), the bloodstream, surgical wounds, and the urinary tract.

CLINICAL MANIFESTATIONS

Fever is the most common, and sometimes the only, presenting symptom of serious infection in cancer and transplant patients. The presence of fever with neutropenia, even in the absence of other signs or symptoms, demands prompt evaluation and empiric antimicrobial therapy because of the potential for life-threatening infection. All symptoms and signs should be evaluated thoroughly. However, some symptoms may be absent based on the underlying immunodeficiency. In the absence of neutrophils to induce localized signs of inflammation, determination of the source of infection by physical examination is often difficult. Chest findings may be absent, despite pneumonia, and revealed only by chest radiograph at presentation or when the neutrophil count recovers.

LABORATORY TESTS AND IMAGING

Evaluation of fever and neutropenia in immunocompromised persons requires blood cultures for bacterial and fungal pathogens obtained by peripheral venipuncture and from all lumens of any indwelling vascular catheters (Table 120.2). A complete blood count with manual differential, C-reactive protein, complete chemistry panel, culture of urine, and Gram staining/culture of potential sites of specific infection found during history and physical should be performed. Chest radiographs are important to assess for the presence of pulmonary infiltrates. Specialized imaging studies, such as computed tomography

FIGURE 120.1 Infectious phases after transplant. The infectious complications that occur most commonly are set against the phases before and after an allogeneic hematopoietic stem cell transplant. Note the time scale progresses from days to weeks, then to months. The fluctuations in the different components of the immune system are represented at the bottom of the figure and show when severe deficiency coincides with the time of engraftment and begins to recover thereafter. The various classes of microorganism change during the different phases, but note that viruses and fungi can cause infections throughout the entire period. CMV, Cytomegalovirus; HHV-6, human herpesvirus 6; HSV, herpes simplex virus; NK, natural killer; RSV, respiratory syncytial virus; VZV, varicella-zoster virus. (From Blijlevens NMA, van der Velden WJFM. Infections in the immunocompromised host: general principles. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 9th ed. Philadelphia: Elsevier; 2020 [fig. 305.5].)

TABLE 120.2 Initial Diagnostic Evaluation of Children with Fever and Neutropenia

- Careful medical history
- Physical examination with attention to the skin, perirectal area, and other mucosal sites (which should be repeated at least daily in febrile neutropenic patients)
- Specimens for culture
 - Blood: peripheral venipuncture and specimens from every lumen or access port of intravascular catheters
 - Urine
 - Respiratory secretions: for bacteria and viruses if symptoms are present
 - Any site with clinical signs of infection, including *Clostridium difficile* toxin assay if diarrhea present and cerebral spinal fluid if headache, meningismus, or mental status change
- Chest imaging
- Other imaging studies or diagnostic procedures as clinically indicated
 - Sinus radiograph or computed tomography (CT)
 - Abdominal ultrasonography or CT
 - Head CT or magnetic resonance imaging with contrast

Modified from Ardura MI, Koh AY. Fever and granulocytopenia. In: Long SS, Prober CG, Fischer M, eds. Principles and Practice of Pediatric Infectious Diseases. 5th ed. Philadelphia: Elsevier; 2018:97 (box 97.1).

(CT) or magnetic resonance imaging (MRI), can be useful in selected cases, such as with suspected sinusitis or intraabdominal infection, or to further delineate the location and extent of abnormalities seen on plain radiographs. Sinus infection with bacteria, *Aspergillus*, or *Zygomycetes* is common in neutropenic hosts and may be detected only on the CT scan. Viruses can be detected in blood, respiratory samples, cerebrospinal fluid, and skin lesions by polymerase chain reaction.

DIFFERENTIAL DIAGNOSIS

Initially, the patient should have a complete physical examination, including careful scrutiny of the oropharynx, nares, external auditory canals, skin and axilla, groin, perineum, and rectal area. The exit site and subcutaneous tunnel of any indwelling vascular catheter should be examined closely for erythema and palpated for tenderness and expression of purulent material. Perirectal abscess is a potentially serious infection in neutropenic hosts, with tenderness being the only clue on examination. Any presumptive infection identified during the evaluation should direct appropriate cultures and tailor antiinfective therapy.

TREATMENT

Treatment should be provided as appropriate for focal infections identified by physical examination or diagnostic imaging. Select *low-risk* patients may be managed as outpatients. Empirical treatment of fever and neutropenia without an identified source should include an extended-spectrum penicillin or cephalosporin with activity against gram-negative bacilli, including *P. aeruginosa*. If the patient has an indwelling vascular catheter, vancomycin may be added because of the increasing prevalence of methicillin-resistant *S. aureus* (MRSA) but can be discontinued if *S. aureus* is not cultured after 48–72 hours. Specific antibiotic regimens should be guided by local antibiotic resistance patterns at each institution.

TABLE 120.3 Modifications of Antimicrobial Therapy During Fever and Neutropenia

CLINICAL EVENT	POSSIBLE MODIFICATIONS IN THERAPY
Breakthrough bacteremia on empirical regimen	If gram-positive isolate, add vancomycin or other gram-positive agent in patient with known history of VRE
	If gram-negative isolate (presumably resistant), change regimen and consider addition of second gram-negative agent
Catheter-associated soft tissue infection	Add vancomycin
Severe oral mucositis or necrotizing gingivitis	Add agent active against β -lactamase-producing anaerobic bacteria; consider acyclovir
Esophagitis	Clotrimazole, ketoconazole, fluconazole, voriconazole, caspofungin, or amphotericin B; consider acyclovir
Diffuse or interstitial pneumonitis	Trimethoprim-sulfamethoxazole; macrolide
New infiltrate in neutropenic patient receiving antibiotics	If neutrophil count rising, can observe If neutrophil count not recovering or has been severe and prolonged, pursue further diagnostics, including possible biopsy; if biopsy not possible, consider agent active against molds
Perianal cellulitis	Add agent active against β -lactamase-producing anaerobic bacteria if not already included in broad-spectrum therapy
Prolonged fever and neutropenia	After 1 wk of antibiotics, add antifungal agent

VRE, Vancomycin-resistant enterococci.

From Ardura MI, Koh AY. Fever and granulocytopenia. In: Long SS, Prober CG, Fischer M, eds. Principles and Practice of Pediatric Infectious Diseases. 5th ed. Philadelphia: Elsevier; 2018:97 (table 97-5).

If no microbiologic cause is isolated, empirical broad-spectrum antibiotics are continued as long as the patient remains neutropenic, regardless of whether the fever resolves. Antibiotic therapy should be modified as indicated by new findings or if the patient's clinical status deteriorates (Table 120.3). Further investigation for fungal infection and empirical treatment with antifungal agents is instituted in patients who have neutropenia and persistent fever without a focus, despite broad-spectrum antibacterial therapy for approximately 5 days.

PREVENTION

Current guidelines discourage the use of broad-spectrum prophylactic antibiotics to prevent fever and neutropenia because of lack of efficacy and concerns about development of antibiotic resistance. Administration of trimethoprim-sulfamethoxazole to prevent *P. jirovecii* infection is routine for patients undergoing intensive chemotherapy or immunosuppression for transplantation. Prophylaxis against *P. jirovecii* generally starts with initiation of chemotherapy and continues until 6 months after it has been completed. In select populations, such as patients undergoing

hematopoietic stem cell transplantation, prophylactic antifungals such as fluconazole or voriconazole are beneficial. Patients at risk for viral reactivation with HSV, VZV, and/or CMV may be placed on antiviral prophylaxis with acyclovir or ganciclovir.

Immunocompromised susceptible persons exposed to chickenpox within 2 days before the onset of rash until 5 days after the onset of rash in the index case should receive varicella-zoster immune globulin (VZIG). Modified infection after VZIG may not result in protective immunity, and persons who receive VZIG prophylaxis should be considered still at risk with any subsequent exposures.

PEARLS FOR PRACTITIONERS

See Infectious Diseases: Pearls for Practitioners at the end of this section.

CHAPTER 121

Infections Associated with Medical Devices

Infections are a common and important complication of indwelling medical devices and are a major part of **health care–associated infections**.

VASCULAR DEVICE INFECTIONS

Vascular catheters are inserted in most inpatients and used in many outpatients. The use of catheters for long-term access to the bloodstream has been an important advance for the care of persons who require parenteral nutrition, chemotherapy, or extended parenteral antibiotic therapy. The major complication of such catheters is infection. Short, peripheral intravenous (IV) catheters used for short-term access in stable patients are associated with a low rate of infection, especially in children. **Peripherally inserted central catheters (PICC)** are commonly used for medium-term venous access. **Central venous catheters** are commonly placed for extended vascular access, such as for chemotherapy, using tunneled silicone elastomer catheters (**Broviac** or **Hickman catheters**) that are surgically inserted into a central vein, passed through a subcutaneous tunnel before exiting the skin, and anchored by a subcutaneous cuff. Contamination of the catheter hub or any connection of the IV tubing is common and is a major predisposition to catheter-associated infection. Totally implanted venous access systems (**Port-a-Cath**, **Infuse-a-Port**) have a silicone elastomer catheter tunneled beneath the skin to a reservoir implanted in a subcutaneous pocket. Implanted catheters or ports decrease, but do not eliminate, the opportunity for microbial entry at the skin site.

Catheter-related thrombosis and catheter-related infection can develop separately or together. Ultrasound can identify thrombi, but infection can only be identified by culture. **Thrombophlebitis** is inflammation with thrombosis in a blood vessel. **Septic thrombophlebitis** is thrombosis with organisms embedded in the clot. **Central line–associated**

TABLE 121.1 Organisms Causing Catheter-Related Infections

CLASSIFICATION OF PATHOGEN	COMMON	UNCOMMON
Gram-positive organisms	Coagulase-negative staphylococci, <i>Staphylococcus aureus</i> , <i>Enterococcus</i>	Diphtheroids, <i>Bacillus</i> , <i>Micrococcus</i>
Gram-negative organisms	<i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Pseudomonas aeruginosa</i>	<i>Acinetobacter</i> , <i>Enterobacter</i> , <i>Neisseria</i>
Fungi	<i>Candida</i> sp.	<i>Malassezia furfur</i>
Miscellaneous		Nontuberculous mycobacteria, <i>Lactobacillus</i>

bloodstream infection (CLABSI) implies isolation of the same organism from a catheter and from peripheral blood of a patient with clinical symptoms of bacteremia and no other apparent source of infection. Confirmation requires quantitative colony counts of both samples, which is not routinely performed. Possible sources of the bacteremia include the infusate, contamination via tubing and catheter connections, or transient bacteremia seeding the catheter, which may or may not be clinically apparent. Infection may be associated with an **exit site infection** limited to the insertion site or may extend along the catheter tunnel of buried catheters to cause a **tunnel infection**. Given the proximity of central venous catheters to cardiac valves, persistent central infections can also be complicated by endocarditis. An echocardiogram should be considered in patients with persistent bacteremia related to a central line (see [Chapter 111](#)).

Many microorganisms cause catheter-related infections ([Table 121.1](#)). Gram-positive cocci, primarily staphylococci, cause more than 50% of CLABSIs and exit site infections. Other skin flora, such as coagulase-negative staphylococci, diphtheroids, and *Bacillus* are often involved. Gram-negative organisms also commonly cause infection. Polymicrobial infections of central venous catheters are common. Fungal catheter infections, usually *Candida* species, are most common among persons receiving broad-spectrum antibiotics or parenteral nutrition.

Risk factors for CLABSI include prematurity, burns, and skin disorders that adversely affect the skin integrity, neutropenia, and other immunodeficiencies (see [Chapter 120](#)). Infection rates are lower for tunneled and implanted catheters. Catheters inserted in emergency settings are more likely to be infected than catheters placed electively.

Clinical signs of catheter-associated bacteremia or fungemia range from mild fever to overwhelming sepsis. Infection at the site of the central catheter entrance is manifested as a localized cellulitis with warmth, tenderness, swelling, erythema, and discharge. Tunnel infection is manifested by similar findings along the tunnel route. Thrombophlebitis is classically manifested as a warm, erythematous, tender palpable cord originating at the IV catheter site but may be subclinical or manifested only by persistent fever without signs of local inflammation.

The treatment of catheter-related infection depends on the site of the infection and the pathogen involved. CLABSI is optimally treated with catheter removal; however, in a stable patient or with certain organisms, antibiotic therapy alone may suffice. Infection with organisms of low virulence may be manifested by fever alone, and removal of the catheter frequently is followed by prompt defervescence and complete resolution of infection. Nonetheless, many patients are dependent on the catheter and removal may be difficult. Empirical initial therapy for suspected infection should generally include antibiotics active against gram-negative organisms and against *S. aureus* and coagulase-negative staphylococci, such as a broad-spectrum cephalosporin in combination with vancomycin. Subsequently, antibiotic regimens should be tailored to the specific organism identified. If the patient is not critically ill and the pathogen is likely to be susceptible to antibiotic therapy, a trial of antibiotics is given through the infected catheter. The total duration of therapy depends on the pathogen and the duration of positive cultures and is usually 10–14 days after sterilization of the bloodstream. Catheter removal is indicated with sepsis, septic thrombophlebitis, clinical deterioration (despite appropriate therapy), persistently positive blood culture results after 48–72 hours of appropriate antimicrobial therapy, embolic lesions, or fungal infection because of poor response to antifungal therapy alone. Catheter removal is also recommended for infection with *Staphylococcus aureus* and *Pseudomonas aeruginosa*. Infection of the pocket around an implanted port is unlikely to respond to antibiotics alone, and removal of the foreign body is usually necessary.

Antibiotic-lock therapy is a method of sterilizing intravascular catheters by using high concentrations of antibiotics or ethanol infused into the portion of the catheter between the hub and the vessel entry. The solution is allowed to dwell within the catheter segment for several hours. It may be useful for treatment of catheter-associated infections in which line salvage is desired and/or for prevention of infection in patients at high risk.

Aseptic technique is essential during catheter insertion. Catheters that are placed during emergency situations should be replaced as soon as medically feasible. Care of indwelling catheters involves meticulous attention to sterile technique whenever the system is entered. Care of the catheter entry site commonly involves a topical antibiotic or disinfectant. Catheters that are no longer necessary should be removed.

VENTILATOR-ASSOCIATED PNEUMONIA

Intubation of the airway provides direct access to the lungs and bypasses normal host defenses. Organisms enter the lungs directly through the lumen of the tube or by descending around the tube, which may result in **ventilator-associated pneumonia**. Contaminated respiratory equipment, humidification systems, or condensate introduces bacteria directly into lower airways. The continuously open upper airway increases the risk of aspiration of oropharyngeal flora and reflux of gastric contents and interferes with clearance of the airway because an effective cough requires a closed glottis.

URINARY CATHETERS

The most important risk factors for urinary tract infections (UTIs) are the presence of catheters, instrumentation, and

anatomic abnormalities (see [Chapter 114](#)). Organisms enter the bladder through the catheter by instillation of contaminated irrigation fluids, backflow of contaminated urine from the drainage bag, or ascent of bacteria around the meatus along the outside of the catheter. Indwelling catheters facilitate direct access to the bladder and should have a closed drainage system. After simple, straight catheterization, the incidence of UTI is 1–2%. Organisms that cause catheter-associated UTIs include fecal flora, such as gram-negative enteric bacilli, most commonly *Escherichia coli* and *Enterococcus*. With concomitant antibiotic treatment, resistant organisms predominate, and fungi may emerge as pathogens.

The most important aspect of prevention is to minimize the duration and use of catheterization. Intermittent catheterization is preferred over indwelling catheter drainage whenever feasible. Insertion of catheters must be performed with aseptic technique, and the drainage system must remain closed at all times, with sterile technique used whenever the system is entered. Drainage bags always should be dependent to avoid backflow of urine into the bladder.

PERITONEAL DIALYSIS–ASSOCIATED INFECTIONS

Indwelling catheters used for peritoneal dialysis may develop exit site infections, tunnel infections, or lead to peritonitis. The usual route of infection is from the skin surface along the tunnel and into the peritoneum. The most common pathogens are skin flora, including *Staphylococcus* species; organisms that contaminate water, such as *Pseudomonas* and *Acinetobacter*; enteric flora, such as *E. coli* and *Klebsiella*; and fungi, such as *C. albicans*. Peritonitis may present with fever, vague abdominal pain, and cloudy dialysate. The diagnosis is established on clinical manifestations and confirmed by culture of the dialysate. Prevention of infection requires careful planning of the location of the exit site to minimize contamination, aseptic insertion of the catheter, meticulous care of the catheter site, securing of the catheter to avoid tension and motion, and aseptic technique during dialysis.

CENTRAL NERVOUS SYSTEM SHUNTS

Important risk factors of health care–associated central nervous system (CNS) infections are surgery, presence of a ventriculoperitoneal shunt (VPS), and cerebrospinal fluid (CSF) leaks. Infection of a VPS results from contamination of the system at the time of placement, breakdown of overlying skin, or from hematogenous seeding. Externalized ventricular drains and subdural bolts allow direct access of skin flora to the CSF. For these devices, the rates of infection increase with the duration of catheterization, especially beyond 5 days. Device-related CNS infections can be diagnosed in the same way as other types of meningitis or ventriculitis with assessment of the CSF for pleocytosis, protein, glucose, and Gram stain and culture.

The most common pathogens causing shunt infections are coagulase-negative staphylococci and *S. aureus*. After skull fracture or cranial surgery, a CSF leak may facilitate ascending infection from the nasopharynx, especially with *Streptococcus pneumoniae*, which frequently colonizes the nasopharynx. Patients with shunt infections may present with only fever

and headache or may present with typical signs and symptoms of meningitis (see [Chapter 100](#)). Infections caused by coagulase-negative staphylococci or *Propionibacterium acnes* typically present with insidious onset of fever, malaise, headache, and vomiting. Empirical therapy is often with vancomycin and a third-generation cephalosporin.

Antibiotics frequently are used perioperatively during placement of shunts and other neurosurgical procedures. It is not clear that antibiotics decrease infection rates in these clean procedures, especially beyond one dose. External ventricular drains should be maintained as closed systems with aseptic technique and removed as soon as possible. Drainage bags always should be dependent to avoid backflow.

PEARLS FOR PRACTITIONERS

See Infectious Diseases: Pearls for Practitioners at the end of this section.

CHAPTER 122

Zoonoses and Vector-Borne Infections

Zoonoses are classically defined as infections that are transmitted in nature between vertebrate animals and humans. Many zoonotic pathogens are maintained in nature by means of an **enzootic cycle**, in which mammalian hosts and arthropod vectors reinfect each other. Humans frequently are only incidentally infected. Of the more than 150 different human zoonotic diseases that have been described (Table 122.1; Fig. 122.1), Lyme disease (*Borrelia burgdorferi*) is the most common tick-borne infection in the United States. Other common pathogens include *Rickettsia rickettsii* (Rocky Mountain spotted fever [RMSF]), ehrlichiosis (*Ehrlichia chaffeensis*), West Nile virus, and anaplasmosis (*Anaplasma phagocytophilum*).

TABLE 122.1 Diseases Transmitted by Animals (Zoonoses)

DISEASE AND/OR ORGANISM	ANIMAL SOURCES/RESERVOIRS	VECTOR OR MODES OF TRANSMISSION
BACTERIAL DISEASES		
<i>Aeromonas</i> species	Aquatic animals, especially shellfish, medical leeches; has also been isolated from feces of horses, pigs, sheep, and cows	Wound infection, ingestion of contaminated food or water, direct contact with infected animal or their environment
Anthrax (<i>Bacillus anthracis</i>)	Herbivores (cattle, goats, horses, sheep) Outbreaks associated with heavy rainfall, flooding, or drought; spores remain viable in soil or animal products, such as wool or hides, for decades	Direct contact with infected animals or their carcasses, or contact with products from infected animals (e.g., meat, hides, hair, or wool) contaminated with <i>B. anthracis</i> spores; ingestion of contaminated meat; inhalation of contaminated dust
Bartonellosis (<i>Bartonella quintana</i> , <i>Bartonella bacilliformis</i>)	Cats, dogs, ruminants, rodents, human body louse	Bites from human body louse, sand flies
Brucellosis (<i>Brucella</i> species)	Cattle, coyotes, hares, chickens, goats, sheep, pigs, dogs, elk, bison, deer, camels, desert rats and other rodents, marine mammals	Direct or indirect contact with aborted fetuses, tissues, or fluids of infected animals; inoculation through mucous membranes or cuts or abrasions of the skin; inhalation of contaminated aerosols; ingestion of unpasteurized dairy products
Campylobacteriosis (<i>Campylobacter jejuni</i>)	Poultry, dogs (especially puppies), kittens, ferrets, pigs, nonhuman primates, pet rodents, cattle, sheep, birds	Ingestion of contaminated food or water, direct contact (particularly with animals with diarrhea), person-to-person (fecal-oral), fomites
<i>Capnocytophaga canimorsus</i>	Dogs, rarely cats	Bites, scratches, and prolonged contact with dogs
Cat-scratch disease (<i>Bartonella henselae</i>)	Cats and other felids, infrequently other animals (<10%)	Scratches, bites; fleas play a role in cat-to-cat transmission (evidence for transmission from cat fleas to humans is lacking)
Erysipeloid (<i>Erysipelothrix rhusiopathiae</i>)	Pigs, horses, dogs, cats, rats, sheep, cattle, wild and domestic birds (including poultry), fresh and saltwater fish, shellfish	Direct contact with animal or contaminated animal product, or water
Hemolytic-uremic syndrome (e.g., Shiga toxin-producing <i>Escherichia coli</i> [STEC])	Cattle, sheep, goats, deer, dogs, pigs, poultry	Ingestion of undercooked contaminated ground beef, unpasteurized milk, or other contaminated foods (e.g., alfalfa sprouts and other vegetable products, mayonnaise, apple cider, and cheddar) or water; contact with infected animals or their environments (e.g., farms and ranches); contact with animals in public settings including petting zoos and agricultural fairs (fecal-oral)

Continued

TABLE 122.1 Diseases Transmitted by Animals (Zoonoses)—cont'd		
DISEASE AND/OR ORGANISM	ANIMAL SOURCES/RESERVOIRS	VECTOR OR MODES OF TRANSMISSION
Leptospirosis (<i>Leptospira</i> species)	Cattle, sheep, goats, pigs, horses, dogs, rodents, and all other mammals, but rare in cats	Contact with or ingestion of water, food, or soil contaminated with urine or fluids from rodents or other infected animals, or direct contact with infected animals or their organs
Lyme disease (<i>Borrelia burgdorferi</i> , <i>Borrelia mayonii</i>)	White-footed mice, squirrels, shrews, and other small rodents; opossums, raccoons, birds; white-tailed deer	Tick bite (blacklegged/deer tick [<i>Ixodes scapularis</i> or <i>Ixodes pacificus</i>] in USA, castor bean tick [<i>Ixodes ricinus</i>] in Europe)
<i>Mycobacterium marinum</i>	Found in brackish water, fresh water, and saltwater; fish (and cleaning aquaria)	Contaminated water sources; skin injury or contamination of existing wound
<i>Mycobacterium bovis</i> and <i>Mycobacterium tuberculosis</i>	Cattle, elephants, giraffes, rhinoceroses, bison, deer, elk, feral pigs, badgers, possums, nonhuman primates	<i>M. tuberculosis</i> is uncommon in nonhuman species, although when it is identified it is typically found in nonhuman primates and elephants Sporadic cases of <i>M. tuberculosis</i> have been reported in other species including cattle Transmission is by the airborne route
Pasteurellosis (<i>Pasteurella multocida</i>)	Cats, dogs, rabbits, pigs, other animals, birds	Bites, scratches, licks, saliva, respiratory droplets from animals (primarily cats and dogs), and contaminated meat
Plague (<i>Yersinia pestis</i>)	Rodents (e.g., prairie dogs, chipmunks, squirrels, mice, voles, rats), cats, dogs, rabbits, wild carnivores (e.g., bobcats, coyotes)	Bite of infected rodent fleas (especially Oriental rat fleas— <i>Xenopsylla cheopis</i>); in USA, most common vector is <i>Oropsylla montana</i> , a flea found on rodents including prairie dogs and squirrels; direct contact with infected animal tissues, airborne from other human or animal (e.g., cat) with pneumonic plague
Q fever (<i>Coxiella burnetii</i>)	Sheep, goats, cows, cats, dogs, rabbits, rodents, horses, pigs, buffalo, camels, pigeons, geese, other wild fowl, ticks	Contact with excreta (birth products, urine, feces, milk) of infected animals, inhalation of pathogen-contaminated dust, ingestion of unpasteurized milk, and fomite transmission (possible role of ticks not well defined); rarely by blood transfusions, sexual contact in humans, or from a pregnant woman to her fetus
Rat-bite fever (<i>Streptobacillus moniliformis</i> , <i>Spirillum minus</i>)	Rodents (especially rats, occasionally squirrels), gerbils	Bites, scratches, contact with secretions, aerosol spread, direct contact with rodent; contaminated food or water; unpasteurized, contaminated milk
Relapsing fever (tick-borne) (<i>Borrelia</i> species)	Wild rodents	Soft tick bites (<i>Ornithodoros</i> species); bites from blacklegged ticks (<i>I. scapularis</i> and <i>I. pacificus</i>) transmit <i>B. miyamotoi</i>
Salmonellosis (<i>Salmonella</i> species)	Cattle, poultry, turtles, frogs, lizards, snakes, salamanders, geckos, iguanas, fish, invertebrates, dogs, cats, pigs, sheep, horses, hedgehogs, hamsters, guinea pigs, mice, rats and other rodents, ferrets, other wild and domestic animals	Fecal-oral transmission most common; ingestion of contaminated food (e.g., meat, poultry, dairy, eggs, produce, processed foods), unpasteurized milk and other raw dairy products, or contaminated water; contact with infected animals or their environments (including healthy reptiles); contaminated animal products including dry dog and cat food and pet treats
<i>Streptococcus iniae</i>	Fish from many regions of the world	Skin wound during handling and preparation of infected fish
Tetanus (<i>Clostridium tetani</i>)	Any animal indirectly via soil containing animal feces	Wound infection, skin injury or soft tissue injury with inoculation of bacteria (as from soil or a contaminated object)
Tularemia (<i>Francisella tularensis</i>)	Sheep, dogs, cats, pigs, horses, wild rabbits, hares, voles, squirrels, beaver, lemmings, muskrats, moles, hamsters, birds, reptiles, fish	Tick bites (wood tick [<i>Dermacentor andersoni</i>], dog tick [<i>D. variabilis</i>], Lone-star tick [<i>Amblyomma americanum</i>]), deerfly bites; direct contact with infected animal, ingestion of contaminated water or meat, mechanical transmission from claws or teeth (cats/dogs), aerosolization of tissues or excreta
<i>Vibrio</i> species	Shellfish	Ingestion of contaminated food or water; skin injury or contamination of existing wound
Yersiniosis (<i>Yersinia enterocolitica</i> , <i>Yersinia pseudotuberculosis</i>)	Pigs, deer, elk, horses, goats, sheep, cattle, rodents, birds, rabbits	Ingestion of contaminated food (particularly raw or undercooked pork products), raw or unpasteurized milk or other dairy products, contaminated water; rarely direct contact
FUNGAL DISEASES		
Cryptococcosis (<i>Cryptococcus neoformans</i>)	Excreta of birds including pigeons, canaries, parakeets, and chickens	Inhalation of aerosols from accumulations of bird feces; can also be isolated from fruit and vegetables, house dust, air conditioners, air, and sawdust; can enter body through skin as well as inhalation

Continued

TABLE 122.1 Diseases Transmitted by Animals (Zoonoses)—cont'd

DISEASE AND/OR ORGANISM	ANIMAL SOURCES/RESERVOIRS	VECTOR OR MODES OF TRANSMISSION
Histoplasmosis (<i>Histoplasma capsulatum</i>)	Excreta of bats, birds such as pigeons and starlings	Inhalation of aerosolized spores from accumulations of bat or bird feces; spores can also be ingested
Ringworm/tinea corporis (<i>Microsporum</i> and <i>Trichophyton</i> species)	Cats, dogs, chickens, pigs, mice, moles, horses, rodents, cattle, monkeys, goats	Direct contact; pathogenic fungi found worldwide; hot and humid climates generally increase incidence
PARASITIC DISEASES		
<i>Angiostrongylus cantonensis</i> (rat lungworm)	Rodents and mollusks (e.g., slugs and snails)	Ingestion of larvae in raw or undercooked snails or slugs, freshwater shrimp, land crabs, frogs or on contaminated raw produce
Anisakiasis (<i>Anisakis</i> species) (herring worm disease)	Crustaceans eat infective larvae from marine mammal feces; fish or squid eat the infected crustaceans	Ingestion of larvae in raw or undercooked fish or squid (e.g., sushi)
Babesiosis (several <i>Babesia</i> species)	Mice and various other rodents and small mammals; wildlife	Tick bite (in the USA, <i>Babesia microti</i> is transmitted mainly by <i>I. scapularis</i> ; in Europe, <i>Babesia divergens</i> is transmitted mainly by <i>Ixodes</i> tick bites)
Balantidiasis (<i>Balantidium coli</i>)	Pigs	Ingestion of contaminated food or water
Baylisascariasis (<i>Baylisascaris procyonis</i>)	Raccoons	Ingestion of eggs shed in raccoon feces found in dirt or animal waste
Clonorchiasis/opisthorchiasis (<i>Clonorchis</i> / <i>Opisthorchis</i> species)	Fish, crabs, crayfish, snails, cats, dogs	Ingestion of metacercariae in raw or undercooked fish, crabs, or crayfish
Cryptosporidiosis (<i>Cryptosporidium</i> species)	<i>Cryptosporidium parvum</i> can infect all mammals; common in calves and other young ruminants; seen in pigs, rarely occurs in cats, dogs, and horses; other <i>Cryptosporidium</i> species can infect birds and reptiles	Fecal-oral route; ingestion of contaminated water (especially groundwater) or foods; infection by inhaling aerosols can also occur
Cutaneous larva migrans (primarily <i>Ancylostoma</i> species hookworms)	Dogs, cats	Penetration of skin by larvae, which develop in soil contaminated with animal feces
Dog tapeworm (<i>Dipylidium caninum</i>)	Dogs are definitive hosts; cats and other animals (e.g., foxes) can also be hosts	Ingestion of fleas infected with cysticercoid stage
Dwarf tapeworm (<i>Hymenolepis nana</i>) and rat tapeworm (<i>Hymenolepis diminuta</i>)	Rodents (humans are more important reservoirs than rodents for <i>H. nana</i> ; for <i>H. diminuta</i> , rodents are primary and human infection is infrequent); arthropods including beetles and fleas can serve as intermediate hosts	Ingestion of eggs in contaminated food or water; animal-to-person (fecal-oral); person-to-person (fecal-oral); infection can occur after ingestion of cysticercoid-infected arthropods Autoinfection may also occur in humans if eggs remain in intestine (<i>H. nana</i>)
Echinococcosis, hydatid disease (<i>Echinococcus</i> species)	Definitive hosts are canids including dogs, coyotes, foxes, dingoes, jackals, hyenas, and wolves; intermediate hosts encompass many domestic and wild animals including herbivores such as sheep, goats, cattle, and deer	Ingestion of eggs shed in animal feces
Fascioliasis (<i>Fasciola</i> species)	Sheep, cattle	Ingestion of larvae in contaminated water, in raw watercress and other contaminated water plants, or eating raw or undercooked sheep or goat liver
Fish tapeworm (<i>Diphyllobothrium latum</i>)	Saltwater and freshwater fish	Ingestion of larvae in raw or undercooked fish (e.g., sushi)
Giardiasis (<i>Giardia duodenalis</i>)	Wild and domestic animals including dogs, cats, cattle, pigs, beavers, muskrats, rats, pet rodents, rabbits, nonhuman primates	Ingestion of contaminated water or foods, and animal-to-person (fecal-oral)

Continued

TABLE 122.1 Diseases Transmitted by Animals (Zoonoses)—cont'd		
DISEASE AND/OR ORGANISM	ANIMAL SOURCES/RESERVOIRS	VECTOR OR MODES OF TRANSMISSION
Myiasis (<i>Dermatobia</i> , <i>Cochliomyia</i> , <i>Chrysomya</i> , <i>Cuterebra</i> , and <i>Wohlfahrtia</i> species)	Flies	Exposure of flies to broken or wounded skin; with <i>Chrysomya</i> screwworm flies, exposure of flies to unbroken soft skin
Taeniasis/beef tapeworm (<i>Taenia saginata</i>)	Cattle (intermediate host)	Ingestion of larvae in raw or undercooked beef; cysticercosis in cattle is caused by ingestion of embryonated eggs excreted by humans with <i>Taenia</i> infection
Taeniasis and cysticercosis/pork tapeworm (<i>Taenia solium</i> ; <i>Taenia asiatica</i> less common)	Pigs (intermediate host)	Ingestion of larvae in raw or undercooked pork resulting in intestinal infection in humans with adult tapeworms (taeniasis); porcine cysticercosis (infection in pigs) is caused by ingestion of embryonated eggs excreted by humans with <i>Taenia</i> infection; human cysticercosis is caused by ingestion of eggs through fecal contamination of food or water, or by autoinfection
Toxoplasmosis (<i>Toxoplasma gondii</i>)	Members of the Felidae family (including domestic cats) are definitive hosts; many mammals (e.g., sheep, goats, and swine) and birds can serve as intermediate hosts	Transmission can be food-borne, zoonotic, congenital, or in rare instances through organ transplantation; zoonotic transmission can occur through ingestion of infective oocysts from hands after cleaning litter boxes or gardening (soil), or ingestion of vegetables/low growing fruits, or ingestion of anything that has become contaminated with cat feces; consumption of cysts in raw or undercooked meat (such as lamb, pork, venison) or shellfish (clams, mussels, oysters); drinking unpasteurized goat milk; drinking contaminated water
Trichinellosis (<i>Trichinella spiralis</i> and other <i>Trichinella</i> species)	Pigs, bears, seals, walruses, rodents, horses, foxes, wolves	Ingestion of larvae in raw or undercooked meat, particularly pork or wild game meat
Ocular or visceral toxocariasis/larva migrans (<i>Toxocara canis</i> and <i>Toxocara cati</i>)	Dogs, cats; puppies are a major source of environmental contamination	Ingestion of infected, larvated eggs, usually from soil, dirty hands, or food contaminated by animal feces
CHLAMYDIAL AND RICKETTSIAL DISEASES		
Human ehrlichiosis (<i>Ehrlichia chaffeensis</i> , <i>Ehrlichia ewingii</i> , and <i>Ehrlichia muris eauclairensis</i>)	Dogs, red foxes, deer, coyotes, goats, lemurs (<i>E. chaffeensis</i>); dogs may be reservoir hosts along with wolves and jackals (<i>Ehrlichia canis</i> and <i>E. ewingii</i>)	Tick bites (Lone star tick [<i>Amblyomma americanum</i>] for <i>E. chaffeensis</i> , <i>E. ewingii</i> ; blacklegged tick [<i>I. scapularis</i>] for <i>E. muris eauclairensis</i>); in rare cases, <i>Ehrlichia</i> species have been spread through blood transfusion and organ transplantation
Human anaplasmosis (<i>Anaplasma phagocytophilum</i>)	Small mammals including wood rats and deer mice; deer may also be involved	Tick bites (<i>I. scapularis</i> and <i>I. pacificus</i>)
Psittacosis (<i>Chlamydia psittaci</i>)	Most birds (especially psittacine birds such as parakeets, parrots, macaws, and cockatoos) and poultry	Inhalation of aerosols from feces of infected birds as well as fecal-oral transmission
Rickettsialpox (<i>Rickettsia akari</i>)	House mice	Mite bites (house mouse mite, <i>Liponyssoides sanguineus</i>)
Rocky Mountain spotted fever (<i>Rickettsia rickettsii</i>)	Dogs, wild rodents, rabbits	Tick bites (American dog tick, <i>Dermacentor variabilis</i> ; Rocky Mountain wood tick, <i>D. andersoni</i> ; and brown dog tick, <i>Rhipicephalus sanguineus</i>)
<i>Rickettsia parkeri</i> infection (maculatum disease, American boutonneuse fever)	Unknown; perhaps cattle, dogs, small wild rodents	Tick bites (Gulf coast tick [<i>Amblyomma maculatum</i>])
Typhus, flea-borne endemic typhus, Murine typhus (<i>Rickettsia typhi</i>)	Rats, opossums, cats, dogs	Infected flea feces scratched into abrasions; oriental rat fleas (<i>Xenopsylla cheopis</i>) and cat fleas (<i>Ctenocephalides felis</i>) are vectors
Typhus, louse-borne epidemic typhus (<i>Rickettsia prowazekii</i>)	Flying squirrels (sylvatic typhus)	Person-to-person via infected body louse, contact with flying squirrels, their nests, or ectoparasites (role and species of ectoparasites undefined)
VIRAL DISEASES		
B virus (formerly herpes B, monkey B virus, herpesvirus simiae, or herpesvirus B)	Macaque monkeys	Bite or exposure to secretions or tissues

Continued

TABLE 122.1 Diseases Transmitted by Animals (Zoonoses)—cont'd

DISEASE AND/OR ORGANISM	ANIMAL SOURCES/RESERVOIRS	VECTOR OR MODES OF TRANSMISSION
Colorado tick fever virus	Rodents (e.g., squirrels, chipmunks)	Tick bites (Rocky Mountain wood tick [<i>Dermacentor andersoni</i>])
Crimean Congo hemorrhagic fever (<i>Nairovirus</i>)	Many wild and domestic animals including cattle, hares, goats, sheep	Infectious blood and body fluids from animal slaughter; ixodid (hard) ticks, genus <i>Hyalomma</i> , are reservoir and vector; person-to-person via contact (droplet, contact) with infectious blood or body fluids; improperly sterilized medical equipment
Eastern equine encephalitis virus	Birds	Mosquito bites (<i>Coquillettidia</i> species, <i>Aedes</i> species, <i>Culex</i> species, <i>Ochlerotatus</i> species); rarely through organ transplantation
Ebola virus	Fruit bats; nonhuman primates may become infected	Direct contact through broken skin or mucous membranes (eyes, nose, mouth) with blood or body fluids, contaminated needles, prolonged presence in semen of infected individuals (possible sexual transmission), infected fruit bats or nonhuman primates
Hantaviruses	Wild and peridomestic rodents	Inhalation of aerosols of infected secretions and excreta; contact with infected rodents or infected droppings and urine
Hendra virus	Flying foxes (<i>Pteropus</i> genus) are the natural reservoir; horses can become infected	Contact with body fluids of infected horses; close contact with fruit bats
Novel influenza (e.g., H5N1, H7N9, H9N2, H3N2 variant)	Chickens, birds, pigs	Contact with infected animals or aerosols (markets, slaughterhouse)
Jamestown Canyon virus	Deer	Mosquito bites (<i>Aedes</i> species, <i>Anopheles</i> species, and <i>Culiseta</i> species)
Japanese encephalitis virus	Pigs, birds	Mosquito bites (<i>Culex tritaeniorhynchus</i>)
Kyasanur forest disease/ Alkhurma hemorrhagic fever	Monkeys, rodents, and shrews are common hosts after being bitten by infected ticks	Primarily tick bites (<i>Haemaphysalis spinigera</i>), contact with infected animal
La Crosse virus	Rodents (e.g., chipmunks and squirrels)	Mosquito bites (<i>Aedes triseriatus</i>)
Lassa fever	Multimammate rat (<i>Mastomys natalensis</i>)	Inhalation of aerosols or direct contact with infected secretions or excreta; consumption of food contaminated by rodents
Lymphocytic choriomeningitis virus	Rodents, particularly house mice and pet hamsters (includes feeder rodents used as reptile food), guinea pigs	Direct contact, inhalation of aerosols, ingestion of food contaminated with rodent excreta
Marburg hemorrhagic fever	African fruit bat (<i>Rousettus aegyptiacus</i>), infected nonhuman primates	Contact with fruit bats or their excreta (e.g., entering caves or mines inhabited by bats); contact with infectious blood or tissue of infected monkeys
Middle East respiratory syndrome (MERS coronavirus)	Uncertain; virus found in camels in several countries	Respiratory droplets from infected individuals (possible airborne transmission in some cases), direct contact
Monkeypox	Natural reservoir unknown; African rodent species play a role in transmission	Animal-to-human direct contact, bite, or scratch; contact with infected body fluids or contaminated bedding
Nipah virus	Fruit bats; pigs can become infected	Close contact with bats; consumption of bat-contaminated fruit/sap; direct contact with infected pigs
Omsk hemorrhagic fever	Infected rodents including muskrats and voles	Handling infected muskrats (e.g., hunting, trapping, skinning), and bites from infected ticks (<i>Dermacentor reticulatus</i> , <i>Ixodes persulcatus</i> , <i>Dermacentor marginatus</i>)
Orf (pox virus of sheep)	Sheep, goats, and occasionally other ruminants	Contact with infected saliva, infected fomites
Powassan virus	Small to medium-sized rodents (e.g., groundhogs, squirrels, mice)	Tick bites (<i>Ixodes cookei</i> , <i>Ixodes marxi</i> , <i>I. scapularis</i>) and rarely blood transfusion
Rabies (<i>Lyssavirus</i>)	In the USA, primarily mammalian wildlife (bats, raccoons, skunks, foxes, coyotes, mongooses) or, less frequently, domestic animals (dogs, cats, cattle, horses, sheep, goats, ferrets)	Bites; rarely contact of open wounds, abrasions (including scratches), or mucous membranes with saliva or other infectious materials (e.g., neural tissue), corneal and organ transplantation

Continued

TABLE 122.1 Diseases Transmitted by Animals (Zoonoses)—cont'd		
DISEASE AND/OR ORGANISM	ANIMAL SOURCES/RESERVOIRS	VECTOR OR MODES OF TRANSMISSION
Rift Valley fever	Domesticated livestock (e.g., cattle, sheep, goats, buffalo, and camels)	Contact with blood, body fluids, or tissues of infected animals; bites from infected mosquitoes; rarely bites from other insects with virus on their mouthparts
Severe acute respiratory virus-1 (SARS-CoV-1)	Bats, civet cats, potentially other animal species	Respiratory droplets (airborne transmission believed to occur in some cases), direct contact
Severe acute respiratory virus-2 (SARS-CoV-2)	Unknown	Respiratory droplets and aerosols
South American arenaviruses (Junin, Machupo, Guanarito, Sabia, Chapare, Lujo)	Rodents	Inhalation of aerosols of infected secretions or excreta, consumption of food or water contaminated with infected secretions or excreta, direct contact of abraded or broken skin with rodent excrement
St. Louis encephalitis virus	Birds	Mosquito bites (<i>Culex</i> species) and rarely blood transfusion
Tick-borne encephalitis virus	Small rodents are primary reservoirs; large animals such as cows, goats and sheep become infected but do not play a role in virus maintenance	Tick bites (<i>Ixodes</i> species), consumption of infected raw milk products, and rarely blood transfusion or organ transplantation
Venezuelan equine encephalitis virus	Sylvatic rodents, possibly birds; horses are dead-end hosts	Mosquito bites (<i>Aedes</i> species, <i>Anopheles</i> species, <i>Culex</i> species, <i>Deinocerites</i> species, <i>Mansonia</i> species, and <i>Psorophora</i> species)
West Nile virus	Birds	Mosquito bites (<i>Culex</i> species) and rarely blood transfusion, organ transplantation
Western equine encephalitis virus	Birds	Mosquito bites (<i>Culex tarsalis</i>)
Yellow fever virus	Nonhuman primates	Mosquito bites (<i>Haemagogus</i> species, <i>Sabethes</i> species, <i>Aedes [Stegomyia]</i> species)

From Kimberlin DW, Barnett ED, Lynfield R, et al., eds. Appendix VII: Diseases transmitted by animals (zoonoses). In: Red Book: 2021-2024 Report of the Committee on Infectious Diseases. Itasca, IL: American Academy of Pediatrics; 2021:1048.

FIGURE 122.1 Proportion of vector-borne zoonoses by pathogenic agent as reported to the U.S. Centers for Disease Control and Prevention in the United States between 2011 and 2016; N = 286,017 cases. (From Dumler JS, Reller ME. Zoonoses. In: Goldman G, Schafer AI, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2015:2029 [fig. 312-2].)

The epidemiology of zoonoses is related to the geographic distribution of the hosts and, if vector-borne, the distribution and seasonal life cycle of the vector.

Many zoonoses are spread by ticks, including Lyme disease, RMSF, ehrlichiosis, tularemia, tick typhus, and babesiosis. Preventive measures to avoid tick-borne diseases include using insect repellents that contain **DEET** (*N,N*-diethyl-*m*-toluamide) on skin and insect repellents that contain **permethrin** on clothing; avoiding tick-infested habitats (thick scrub oak, briar, poison ivy sites); avoiding excretory products of wild animals; wearing appropriate protective clothing (closed-toe shoes, long pants); and promptly removing ticks.

Ticks are best removed using blunt forceps or tweezers to grasp the tick as close to the skin as possible to pull the tick steadily outward. Squeezing, twisting, or crushing the tick should be avoided because the tick's bloated abdomen can act like a syringe if squeezed. Transmission of infection seems to be most efficient after 24–48 hours of nymphal tick attachment for human granulocytic ehrlichiosis, after 36 hours for *B. burgdorferi*, and after 36–48 hours for *Babesia*. Prophylactic antimicrobial therapy after a tick bite or exposure is not recommended.

LYME DISEASE (*BORRELIA BURGDORFERI*)

Etiology

Lyme disease is a tick-borne infection caused by the spirochete, *B. burgdorferi*. The vector in the eastern and midwestern United States is *Ixodes scapularis*, the **black-legged tick** that is commonly known as the **deer tick**. The vector on the Pacific coast is *Ixodes pacificus*, the **western black-legged tick**. Ticks usually become infected by feeding on the white-footed mouse (*Peromyscus leucopus*), which is a natural reservoir for *B. burgdorferi*. The larvae are dormant over winter and emerge the following spring in the nymphal stage, the stage of the tick that is most likely to transmit the infection to humans.

Epidemiology

Over 20,000 cases are reported annually in the United States, with more than 90% of cases reported from New England and the eastern parts of the middle Atlantic states (Fig. 122.2). In Europe most cases occur in Scandinavian countries and central Europe. Because exposure to ticks is more common in warm months, Lyme disease is noted predominantly in spring and summer. The incidence is highest among children 5–9 years old, at almost twice the incidence among adolescents and adults.

Clinical Manifestations

The clinical manifestations are divided into early and late stages. Early infection may be localized or disseminated. **Early localized disease** develops 7–14 days after a tick bite as the site forms an erythematous papule that expands to form a red, raised border, often with central clearing (Fig. 122.3). The lesion, **erythema migrans**, is pruritic or painful, harbors *B. burgdorferi*, and, without treatment, may expand to as much as 15 cm in diameter. Systemic manifestations may include malaise, lethargy, fever, headache, arthralgias, stiff neck, myalgias, and lymphadenopathy. The skin lesions and early manifestations resolve without treatment over 2–4 weeks. Not all patients with Lyme disease recall a tick bite or develop erythema migrans.

Approximately 25% of children with Lyme disease are initially diagnosed with **early disseminated disease**, which

is a consequence of bacteremic dissemination of *B. burgdorferi* to multiple sites. Early disseminated disease is characterized by multiple secondary skin lesions, aseptic meningitis, pseudotumor, papilledema, neuropathies including Bell palsy, polyradiculitis, peripheral neuropathy, mononeuritis multiplex, or transverse myelitis. Carditis with various degrees of heart block rarely may develop during this stage. Neurologic manifestations usually resolve by 3 months but may recur or become chronic.

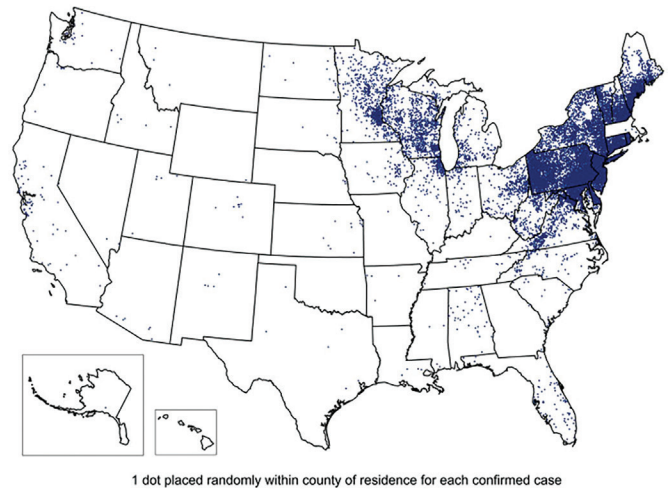

FIGURE 122.2 Reported cases of Lyme disease—United States, 2019. Each dot represents one case of Lyme disease and is placed randomly in the patient's county of residence. The presence of a dot in a state does not necessarily mean that Lyme disease was acquired in that state. People travel between states, and the place of residence is sometimes different from the place where the patient became infected. Many high-incidence states have modified surveillance practices. Contact your state health department for more information. (From Centers for Disease Control and Prevention. <https://www.cdc.gov/lyme/stats/maps.html>.)

FIGURE 122.3 Expanding annular lesion of erythema migrans at the site of a tick bite. (Courtesy Dr. Jay Capra, Abilene, TX.)

Late disease begins weeks to months after infection and is diagnosed in approximately 7% of children at initial presentation. Arthritis is the usual manifestation and may develop in 50–60% of untreated patients. The knee is involved in greater than 90% of cases, but any joint may be affected. Symptoms may resolve over 1–2 weeks but often recur in other joints. **Neuroborreliosis**, the late manifestations of Lyme disease involving the central nervous system (CNS), is rarely reported in children.

LABORATORY AND IMAGING STUDIES

Antibody tests during early, localized Lyme disease may be negative and are not useful. Additionally, patients appropriately treated for their early, localized Lyme disease may not develop a positive antibody test. The diagnosis of late disease is confirmed by serologic tests specific for *B. burgdorferi*. The sensitivity and specificity of serologic tests for Lyme disease vary substantially. A positive enzyme-linked immunosorbent assay (ELISA) or immunofluorescence assay result must be confirmed by immunoblot showing antibodies against at least either two to three (for immunoglobulin M [IgM]) or five (for IgG) proteins of *B. burgdorferi* (at least one of which is one of the more specific, low molecular weight, outer-surface proteins).

In late disease, the erythrocyte sedimentation rate (ESR) may be elevated and complement may be reduced. The joint fluid shows an inflammatory response with total white blood cell count of 25,000–125,000 cells/mm³, often with a polymorphonuclear predominance (see Table 118.2). The rheumatoid factor and antinuclear antibody are negative, but the Venereal Disease Research Laboratory test may be falsely positive. With CNS involvement, the cerebrospinal fluid shows a lymphocytic pleocytosis with normal glucose and slightly elevated protein.

Differential Diagnosis

A history of a tick bite and the classic rash is helpful but is not always present. Erythema migrans of early, localized disease may be confused with nummular eczema, tinea corporis, granuloma annulare, an insect bite, or cellulitis. **Southern tick-associated rash illness (STARI)**, which is similar to erythema migrans but not associated with any of the disseminated complications of Lyme disease, occurs in southeastern and south-central states and is associated with the bite of *Amblyomma americanum*, the Lone star tick, which is abundant in the southern states and incapable of transmitting *B. burgdorferi*.

During early, disseminated Lyme disease, multiple lesions may appear as erythema multiforme or urticaria. The aseptic meningitis is similar to viral meningitis, and the seventh nerve palsy is indistinguishable from herpetic or idiopathic Bell palsy. Lyme carditis is similar to viral myocarditis. Monoarticular or pauciarticular arthritis of late Lyme disease may mimic suppurative arthritis, juvenile idiopathic arthritis, or rheumatic fever (see Chapter 89). The differential diagnosis of neuroborreliosis includes degenerative neurologic illness, encephalitis, and depression.

Treatment

Erythema migrans (early localized disease) and carditis with first-degree or second-degree heart block (early disseminated

disease) are treated with doxycycline for 10 days or amoxicillin for 14 days. Doxycycline for 14 days is the preferred regimen for children of any age with facial nerve palsy. Early disseminated disease with carditis with third-degree heart block or meningitis and late neurologic disease are treated with intravenous or intramuscular ceftriaxone or oral doxycycline for 14–21 days. Arthritis is treated with doxycycline (for children ≥8 years of age) or amoxicillin for 28 days. If there is recurrence, treatment should be with a repeated oral regimen or with the regimen for late neurologic disease.

Complications and Prognosis

Carditis, especially conduction disturbances, and arthritis are the major complications of Lyme disease. Even untreated, most cases eventually resolve without sequelae. Lyme disease is readily treatable and curable. The long-term prognosis is excellent when early and late disease are treated. Early treatment of erythema migrans almost always prevents progression to later stages. Recurrences of arthritis after treatment occur in 5–10% of patients. The most common reason patients “recur” or do not respond to treatment is that the initial diagnosis was incorrect.

Prevention

Measures to minimize exposure to tick-borne diseases are the most reasonable means of preventing Lyme disease. Postexposure prophylaxis is not routinely recommended because the overall risk of acquiring Lyme disease after a tick bite is only 1–3% even in endemic areas, and treatment of the infection, if it develops, is highly effective. Nymphal stage ticks must feed for more than 36 hours before the risk of transmission of *B. burgdorferi* from infected ticks becomes substantial. In hyperendemic regions, prophylaxis of adults with doxycycline, 200 mg as a single dose, within 72 hours of a nymphal tick bite is effective in preventing Lyme disease.

ROCKY MOUNTAIN SPOTTED FEVER (RICKETTSIA RICKETTSII)

Etiology

The cause of RMSF is *R. rickettsii*, gram-negative coccobacillary organisms that resemble bacteria but have incomplete cell walls and require an intracellular site for replication. The organism invades and proliferates within the endothelial cells of blood vessels of all major organs and tissues, causing vasculitis and resulting in increased vascular permeability, edema, and, eventually, decreased vascular volume, altered tissue perfusion, and widespread organ failure. Many tick species are capable of transmitting *R. rickettsii*. The principal ticks are the **American dog tick** (*Dermacentor variabilis*) in the eastern United States and Canada, the **wood tick** (*Dermacentor andersoni*) in the western United States and Canada, the **brown dog tick** (*Rhipicephalus sanguineus*) in Mexico and southwestern United States, and *Amblyomma cajennense* in Central and South America.

Epidemiology

RMSF is the most common rickettsial illness in the United States, occurring primarily in the eastern coastal, southeastern, and south-central states. Most cases occur from April to September after outdoor activity in wooded areas. RMSF occurs more commonly in adults, but the case fatality rate is

FIGURE 122.4 Clinical signs identified in children with Rocky Mountain spotted fever. (A) Edema of the dorsum of the hand. (B) Periorbital edema. (C and D) Petechial rashes involving the palm and sole. (From Paddock CD, Alvarez-Hernández G. *Rickettsia rickettsii* [Rocky Mountain spotted fever]. In: Long SS, Prober CG, Fischer M, eds. *Principles and Practice of Pediatric Infectious Diseases*. 5th ed. Philadelphia: Churchill Livingstone; 2018 [fig. 178.3].)

highest in children 5–9 years of age. In approximately 50% of pediatric cases of RMSF there is no recall of a tick bite.

Clinical Manifestations

The incubation period of RMSF is 2–14 days, with an average of 7 days. The onset is nonspecific with headache, malaise, and fever. A pale, rose red macular or maculopapular rash appears in 90% of cases usually 2–5 days after fever onset. The early rash blanches on pressure and is accentuated by warmth. It progresses over hours or days to a petechial and purpuric eruption that appears first on the feet and ankles, then the wrists and hands, and progresses centripetally to the trunk and head. A hallmark feature is the involvement of the palms and soles (Fig. 122.4). Myalgias, especially of the lower extremities, and intractable headaches are common. Severe cases progress with splenomegaly, myocarditis, renal impairment, pneumonitis, and shock.

Laboratory and Imaging Studies

Thrombocytopenia, anemia, hyponatremia, hypoalbuminemia, and elevated hepatic transaminase levels are common laboratory findings. Organisms can be detected in skin biopsy specimens by fluorescent antibodies or polymerase chain reaction (PCR), although this test is not widely available. Serologic testing is used to confirm the diagnosis. Approximately 50% of patients will not have detectable antibody until the second week of illness, and treatment should not be withheld pending confirmation.

Differential Diagnosis

The differential diagnosis includes meningococcemia, bacterial sepsis, toxic shock syndrome, leptospirosis, ehrlichiosis, measles, enteroviruses, infectious mononucleosis, collagen vascular diseases, Henoch-Schönlein purpura, COVID-19-associated multisystem inflammatory syndrome in children (MIS-C), and idiopathic thrombocytopenic purpura. The diagnosis of RMSF should be suspected with fever and petechial rash, especially with a history of a tick bite or outdoor activities during spring and summer in endemic regions. Delayed diagnosis and late treatment usually result from atypical initial symptoms and late appearance of the rash.

Treatment

Therapy for suspected RMSF should not be postponed pending results of diagnostic tests. Doxycycline is the drug of choice, even for young children, despite the theoretical risk of dental staining in children younger than 8 years of age.

Complications and Prognosis

In severe infections, capillary leakage results in noncardiogenic pulmonary edema (acute respiratory distress syndrome), hypotension, disseminated intravascular coagulation, circulatory collapse, and multiple organ failure, including encephalitis, myocarditis, hepatitis, and renal failure.

Untreated illness may persist for 3 weeks and progress to multisystem involvement. The mortality rate is as high as 40%

FIGURE 122.5 Human monocytotropic ehrlichiosis. Peripheral blood smear (buffy coat preparation) showing intracellular inclusions (arrows) in mononuclear cells of a patient with human monocytotropic ehrlichiosis (Wright stain, $\times 400$). (From Dumler JS, Walker DH. *Ehrlichia chaffeensis* [human monocytotropic ehrlichiosis], *Anaplasma phagocytophilum* [human granulocytotropic anaplasmosis], and other Anaplasmataceae. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 9th ed. Philadelphia: Elsevier; 2020 [fig. 192.1].)

without treatment, which is reduced to 1–3% with treatment. Permanent sequelae are common after severe disease.

Prevention

Preventive measures to avoid tick-borne infections and careful removal of ticks are recommended.

EHRlichiosis (Ehrlichia chaffeensis) AND ANAPLASMOSIS (Anaplasma phagocytophilum)

Etiology

The term **ehrlichiosis** often is used to refer to all forms of infection with *Ehrlichia*. **Human monocytic ehrlichiosis** is caused by *E. chaffeensis*, which infects predominantly monocytic cells and is transmitted by the tick *A. americanum* (Lone star tick). Disease may also be caused by *Ehrlichia ewingii* (granulocytes) and *Ehrlichia muris*-like agent (unknown, suspected monocytes). **Human anaplasmosis** is caused by *A. phagocytophilum* and is transmitted by the tick *I. scapularis* (black-legged tick) or *I. pacificus* (western black-legged tick).

Epidemiology

Human monocytic ehrlichiosis occurs in broad areas across the southeastern, south-central, and mid-Atlantic United States in a distribution that parallels that of RMSF. Anaplasmosis is found mostly in the northeastern and upper midwestern United States, but infections have been identified in northern California, the mid-Atlantic states, and broadly across Europe. Ehrlichiosis due to *E. muris*-like agents has been reported only from Wisconsin and Minnesota.

Clinical Manifestations

Human monocytic ehrlichiosis, anaplasmosis, and *Ehrlichiosis ewingii* cause similar acute febrile illnesses characterized by fever, malaise, headache, myalgias, anorexia, and nausea. Rash occurs more commonly in ehrlichiosis than anaplasmosis but even so is uncommon in adults. In contrast to adult patients, nearly two thirds of children with human monocytic ehrlichiosis present with a macular or maculopapular rash, although petechial lesions may occur. Symptoms usually last for 1–2 weeks.

Laboratory and Imaging Studies

Characteristic laboratory findings include leukopenia, lymphocytopenia, thrombocytopenia, anemia, and elevated hepatic transaminases. Hyponatremia is common. Morulae are found infrequently in circulating monocytes of persons with human monocytic ehrlichiosis but are found in 20–60% of persons with anaplasmosis (Fig. 122.5). Seroconversion or fourfold rise in antibody titer confirms the diagnosis; this requires acute and convalescent samples and is not helpful during the acute illness. PCR tests for both ehrlichiosis and anaplasmosis are available and can confirm diagnosis during the acute illness.

Differential Diagnosis

Ehrlichiosis is clinically similar to other arthropod-borne infections, including RMSF, tularemia, babesiosis, early Lyme disease, murine typhus, relapsing fever, and Colorado tick fever. The differential diagnosis also includes infectious mononucleosis, Kawasaki disease, COVID-19-associated MIS-C, endocarditis, viral infections, hepatitis, leptospirosis, Q fever, collagen vascular diseases, and leukemia.

Treatment

As with RMSF, therapy for suspected ehrlichiosis should not be postponed pending results of diagnostic tests. Ehrlichiosis and anaplasmosis are treated with doxycycline.

Complications and Prognosis

Severe pulmonary involvement with acute respiratory distress syndrome has been reported in several cases. Other reported severe complications include meningoencephalitis and myocarditis. Most patients improve within 48 hours. Failure to respond to doxycycline within 3 days suggests either misdiagnosis or co-infection with another organism.

Prevention

Preventive measures to avoid tick-borne infections and careful removal of ticks are recommended.

WEST NILE VIRUS (SEE CHAPTER 101)

Dengue Fever

There are four dengue fever virus types (flaviviruses) transmitted to humans predominantly by the *A. aegypti* mosquito

vector. Enzootic transmission via monkeys may occur, but person (viremic) to mosquito to person is the most frequent mechanism of viral infection. Dengue virus is most prevalent in the tropics, and endogenous infections have been reported in Florida and Texas.

Infected patients may have subclinical disease or a self-limited febrile illness. Dengue hemorrhagic fever, the most severe manifestation of the illness, occurs in patients who have had a previous dengue virus infection (different serotype) and who manifest an exaggerated immunologic response to the new dengue virus serotype.

Dengue viremia usually precedes the influenza-like illness characterized by fever, myalgias, musculoskeletal pain (**break bone fever**), headaches, macular rash, elevated liver enzymes, acute respiratory distress syndrome, and peripheral cytopenias. Shock may occur with third space fluid losses, which may be associated with an increasing hematocrit. Epistaxis, hemoptysis, gastrointestinal, and uterine bleeding may occur.

Diagnosis is based on the geographic epidemiology, clinical presentation, and detection of dengue virus by PCR. Therapy requires good supportive care with fluid and blood replacement as needed.

Ebola Virus

Ebola virus is a filovirus producing a severe and often lethal hemorrhagic fever syndrome. It is transmitted by direct person-to-person contact, particularly body fluids; the fruit bat may be the animal reservoir for Ebola and the related Marburg virus. Ebola is most often seen in central Africa, although imported cases have been reported in persons traveling from endemic or epidemic regions.

Clinical manifestations may begin with a sudden onset of fever, myalgias, diarrhea, and malaise but are then followed by significant hemorrhagic manifestations. Leukopenia, lymphopenia, thrombocytopenia, elevated liver enzymes, and prolonged clotting times are common. The diagnosis is confirmed by the presence of IgM and IgG antibodies to the virus. Treatment is supportive, including replacement of blood and fluid losses.

Chikungunya Virus

Chikungunya virus (CHIK) is an alphavirus in the togavirus family and is transmitted by most *Aedes* species of mosquitos in Africa and Latin America. Nonhuman primates may be the animal reservoir.

CHIK fever is characterized by a sudden illness with high fever, rash, and severe arthralgias. Fever may abate but return in the “saddleback” pattern. Polyarthralgias involve the small joints, which are exquisitely tender, and may persist for several weeks. The rash appears as facial flushing but evolves to a maculopapular occasionally pruritic eruption on the trunk, extremities, soles, and palms. Children may have CNS symptoms (irritability, seizures). Leukopenia, lymphocytosis, and an elevated ESR or C-reactive protein (CRP) are common.

The diagnosis is confirmed by PCR or antibody responses. Treatment is supportive, particularly for the incapacitating joint manifestations. Tumor necrosis factor (TNF)-blocking agents may be beneficial for severe and persistent arthritis.

Zika Virus

Zika virus, a member of the flavivirus group, is transmitted by many *Aedes* mosquito species and is prevalent in equatorial regions of South America and Asia. Monkeys may be the animal reservoir. Zika virus infection manifests with fever, rash, arthralgia, nonpurulent conjunctivitis, and headache. Infection in children and adults is usually self-limited; the greatest concern is infection during pregnancy resulting in transplacental transmission to the fetus with subsequent severe microcephaly and other congenital malformations. Diagnosis is confirmed by Zika virus antibody titers or PCR.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 123

Parasitic Diseases

PROTOZOAL DISEASES

Protozoa are the simplest organisms of the animal kingdom. They are unicellular. Most are free living, but some have a commensal or parasitic existence. Protozoal diseases include malaria, toxoplasmosis, babesiosis, and the intestinal protozoal diseases amebiasis, cryptosporidiosis, and giardiasis.

Malaria**Etiology**

Malaria is caused by obligate intracellular protozoa of the genus *Plasmodium*, including *P. falciparum*, *P. malariae*, *P. ovale*, *P. vivax*, and *P. knowlesi*. *Plasmodium* has a complex life cycle that enables survival in different cellular environments in the human host and in the mosquito vector. There are two major phases in the life cycle, an **asexual phase (schizogony)** in humans and a **sexual phase (sporogony)** in mosquitoes. The **erythrocytic phase** of *Plasmodium* asexual development begins when the merozoites released from exoerythrocytic schizonts in the liver penetrate erythrocytes. When inside the erythrocyte, the parasite transforms into the **ring form**, which enlarges to become a **trophozoite**. These latter two forms can be identified with Giemsa stain on blood smear, which is the primary means of confirming the diagnosis of malaria.

The parasites usually are transmitted to humans by female *Anopheles* mosquitoes. Malaria also can be transmitted through blood transfusion, via contaminated needles, and transplacentally to a fetus.

Epidemiology

Malaria is a worldwide problem with transmission in more than 100 countries with a combined population of more than 3.2 billion people. Malaria is an important cause of fever and morbidity in the tropical world. The principal areas of transmission are sub-Saharan Africa, southern Asia, Southeast Asia, and Central and South America. Approximately 1,500–2,000 imported cases are recognized annually in the United States,

CHARACTERISTIC	<i>P. FALCIPARUM</i>	<i>P. VIVAX</i>	<i>P. OVALE</i>	<i>P. MALARIAE</i>	<i>P. KNOWLESI</i>
Exoerythrocytic cycle	5.5–7 days	6–8 days	12 days	9 days	16 days
Erythrocytic cycle	43–52hr	48hr	48hr	72hr	24hr
Usual incubation period (range)	13–14 days	13–14 days	13–14 days	35 days	12–16 days
Erythrocyte preference	Can infect all	Reticulocytes	Reticulocytes	Older red cells	Can infect all
Usual parasite load (% erythrocytes infected)	High	Low	Low	Low	May be high
Secondary exoerythrocytic cycle (hypnozoites) and relapses	Absent	Present	Present	Absent	Absent
Severity of primary attack	Can be severe	Mild to severe	Mild	Mild—severe disease in a patient suspected of having <i>P. malariae</i> should raise the suspicion of <i>P. knowlesi</i>	Mild to severe
Usual periodicity of febrile attacks	43–52hr	48hr	48hr	72hr	24hr

Modified from Ansong D, Seydel KB, Taylor T. Malaria. In: Ryan ET, Hill DR, Solomon T, et al., eds. Hunter's Tropical Medicine and Emerging Infectious Disease. 10th ed. Philadelphia: Saunders; 2020.

FIGURE 123.1 The *Plasmodium* life cycle and disease patterns of recrudescence and relapse. Anopheline mosquitoes transmit malaria by injecting sporozoites into the human host. The sporozoites then invade hepatocytes, in which they develop into schizonts. Each infected hepatocyte ruptures to liberate 10,000–30,000 merozoites that invade circulating erythrocytes. Growth and development of the parasites in red cells result in subsequent waves of merozoite invasion. This asexual blood cycle repeats every 24 (*Plasmodium knowlesi*), 48 (*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*), or 72 (*Plasmodium malariae*) hours, leading to amplification of parasite density; paroxysms of chills, fevers, and sweats; and other manifestations of disease. Malaria symptoms are typically experienced 2–4 weeks after the mosquito bite. If the parasites are not cleared (e.g., patient receives partially effective therapy), recrudescence of parasitemia and malaria symptoms can occur. Eradicating parasites with an effective drug regimen cures malaria. Some *P. vivax* and *P. ovale* parasites can postpone their development in the liver, persisting as latent forms called hypnozoites. Hypnozoites are not eradicated by standard therapy (e.g., chloroquine) directed against blood stages. Resumption of hypnozoite development months to years after initial infection can lead to malaria relapse that requires an additional round of drug therapy to treat recurrent symptoms and eradicate blood-stage parasites. A course of primaquine can prevent relapses of malaria, but this treatment may not always be successful because of inadequate patient compliance, interindividual variations of drug metabolism, or variable parasite responses to low or high drug doses. (From Fairhurst RM, Wellem TE. Malaria [*Plasmodium* species]. In: Bennett JE, Dolin R, Blaser MJ, eds. Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases. 9th ed. Philadelphia: Elsevier; 2020 [fig. 274.2].)

with most cases occurring among infected foreign civilians from endemic areas who travel to the United States and among U.S. citizens who travel to endemic areas without appropriate chemoprophylaxis.

Clinical Manifestations

The clinical manifestations of malaria range from asymptomatic infection to fulminant illness and death, depending on the virulence of the infecting malaria species and the host immune response. The incubation period ranges from 7–30 days, depending on the *Plasmodium* species (Table 123.1). The most characteristic clinical feature of malaria, which is seldom noted with other infectious diseases, is **febrile paroxysms** alternating with periods of fatigue but otherwise relative wellness. The classic symptoms of the febrile paroxysms of malaria include high fever, rigors, sweats, and headache. Paroxysms coincide with the ruptures of schizonts that occur every 48 hours with *P. vivax* and *P. ovale* (**tertian periodicity**), every 72 hours with *P. malariae* (**quartan periodicity**), and every 24 hours with *P. knowlesi*. Periodicity can be tertian with *P. falciparum* infections but is often irregular.

Short-term relapse describes the recurrence of symptoms after a primary attack that is due to the survival of erythrocyte forms in the bloodstream. **Long-term relapse** describes the renewal of symptoms long after the primary attack, usually due to the release of merozoites from an exoerythrocytic source in the liver. Long-term relapse occurs with *P. vivax* and *P. ovale* because of persistence in the liver (Fig. 123.1).

Laboratory and Imaging Studies

The diagnosis of malaria is established by the identification of organisms on stained smears of peripheral blood. In nonimmune persons, symptoms typically occur 1–2 days before parasites are detectable on blood smear. Although *P. falciparum* is most likely to be identified from blood during a febrile paroxysm, the timing of the smears is less important than obtaining smears several times each day over 3 successive days. Both thick and thin blood smears should be examined. The concentration of erythrocytes on a **thick smear** is approximately 20–40 times greater than that on a **thin smear**. Thick smears are used to scan large numbers of erythrocytes quickly. Thin smears allow for positive identification of the malaria species and determination of the percentage of infected erythrocytes, called parasitemia, which also is useful in following the response to therapy. **Rapid diagnostic tests** are available as point-of-care tests. Such tests provide results in 15–20 minutes and are particularly useful in areas where reliable microscopic diagnosis is not available. The rapid tests are able to detect *P. falciparum* but are unable to differentiate between *P. vivax*, *P. ovale*, and *P. malariae*. Sensitivity is low for non-*falciparum* species and in patients with low-level parasitemia. For these reasons, as well as to guide management decisions, all rapid tests should be followed by microscopic examination regardless of the results.

Differential Diagnosis

The most important aspect of diagnosing malaria in children is to consider the possibility of malaria in any child who has fever,

TABLE 123.2 Major Pediatric Syndromes Caused by Parasitic Nematodes

SYNDROME	ETIOLOGIC AGENT	TRANSMISSION	TREATMENT
Hookworm iron deficiency	<i>Ancylostoma duodenale</i> <i>Necator americanus</i>	Larval ingestion and penetration Larval penetration	Albendazole or mebendazole or pyrantel pamoate
Cutaneous larva migrans	<i>Ancylostoma braziliense</i> (a zoonotic hookworm)	Larval penetration (and failure to migrate)	Generally self-limited; albendazole or ivermectin
<i>Trichuris</i> dysentery or colitis	<i>Trichuris trichiura</i>	Egg ingestion	Mebendazole or albendazole or ivermectin
Intestinal ascariasis	<i>Ascaris lumbricoides</i>	Ingestion of <i>Ascaris</i> eggs	Albendazole or mebendazole or ivermectin
Visceral larva migrans	<i>Toxocara canis</i> <i>T. cati</i> <i>Baylisascaris procyonis</i>	Egg ingestion	Albendazole or mebendazole or ivermectin
Ocular larva migrans	<i>Toxocara canis</i> <i>T. cati</i> <i>Baylisascaris procyonis</i>	Egg ingestion	Albendazole or mebendazole or ivermectin
Diarrhea, malabsorption (celiac-like)	<i>Strongyloides stercoralis</i>	Larval penetration	Ivermectin
Pinworm	<i>Enterobius vermicularis</i>	Egg ingestion	Albendazole or mebendazole or pyrantel pamoate
Trichinellosis	<i>Trichinella spiralis</i>	Ingestion of infected undercooked meat	Albendazole or mebendazole plus corticosteroids for severe symptoms
Abdominal angiostrongyliasis	<i>Angiostrongylus costaricensis</i>	Ingestion of contaminated food	Albendazole or mebendazole
Eosinophilic meningitis	<i>Angiostrongylus cantonensis</i> (rat lungworm)	Ingestion of undercooked contaminated seafood	Albendazole

chills, splenomegaly, anemia, or decreased level of consciousness with a history of recent travel or residence in an endemic area, regardless of the use of chemoprophylaxis. The differential diagnosis is broad and includes many infectious diseases, such as typhoid fever, tuberculosis, brucellosis, relapsing fever, infective endocarditis, influenza, poliomyelitis, yellow fever, trypanosomiasis, kala-azar, and amebic liver abscess.

Treatment

Oral chloroquine is the recommended treatment except for chloroquine-resistant *P. falciparum*. Artemether-lumefantrine (preferred), atovaquone-proguanil (second line), quinine sulfate plus doxycycline or tetracycline or clindamycin, or mefloquine are appropriate therapies for malaria acquired in areas of chloroquine resistance. Specific treatment should be guided by where the patient acquired the infection and the local resistance patterns. Patients with malaria usually require hospitalization and may require intensive care unit admission. In the past, quinidine gluconate was first-line treatment for severe malaria in the United States, but it is no longer manufactured. Artesunate is available as a commercial product, but it is not consistently stocked in all hospitals. Patients presenting with severe malaria to a hospital where artesunate is not in stock should be treated with an effective oral antimalarial until intravenous artesunate is obtained from a commercial source or the Centers for Disease Control and Prevention (CDC), whichever is fastest. The preferred interim oral antimalarial treatment is artemether-lumefantrine because of its fast onset of action. Atovaquone-proguanil, quinine sulfate, and mefloquine are other potential oral options.

Complications and Prognosis

Cerebral malaria is a complication of *P. falciparum* infection and a frequent cause of death (10–40% of cases), especially among children and nonimmune adults. Similar to other complications, cerebral malaria is more likely to occur among patients with intense parasitemia (>5% of erythrocytes on a blood smear). Other complications include splenic rupture, renal failure, severe hemolysis (**blackwater fever**), pulmonary edema, hypoglycemia, thrombocytopenia, and **algid malaria** (sepsis syndrome with vascular collapse).

Death may occur with any of the malarial species but is most frequent with complicated *P. falciparum* malaria. The likelihood of death is increased in children with pre-existing health problems, such as measles, intestinal parasites, schistosomiasis, anemia, and malnutrition. Death is much more common in developing countries.

Prevention

There are two components of malaria prevention: reduction of exposure to infected mosquitoes and chemoprophylaxis. Mosquito protection is necessary because no prophylactic regimen can guarantee protection in every instance due to the widespread development of resistant organisms.

Chemoprophylaxis is necessary for all visitors to, and residents of, the tropics who have not lived there since infancy. Children of nonimmune women should have chemoprophylaxis from birth. Children of women from endemic areas have passive immunity until 3–6 months of age, after which they are increasingly likely to acquire malaria. Specific chemoprophylaxis should be guided by the distribution of resistance pattern and determined before making specific recommendations (http://www.cdc.gov/malaria/travelers/country_table/a.html).

Mefloquine, doxycycline, chloroquine, and atovaquone-proguanil are commonly prescribed medications.

Toxoplasmosis

Toxoplasmosis is a zoonosis caused by *Toxoplasma gondii*, an intracellular protozoan parasite. Infection is acquired by infectious oocysts, such as those excreted by newly infected cats, which play an important role in amplifying the organism in nature, or from ingesting cysts in contaminated, undercooked meat. Less commonly, transmission occurs transplacentally during acute infection of pregnant women. In the United States, the incidence of congenital infection is 1–10 per 10,000 live births.

Acquired toxoplasmosis is usually asymptomatic. Symptomatic infection is typically a heterophile-negative mononucleosis syndrome that includes lymphadenopathy, fever, and hepatosplenomegaly. Disseminated infection, including myocarditis, pneumonia, and central nervous system (CNS) toxoplasmosis, is more common among immunocompromised persons, especially persons with AIDS. Among women infected during pregnancy, 50–60% give birth to an infected infant. The later in pregnancy that infection occurs, the more likely it is that the fetus will be infected, but the less severe the illness (see [Chapter 66](#)). Serologic diagnosis can be established by a fourfold increase in antibody titer or seroconversion, a positive immunoglobulin M (IgM) antibody titer, or positive polymerase chain reaction for *T. gondii* in peripheral white blood cells, cerebrospinal fluid (CSF), serum, or amniotic fluid.

Treatment includes pyrimethamine and sulfadiazine, which act synergistically against *Toxoplasma*. Because these compounds are folic acid inhibitors, they are used in conjunction with folic acid. Spiramycin, which can be obtained from the U.S. Food and Drug Administration, is also used in therapy of pregnant women with toxoplasmosis. Corticosteroids are reserved for patients with acute CNS or ocular infection.

Ingesting only well-cooked meat and avoiding cats or soil in areas where cats defecate are prudent measures for pregnant or immunocompromised persons. Administration of spiramycin to infected pregnant women has been associated with lower risks of congenital infection in their offspring.

HELMINTHIASES

Helminths are divided into three groups: roundworms, or nematodes, and two groups of flatworms, the trematodes (flukes) and the cestodes (tapeworms).

Hookworm Infections

Hookworm infection is caused by several species of hookworms, with *Ancylostoma duodenale* and *Necator americanus* being the most important ([Table 123.2](#)). There are more than 600 million humans worldwide infected with hookworms. *A. duodenale* is the predominant species in the Mediterranean region, northern Asia, and certain areas of South America. *N. americanus* predominates in the Western hemisphere, sub-Saharan Africa, and Southeast Asia. Optimal soil conditions and fecal contamination are found in many agrarian tropical countries and in the southeastern United States. Infection typically occurs in young children, especially during the first decade of life. The larvae are found in warm, damp soil and infect humans by penetrating the skin. They migrate to the lungs, ascend the

TABLE 123.3 Major Pediatric Syndromes Caused by Parasitic Trematodes

SYNDROME	ETIOLOGIC AGENT	TRANSMISSION	TREATMENT
Schistosomiasis		Freshwater contact with penetration through the skin	
Intestinal or hepatic schistosomiasis	<i>Schistosoma mansoni</i> <i>Schistosoma japonicum</i> <i>Schistosoma mekongi</i>		Praziquantel or oxamniquine
Urinary schistosomiasis	<i>Schistosoma haematobium</i>		
Parasitoses due to other trematodes		Ingestion of raw or inadequately cooked foods	
Clonorchiasis	<i>Clonorchis sinensis</i> (Chinese liver fluke)		Praziquantel or albendazole
Fascioliasis	<i>Fasciola hepatica</i> (sheep liver fluke)		Triclabendazole
Fasciolopsiasis	<i>Fasciolopsis buski</i>		Praziquantel
Heterophyiasis	<i>Heterophyes heterophyes</i>		Praziquantel
Metagonimiasis	<i>Metagonimus yokogawai</i>		Praziquantel
Metorchiasis	<i>Metorchis conjunctus</i> (North American liver fluke)		Praziquantel
Nanophyetiasis	<i>Nanophyetus salmincola</i> (salmon fluke)		Praziquantel
Opisthorchiasis	<i>Opisthorchis viverrini</i> (Southeast Asian liver fluke)		Praziquantel or albendazole
Paragonimiasis	<i>Paragonimus westermani</i> , <i>P. kellicotti</i> , <i>P. uterobilateralis</i> , <i>P. skjabinii</i> , <i>P. heterotremus</i> , <i>P. africanus</i> (lung flukes)		Praziquantel or triclabendazole

trachea, are swallowed, and reside in the intestine. The worms mature and attach to the intestinal wall, where they suck blood and shed eggs.

Infections are usually asymptomatic. Intense pruritus (*ground itch*) occurs at the site of larval penetration, usually the soles of the feet or between the toes, and may include papules and vesicles. Migration of larvae through the lungs usually is asymptomatic. Symptoms of abdominal pain, anorexia, indigestion, fullness, and diarrhea occur with hookworm infestation. The major manifestation of infection is anemia. Examination of fresh stool for hookworm eggs is diagnostic. Therapy includes anthelmintic treatment with albendazole, mebendazole, or pyrantel pamoate and treatment for anemia. Eradication depends on sanitation of the patient's environment and treatment with antiparasitics.

Ascariasis

Ascariasis is caused by *Ascaris lumbricoides*, a large nematode. It is the most prevalent helminthiasis, affecting more than 800 million people (see Table 123.2). After humans ingest the eggs, larvae are released and penetrate the intestine, migrate to the lungs, ascend the trachea, and are swallowed. On entering the intestines again, they mature and produce eggs that are excreted in the stool and are deposited in the soil, where they survive for prolonged periods.

Manifestations may be the result of migration of the larvae to other sites of the body or the presence of adult worms in the intestine. **Pulmonary ascariasis** occurs as the larvae migrate through the lung, producing cough, blood-stained sputum, eosinophilia, and transient infiltrates on chest x-ray films. Adult larvae in the small intestine may cause abdominal pain and distention. Intestinal obstruction from adult worms

can occur, particularly in children due to the small diameter of their intestinal lumens and their propensity to acquire large worm burdens. Migration of worms into the bile duct may rarely cause acute biliary obstruction. Examination of fresh stool for characteristic eggs is diagnostic. Effective control depends on adequate sanitary treatment and disposal of infected human feces.

Visceral Larva Migrans

Visceral larva migrans is a systemic nematodiasis caused by ingestion of the eggs of the dog tapeworm, *Toxocara canis*, or, less commonly, the cat tapeworm, *Toxocara cati*, or the raccoon tapeworm, *Baylisascaris procyonis* (see Table 123.2). These organisms also cause **ocular larva migrans**.

Visceral larva migrans is most common in young children with pica who have dogs or cats as pets. Ocular toxocariasis occurs in older children. The eggs of these roundworms are produced by adult worms residing in the dog and cat intestine. Ingested eggs hatch into larvae that penetrate the gastrointestinal tract and migrate to the liver, lung, eye, CNS, and heart, where they die and calcify.

Symptoms of visceral larva migrans are the result of the number of migrating larvae and the associated immune response. Light infections are often asymptomatic. Symptoms include fever, cough, wheezing, and seizures. Physical findings may include hepatomegaly, lung crackles, rash, and lymphadenopathy. Visual symptoms may include decreased acuity, strabismus, periorbital edema, or blindness. Eye examination may reveal granulomatous lesions near the macula or disc. Ocular larva migrans is generally characterized by isolated, unilateral ocular disease and no systemic findings.

SYNDROME	ETIOLOGIC AGENT	TRANSMISSION	TREATMENT
Echinococcosis		Ingestion of <i>Echinococcus</i> eggs	
Unilocular	<i>E. granulosus</i>		Surgical resection plus albendazole
Alveolar echinococcosis	<i>E. multilocularis</i>		Surgical resection is only reliable means of treatment; some reports suggest adjunct use of albendazole or mebendazole
Neurocysticercosis	Larval stage of <i>Taenia solium</i> (cysticerci)	Ingestion of eggs through direct fecal-oral contact or ingestion of fecally contaminated foods	Albendazole or praziquantel
Adult tapeworm infections	<i>T. solium</i> (pork tapeworm)	Ingestion of contaminated raw/undercooked pork	Praziquantel
	<i>Hymenolepis diminuta</i>	Ingestion of infected insect	Praziquantel
	<i>Hymenolepis nana</i>	Fecal-oral	Praziquantel

Eosinophilia and hypergammaglobulinemia associated with elevated isohemagglutinin levels suggest the diagnosis, which is confirmed by serology (enzyme-linked immunosorbent assay) or, less commonly, by biopsy. This is usually a self-limited illness. In severe disease, albendazole or mebendazole is used, often with adjunctive corticosteroids to limit the inflammatory response of *Toxocara* antigens by dying parasites. Deworming puppies and kittens, major excretors of eggs, decreases the risk of infection.

Enterobiasis (Pinworm)

Pinworm is caused by *Enterobius vermicularis*, a nematode that is distributed worldwide. Enterobiasis affects individuals at all socioeconomic levels, especially children. Crowded living conditions predispose to infection. Humans ingest the eggs carried on hands, which are present in house dust or on bedclothes. The eggs hatch in the stomach, and the larvae migrate to the cecum and mature. At night, the females migrate to the perianal area to lay their eggs (up to 10,000 eggs), which remain infective in the indoor environment for 2–3 weeks.

The most common symptoms are nocturnal anal pruritus (**pruritus ani**) and sleeplessness, presumably resulting from the migratory female worms. Vaginitis and salpingitis may develop secondary to aberrant worm migration. The eggs are detected by microscopically examining adhesive cellophane tape pressed against the anus in the morning to collect eggs. Less commonly, a worm may be seen in the perianal region. Treatment is with albendazole, mebendazole, or pyrantel pamoate each given as a single oral dose and repeated in 2–3 weeks.

Schistosomiasis

Schistosomiasis (bilharziasis) is caused by flukes that parasitize the bloodstream, including *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, and, rarely, *S. intercalatum* and *S. mekongi* (Table 123.3). Schistosomiasis affects more than 190 million people. Humans are infected by cercariae in contaminated water that emerge in an infectious form from snails and

penetrate intact skin. Each adult worm migrates to specific sites: *S. haematobium* to the **bladder plexus** and *S. mansoni* and *S. japonicum* to the **mesenteric vessels**. The eggs are deposited by the adult flukes in urine (*S. haematobium*) or stool (*S. mansoni* and *S. japonicum*). *S. haematobium* is prevalent in Africa and the Middle East; *S. mansoni* in Africa, the Middle East, the Caribbean, and South America; *S. japonicum* in China, the Philippines, and Indonesia; *S. mekongi* in Cambodia and Laos; and *S. intercalatum* in West and Central Africa.

The manifestations of schistosomiasis result from eggs that are trapped at the site of deposition or at metastatic locations. Within 4–8 weeks of infection, while the worms are maturing, a syndrome of fever, malaise, cough, abdominal pain, hepatosplenomegaly, eosinophilia, and rash can occur (**Katayama fever**). This syndrome is followed by a resultant inflammatory response that leads to further symptoms. Eggs may be found in the urine (*S. haematobium*) or stool (*S. mansoni* and *S. japonicum*) of infected individuals. Sanitary measures, molluscicides, and therapy for infected individuals may help control the illness.

Echinococcosis

Echinococcosis includes **hydatid or unilocular cyst disease**, caused by *Echinococcus granulosus* (the **minute dog tapeworm**), polycystic disease, caused by *Echinococcus vogeli*, and **alveolar cyst disease**, caused by *Echinococcus multilocularis* (Table 123.4). Dogs become infected with tapeworms by eating infected sheep or cattle viscera and excrete eggs in their stools. Humans acquire echinococcosis by ingesting eggs and become an intermediate host. The eggs hatch in the intestinal tract, and the larva (**oncospheres**) penetrate the mucosa and enter the circulation to pass to the liver and other visceral organs, forming cysts.

E. granulosus has a worldwide distribution and is endemic in sheep-raising and cattle-raising areas of Australia, South America, South Africa, the former Soviet Union, and the Mediterranean region. The prevalence is highest in children. Symptoms caused by *E. granulosus* result from space-occupying cysts. Pulmonary cysts may cause hemoptysis, cough, dyspnea, and respiratory distress. Brain cysts appear

as tumors; liver cysts cause problems as they compress and obstruct blood flow. Ultrasonography identifies cystic lesions, and the diagnosis is confirmed by serologic testing. Large or asymptomatic granulosa cysts are removed surgically. Treatment with albendazole has shown some benefit.

Neurocysticercosis

Neurocysticercosis is caused by infection with the embryonated eggs of the **pork tapeworm**, *Taenia solium*, and is the most frequent helminthic infection of the CNS (see [Table 123.4](#)). Humans are infected after consuming cysticerci in raw or undercooked larva-containing pork. Infected humans then pass *T. solium* eggs in their feces. Fecal-oral transmission of eggs, either to the originally infected host or other individuals, then results in cysticerci development in organs—in particular, in subcutaneous tissues, brain, and eyes. *T. solium* is endemic in Asia, Africa, and Central and South America.

Cysts typically enlarge slowly, causing no or minimal symptoms for years or decades until the organism begins to die. The cyst then begins to swell, and leakage of antigen incites an inflammatory response, resulting in the presenting signs of focal or generalized seizures and calcified cerebral cysts identified by computed tomography or magnetic resonance imaging. The CSF shows lymphocytic or eosinophilic pleocytosis. The diagnosis is confirmed by serologic testing. Neurocysticercosis is treated with albendazole or praziquantel, corticosteroids for concomitant cerebral inflammation from cyst death, and anti-convulsant drugs.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 124

Tuberculosis

ETIOLOGY

Mycobacterium tuberculosis bacilli are pleomorphic, weakly gram-positive curved rods that are **acid fast**, which is the capacity to form stable mycolate complexes with arylmethane dyes. *M. tuberculosis* grows slowly; culture from clinical specimens on solid synthetic media usually takes 3–6 weeks. Drug-susceptibility testing requires an additional 4 weeks. Growth can be detected in 1–3 weeks in selective liquid media using radio-labeled nutrients. Polymerase chain reaction (PCR) of clinical specimens may allow rapid diagnosis in many laboratories.

EPIDEMIOLOGY

It is estimated that one third of the world's population is infected with tuberculosis (TB). Most of these are latent infections. Without treatment, tuberculosis *disease* develops in 5–10% of immunologically normal adults with tuberculosis *infection* at some time during their lives; the risk is higher in infants and those who are immunocompromised, especially HIV-positive individuals. An estimated 10 million new cases of TB occur each year worldwide, including 1 million children. One to 2 million

deaths are attributed to the disease annually. Almost 9,000 TB cases were reported in the United States in 2019.

Transmission of *M. tuberculosis* is from person to person, usually by respiratory droplets that become airborne when a symptomatic individual coughs, sneezes, laughs, or even breathes. Infected droplets dry and become droplet nuclei, which may remain suspended in the air for hours, long after the infectious person has left the environment.

Several patient-related factors are associated with an increased chance of transmission. Of these, a positive acid-fast smear of the sputum most closely correlates with infectivity. Children with primary pulmonary tuberculosis disease rarely, if ever, infect others because tubercle bacilli are relatively sparse in the endobronchial secretions of children with pulmonary tuberculosis. In addition, when young children cough, they rarely produce sputum, lacking the tussive force necessary to project and suspend infectious particles of the requisite size. Hospitalized patients with suspected pulmonary tuberculosis should be placed initially in airborne isolation. Most infectious patients become noninfectious within 2 weeks of starting effective treatment. Cavitory disease, nonadherence to treatment, and resistant infection increase the risk of transmission.

In North America, TB rates are highest in foreign-born persons from high-prevalence countries, residents of prisons, residents of nursing homes, homeless persons, users of illegal drugs, persons who are poor and without health care, health care workers, and children exposed to adults in high-risk groups. Most children are infected with *M. tuberculosis* from household contacts, but outbreaks of childhood tuberculosis centered in schools, daycares, churches, school buses, and stores still occur. A high-risk adult working in the area has been the source of the outbreak in most cases. Certain biologic response modifiers (anti-tumor necrosis factor [TNF] antibodies), often used for treatment of inflammatory conditions, can increase risk of development of tuberculosis disease. Genes involved in **Mendelian susceptibility to mycobacterial diseases (MDMD)** increase the risk of infection for environmental (atypical) mycobacterium and dissemination of **bacille Calmette-Guérin (BCG)** vaccine and possibly *M. tuberculosis*. These mutations affect the interleukin 12 (IL-12)/interferon- γ (IFN- γ)-mediated immunity pathway.

CLINICAL MANIFESTATIONS

Latent tuberculosis describes the asymptomatic stage of infection with *M. tuberculosis*. The **tuberculin skin test (TST)** or **interferon- γ release assay (IGRA)** is positive, but the chest radiograph is normal or shows healed infection (calcification). **Tuberculosis disease** occurs when there are clinical signs and symptoms and/or an abnormal chest radiograph or other extrapulmonary manifestation. The interval between latent TB and the onset of disease may be several weeks in children or many decades in adults. In young children, TB usually develops as an immediate complication of the primary infection, and the distinction between infection and disease may be less obvious.

Primary TB in children is often an asymptomatic infection. Often the disease is manifested by a positive TST or IGRA with mild abnormalities on the chest radiograph, such as atelectasis or an infiltrate accompanied by hilar or other adenopathy (**Ghon complex**). Malaise, low-grade fever, erythema nodosum, or symptoms resulting from lymph node

enlargement may occur after the development of delayed hypersensitivity. **Progressive primary disease** is characterized by a primary pneumonia that develops shortly after initial infection. Progression to disseminated miliary disease or central nervous system (CNS) infection occurs most commonly in the first year of life. Cavitation is rare in children but more typical with reactivation pulmonary TB in adolescents and adults.

Tuberculous pleural effusion, which may accompany primary infection, generally represents the immune response to the organisms and most commonly occurs in older children or adolescents. Pleurocentesis reveals lymphocytes and an increased protein level, but the pleural fluid usually does not contain bacilli.

Reactivation pulmonary tuberculosis, common in adolescents and typical in adults, usually is confined to apical segments of upper lobes or superior segments of lower lobes. There is usually little lymphadenopathy and no extrathoracic infection. This is a manifestation of a secondary expansion of infection at a site seeded years previously during primary infection. Advanced disease is associated with cavitation and endobronchial spread of bacilli. Symptoms include fever, night sweats, malaise, and weight loss. A productive cough and hemoptysis often herald cavitation and bronchial erosion.

Miliary tuberculosis refers to widespread hematogenous dissemination to multiple organs. The lesions are of roughly the same size as a millet seed, from which the name *miliary* is derived. Miliary TB is characterized by fever, general malaise, weight loss, lymphadenopathy, night sweats, and hepatosplenomegaly. Diffuse bilateral pneumonitis is common, and meningitis is often present. The chest radiograph reveals bilateral miliary infiltrates, showing overwhelming infection. The TST may be nonreactive as a result of **anergy**. Liver or bone marrow biopsy may be useful for diagnosis.

Tuberculous meningitis most commonly occurs in children younger than 5 years or immunocompromised patients, often within 6 months of primary infection. Tubercle bacilli that seed the meninges during the primary infection replicate, triggering an inflammatory response. This condition may have an insidious onset, initially characterized by low-grade fever, headache, and subtle personality change. Progression of the infection results in basilar meningitis with impingement of the cranial nerves and is manifested by meningeal irritation and, eventually, increased intracranial pressure, deterioration of mental status, and coma. Computed tomography (CT) scans show hydrocephalus, edema, periventricular lucencies, and infarctions. Cerebrospinal fluid (CSF) analysis reveals pleocytosis (50–500 leukocytes/mm³), which early in the course of disease may be either lymphocytes or polymorphonuclear leukocytes. Glucose is low, and protein is significantly elevated. Acid-fast bacilli are not detected frequently in the CSF by either routine or fluorescent staining procedures. Although culture is the standard for diagnosis, PCR for *M. tuberculosis* may be useful to confirm meningitis but lacks sensitivity.

Skeletal tuberculosis results from either hematogenous seeding or direct extension from a caseous lymph node. This is usually a chronic disease with an insidious onset that may be mistaken for chronic osteomyelitis. Radiographs reveal cortical destruction. Biopsy and culture are essential for proper diagnosis. Tuberculosis of the spine, **Pott disease**, is the most common skeletal site.

TABLE 124.1 TST and IGRA Recommendations for Infants, Children, and Adolescents

Children for Whom Immediate TST or IGRA is Indicated[†]:

- Contacts of people with confirmed or suspected contagious tuberculosis (contact investigation)
- Children with radiographic or clinical findings suggesting tuberculosis disease
- Children immigrating from countries with endemic infection (e.g., Asia, Middle East, Africa, Latin America, countries of the former Soviet Union), including international adoptees
- Children with history of significant[‡] travel to countries with endemic infection who have substantial contact with the resident population[§]

Children Who Should Have Annual TST or IGRA:

- Children living with HIV infection

Children at increased risk of progression of TBI to TB disease: Children with other medical conditions, including diabetes mellitus, chronic renal failure, malnutrition, congenital or acquired immunodeficiencies, and children receiving TNF antagonists, deserve special consideration. Underlying immune deficiencies associated with these conditions theoretically would enhance the possibility for progression to severe disease. Initial histories of potential exposure to tuberculosis should be included for all these patients. If these histories or local epidemiologic factors suggest a possibility of exposure, immediate and periodic TST or IGRA should be considered. **A TST or IGRA should be performed before initiation of immunosuppressive therapy, including prolonged systemic corticosteroid administration, organ transplantation, use of TNF- α antagonists or blockers, or other immunosuppressive therapy in any child requiring these treatments.**

[†]Bacille Calmette-Guérin (BCG) immunization is not a contraindication to a TST; IGRA is generally preferred for BCG-vaccinated children.

[‡]Beginning as early as 3 mo of age for TST and 2 yr of age for IGRAs, for TBI and disease.

[§]Some experts define significant travel as birth, travel, or residence in a country with an elevated tuberculosis rate for at least 1 mo.

[¶]If the child is well and has no history of exposure, the TST or IGRA should be delayed for 8 to 10 wk after return.

HIV, Human immunodeficiency virus; IGRA, interferon-gamma release assay; TBI, *Mycobacterium tuberculosis* infection; TNF, tumor necrosis factor; TST, tuberculin skin test.

From American Academy of Pediatrics. Tuberculosis. In: Kimberlin DW, Barnett ED, Lynfield R, et al., eds. Red Book: 2021-2024 Report of the Committee on Infectious Diseases. Itasca, IL: American Academy of Pediatrics; 2021;786–814.

Other forms of TB include **abdominal tuberculosis** that occurs from swallowing infected material. This is a relatively uncommon complication in developed nations where dairy herds are inspected for bovine tuberculosis. Gastrointestinal TB can present with signs and symptoms similar to inflammatory bowel disease. **Tuberculous peritonitis** is associated with abdominal TB and presents as fever, anorexia, ascites, and abdominal pain. **Urogenital tuberculosis** is a late reactivation complication and is rare in children. Symptomatic illness presents as dysuria, frequency, urgency, hematuria, and sterile pyuria or infertility. TB may also result in extrathoracic lymphadenitis in the cervical, supraclavicular, and submandibular areas (**scrofula**).

Congenital tuberculosis can mimic neonatal sepsis or present at days to weeks of age with hepatosplenomegaly and respiratory disease.

INDURATION ≥ 5 MM
Children in close contact with known or suspected contagious people with TB disease
Children suspected to have TB disease: <ul style="list-style-type: none"> • Findings on chest radiograph consistent with active or previous TB disease • Clinical evidence of TB disease[‡]
Children receiving immunosuppressive therapy [§] or with immunosuppressive conditions, including HIV infection
INDURATION ≥ 10 MM
Children at increased risk of disseminated TB disease: <ul style="list-style-type: none"> • Children <4yr • Children with other medical conditions, including Hodgkin disease, lymphoma, diabetes mellitus, chronic renal failure, or malnutrition (see Table 124.1) • Children born in high-prevalence regions of the world • Children with significant travel to high-prevalence regions of the world[¶] • Children frequently exposed to adults who are living with HIV, experiencing homelessness, or incarcerated, or to people who inject or use drugs or have alcohol use disorder
INDURATION ≥ 15 MM
Children without any risk factors

*See www.cdc.gov/tb/publications/guidelines/pdf/ciw778.pdf.

[†]These definitions apply regardless of previous bacille Calmette-Guérin immunization; erythema alone at TST site does not indicate a positive test result. Tests should be read at 48 to 72 hr after placement.

[‡]Evidence by physical examination or laboratory assessment that would include TB in the working differential diagnosis (e.g., meningitis).

[§]Including immunosuppressive doses of corticosteroids or tumor necrosis factor- α antagonists or blockers or immunosuppressive drugs used in transplant recipients.

[¶]Some experts define significant travel as travel or residence in a country with an elevated TB rate for at least 1 mo.

From American Academy of Pediatrics. Tuberculosis. In: Kimberlin DW, Barnett ED, Lynfield R, et al., eds. Red Book: 2021-2024 Report of the Committee on Infectious Diseases. Itasca, IL: American Academy of Pediatrics; 2021;786-814. HIV, Human immunodeficiency virus; TB, tuberculosis; TST, tuberculin skin test.

LABORATORY AND IMAGING STUDIES

Two types of tests are used to detect the immune response to *M. tuberculosis* and are used to screen patients for latent TB and investigation of active TB. The TST response to tuberculin antigen is a manifestation of a T-cell-mediated delayed hypersensitivity. The **Mantoux test**, an intradermal injection of **purified protein derivative standard (PPD-S)**, usually on the volar surface of the forearm, is the standard TST. It is usually positive 2–6 weeks after onset of infection (up to 3 months) and at the time of symptomatic illness. This test is preferred in children less than 2–4 years of age (Table 124.1). False-negative responses may occur early in the illness, with overwhelming TB infection, with concomitant viral infection, or as a result of immunosuppression (secondary to underlying illness, HIV, or malnutrition). Tests with questionable results should be repeated after several weeks. All internationally adopted children with an initially negative TST should have a repeat TST after 3 months in the United States. The TST is interpreted based on the host status and size of induration (Table 124.2). In general, interpretation of TST in people who have had previous BCG vaccine can be difficult, given the cross reaction of TST with antigens present in the vaccine.

However, in situations when a TB exposure has occurred, the TST should be read and interpreted as if no vaccine had been given.

An IGRA is a whole blood test that measures INF- γ production by T lymphocytes in response to antigens from the *M. tuberculosis* complex, which includes *M. bovis* but not antigens found in the BCG vaccine. An IGRA is the recommended diagnostic test for persons older than 2–4 years of age in the United States. It has similar sensitivity to the TST but improved specificity because it is unaffected by prior BCG vaccination. It is also practically easier to obtain, as it requires only one visit to complete. As with the TST, in immunocompromised persons and in active tuberculosis, IGRA findings may be indeterminate.

The ultimate diagnostic confirmation relies on culture of the organism. Sputum is an excellent source for diagnosis in pulmonary disease in adults but is difficult to obtain in young children. Induced sputum or gastric fluid obtained via an indwelling nasogastric tube with samples taken before or immediately on waking contains swallowed sputum and provides alternate samples in young children. Large volumes of fluid (CSF, pericardial fluid) yield a higher rate of recovery of organisms, but slow growth of the mycobacteria makes culture less helpful in acute illness. Even with optimal collection, cultures are positive in less than half of children with TB. When the organism is grown, drug susceptibilities should be determined because of the increasing incidence of resistant organisms. Utilization of culture and susceptibility results from the source case is often necessary given the difficulty of obtaining timely results.

PCR testing for mycobacteria has expedited diagnosis, especially with CNS disease. However, these assays have limited sensitivity and provide no susceptibility data. Most experts would recommend that infants younger than 12 months with suspected TB undergo lumbar puncture for evaluation of CNS involvement.

Diagnostic Imaging

Because many cases of pulmonary tuberculosis in children are clinically relatively silent, radiography is a cornerstone for the diagnosis of disease (Figs. 124.1 and 124.2). All lobar segments of the lung are at equal risk of being the focus of the initial infection. In 25% of cases, two or more lobes of the lungs are involved, although disease usually occurs at one site only. Spread of infection to regional lymph nodes occurs early. Hilar lymphadenopathy is inevitably present with childhood TB. Partial bronchial obstruction caused by external compression from the enlarging nodes can cause air trapping, hyperinflation, and lobar emphysema. Occasionally, children have a picture of lobar pneumonia without impressive hilar lymphadenopathy. If the infection is progressively destructive, liquefaction of the lung parenchyma leads to formation of a thin-walled primary tuberculous cavity. Adolescents with pulmonary tuberculosis may develop segmental lesions with hilar lymphadenopathy or the apical infiltrates, with or without cavitation, that are typical of adult reactivation tuberculosis.

Radiographic studies aid greatly in the diagnosis of **extrapulmonary tuberculosis** in children. Plain radiographs, CT, and magnetic resonance imaging (MRI) of the tuberculous spine usually show collapse and destruction of the vertebral body with narrowing of the involved disk spaces.

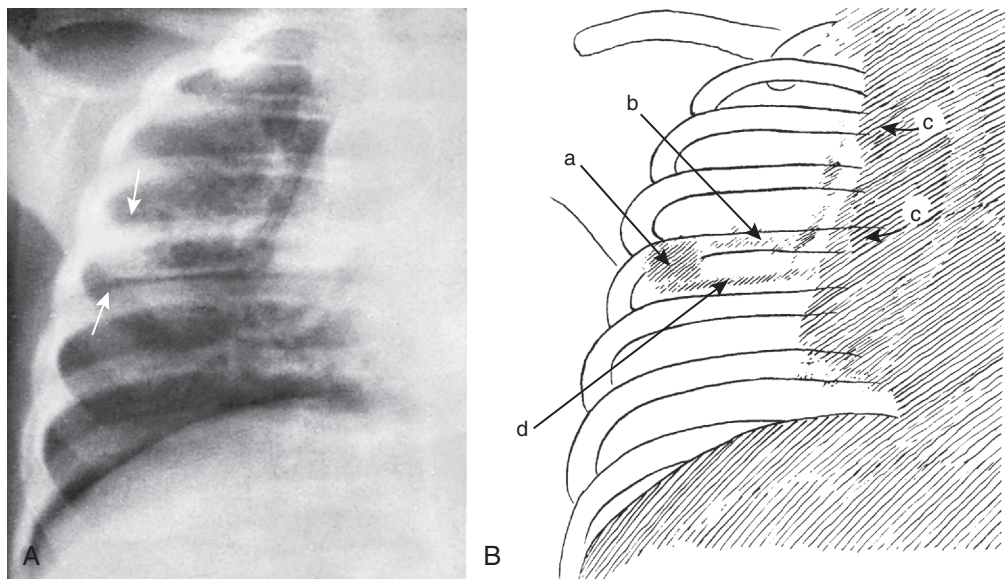

FIGURE 124.1 Fresh primary tuberculous complex in an infant 4 months of age. The pulmonary focus is the small shadow of increased density (arrows) in the inferolateral segment of the right upper lobe. (A) Roentgenogram. (B) Schematic drawing: a, primary focus; b, lymphangitis; c, enlarged hilar and mediastinal nodes; d, loculated pleural exudate. (From Silverman FN, Kuhn JP, et al. *Essentials of Caffey's Pediatric X-Ray Diagnosis*. Philadelphia: Saunders; 1990:292 [fig. 11.23].)

FIGURE 124.2 Huge calcifying primary tuberculous focus in the right lower lobe that dwarfs the rest of the complex in an asymptomatic girl 6 years of age. The healing and calcification of this huge necrotic focus without manifest clinical disease at any time demonstrates the often benign clinical aspects of severe structural tuberculous disease. In (A), a frontal projection, the large calcifying focus appears to be perihilar, but in (B), a lateral projection, this focus lies far behind the lung root in a dorsal subsegment of the right lower lobe near the dorsal pleura. (From Silverman FN, Kuhn JP, et al. *Essentials of Caffey's Pediatric X-Ray Diagnosis*. Philadelphia: Saunders; 1990:293 [fig. 11.26].)

Radiographic findings in bone and joint TB range from mild joint effusions and small lytic lesions to massive destruction of the bone. CT or MRI of the brains of patients with CNS involvement may be normal during early stages of the infection. As disease progresses, basilar enhancement and communicating hydrocephalus with signs of cerebral edema or early focal ischemia are the most common findings.

Granulomas on pathology of tissue can also help to establish the diagnosis of TB on samples from lymph nodes and other biopsies.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of TB includes a multitude of diagnoses because TB may affect any organ, and in early disease the symptoms and signs may be nonspecific. In pulmonary disease, TB may appear similar to bacterial or fungal pneumonia, malignancy, and any systemic disease in which generalized lymphadenopathy occurs. The diagnosis of TB should be suspected if the TST or IGRA is positive or if there is history of TB exposure.

TABLE 124.3 Recommended Usual Treatment Regimens for Drug-Susceptible TB Infection and TB Disease in Infants, Children, and Adolescents

INFECTION OR DISEASE CATEGORY	REGIMEN	REMARKS	
<i>Mycobacterium tuberculosis</i> infection (positive TST or IGRA result, no disease)*	• Isoniazid susceptible	12 wk of isoniazid plus rifapentine, once a week	Most experts consider isoniazid-rifapentine to be the preferred regimen for treatment of TBI for children ≥2yr, and some experts prefer isoniazid-rifapentine therapy for TBI in children ≥2yr.
		or	
		4 mo of rifampin, once a day	Continuous daily therapy is required. Intermittent therapy even by DOT is not recommended.
		or	
		3 mo of isoniazid plus rifampin, once a day	To be considered if above 2 regimens are not feasible.
		or	
	6 or 9 mo of isoniazid, once a day	If daily therapy is not possible, DOT twice a week can be used; medication doses differ with daily and twice-weekly regimens.	
• Isoniazid resistant	4 mo of rifampin, once a day	Continuous daily therapy is required. Intermittent therapy even by DOT is not recommended.	
• Isoniazid-rifampin resistant	Consult a TB specialist	Moxifloxacin or levofloxacin with or without ethambutol or pyrazinamide are most commonly given.	
Pulmonary and extrapulmonary disease (except meningitis) [†]	2 mo of rifampin, isoniazid, pyrazinamide, and ethambutol (RIPE) daily or 3 times per week, followed by 4 mo of isoniazid and rifampin [‡] by DOT [§] for drug-susceptible <i>M. tuberculosis</i>	Some experts recommend a 3-drug initial regimen (isoniazid, rifampin, and pyrazinamide) if the risk of drug resistance is low. DOT is highly desirable. If hilar adenopathy only and the risk of drug resistance is low, a 6-mo course of isoniazid and rifampin is sufficient. DOT is required for intermittent regimens. Drugs can be given daily or 3 times per week; 2 times per week is acceptable if DOT resources are scarce.	
	At least 9 mo of isoniazid and rifampin for <i>Mycobacterium bovis</i> susceptible to these drugs		
Meningitis	2 mo of isoniazid, rifampin, pyrazinamide, and ethionamide, if possible, or an aminoglycoside or capreomycin, once a day, ^{¶,**} followed by 4–10 mo of isoniazid and rifampin, once a day or 3 times per week (9–12 mo total) for drug-susceptible <i>M. tuberculosis</i> At least 12 mo of therapy without pyrazinamide for <i>M. bovis</i> susceptible to isoniazid and rifampin	See text for information on corticosteroids.	

*See text for comments and additional acceptable/alternative regimens.

[†]Duration of therapy may be longer for people living with HIV infection, and additional drugs and dosing intervals may be indicated.

[‡]Medications should be administered daily for the first 2 wk to 2 mo of treatment and then can be administered daily or 3 times per week by DOT; twice weekly is acceptable if resources for DOT are limited. Intermittent therapy is not recommended for people living with HIV infection.

[§]If initial chest radiograph shows pulmonary cavities and/or sputum culture after 2 mo of therapy remains positive, the continuation phase is extended to 7 mo, for a total treatment duration 9 of mo.

^{||}Parenteral streptomycin, kanamycin, or amikacin.

[¶]Many experts add a fluoroquinolone to this initial regimen.

^{**}When susceptibility to first-line drugs is established, the ethionamide, aminoglycoside (or capreomycin), and/or fluoroquinolone can be discontinued.

From American Academy of Pediatrics. Tuberculosis. In: Kimberlin DW, Barnett ED, Lynfield R, et al., eds. Red Book: 2021-2024 Report of the Committee on Infectious Diseases. Itasca, IL: American Academy of Pediatrics; 2021;786–814.

DOT, Directly observed therapy; IGRA, interferon-gamma release assay; TB, tuberculosis; TBI, *Mycobacterium tuberculosis* infection; TST, tuberculin skin test.

The differential diagnosis of tuberculous lymphadenopathy includes infections caused by atypical mycobacteria, *Bartonella*, fungi, viruses, and bacteria, as well as toxoplasmosis, sarcoidosis, drug reactions, and malignancy.

TREATMENT

Combination therapy is the backbone of therapy for tuberculosis disease to prevent the emergence of resistance. The treatment of TB is affected by the presence of naturally occurring drug-resistant organisms in large bacterial populations, even before therapy is initiated, and the fact that mycobacteria replicate slowly and can remain dormant in the body for prolonged periods. Several regimens are available for treatment of latent tuberculosis infection in children. These include **isoniazid (INH)** for 9 months or **rifampin (RIF)** for 4 months. For children over age 2 years, combination therapy with once-weekly INH and rifapentine for 12 weeks is another option. Therapy for latent infection is aimed at eradicating organisms sequestered within macrophages and suppressed by normal T-cell activity.

Children with primary pulmonary tuberculosis and patients with extrapulmonary tuberculosis have medium-sized populations in which significant numbers of drug-resistant organisms may or may not be present. In general, these patients are treated with combination therapy (Table 124.3) for a prolonged course, typically 6–9 months, depending on the type of disease. INH and RIF are bactericidal for *M. tuberculosis*. Along with pyrazinamide ± ethambutol, they form the backbone of the antimicrobial treatment of tuberculosis. Other drugs and prolonged regimens are used in special circumstances, such as CNS infection and multidrug-resistant (MDR) or extensively drug-resistant (XDR) tuberculosis, which are unfortunately increasing in prevalence in some parts of the world and are associated with increased treatment failure and mortality.

In the United States, drug-susceptible pulmonary tuberculosis is treated with 2 months of four drugs and then completed with INH and RIF for an additional 4 months. Noncompliance or nonadherence is a major problem in TB control because of the long-term nature of treatment and the sometimes-difficult social circumstances of the patients. As treatment regimens become shorter, adherence assumes an even greater importance. Improvement in compliance occurs with **directly observed therapy (DOT)**, which requires a health care worker to witness the administration of medications and is the standard of care in most settings.

COMPLICATIONS AND PROGNOSIS

The prognosis of TB in infants, children, and adolescents is excellent with early recognition and effective chemotherapy. In most children with pulmonary tuberculosis, the disease completely resolves, and ultimately radiographic findings are normal. The prognosis for children with bone and joint tuberculosis and tuberculous meningitis depends directly on the stage of disease at the time antituberculosis medications are started. Tuberculosis of the spine may result in angulation or **gibbus** formation that requires surgical correction after the infection is cured. Most childhood tuberculous meningitis occurs in developing countries, where the prognosis is poor. Resistant organisms are more difficult to treat and worsen prognosis.

PREVENTION

TB control programs work on case finding and treatment, which interrupts secondary transmission of infection from close contacts. Infected close contacts are identified by positive TST or IGRA testing and can be started on appropriate treatment to prevent transmission.

Prevention of transmission in health care settings involves appropriate physical ventilation of the air around the source case. Offices, clinics, and hospital rooms used by adults with possible TB should have adequate ventilation, with air exhausted to the outside (**negative-pressure ventilation**). Health care providers should have annual screening with a TST or IGRA.

The only available vaccine against TB is the **BCG vaccine**. The original vaccine organism was a strain of attenuated *Mycobacterium bovis*. The preferred route of administration is intradermal injection with a syringe and needle because this is the only method that permits accurate measurement of an individual dose. The official recommendation of the World Health Organization is a single dose administered during infancy. This vaccine is not routinely used in the United States. Studies show BCG provides up to 80–90% protection from TB. In general, it is thought that vaccination reduces the incidence of miliary disease and TB meningitis in infants. Many who receive BCG vaccine never have a positive TST reaction. When a reaction does occur, the induration size is usually less than 10 mm, and it variably wanes after several years. BCG vaccination does not affect results of an IGRA.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 125

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

ETIOLOGY

The cause of acquired immunodeficiency syndrome (AIDS) is the human immunodeficiency virus (HIV), a single-stranded RNA virus of the retrovirus family that produces a reverse transcriptase enabling the viral RNA to act as a template for DNA transcription and integration into the host genome. HIV-1 causes 99% of all human cases. HIV-2, which is less virulent, causes 1–9% of cases in parts of Africa and is very rare in the United States.

HIV infects **helper T cells (CD4 cells)** and cells of monocyte-macrophage lineage via interaction of viral protein gp120 with the CD4 molecule and chemokines (CXCR4 and CCR5) that serve as co-receptors. Interaction with these molecules facilitates membrane fusion and cell entry by the virus. HIV infection directly and indirectly depletes CD4 T cells. Because helper T cells are important for delayed hypersensitivity,

T-cell-dependent B-cell antibody production, and T-cell-mediated lymphokine activation of macrophages, their destruction produces a profound combined (B- and T-cell) immunodeficiency. A lack of T-cell regulation and unrestrained antigenic stimulation result in polyclonal hypergammaglobulinemia with nonspecific and ineffective globulins. Other cells bearing CD4, such as microglia, astrocytes, oligodendroglia, and placental tissues, also may be infected with HIV.

HIV infection is a continuously progressive process with a variable period of clinical latency before development of AIDS-defining conditions. All untreated patients have evidence of ongoing viral replication and progressive CD4 lymphocyte depletion. There are no overt manifestations of immunodeficiency until CD4 cell numbers decline to critical threshold levels. Quantitation of the viral load (HIV-1 RNA level) has become an important parameter in management.

Horizontal transmission of HIV is by sexual contact (vaginal, anal, or orogenital), percutaneous contact (from contaminated needles or other sharp objects), or mucous membrane exposure to contaminated blood or body fluid. Transmission by contaminated blood and blood products has been nearly eliminated in developed countries by screening donated blood products but still occurs in developing countries. **Vertical transmission** of HIV from mother to infant may occur transplacentally in utero, during birth, or via breast-feeding. Risk factors for perinatal transmission include prematurity, prolonged rupture of membranes, and high maternal HIV viral load at delivery. In non-breast-feeding infants, perinatal transmission can be decreased from approximately 25% to less than 8% with administration of intravenous (IV) zidovudine during labor and postnatal treatment of the infant with oral zidovudine. Maternal treatment during pregnancy with combination antiretroviral therapy (cART) can reduce the risk of transmission to less than 1%. Breast-feeding by HIV-infected mothers increases the risk of vertical transmission. In developing countries where breast-feeding is associated with increased survival and decreased morbidity from malnutrition, diarrheal diseases, and other infections, continued administration of either cART for the mother or postnatal prophylactic ART for the infant can reduce transmission risk from breast-feeding. In untreated infants, the mean incubation interval for development of an AIDS-defining condition after vertical transmission is 5 months (range, 1–24 months) compared with a longer incubation period after horizontal transmission of 7–10 years.

EPIDEMIOLOGY

Worldwide, as of 2019, approximately 38 million persons are living with HIV, and 1.8 million of them are children. There were 1.7 million new infections in 2019 with approximately 150,000 new infections in children. Approximately 65% of all people living with HIV reside in sub-Saharan Africa. Worldwide, 690,000 people died from HIV-related illnesses in 2019. In 2018, the estimated number of people over the age of 13 years and living with HIV in the United States was 1.2 million. Vertical transmission is decreasing with less than 100 infants each year in the United States acquiring HIV perinatally. Most pediatric cases in the United States occur in adolescents who engage in unprotected sexual activities. Worldwide the number of deaths related to HIV and the

numbers of children infected with HIV have steadily decreased in large part due to treatment with ART.

CLINICAL MANIFESTATIONS

In adolescents and adults, primary infection results in the **acute retroviral syndrome** (resembling mononucleosis) that develops after an incubation period of 2–6 weeks and consists of fever, malaise, weight loss, pharyngitis, lymphadenopathy, and often a maculopapular rash. The risk of opportunistic infections and other AIDS-defining conditions is related to the depletion of CD4 T cells. A combination of CD4 cell count and percentage and clinical manifestations is used to classify HIV infection in children (Tables 125.1 and 125.2).

Initial symptoms with vertical transmission vary and may include failure to thrive, neurodevelopmental delay, lymphadenopathy, hepatosplenomegaly, chronic or recurrent diarrhea, interstitial pneumonitis, or oral thrush. These findings may be subtle and remarkable only by their persistence. Manifestations that are more common in children than adults with HIV infection include recurrent bacterial infections, lymphoid hyperplasia, chronic parotid swelling, lymphocytic interstitial pneumonitis, and earlier onset of progressive neurologic deterioration. Pulmonary manifestations of HIV infection are common and include *Pneumocystis jirovecii* pneumonia, which can present early in infancy as a primary pneumonia characterized by hypoxia, tachypnea, retractions, elevated serum lactate dehydrogenase, and fever.

In the United States, most pregnant women are screened and, if indicated, treated for HIV infection. Women with high HIV viral loads at delivery will be offered a cesarean section. All infants born to HIV-infected mothers are bathed prior to receiving their newborn hepatitis B vaccine and vitamin K injection, receive antiretroviral prophylaxis, are exclusively formula fed, and are prospectively tested for infection. The diagnosis of HIV infection in most infants born in the United States is confirmed before development of clinical signs of infection.

LABORATORY AND IMAGING STUDIES

HIV infection can be diagnosed definitively in non-breast-fed infants by 1 month of age and in virtually all infected infants by 6 months of age using viral diagnostic assays (RNA polymerase chain reaction [PCR] or DNA PCR). Maternal antibodies may be detectable until 12–15 months of age, and a positive serologic test in the infant is not considered diagnostic until 18 months of age. *HIV PCR (RNA or DNA) is the preferred method for diagnosing HIV infection during infancy and identifies ~50% of infected newborns at 48 hours and ~90% at 28 days.* Timing of diagnostic viral testing varies depending on specific risk factors but typically involves testing at 2–3 weeks of age, at 1–2 months of age, and at 4–6 months of age. Testing at birth and 2–6 weeks after cessation of antiretroviral prophylaxis should be considered for infants at high risk for in utero infection (high maternal HIV viral load at delivery). HIV RNA PCR has 25–60% sensitivity during the first weeks of life, increasing to 90–100% by 2–3 months of age.

HIV infection of an exposed infant is confirmed if virologic tests are positive on two separate occasions. HIV infection can be reasonably excluded in non-breast-fed infants with at least two virologic tests performed at older than 1 month of age, with one test being performed after 4 months of age. Loss of

†Only among adults, adolescents, and children aged ≥6 yr.

HIV, Human immunodeficiency virus; HSV, herpes simplex virus.

From the Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. Guidelines for the use of antiretroviral agents in pediatric HIV infection [table 6]. <https://clinicalinfo.hiv.gov/sites/default/files/guidelines/documents/PediatricGuidelines.pdf>.

HIV antibody combined with negative HIV DNA PCR confirms absence of HIV infection. Persistence of a positive HIV antibody test after 18 months of age indicates HIV infection.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of AIDS in infants includes primary immunodeficiency syndromes and intrauterine infections such as cytomegalovirus (CMV) and syphilis. Prominence of individual symptoms, such as diarrhea, may suggest other etiologies.

TREATMENT

Management of HIV infection in children and adolescents is evolving and complex. It should be directed by a specialist in the treatment of HIV infection. Rapid initiation of cART is recommended for all HIV-infected children, irrespective of age or immune status.

Effective cART significantly reduces viral loads and leads to the amelioration of clinical symptoms and opportunistic infections. Combination therapy that includes either a

non-nucleoside reverse transcriptase inhibitor (NNRTI), a protease inhibitor (PI), or an integrase inhibitor depending on the child's age plus a dual-nucleoside/nucleotide reverse transcriptase inhibitor (NRTI) backbone is recommended for initial treatment of all HIV-infected children. The goal of therapy is to reduce the HIV viral load to below the level of detection and normalize or preserve the patient's immune status. The most recent specific recommendations for treatment regimens (<https://clinicalinfo.hiv.gov/en/guidelines>) should be consulted before initiating therapy for any patient.

The ability of HIV to develop resistance to antiretroviral agents rapidly and the development of cross-resistance to several classes of agents simultaneously are major problems. Determination of HIV viral load, CD4 cell count, and HIV resistance genotype is essential for monitoring and modifying antiretroviral treatment.

Routine immunizations are recommended but may result in suboptimal immune responses. Additional vaccines are also recommended, such as the 23-valent pneumococcal polysaccharide vaccine for children aged 2 years and older following receipt of pneumococcal conjugate vaccine, and the MenACWY vaccine beginning at age 2 months. Because of the risk of fatal measles in children with AIDS, children without severe immunosuppression should receive their first dose of measles, mumps, rubella (MMR) at 12 months of age and the second dose at 4–6 years of age. Varicella-zoster virus (VZV) vaccine should be given only to asymptomatic, nonimmunosuppressed children beginning at 12 months of age as two doses of vaccine at least 3 months apart. Inactivated split influenza virus vaccine should be administered annually to all HIV-infected children at or after 6 months of age.

COMPLICATIONS

The approach to the numerous opportunistic infections in HIV-infected patients involves treatment and prophylaxis for infections likely to occur as CD4 cells are depleted. With potent ART and immune reconstitution, routine prophylaxis for common opportunistic infections depends on the child's age and CD4 count. Infants born to HIV-infected mothers receive prophylaxis for *P. jirovecii* pneumonia with trimethoprim-sulfamethoxazole (TMP-SMX) beginning at 4–6 weeks of age and continued for the first year of life or until HIV infection has been excluded. TMP-SMX prophylaxis for *P. jirovecii* pneumonia for older children and adolescents is provided if CD4 cell counts are less than 500 cells/mm³ or CD4 percentage is less than 15% for children 1 to less than 6 years of age, or less than 200 cells/mm³ or CD4 percentage is less than 15% for children 6–12 years of age. Clarithromycin prophylaxis for *Mycobacterium avium* complex infection is provided if CD4 cell counts are below 750 cells/mm³ for children younger than 1 year, below 500 cells/mm³ for children 1 to less than 2 years of age, below 75 cells/mm³ for children 2 to less than 6 years of age, and below 50 cells/mm³ for children 6 years of age and older.

P. jirovecii pneumonia is treated with high-dose TMP-SMX and corticosteroids. Oral and gastrointestinal candidiasis is common in children and usually responds to fluconazole therapy. VZV infection may be severe and should be treated with acyclovir or other antivirals. Recurrent herpes simplex virus (HSV) infections also may require long-term antiviral prophylaxis. Other common infections in HIV-infected patients include toxoplasmosis, CMV, Epstein-Barr virus infection, salmonellosis, and tuberculosis.

PROGNOSIS

The availability of cART has improved the prognosis for HIV and AIDS dramatically. Risk of death is directly related to the degree of immunosuppression, viral load, and young age. Children less than 1 year of age with very low CD4 percentiles and high viral loads have the poorest prognosis.

PREVENTION

Identification of HIV-infected women before or during pregnancy is crucial to providing optimal therapy for infected women and their infants and to preventing perinatal transmission. Prenatal HIV counseling and testing with consent should be provided for all pregnant women in the United States.

The rate of vertical transmission is reduced to less than 8% by chemoprophylaxis with a regimen of oral zidovudine to the mother started during pregnancy, continued during delivery with IV zidovudine, and then administered orally to the newborn for the first 6 weeks of life. Administration of maternal cART throughout pregnancy to achieve viral suppression (viral load <1,000 copies/mL) with postnatal antiretroviral prophylaxis to the infant reduces the risk of transmission even further to less than 1% in non-breast-feeding infants. The current recommendations for the United States include a 4- to 6-week prophylactic regimen with zidovudine for the infant in combination with maternal intrapartum therapy. The maternal regimen includes continuation or initiation of ART. In high-risk situations (e.g., mother's viral load is >1,000 copies/mL or is unknown, mother did not receive cART during pregnancy), IV zidovudine during delivery is administered and additional antiretrovirals may be given to the infant postnatally (<https://clinicalinfo.hiv.gov/en/guidelines/perinatal/intrapartum-antiretroviral-therapyprophylaxis?view=full>). Scheduled cesarean section at 38 weeks to prevent vertical transmission is recommended for women with HIV RNA levels greater than 1,000 copies/mL, but it is unclear whether cesarean section is beneficial when viral load is less than 1,000 copies/mL or when membranes have already ruptured.

Preventing HIV infection in adults decreases the incidence of infection in children. Adult prevention results from behavior changes such as safe-sex practices, decrease in IV drug use, and needle exchange programs. Screening of blood donors has almost eliminated the risk of HIV transmission from blood products. HIV infection almost never is transmitted in a casual or nonsexual household setting.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

PEARLS FOR PRACTITIONERS

CHAPTER 93

Infectious Disease Assessment

- A complete infectious diseases history should include environmental exposures, sick contacts, travel to endemic areas, immune status, and immunization history.
- Routine screening tests may include complete blood count with differential, inflammatory markers, transaminases, urinalysis and culture, lumbar puncture, or blood culture.
- A microbiologic diagnosis of infection may be confirmed or suggested by rapid antigen tests, cultures, serologic tests, or molecular tests (e.g., polymerase chain reaction).

CHAPTER 94

Immunization and Prophylaxis

- Purified polysaccharide vaccines are poor immunogens for children younger than 2 years. Conjugation of a polysaccharide to a protein carrier creates immunogenic vaccines for *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, and *Neisseria meningitidis* for this age group.
- Contraindications to vaccination include anaphylaxis to prior immunization and immunocompromised patients (live-virus vaccines).
- Administration of blood products and immunoglobulin can diminish response to live-virus vaccines if administered before the recommended interval.

CHAPTER 95

Antiinfective Therapy

- Obtain relevant cultures prior to initiating empiric antibiotics.
- Use of broad-spectrum empiric therapy is recommended for critically ill or immunocompromised patients.
- Sites with poor antimicrobial drug penetration may need drainage (abscess, osteomyelitis).
- Use targeted antimicrobial therapy to employ the least toxic, most narrow-spectrum agent effective against the causative pathogen.

CHAPTER 96

Fever Without a Focus

- Children younger than 1 month with fever should have a complete evaluation of blood, urine, and cerebrospinal fluid and should receive empirical antibiotics.
- Urinary tract infection is the most common serious bacterial infection in children younger than 6 months.
- Children 2–36 months with fever should have a careful history and physical exam. Those without localizing signs or symptoms may need urine and blood cultures.

- Children with sickle cell anemia are at increased risk of bacteremia with encapsulated organisms.
- Children with unexplained fevers lasting more than 14 days have fever of unknown origin (FUO). Among these episodes of FUO, infections cause ~40–50%, inflammatory diseases ~20%, and malignancy ~10%.

CHAPTER 97

Infections Characterized by Fever and Rash

- Common childhood causes of febrile illnesses with rash include measles, rubella, human herpesvirus type 6 (HHV-6), parvovirus B19, and varicella.
- Chickenpox is characterized by fever and a pruritic vesicular rash that comes in crops; secondary staphylococcal or streptococcal skin infection is a common complication.
- Measles is characterized by cough, coryza, conjunctivitis, fever, rash, and Koplik spots on the buccal mucosa, and is extremely contagious.
- Congenital rubella syndrome is characterized by intrauterine growth restriction, retinitis, blueberry muffin rash, and patent ductus arteriosus.
- Roseola (due to HHV-6 and HHV-7) is characterized by an abrupt onset of a rash that appears after defervescence of 4–5 days of fever.
- Erythema infectiosum (due to parvovirus B19) is characterized by fever, malaise, a slapped-cheek rash, and transient aplastic crisis in children with sickle cell anemia.

CHAPTER 98

Cutaneous Infections

- Many childhood cutaneous infections are caused by *Staphylococcus aureus* or group A streptococci.
- Local epidemiology of methicillin-resistant *S. aureus* infections often guides treatment.
- Crusted impetigo is often caused by *S. aureus*.
- Necrotizing fasciitis is a surgical emergency and is suggested by rapid extension of lesions, pain out of proportion to lesions, toxic appearance, or crepitus.
- Common viral causes of superficial skin infections include herpes simplex virus (HSV), human papillomavirus (HPV), and molluscum contagiosum virus.

CHAPTER 99

Lymphadenopathy

- Cervical lymphadenitis is the most common childhood regional lymphadenitis; common causes include streptococcal pharyngitis, respiratory viruses, Epstein-Barr virus (EBV), and cytomegalovirus (CMV).

- The differential diagnosis of cervical adenitis should include Kawasaki disease, cat-scratch disease, atypical tuberculosis, mononucleosis, HIV, and lymphoma.
- Hilar or mediastinal lymphadenopathy can suggest tuberculosis, endemic mycoses, or autoimmune diseases.

CHAPTER 100

Meningitis

- The organisms that most commonly cause neonatal meningitis are group B streptococcus, *Escherichia coli*, and *Listeria monocytogenes*. Older children are more likely to have *Streptococcus pneumoniae* and *Neisseria meningitidis* as a cause of meningitis.
- Partially treated bacterial meningitis may decrease the ability to grow the organism; polymerase chain reaction (PCR) is useful to detect the pathogen but does not provide antimicrobial pathogen sensitivities.
- Enteroviruses and parechovirus are common causes of viral meningitis.
- Herpes simplex may produce meningoencephalitis and requires treatment with intravenous acyclovir.
- Presumptive therapy for neonatal meningitis includes ampicillin and ceftazidime and for older children should be ceftriaxone and vancomycin.

CHAPTER 101

Encephalitis

- Viruses are the most common infectious cause of aseptic meningitis and encephalitis. Intravenous acyclovir should be used empirically if herpes simplex virus or varicella-zoster virus are suspected.
- Acute flaccid myelitis is an emerging condition that appears to be seasonal, presents with acute weakness in the affected limb, and is associated with multiple viral infections.
- Autoimmune encephalitis should be considered in all patients with encephalitis; diagnosis is by detecting brain-specific autoantibodies in blood and cerebrospinal fluid.

CHAPTER 102

The Common Cold

- Young children typically have multiple upper respiratory tract infections (URIs) each year, up to 8–12. Antibiotics are not beneficial in treating these episodes and may instead cause harm.
- Complications of a URI include otitis media, sinusitis, and exacerbation of asthma.

CHAPTER 103

Pharyngitis

- Viruses are the most common cause of pharyngitis. However, if group A streptococcus is isolated by rapid antigen test or culture, it should be treated in order to prevent acute rheumatic fever. Penicillin or amoxicillin are first-line therapies.

- Approximately 20% of school-age children are colonized with group A streptococcus without symptoms.
- A major reason to treat streptococcal pharyngitis is to prevent rheumatic fever. Streptococcal pharyngitis is relatively uncommon in young children under 3 years of age.

CHAPTER 104

Sinusitis

- The bacterial causes of acute sinusitis mirror those of otitis media and are *Streptococcus pneumoniae*, nontypable *Haemophilus influenzae*, and *Moraxella catarrhalis*.
- Complications of sinusitis include orbital cellulitis, Potts puffy tumor, and brain abscess.

CHAPTER 105

Otitis Media

- Poor or absent tympanic membrane mobility to negative and positive pressure using pneumatic otoscopy is a necessary finding for the diagnosis of acute otitis media (AOM).
- Complications of AOM include persistent middle ear effusion, hearing loss, mastoiditis, brain abscess, perforated tympanic membrane, and cholesteatoma.
- OM with effusion is the most frequent sequela of AOM and may result in persistent middle ear effusion, which may be associated with hearing loss.
- Not all episodes of AOM require antibiotic treatment.

CHAPTER 106

Otitis Externa

- Otitis externa is most frequently caused by *Pseudomonas aeruginosa*.
- Topical antibiotic/corticosteroid preparations are effective treatments.

CHAPTER 107

Croup (Laryngotracheobronchitis)

- Croup (laryngotracheobronchitis) is the most common infection of the middle respiratory tract; it is typically caused by parainfluenza virus and presents with stridor.
- The differential diagnosis of croup includes a foreign body, tracheitis, epiglottitis, tracheomalacia, and a vascular ring.
- Treatment includes use of cool mist, oral steroids, and nebulized racemic epinephrine.

CHAPTER 108

Pertussis

- Pertussis typically lasts 6–8 weeks; it is marked by catarrhal, paroxysmal, and convalescent stages and can lead to apnea and severe respiratory distress in infants.

- Vaccination with DTaP and Tdap have reduced the incidence of pertussis, but pertussis remains a common infection among infants younger than 6 months.
- Pertussis is associated with lymphocytosis and post-tussive emesis.

CHAPTER 109

Bronchiolitis

- Bronchiolitis is a common lower respiratory infection in children younger than 2 years, is typically caused by respiratory syncytial virus (RSV), and requires only supportive treatment.
- The differential diagnosis of bronchiolitis includes asthma, heart failure, pneumonia, foreign body, and congenital airway or lung anomalies.

CHAPTER 110

Pneumonia

- *Streptococcus pneumoniae* is the most common bacterial cause of pneumonia outside the neonatal period and is the target of antibiotic selection for community-acquired pneumonia.
- Diagnostic evaluation for children hospitalized for pneumonia often includes complete blood count, blood culture, chest radiography, and occasionally rapid viral diagnostic testing.
- Amoxicillin and ampicillin are first-line antibiotic selections for community-acquired pneumonia in children.
- SARS-CoV-2 is an emerging coronavirus associated with a worldwide pandemic starting in 2019; it can cause lethal respiratory disease as well as a multisystem postinfectious inflammatory syndrome in children.

CHAPTER 111

Infective Endocarditis

- Streptococci are the most common cause of native valve endocarditis in children, whereas staphylococci are more common in those with prosthetic material.
- If infectious endocarditis is suspected, multiple optimal-volume blood cultures should be obtained prior to starting antimicrobial therapy.
- The modified Duke criteria are used to make the diagnosis.
- Treatment is typically given entirely parenterally and is guided by the pathogen identified.

CHAPTER 112

Acute Gastroenteritis

- Management of acute gastroenteritis should include supportive care (correcting dehydration and electrolyte abnormalities) and not antibiotics in most circumstances.
- Enterohemorrhagic *Escherichia coli*-producing Shiga toxin causes hemolytic uremic syndrome characterized by

microangiopathic hemolytic anemia, thrombocytopenia, and acute kidney injury.

- Nucleic acid amplification tests (NAAT) are the tests of choice for the most common causes of viral and bacterial gastroenteritis.
- When indicated, first-line therapy for traveler's diarrhea in children is azithromycin.

CHAPTER 113

Viral Hepatitis

- Various types of viral hepatitis are difficult to distinguish during acute infection; most have a nonspecific prodromal phase followed by an icteric phase. Often acute illness with hepatitis A virus (HAV), HBV, and HCV is mild or even asymptomatic in children.
- Vaccines are available to prevent HAV and HBV infection.
- HBV and HCV infection may become chronic with a risk for cirrhosis or hepatic cancer.
- Treatment of HBV and HCV infection is rapidly changing with the recent availability of new direct-acting antiviral medications.

CHAPTER 114

Urinary Tract Infection

- *Escherichia coli* accounts for the vast majority of pediatric urinary tract infections (UTIs).
- A renal ultrasound should be performed in young children to detect scarring, reflux, and congenital renal anomalies.
- UTI diagnosis requires a positive urine culture.
- Urine leukocyte esterase and nitrite testing aids in the diagnosis of a UTI.

CHAPTER 115

Vulvovaginitis

- Bacterial vaginosis represents disruption of the normal vaginal flora with reduction in lactobacillus and overgrowth of other organisms.
- Nonspecific vaginitis is the most common cause of vulvovaginitis in prepubertal girls.

CHAPTER 116

Sexually Transmitted Infections

- There is increasing antibiotic resistance in *Neisseria gonorrhoeae*. Outpatient treatment of gonococcal urethritis or endocervicitis should include a single intramuscular dose of ceftriaxone. If concurrent *Chlamydia trachomatis* infection has not been ruled out, the patient should also be treated with doxycycline.

- Chlamydia is the most frequently diagnosed bacterial sexually transmitted infection in adolescents and accounts for most cases of nongonococcal urethritis and cervicitis.
- Chlamydial cervicitis is often asymptomatic.

CHAPTER 117

Osteomyelitis

- *Staphylococcus aureus* is the most common bacterial cause of osteomyelitis and is the target of antibiotic selection for this condition.
- Magnetic resonance imaging is the most sensitive diagnostic imaging test for osteomyelitis and will identify lesions early in the course of disease.
- An antistaphylococcal agent (nafcillin, oxacillin, or cefazolin) is the preferred empirical therapy for osteomyelitis in areas where methicillin-resistant *S. aureus* rates are low.
- Most patients are transitioned to oral therapy at hospital discharge to complete a minimum of 3–4 total weeks of therapy.

CHAPTER 118

Infectious Arthritis

- *Staphylococcus aureus* is the most common bacterial cause of septic arthritis and is the target of antibiotic selection for this condition.
- Diagnostic evaluation for septic arthritis should include joint aspirate for cell count, Gram stain, and culture.
- Polymerase chain reaction evaluation for *Kingella kingae* is sometimes useful.
- An antistaphylococcal agent (nafcillin, oxacillin, or cefazolin) is the preferred empirical therapy for septic arthritis in areas where methicillin-resistant *S. aureus* rates are low.

CHAPTER 119

Ocular Infections

- All newborns should receive prophylaxis for ophthalmia neonatorum, typically with erythromycin 0.5% ointment, which will prevent gonococcal but not chlamydial ophthalmia.
- Chlamydia conjunctivitis in the newborn is treated with oral antibiotics to prevent chlamydial pneumonia.
- Neonatal conjunctivitis due to gonococcus is treated with intramuscular or intravenous ceftriaxone.
- Conjunctivitis and/or keratitis in patients who use contact lenses may be due to *Pseudomonas*.

CHAPTER 120

Infection in the Immunocompromised Person

- The presence of fever with neutropenia, even in the absence of other symptoms, demands prompt and thorough evaluation and empirical antimicrobial therapy.

- Fever is often the only sign of serious infection in immunocompromised patients.
- Rectal tenderness or pain on defecation may suggest a perianal abscess.
- The central-line exit site and subcutaneous track should be inspected and blood drawn for culture from each lumen to detect line infections.
- Pneumonia, sinusitis, and bacteremia are the most common sites of infection in patients with fever and neutropenia.

CHAPTER 121

Infections Associated with Medical Devices

- The major complication of indwelling medical devices such as central lines, ventriculoperitoneal shunts, and urinary catheters is infection (health care–associated infections).
- Antibiotic-lock therapy may be used to aid in treatment or prevention of catheter line infections.

CHAPTER 122

Zoonoses and Vector-Borne Infections

- Lyme disease (*Borrelia burgdorferi*) is the most common tick-borne infection in the United States.
- Early treatment of erythema migrans almost always prevents progression to later stages of Lyme disease.
- Ehrlichiosis and anaplasmosis present like Rocky Mountain spotted fever (RMSF).
- RMSF is a severe life-threatening illness that has a 20–80% case fatality rate if untreated.
- Dengue hemorrhagic fever is seen in patients with a previous infection with dengue virus.

CHAPTER 123

Parasitic Diseases

- Chemoprophylaxis for malaria is necessary for all visitors to and residents of the tropics who have not lived there since infancy.
- Malaria is characterized by febrile paroxysms.
- Long-term relapse with malaria occurs because of persistent hepatic infection with either *Plasmodium vivax* or *P. ovale*.

CHAPTER 124

Tuberculosis

- The diagnosis of *Mycobacterium tuberculosis* infection can be difficult. Young children under 2 years should have a purified protein derivative (PPD) test, whereas older children can have a PPD or interferon- γ release assay. Both may not be positive during active infection.
- Pulmonary tuberculosis (TB) initially presents as a pulmonary infiltrate with hilar adenopathy.

- Bone or brain involvement with TB occurs due to hematogenous spread following primary pulmonary TB.
- Reactivation of TB occurs most often in adolescents and patients exposed to corticosteroids or anti-tumor necrosis factor antibodies.

CHAPTER 125

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

- Vertical transmission of HIV, from mother to child, is now an uncommon occurrence in the United States due to

the effectiveness of preventative measures including early maternal diagnosis, maternal treatment during pregnancy and delivery, postnatal prophylactic treatment of the infant, and avoidance of breast-feeding.

- Perinatal acquired HIV presents with failure to thrive, lymphadenopathy, hepatosplenomegaly, parotitis, diarrhea, and opportunistic infections.

THE DIGESTIVE SYSTEM

Dawn R. Ebach | Warren P. Bishop

CHAPTER 126

Digestive System Assessment

HISTORY

After identifying the major gastrointestinal (GI) symptoms, the onset and progression should be determined (improved, unchanged, worsening, involvement of other organ systems). Characterization of signs and symptoms should identify factors that trigger, aggravate, or alleviate the symptoms; the timing, frequency, and duration of symptoms; relationship to meals and defecation; and associated symptoms (e.g., fever or weight loss). Other key history includes exposures to others (family, school contacts, pets), travel, environmental exposure, and impact of illness on the child (school absences, weight loss).

PHYSICAL EXAMINATION

The history may suggest a diagnosis and direct the evaluation, which should include a full examination as well as a thorough abdominal examination. Extraintestinal disorders may produce GI manifestations (e.g., emesis with group A streptococcal pharyngitis, abdominal pain with lower lobe pneumonia, respiratory distress with COVID-19). The examination should begin with a careful external visual inspection for abdominal distention, bruising or discoloration, abnormal abdominal veins, jaundice, surgical scars, and ostomies. Abnormalities of intensity and pitch of bowel sounds can occur with bowel obstruction. When palpating for tenderness, the examiner should note location, facial expression, guarding, and rebound tenderness. Palpation can also detect enlargement of the liver or spleen as well as feces and masses. If detected, organomegaly should be measured (with a tape measure), noting tenderness or abnormal firmness or contour. A rectal examination, including inspection for fissures, skin tags, abscesses, and fistulous openings, may be performed for children with history suggesting constipation, GI bleeding, abdominal pain, chronic diarrhea, and suspicion of inflammatory bowel disease (IBD). Digital rectal examination should include assessment of anal sphincter tone, anal canal size and elasticity, tenderness, extrinsic masses, presence of fecal impaction, and caliber of the rectum. Stool should be tested for occult blood.

SCREENING TESTS

A **complete blood count** may provide evidence for inflammation (white blood cell [WBC] and platelet count), poor nutrition

or bleeding (hemoglobin, red blood cell [RBC] volume, reticulocyte count), and infection (WBC number and differential, presence of toxic granulation). Serum electrolytes, blood urea nitrogen (BUN), and creatinine help define hydration status. Tests of liver dysfunction include total and direct bilirubin, alanine aminotransferase, aspartate aminotransferase for evidence of hepatocellular injury, and γ -glutamyltransferase or alkaline phosphatase for evidence of bile duct injury. **Hepatic synthetic function** can be assessed by coagulation factor levels, prothrombin time, and albumin level. Pancreatic enzyme tests (amylase, lipase) provide evidence of pancreatic injury or inflammation. Urinalysis can gauge dehydration and identify a possible source of protein loss. Stool may be examined for blood or calprotectin (inflammation).

DIAGNOSTIC IMAGING

Radiology

A plain abdominal x-ray to document excessive retained stool when history is consistent with constipation and encopresis is not necessary, as physical examination alone can confirm the diagnosis. A kidney-ureter-bladder (KUB) x-ray may demonstrate lower lobe pneumonia.

Endoscopy

Endoscopy permits the direct visualization of the interior of the gut. **Video endoscopes** may be used in very small infants by pediatric gastroenterologists. **Wireless capsule endoscopy** (Fig. 126.1) enables visualization of lesions beyond the reach of conventional endoscopes.

Consultation with a pediatric gastroenterologist for endoscopy is recommended for further evaluation of suspected esophageal or gastric inflammation unresponsive to medications, to confirm the diagnosis of eosinophilic esophagitis or celiac disease, to evaluate GI bleeding, to investigate suspected IBD, or to screen for polyp disorders. In addition, a trained endoscopist can remove esophageal and gastric foreign bodies, place feeding tubes, and treat bleeding ulcers or varices.

COMMON MANIFESTATIONS OF GASTROINTESTINAL DISORDERS

Abdominal Pain

General Considerations

Abdominal pain can result from injury to the intraabdominal organs or overlying somatic structures in the abdominal wall, or from extraabdominal diseases. **Visceral pain** results

FIGURE 126.1 Wireless capsule endoscopy: Aphthous ulcers (arrows) in jejunum diagnostic of Crohn disease in patient with negative findings on upper endoscopy and colonoscopy.

when autonomic nerves within the gut detect injury, transmitting sensation by nonmyelinated fibers. The pain is vague, dull, slow in onset, and poorly localized. A variety of stimuli, including normal peristalsis and various intraluminal chemical and osmotic states, activate these fibers to some degree. Regardless of the stimulus, visceral pain is perceived when a threshold of intensity or duration is crossed. Lower degrees of activation may result in perception of nonpainful or perhaps vaguely uncomfortable sensations, whereas more intensive stimulation of these fibers results in pain. Overactive sensation may be the basis of some kinds of abdominal pain, such as **functional abdominal pain** and **irritable bowel syndrome (IBS)**.

In contrast to visceral pain, **somatic pain** results when overlying body structures are injured. Somatic structures include the parietal peritoneum, fascia, muscles, and skin of the abdominal wall. In contrast to pain emanating from visceral injury, somatic nociceptive fibers are myelinated and are capable of rapid transmission of well-localized painful stimuli. When intraabdominal processes cause inflammation or injury to the parietal peritoneum or abdominal wall structures, poorly localized visceral pain becomes well-localized somatic pain. In acute appendicitis, the initial activation of visceral nociceptive fibers yields poorly localized discomfort in the mid-abdomen. When the inflammatory process extends to the overlying parietal peritoneum, the pain becomes severe and localizes to the right lower quadrant. This is called **somatoparietal pain**.

Referred pain is a painful sensation in a body region distant from the true source of pain. The location of referred pain is predictable based on the locus of visceral injury. Stomach pain is referred to the epigastric and retrosternal regions, and liver and pancreas pain is referred to the epigastric region. Gallbladder pain often is referred to the region below the right scapula. Somatic pathways stimulated by small bowel visceral afferents affect the periumbilical area, and colonic injury results in infraumbilical referred pain.

Acute Abdominal Pain

Distinguishing Features

Acute abdominal pain can signal the presence of a dangerous intraabdominal process (e.g., appendicitis or bowel obstruction) or may originate from extraintestinal sources (e.g., lower lobe pneumonia or urinary tract stone). Not all episodes of acute abdominal pain require emergency intervention. Appendicitis and volvulus, for example, must be ruled out as quickly as possible. Few patients presenting with acute abdominal pain actually have a surgical emergency, but they must be separated from cases that can be managed conservatively.

Initial Diagnostic Evaluation

Table 126.1 lists a diagnostic approach to acute abdominal pain in children. Events that occur with a discrete, abrupt onset, such as passage of a stone, perforation of a viscus, or vascular infarction, result in a sudden **onset of pain**. Gradual onset of pain is common with infectious or inflammatory causes, such as appendicitis and IBD.

A standard group of laboratory tests usually is performed for acute abdominal pain (see Table 126.1). An abdominal x-ray series evaluates for bowel obstruction, fecalith, or nephrolithiasis. Ultrasound or computed tomography (CT) can visualize the appendix if appendicitis is suspected but the diagnosis remains in doubt. If the initial evaluation suggests intussusception, ultrasound followed by a barium or pneumatic (air) enema may be used to initially diagnose and then treat this condition (see Chapter 129).

Differential Diagnosis

Table 126.2 lists the differential diagnosis of acute abdominal pain in children. The urgent task of the clinician is to rule out surgical emergencies. In young children, malrotation with volvulus, incarcerated hernia, congenital anomalies, and intussusception are common concerns. In older children and teenagers, appendicitis is more common. An acute surgical abdomen is characterized by signs of peritonitis, including tenderness, abdominal wall rigidity, guarding, and absent or diminished bowel sounds. Helpful characteristics of onset, location, referral, and quality of pain are noted in Table 126.3.

Functional Abdominal Pain and Irritable Bowel Syndrome

Recurrent abdominal pain is a common problem, affecting more than 10% of all children. The peak incidence occurs between ages 7 and 12 years. Although the differential diagnosis of recurrent abdominal pain is fairly extensive (Table 126.4), most children do not have a serious (or even identifiable) underlying illness causing the pain.

Differential Diagnosis

Children with **functional abdominal pain** characteristically have pain almost daily. The pain is not associated with meals or relieved by defecation and is often associated with a tendency toward anxiety and perfectionism. Symptoms are often exacerbated by stress at school or novel social situations. The pain often is worst in the morning and often prevents or delays children from attending school. **IBS** is a subset of functional abdominal pain, characterized by onset of pain at the time of a change in stool frequency or consistency, and relief of pain with defecation. Symptoms in IBS are linked to gut motility.

TABLE 126.1 Diagnostic Approach to Acute Abdominal Pain	
HISTORY	
Onset	Sudden or gradual, prior episodes, association with meals, history of injury
Nature	Sharp vs dull, colicky or constant, burning
Location	Epigastric, periumbilical, generalized, right or left lower quadrant, change in location over time
Associated symptoms	Fever, vomiting (bilious?), diarrhea (bloody?), abdominal distention
Extraintestinal symptoms	Cough, dyspnea, dysuria, urinary frequency, flank pain, hematuria
Course of symptoms	Worsening or improving, change in nature or location of pain, aggravating and alleviating factors, last menstrual period
PHYSICAL EXAMINATION	
General position	Growth and nutrition, general appearance, hydration, degree of discomfort, body position
Abdominal	Tenderness, distention, bowel sounds, rigidity, guarding, mass
Genitalia	Testicular torsion, hernia, pelvic inflammatory disease, ectopic pregnancy
Surrounding structures	Breath sounds, rales, rhonchi, wheezing, flank tenderness, tenderness of abdominal wall structures, ribs, costochondral joints
Rectal examination	Perianal lesions, stricture, tenderness, fecal impaction, blood
LABORATORY	
CBC, C-reactive protein, ESR	Evidence of infection or inflammation
AST, ALT, GGT, bilirubin	Biliary or liver disease
Amylase, lipase	Pancreatitis
Urinalysis	Urinary tract infection; bleeding due to stone, trauma, or obstruction
Pregnancy test	Ectopic pregnancy
RADIOLOGY	
Plain flat and upright abdominal films	Bowel obstruction, appendiceal fecalith, free intraperitoneal air, kidney stones, constipation, mass, lower lobe pneumonia
CT or MRI scan	Intraabdominal or pelvic abscess, appendicitis, Crohn disease, pancreatitis, gallstones, kidney stones
Barium enema	Intussusception, malrotation
Ultrasound	Gallstones, appendicitis, intussusception, pancreatitis, kidney stones
Colonoscopy	Colitis
Upper endoscopy	Suspected peptic ulcer or esophagitis

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; CBC, complete blood count; CT, computed tomography; ESR, erythrocyte sedimentation rate; GGT, γ -glutamyltransferase; MRI, magnetic resonance imaging.

*Common.

Pain is commonly accompanied in both groups of children by school avoidance, secondary gains, anxiety about imagined causes, lack of coping skills, and disordered peer relationships (Table 126.5).

Distinguishing Features

One needs to distinguish between functional pain/IBS and more serious underlying disorders. **Warning signs** for underlying illness are listed in Table 126.6. If present, further investigation is necessary. Some laboratory evaluation is warranted even in the absence of warning signs. The initial evaluation recommended in Table 126.7 is a sensible approach, avoiding unnecessary testing and providing ample sensitivity for most serious underlying disorders. While waiting for laboratory and ultrasound results, a 3-day trial of a lactose-free diet can evaluate for lactose intolerance. If tests are normal and no warning signs are present, testing should be stopped. If there are warning signs, progression of symptoms, or laboratory abnormalities that suggest a specific diagnosis, additional investigation may be warranted.

Treatment of Recurrent Abdominal Pain

A child who is repeatedly kept home from school because of pain receives reinforcement in the form of being excused from

TABLE 126.3 Distinguishing Features of Abdominal Pain in Children					
DISEASE	ONSET	LOCATION	REFERRAL	QUALITY	COMMENTS
Functional: irritable bowel syndrome	Recurrent	Periumbilical, splenic, and hepatic flexures	None	Dull, crampy, intermittent; duration 2 hr	Family stress, school phobia, diarrhea and constipation; hypersensitive to pain from distention
Esophageal reflux	Recurrent, after meals, at bedtime	Substernal	Chest	Burning	Sour taste in mouth; Sandifer syndrome
Duodenal ulcer	Recurrent, before meals, at night	Epigastric	Back	Severe burning, gnawing	Relieved by food, milk, antacids; family history important; gastrointestinal bleeding
Pancreatitis	Acute	Epigastric-hypogastric	Back	Constant, sharp, boring	Nausea, emesis, marked tenderness
Intestinal obstruction	Acute or gradual	Periumbilical–lower abdomen	Back	Alternating cramping (colic) and painless periods	Distention, obstipation, bilious emesis, increased bowel sounds
Appendicitis	Acute	Periumbilical or epigastric; localizes to right lower quadrant	Back or pelvis if retrocecal	Sharp, steady	Nausea, emesis, local tenderness, ± fever, avoids motion
Meckel diverticulum	Recurrent	Periumbilical–lower abdomen	None	Sharp	Hematochezia; painless unless intussusception, diverticulitis, or perforation
Inflammatory bowel disease	Recurrent	Depends on site of involvement		Dull cramping, tenesmus	Fever, weight loss, ± hematochezia
Intussusception	Acute	Periumbilical–lower abdomen	None	Cramping, with painless periods	Guarded position with knees pulled up, currant jelly stools, lethargy
Lactose intolerance	Recurrent with milk products	Lower abdomen	None	Cramping	Distention, gaseousness, diarrhea
Urolithiasis	Acute, sudden	Back	Groin	Severe, colicky pain	Hematuria
Pyelonephritis	Acute, sudden	Back	None	Dull to sharp	Fever, costochondral tenderness, dysuria, urinary frequency, emesis
Cholecystitis and cholelithiasis	Acute	Right upper quadrant	Right shoulder	Severe, colicky pain	Hemolysis ± jaundice, nausea, emesis

*Common.

responsibilities and withdraws from full social functioning. This tends to both increase anxiety and prolong the course. To break the cycle of pain and disability, the child with functional pain must be assisted in **returning to normal activities** immediately. Instead of being sent home from school with stomachaches, a child may be allowed to take a short break from class until symptoms abate. The child and parents should be informed that pain is likely to be worse on the day the child returns to school as anxiety worsens dysmotility and enhances pain perception. Medications may be helpful. Probiotics and peppermint oil can be beneficial in treating IBS. Dietary changes such as the low FODMAP (fermentable oligo-di-mono-saccharides and polyols) diet (reducing highly fermentable sugars in the diet) can be beneficial in a subset of patients. In difficult and persistent cases, cognitive behavioral therapy, amitriptyline, or a selective serotonin reuptake inhibitor may be helpful. When significant anxiety or social dysfunction persists, a mental health professional should be consulted.

Vomiting

Vomiting is a coordinated, sequential series of events that leads to forceful oral emptying of gastric contents. It is a common problem in children and has many causes. Vomiting should

TABLE 126.5 Rome IV Criteria for Pediatric Functional Gastrointestinal Syndromes

A. DIAGNOSTIC CRITERIA FOR CHILDHOOD FUNCTIONAL ABDOMINAL PAIN

Must be fulfilled for at least 2 months before diagnosis; must be met at least 4 times per month and include all of the following:

1. Episodic or continuous abdominal pain that does not occur solely during physiological events such as eating and menses
2. Insufficient criteria for other functional gastrointestinal diseases including irritable bowel syndrome, functional dyspepsia, or abdominal migraine.
3. After appropriate evaluation, the abdominal pain cannot be fully explained by another medical condition.

B. DIAGNOSTIC CRITERIA FOR IRRITABLE BOWEL SYNDROME

Must include all of the following:

1. Abdominal pain at least 4 days per month associated with one or more of the following:
 - a. Related to defecation
 - b. A change in the frequency of stool.
 - c. A change in the form (appearance of stool)
2. In children with constipation, the pain does not resolve with resolution of the constipation.
3. After appropriate evaluation, the symptoms cannot be fully explained by another medical condition.

*Criteria fulfilled at least 2 months before diagnosis.

C. DIAGNOSTIC CRITERIA FOR ABDOMINAL MIGRAINE

Must include all of the following occurring at least twice:*

1. Paroxysmal episodes of intense, acute periumbilical midline or diffuse abdominal pain lasting 1 hour or more (should be the most severe and distressing symptom).
2. Episodes are separated by weeks to months.
3. The pain is incapacitating and interferes with normal activities.
4. Stereotypical pattern and symptoms in the individual patient.
5. The pain is associated with 2 or more of the following:
 - a. anorexia
 - b. nausea
 - c. vomiting
 - d. headache
 - e. photophobia
 - f. pallor
6. After appropriate evaluation, the symptoms cannot be fully explained by another medical condition.

*Criteria fulfilled for at least 6 months before diagnosis.

D. DIAGNOSTIC CRITERIA FOR CYCLIC VOMITING SYNDROME

Must include all of the following:

1. The occurrence of 2 or more periods of intense, unremitting nausea and paroxysmal vomiting, lasting hours to days within a 6-month period.
2. Episodes are stereotypical in each patient.
3. Episodes are separated by weeks to months with return to baseline health between episodes.
4. After appropriate medical evaluation, the symptoms cannot be attributed to another condition.

E. FUNCTIONAL CONSTIPATION

Must include 2 or more of the following occurring at least once per week for a minimum of 1 month with insufficient criteria for the diagnosis of irritable bowel syndrome:

1. 2 or fewer defecations in the toilet per week in a child of developmental age of at least 4 years.
2. At least 1 episode of fecal incontinence per week.
3. History of retentive posturing or excessive volitional stool retention.
4. History of painful or hard bowel movements.
5. Presence of a large fecal mass in the rectum.
6. History of large diameter stools that can obstruct the toilet.

After appropriate evaluation, the symptoms cannot be fully explained by another medical condition.

TABLE 126.6 Warning Signs of Underlying Illness in Recurrent Abdominal Pain

Vomiting
Abnormal screening laboratory study (anemia, hypoalbuminemia, inflammatory markers)
Fever
Bilious emesis
Growth failure
Pain awakening child from sleep
Weight loss
Location away from periumbilical region
Blood in stools or emesis
Delayed puberty
Nocturnal diarrhea
Dysphagia
Arthritis
Perianal disease
Family history of inflammatory bowel disease, celiac disease, or peptic ulcer disease

TABLE 126.7 Suggested Evaluation of Recurrent Abdominal Pain

INITIAL EVALUATION	FOLLOW-UP EVALUATION*
Complete history and physical examination	CT or MRI scan of the abdomen and pelvis with oral, rectal, and intravenous contrast
Ask about “warning signs” (see Table 126.6)	Celiac disease serology—tissue transglutaminase IgA antibody
Determine degree of functional impairment (e.g., missing school)	Barium upper GI series with small bowel follow-through
CBC	Endoscopy of the esophagus, stomach, and duodenum
ESR	Colonoscopy
Amylase, lipase	
Urinalysis	
Abdominal ultrasound—examine liver, bile ducts, gallbladder, pancreas, kidneys, ureters	
Trial of 3-day lactose-free diet	

*Consider using one or more of these to investigate warning signs, abnormal laboratory tests, or specific or persistent symptoms.

CBC, Complete blood count; CT, computed tomography; ESR, erythrocyte sedimentation rate; GI, gastrointestinal.

be distinguished from **regurgitation** of stomach contents, also known as gastroesophageal reflux (GER) or “spitting up.” Although the end result of vomiting and regurgitation is similar, they have completely different characteristics. Vomiting is usually preceded by nausea and is accompanied by forceful gagging and retching. Regurgitation, on the other hand, is effortless and not preceded by nausea.

Differential Diagnosis

In neonates with true vomiting, congenital obstructive lesions should be considered. Allergic reactions to formula in the first

2 months of life may present with vomiting. **Infantile GER** (“spitting up”) occurs in up to half of infants and can be large in volume, but is effortless, and these infants do not appear ill. **Pyloric stenosis** occurs in the first 1–2 months of life and is characterized by steadily worsening, forceful vomiting that occurs immediately after feedings. A visibly distended stomach, often with visible peristaltic waves, is often seen before vomiting. Pyloric stenosis is more common in male infants; the family history may be positive. Other congenital obstructive lesions, such as intestinal duplication cysts, atresias, webs, and midgut malrotation, should be considered. Metabolic disorders (e.g., organic acidemias, galactosemia, urea cycle defects, adrenogenital syndromes) may present with vomiting in infants. In older children with acute vomiting, viruses and food poisoning are common. Other infections, especially streptococcal pharyngitis, urinary tract infections, and otitis media, commonly result in vomiting. When vomiting is chronic, central nervous system (CNS) causes (increased intracranial pressure, migraine) must be considered. **Cyclic vomiting syndrome** or abdominal migraine may be the etiology of recurrent vomiting. When abdominal pain or bilious emesis accompanies vomiting, evaluation for bowel obstruction, peptic disorders, and appendicitis must be immediately initiated.

Distinguishing Features

Table 126.8 lists common diagnoses that must be considered and their important historical features. Given the frequency of viral gastroenteritis as the etiology, it is important to be alert for unusual features that suggest another diagnosis. Viral gastroenteritis usually is not associated with severe abdominal pain or headache and does not recur at frequent intervals.

Physical examination should include assessment of the child’s hydration status, including examination of vital signs as well as capillary refill, moistness of mucous membranes, and skin turgor (see Chapter 38). The chest should be auscultated for evidence of rales or other signs of pulmonary involvement. The abdomen must be examined carefully for distention, organomegaly, bowel sounds, tenderness, and guarding. Testing stool for occult blood should be considered if ulcer disease or severe esophagitis is suspected.

Laboratory evaluation of vomiting should include serum electrolytes, tests of renal function, complete blood count, amylase, lipase, and liver function tests. Additional testing may be required immediately when history and examination suggest a specific etiology. Ultrasound is useful to look for pyloric stenosis, gallstones, renal stones, hydronephrosis, biliary obstruction, pancreatitis, malrotation, intussusception, and other anatomic abnormalities. CT may be indicated to rule out appendicitis or to observe structures that cannot be visualized well by ultrasound. Barium studies can show obstructive or inflammatory lesions of the gut and can be therapeutic, as in the use of contrast enemas for intussusception (see Chapter 129).

Treatment needs to address the consequences and the causes of the vomiting. Dehydration must be treated with fluid resuscitation. This can be accomplished in most cases with oral fluid-electrolyte solutions, but intravenous (IV) fluids may be required. Electrolyte imbalances should be corrected by appropriate choice of fluids. Underlying causes should be treated when possible.

TABLE 126.8 Differential Diagnosis and Historical Features of Vomiting

DIFFERENTIAL DIAGNOSIS	HISTORICAL CLUES
Viral gastroenteritis	Fever, diarrhea, sudden onset, absence of pain
Gastroesophageal reflux	Effortless, not preceded by nausea, chronic
Hepatitis	Jaundice, history of exposure
Extragastrintestinal infections	
Otitis media	Fever, ear pain
Urinary tract infection	Dysuria, unusual urine odor, frequency, incontinence
Pneumonia	Cough, fever, chest discomfort
Allergic	
Milk or soy protein intolerance (infants)	Associated with particular formula or food, blood in stools
Other food allergy (older children)	
FPIES	Acute onset vomiting, diarrhea, dehydration, shock
Peptic ulcer or gastritis	Epigastric pain, blood or coffee-ground material in emesis, pain relieved by acid blockade
Appendicitis	Fever, abdominal pain migrating to the right lower quadrant, tenderness
Pancreatitis	Severe epigastric abdominal pain
Anatomic obstruction	
Intestinal atresia	Neonate, usually bilious, polyhydramnios
Midgut malrotation	Pain, bilious vomiting, GI bleeding, shock
Intussusception	Colicky pain, lethargy, vomiting, currant jelly stools, mass occasionally
Duplication cysts	Colic, mass
Pyloric stenosis	Nonbilious vomiting, postprandial, <4 mo old, hunger, progressive weight loss
Hirschsprung disease	Abdominal distention, lack of stools
Bacterial gastroenteritis	Fever, often with bloody diarrhea
CNS	
Hydrocephalus	Large head, altered mental status, bulging fontanelles
Meningitis	Fever, stiff neck
Migraine syndrome	Attacks scattered in time, relieved by sleep; headache
Cyclic vomiting syndrome	Similar to migraine, usually no headache
Brain tumor	Morning vomiting, accelerating over time, headache, diplopia
Motion sickness	Associated with travel in vehicle
Labyrinthitis	Vertigo
Metabolic disease	Presentation early in life, worsens when catabolic or exposure to substrate
Pregnancy	Morning, sexually active, cessation of menses
Drug reaction or side effect	Associated with increased dose or new medication
Cancer chemotherapy	Temporarily related to administration of chemotherapeutic drugs
Eosinophilic esophagitis	May have dysphagia or abdominal pain

CNS, Central nervous system; FPIES, food protein–induced enterocolitis syndrome; GI, gastrointestinal.

Antiemetic medications should not be prescribed until the etiology of the vomiting is known, and then only for severe symptoms. Drugs that block serotonin 5-HT₃ receptors, such as ondansetron and granisetron, are frequently used for viral gastroenteritis and can improve tolerance of oral rehydration therapy. They are helpful for chemotherapy-induced vomiting, often combined with dexamethasone. No antiemetic should be used in patients with surgical emergencies or when a specific

treatment of the underlying condition is possible. Correction of dehydration, ketosis, and acidosis is helpful to reduce vomiting in most patients with viral gastroenteritis.

Acute and Chronic Diarrhea

Diarrhea is a major cause of childhood morbidity and mortality worldwide. Deaths from diarrhea are rare in

industrialized countries but are common elsewhere. **Acute diarrhea** is a major problem when it occurs with malnutrition or in the absence of basic medical care (see [Chapter 30](#)). In North America, most acute diarrhea is viral and is self-limited, requiring no diagnostic testing or specific intervention. Bacterial agents tend to cause much more severe illness and typically are seen in food-associated outbreaks or in regions with poor public sanitation. Bacterial enteritis should be suspected when there is **dysentery** (bloody diarrhea with fever) and whenever severe symptoms are present. These infections can be diagnosed by stool culture or other nucleic acid assays for specific pathogens. **Chronic diarrhea** lasts more than 2 weeks and has a wide range of possible causes, including serious and benign conditions that are more difficult to diagnose.

Parents use the word *diarrhea* to describe loose or watery stools, excessively frequent stools, or stools that are large in volume. Constipation with overflow incontinence can be mislabeled as diarrhea. A more exact definition of diarrhea is excessive daily stool liquid volume (>10 mL stool/kg body weight/day). Stool texture, volume, and frequency help to characterize the episode of diarrhea.

Differential Diagnosis

Diarrhea may be classified by etiology or by physiologic mechanisms (secretory or osmotic) and chronicity (acute vs chronic). Etiologic agents include viruses, bacteria or their toxins, chemicals, parasites, malabsorbed substances, and inflammation. [Table 126.9](#) lists common causes of diarrhea in childhood. **Secretory diarrhea** occurs when the intestinal mucosa directly secretes fluid and electrolytes into the stool and is the result of inflammation (e.g., IBD, chemical stimulus). Secretion also is stimulated by mediators of inflammation and by various hormones, such as vasoactive intestinal peptide secreted by a neuroendocrine tumor. Cholera is a secretory diarrhea stimulated by the enterotoxin of *Vibrio cholerae*, which causes increased levels of cyclic adenosine monophosphate (cAMP) within enterocytes and leads to secretion into the small-bowel lumen.

Osmotic diarrhea occurs after malabsorption of an ingested substance, which “pulls” water into the bowel lumen. A classic example is the diarrhea of lactose intolerance. Osmotic diarrhea also can result from generalized maldigestion, such as that seen with pancreatic insufficiency or with

TABLE 126.9 Differential Diagnosis of Diarrhea

	INFANT	CHILD	ADOLESCENT
ACUTE			
Common	Gastroenteritis* Systemic infection Antibiotic associated	Gastroenteritis* Food poisoning Systemic infection Antibiotic associated	Gastroenteritis* Food poisoning Antibiotic associated
Rare	Primary disaccharidase deficiency FPIES Hirschsprung toxic colitis Adrenogenital syndrome Opiate withdrawal (neonate)		Hyperthyroidism Appendicitis
CHRONIC			
Common	Postinfectious secondary lactase deficiency Cow's milk/soy protein intolerance Chronic nonspecific diarrhea of infancy (toddler's diarrhea) Celiac disease Cystic fibrosis	Postinfectious secondary lactase deficiency Irritable bowel syndrome Celiac disease Lactose intolerance Giardiasis Inflammatory bowel disease	Irritable bowel syndrome Inflammatory bowel disease Lactose intolerance Giardiasis Laxative abuse (anorexia nervosa) Celiac disease
Rare	Primary immune defects Familial villous atrophy Secretory tumors Congenital chloride diarrhea Acrodermatitis enteropathica Lymphangiectasia Abetalipoproteinemia Eosinophilic gastroenteritis Short-bowel syndrome Autoimmune enteropathy/IPEX-like disorders Malabsorption syndromes Factitious	Acquired immune defects Secretory tumor Pseudoobstruction Factitious AIDS enteropathy Eosinophilic gastroenteritis	Secretory tumors Primary bowel tumor AIDS enteropathy Addison disease Parasitic infections

*Gastroenteritis includes viral (rotavirus, norovirus, astrovirus) and bacterial (Salmonella, Shigella, Escherichia coli, Clostridium difficile, Yersinia, Campylobacter, other) agents.

FPIES, Food protein–induced enterocolitis syndrome; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked.

intestinal injury. Certain nonabsorbable laxatives, such as polyethylene glycol and milk of magnesia, also cause osmotic diarrhea. Fermentation of malabsorbed substances (e.g., lactose) often occurs, resulting in gas, cramps, and acidic stools. A common cause of chronic loose stools in early childhood is **functional diarrhea**, commonly known as **toddler's diarrhea**. This condition is defined by frequent watery stools in the setting of normal growth and weight gain and is caused by excessive intake of sweetened liquids overwhelming the disaccharide absorptive capacity of the intestine. Diarrhea typically improves tremendously when the child's beverage intake is reduced or changed.

Distinguishing Features

Stools are isosmotic, even in osmotic diarrhea, because of the relatively free exchange of water across the intestinal mucosa. Osmoles present in the stool are a mixture of electrolytes and other osmotically active solutes. To determine whether the diarrhea is osmotic or secretory, the **osmotic gap** is calculated:

$$\text{Osmotic gap} = 290 - 2([\text{Na}^+] + [\text{K}^+])$$

Assuming the stool is isosmotic (an osmolarity of 290 mOsm/L), the measured stool sodium and potassium (and their associated anions, accounting for an equal amount) accounts for much of the osmolality. Secretory diarrhea is characterized by an osmotic gap of less than 50. A number significantly higher than 50 defines osmotic diarrhea and indicates that malabsorbed substances other than electrolytes account for fecal osmolarity.

Another way to differentiate between osmotic and secretory diarrhea is to stop all feedings (in hospitalized patients receiving IV fluids). If the diarrhea stops completely while the child is NPO (nothing by mouth), the patient has osmotic diarrhea. A child with a pure secretory diarrhea would continue to have massive stool output. Neither method for classifying diarrhea works perfectly because most diarrheal illnesses are a mixture of secretory and osmotic components. Viral enteritis damages the intestinal lining, causing malabsorption and osmotic diarrhea. The associated inflammation results in release of mediators that cause excessive secretion. A child with viral enteritis may have decreased stool volume while NPO, but the secretory component of the diarrhea persists until the inflammation resolves.

The **history** should include the onset of diarrhea, number and character of stools, estimates of stool volume, and presence of other symptoms, such as blood in the stool, fever, and weight loss. Recent travel and exposures should be documented, dietary factors should be investigated, and a list of medications recently used should be obtained. Factors that seem to worsen or improve the diarrhea should be determined. **Physical examination** should be thorough, evaluating for abdominal distention, tenderness, quality of bowel sounds, presence of blood in the stool or a large fecal mass on rectal examination, and anal sphincter tone.

Laboratory testing should include stool culture and complete blood count if bacterial enteritis is suspected. If diarrhea occurs after a course of antibiotics, a *Clostridium difficile* toxin assay should be ordered; if stools are reported to be oily or fatty, fecal fat content or fecal elastase to test for pancreatic insufficiency should be measured. Tests for specific diagnoses should be sent when appropriate (e.g., serum antibody tests for celiac disease; colonoscopy for suspected ulcerative colitis). A trial of

lactose restriction for several days or lactose breath hydrogen testing is helpful in the evaluation of lactose intolerance.

Constipation and Encopresis

Constipation is a common problem in childhood. When a child is thought to be constipated, the parents may be concerned about straining with defecation, hard stool consistency, large stool size, decreased stool frequency, fear of passing stools, or any combination of these. Physicians define **constipation** as *two or fewer stools per week or passage of hard, pellet-like stools for at least 2 weeks*. A common pattern of constipation is **functional constipation**, which is characterized by two or fewer stools per week, voluntary withholding of stool, and infrequent passage of large-diameter, often painful stools. Children with functional fecal retention often exhibit "retentive posturing" (standing or sitting with legs extended and stiff or crossed legs) and have associated fecal incontinence caused by leakage of retained stool (**encopresis**).

Differential Diagnosis

The differential diagnosis is listed in [Table 126.10](#). **Functional constipation** commonly occurs during toilet training, when the child is unwilling to defecate on the toilet. Retained stool becomes harder and larger over time, leading to painful defecation. This aggravates voluntary withholding of stool, with perpetuation of the constipation.

Hirschsprung disease is characterized by delayed meconium passage in newborns, abdominal distention, vomiting, occasional fever, and foul-smelling stools. This condition is caused by failure of ganglion cells to migrate into the distal bowel, resulting in spasm and functional obstruction of the aganglionic segment. Only about 6% of infants with Hirschsprung disease pass meconium in the first 24 hours of life, compared with 95% of normal infants. Most affected babies rapidly become ill with symptoms of enterocolitis or obstruction. Affected older children do not pass large-caliber stools because of rectal spasm, and they do not have encopresis. Other causes of constipation include spinal cord abnormalities, hypothyroidism, medications, cystic fibrosis, intestinal pseudoobstruction syndromes, and anorectal malformations (see [Table 126.10](#)). A variety of systemic disorders affecting metabolism or muscle function can result in constipation. Children with **developmental disabilities** have a great propensity for constipation because of diminished capacity to cooperate with toileting, reduced effort or control of pelvic floor muscles during defecation, and diminished perception of the need to pass stool.

Distinguishing Features

[Table 126.10](#) includes typical characteristics of the common causes of constipation. Congenital malformations usually cause symptoms from birth. Functional constipation is overwhelmingly the most common diagnosis in older patients. Constipation in older children often begins after starting school, when free and private access to toilets may be restricted. Use of some drugs, especially opiates and some psychotropic medications, also is associated with constipation.

For a few specific causes of constipation, directed diagnostic testing can make the diagnosis. A narrowed, aganglionic distal bowel and dilated proximal bowel on barium enema suggests Hirschsprung disease. Rectal suction biopsy confirms

TABLE 126.10 Common Causes of Constipation and Characteristic Features

CAUSES OF CONSTIPATION	CLINICAL FEATURES
Hirschsprung disease	<i>History:</i> Failure to pass stool in first 24 hr, abdominal distention, vomiting, symptoms of enterocolitis (fever, foul-smelling diarrhea, megacolon). Not associated with large-caliber stools or encopresis <i>Examination:</i> Snug anal sphincter, empty, contracted rectum. May have explosive release of stool as examiner's finger is withdrawn <i>Laboratory:</i> Absence of ganglion cells on rectal suction biopsy specimen, absent relaxation of the internal sphincter, "transition zone" from narrow distal bowel to dilated proximal bowel on barium enema
Functional constipation	<i>History:</i> No history of significant neonatal constipation, onset at potty training, large-caliber stools, retentive posturing, may have encopresis <i>Examination:</i> Normal or reduced sphincter tone, dilated rectal vault, fecal impaction, soiled underwear, palpable fecal mass in left lower quadrant <i>Laboratory:</i> No abnormalities, barium enema would show dilated distal bowel
Anorectal, intestinal and colonic malformations/syndromes	<i>History:</i> Constipation from birth due to abnormal anatomy <i>Examination:</i> Anorectal abnormalities are shown easily on physical examination
Anal stenosis	Anteriorly displaced anus is found chiefly in females, with a normal-appearing anus located close to the posterior fourchette of the vagina
Anteriorly displaced anus	
Imperforate anus	<i>Laboratory:</i> Barium enema shows the anomaly
Colonic stricture	Genetic or idiopathic decreased or absent peristalsis
Intestinal pseudoobstruction	
Multisystem disease	<i>History:</i> Presence of other symptoms or prior diagnosis
Muscular dystrophy	<i>Examination:</i> Specific abnormalities may be present that directly relate to the underlying diagnosis
Cystic fibrosis	<i>Laboratory:</i> Tests directed at suspected disorder confirm the diagnosis
Diabetes mellitus	
Developmental delay	
Celiac disease	
Spinal cord abnormalities	<i>History:</i> History of swelling or exposed neural tissue in the lower back, history of urinary incontinence
Meningocele	<i>Examination:</i> Lax sphincter tone due to impaired innervation, visible or palpable abnormality of lower back usually (but not always) present
Tethered cord	
Sacral teratoma or lipoma	<i>Laboratory:</i> Bony abnormalities often present on plain x-ray. Magnetic resonance imaging (MRI) of spinal cord reveals characteristic abnormalities
Drugs	<i>History:</i> Recent use of drugs known to cause constipation (lead poisoning, opiates)
Narcotics	<i>Examination:</i> Features suggest functional constipation
Psychotropics	<i>Laboratory:</i> No specific tests available

the absence of ganglion cells in the rectal submucosal plexus, with hypertrophy of nerve fibers. Lack of internal anal sphincter relaxation can be shown by anorectal manometry in Hirschsprung disease. Hypothyroidism is diagnosed by examination and by thyroid function testing. Anorectal malformations are easily detected by rectal examination. Cystic fibrosis (meconium ileus) is diagnosed by sweat chloride determination or *CFTR* gene mutation analysis (see [Chapter 137](#)). Most children with constipation have functional constipation and do not have any laboratory abnormality. Examination reveals normal or reduced anal sphincter tone (owing to stretching by passage of large stools). Fecal impaction is usually present, but a large-caliber, empty rectum may be found if a stool has just been passed.

Evaluation and Treatment of Functional Constipation

In most cases of constipation, the history is consistent with functional constipation—absence of neonatal constipation, active fecal retention, and infrequent, large stools with soiling. In these patients, no testing other than a good physical

examination is necessary. Young children with painful defecation must have a prolonged course of stool softener therapy to alleviate fear of defecation. The child should be asked to sit on the toilet for a few minutes on awakening in the morning and immediately after meals, when the colon is most active and it is easiest to pass a stool. Use of a positive reinforcement system for taking medication and sitting on the toilet is helpful for younger children. The stool softener chosen should be non-habit forming, safe, and palatable. Polyethylene glycol and milk of magnesia are the most commonly used agents.

Gastrointestinal Bleeding

GI tract bleeding can be an emergency when large-volume bleeding is present, but even the presence of small amounts of blood in stool or emesis is sufficient to cause concern. Evaluation of bleeding should include confirmation that blood truly is present, estimation of the amount of bleeding, stabilization of the patient's intravascular blood volume, localization of the source of bleeding, and appropriate treatment of the underlying cause. When bleeding is massive, it is crucial that

TABLE 126.11 Causes and Distinguishing Characteristics of Gastrointestinal Bleeding

AGE	TYPE OF BLEEDING	CHARACTERISTICS
NEWBORN		
Ingested maternal blood*	Hematemesis or rectal, large	Apt test indicates adult hemoglobin is present, cracked maternal nipples
Peptic disease	Hematemesis, amount varies	Blood found in stomach on lavage
Coagulopathy	Hematemesis or rectal, bruising, other sites	History of home birth (no vitamin K)
Allergic colitis*	Streaks of bloody mucus in stool	Eosinophils in feces and in rectal mucosa
Necrotizing enterocolitis	Rectal	Sick infant with tender and distended abdomen
Duplication cyst	Hematemesis	Cystic mass in abdomen on imaging study
Volvulus	Hematemesis, hematochezia	Acute tender, distended abdomen
INFANCY TO 2 YEARS OLD		
Peptic disease	Usually hematemesis, rectal possible	Epigastric pain, coffee-ground emesis
Esophageal varices	Hematemesis	History or evidence of liver disease
Intussusception*	Rectal bleeding	Crampy pain, distention, mass
Meckel diverticulum*	Rectal	Massive, bright red or maroon blood; no pain
Bacterial enteritis*	Rectal	Bloody diarrhea, fever
NSAID injury	Usually hematemesis, rectal possible	Epigastric pain, coffee-ground emesis
>2 YEARS OLD		
Peptic disease	See above	See above
Esophageal varices	See above	See above
NSAID injury*	See above	See above
Inflammatory bowel disease	Usually rectal	Crampy pain, poor weight gain, diarrhea
Bacterial enteritis*	See above	See above
Pseudomembranous colitis	Rectal	History of antibiotic use, bloody diarrhea
Juvenile polyp	Rectal	Painless, bright red blood in stool; not massive
Meckel diverticulum*	See above	See above
Nodular lymphoid hyperplasia	Rectal	Streaks of blood in stool, no other symptoms
Angiodysplasia	Rectal	Difficult to diagnosis, often requires capsule endoscopy
Mallory-Weiss syndrome*	Hematemesis	Bright red or coffee-ground, follows retching
Hemolytic uremic syndrome	Rectal	Thrombocytopenia, anemia, uremia
Henoch-Schönlein purpura	Rectal	Purpuric rash, nephritis, arthritis, colitis
Hemorrhoids	Rectal	Dilated external veins, blood with wiping

*Common.

NSAID, Nonsteroidal antiinflammatory drug.

the patient receive adequate resuscitation with fluid and blood products before moving ahead with diagnostic testing.

Differential Diagnosis

GI bleeding has different causes at different ages (Table 126.11).

Distinguishing Features

Red substances in foods, beverages, or medications (such as cefdinir) occasionally can be mistaken for blood. A test for occult blood is worth performing whenever the diagnosis is in doubt.

The GI tract may not be the source of the observed fecal blood. A history of cough and examination of the mouth, nostrils, and lungs is needed to exclude these as a source of hematemesis. Blood in the toilet or diaper may be coming from the urinary tract, vagina, or even a severe diaper rash. If the bleeding is GI, it is important to determine the source as the upper GI tract or distal to the ligament of Treitz. Vomited blood is always proximal. Rectal bleeding may be coming from anywhere in the gut. When dark clots or melena are seen mixed with stool, a higher location is suspected, whereas bright red

TABLE 126.12 Evaluation of Gastrointestinal Bleeding

LABORATORY INVESTIGATION	
All Patients	
CBC and platelet count	
Coagulation tests: prothrombin time, partial thromboplastin time	
Tests of liver dysfunction: AST, ALT, GGT, bilirubin	
Occult blood test of stool or vomitus	
Blood type and crossmatch	
Evaluation of Bloody Diarrhea	
Stool culture or PCR, <i>Clostridium difficile</i> toxin	
Sigmoidoscopy or colonoscopy	
CT or MRI enteroscopy	
Evaluation of Rectal Bleeding with Formed Stools	
External and digital rectal examination	
Sigmoidoscopy or colonoscopy	
Meckel scan	
Mesenteric arteriogram	
Video capsule endoscopy	
INITIAL RADIOLOGIC EVALUATION

Barium upper GI series if endoscopy not available	
Evaluation of Bleeding with Pain and Vomiting (Bowel Obstruction)	
Abdominal x-ray series	
Pneumatic or contrast enema	
Upper GI series	

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; CBC, complete blood count; CT, computed tomography; GGT, γ -glutamyltransferase; GI, gastrointestinal.

blood on the surface of stool probably is coming from lower in the colon. When upper GI tract bleeding is suspected, a nasogastric tube may be placed and gastric contents aspirated for evidence of recent bleeding.

The location and hemodynamic significance of the bleeding can also be assessed by history and examination. The parents should be asked to quantify the bleeding. Details of associated symptoms should be sought. Assessment of the vital signs including orthostatic changes when bleeding volume is large, pulses, capillary refill, and assessment of pallor of the mucous membranes provides valuable information. Laboratory assessment and imaging studies should be ordered as indicated (Table 126.12).

Treatment

Treatment of GI bleeding should begin with an initial assessment, rapid stabilization, and a logical sequence of diagnostic tests. When a treatable cause is identified, specific therapy should be started. In many cases, the amount of blood is small, and no resuscitation is required. For children with large-volume bleeds, the ABCs of resuscitation (airway, breathing, circulation) should be addressed first (see Chapters 38 and 40). Oxygen should be administered, and the airway should be protected with an endotracheal tube if massive hematemesis is present. Fluid boluses and transfusion with packed RBCs as required should be administered through two large-bore IVs. Frequent reassessment should continue to ensure maintenance of physiologic stability (Fig. 126.2).

PEARLS FOR PRACTITIONERS

See *The Digestive System: Pearls for Practitioners* at the end of this section.

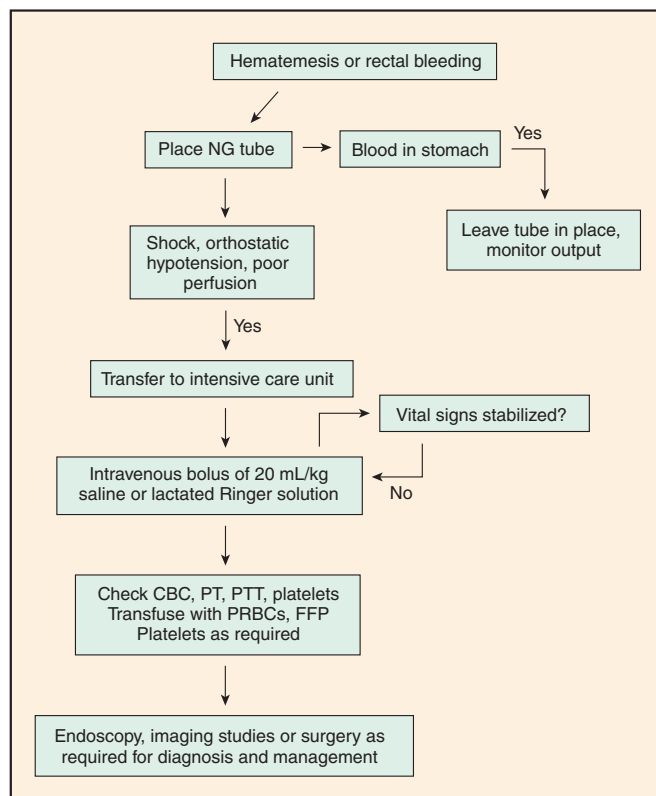

FIGURE 126.2 Initial management of gastrointestinal bleeding. CBC, Complete blood count; FFP, fresh frozen plasma; NG, nasogastric; PRBCs, packed red blood cells; PT, prothrombin time; PTT, partial thromboplastin time.

CHAPTER 127

Oral Cavity

EFFECTS OF SYSTEMIC DISEASE ON THE ORAL CAVITY

Medications taken for a variety of conditions may cause oral abnormalities. Drugs with anticholinergic properties diminish saliva production and increase the risk of dental caries and parotitis. Tetracyclines taken before the eruption of the permanent teeth stain the enamel. Excessive fluoride in vitamin preparations or in drinking water can result in mottled teeth. Gingival hypertrophy may be caused by cyclosporine, phenytoin, and calcium channel blockers.

Gastroesophageal reflux disease (GERD) can lead to substantial enamel erosion and caries. Neonatal hyperbilirubinemia can result in discoloration of the deciduous teeth. Renal failure is associated with mottled enamel of the permanent teeth. Congenital syphilis causes marked abnormalities in the shape of teeth, especially incisors and molars. Celiac disease can result in enamel defects. Crohn disease is associated with oral aphthous ulcers. Abnormal pigmentation of the lips and buccal mucosa is seen with Peutz-Jeghers syndrome (freckling) and Addison disease (hyperpigmented macules). Candidiasis is seen commonly with immunodeficiency disorders and diabetes. Leukemic infiltrates result in gum hyperplasia and bleeding; treatment of neoplastic conditions can cause severe mucositis. Some tumors, including lymphoma, may present as mass lesions of the buccal cavity.

Osteogenesis imperfecta is associated with abnormal dentin and risk of caries. Children with *ectodermal dysplasias* commonly have malformed or missing teeth. Pierre Robin and Stickler syndromes are associated with micrognathia and cleft palate. Disorders resulting in facial dysmorphism can have a profound effect on dental occlusion and mandibular function. Examples include mandibulofacial dysostosis, Crouzon syndrome, conditions associated with skeletal dysplasias, and others.

DECIDUOUS AND PRIMARY TEETH

Most infants are born without teeth. *Natal teeth* are present at birth, are usually supernumerary, and may be poorly attached. Usually, no treatment is necessary, but removal by a dentist may be needed if they are causing difficulties with feeding or injuries to the tongue. Table 127.1 presents the ages when normal **deciduous teeth** are acquired. The lower central incisors are typically the first to erupt, followed by the upper central incisors, lateral incisors, first molars, and bicuspid. **Delayed eruption** may occur in association with hypopituitarism, hypothyroidism, osteopetrosis, Gaucher disease, Down syndrome, cleidocranial dysplasia, and rickets. Deciduous teeth begin to be replaced by the permanent teeth at around age 6 years. The sequence of replacement is similar to that of the appearance of deciduous teeth.

DENTAL CARIES

Etiology

Dental caries, commonly referred to as “cavities,” occurs as a result of interactions between the tooth enamel, dietary carbohydrates, and oral flora. There is increased susceptibility if

TABLE 127.1 Time of Eruption of the Primary and Permanent Teeth

TOOTH TYPE	PRIMARY, AGE (mo)		PERMANENT, AGE (yr)	
	UPPER	LOWER	UPPER	LOWER
Central incisor	6 ± 2	7 ± 2	7–8	6–7
Lateral incisor	9 ± 2	7 ± 2	8–9	7–8
Cuspids	18 ± 2	16 ± 2	11–12	9–10
First bicuspid	—	—	10–11	10–12
Second bicuspid	—	—	10–12	11–12
First molars	14 ± 2	12 ± 2	6–7	6–7
Second molars	24 ± 2	20 ± 2	12–13	11–13
Third molars	—	—	17–21	17–21

the enamel is abnormal or hypoplastic. Bacteria (*Streptococcus mutans*) that can adhere to and colonize the teeth, survive at low pH, and produce acids during fermentation of carbohydrates cause dental caries. The diet has a significant role. A classic example is “bottle mouth,” or **baby bottle caries**. This condition results when infants are allowed to have a bottle in the mouth for prolonged periods, especially during sleep, and with sweet beverages or milk in the bottle. Bacteria then have continuous substrate for acid production and can destroy multiple teeth, especially the upper incisors. Sticky sweet foods, such as candy, have the same effect.

Epidemiology and Treatment

Risk of caries is associated with lack of dental care and poor socioeconomic status and, predictably, is greatest in developing countries. Baby bottle caries is seen in 50–70% of low-income infants. Treatment of caries is with dental restorative surgery. The carious portion is removed and filled with silver amalgam or plastic. If the damage is severe, a protective crown may be required; extraction of the tooth may be necessary when not salvageable. If not properly treated, dental decay results in inflammation and infection of the dental pulp and surrounding alveolar bone, which can lead to abscess and facial space infections.

Prevention

Avoiding inappropriate use of bottles and excessive sweets is a commonsense remedy for baby bottle caries. Oral hygiene offers some protection, but young children (<8 years old) do not have the ability to brush their own teeth adequately; brushing should be done by the parents. Fluoride supplementation of community water supplies to a concentration of 1 ppm is highly effective in reducing dental caries. Home water supplies, such as from a well, should have the fluoride content tested before supplements are prescribed. If the child spends part of the day at another location, the total fluoride concentration from all sources must be considered before prescribing any oral supplements. Excessive fluoride supplementation causes fluorosis, a largely cosmetic defect of chalky white marks and brown staining of the teeth.

The American Academy of Pediatrics recommends that primary care physicians apply fluoride varnish to the teeth of all children every 3–6 months, starting at the emergence of the first tooth. Fluoride varnish is a concentrated fluoride preparation that adheres to the teeth on contact with saliva. It is painted onto the teeth with a small brush, after first drying the tooth with a gauze pad, and has a prolonged cavity-prevention effect.

CLEFT LIP AND PALATE

Epidemiology

Cleft lip and palate occur separately or together and affect approximately 1 in 700 infants. It is more common in Asians (1:500) and least common in Africans (1:2,500). Clefting occurs with two possible patterns: isolated soft tissue cleft palate or cleft lip with or without associated clefts of the hard palate. Isolated cleft palate is associated with a higher risk of other congenital malformations. The combined cleft lip/palate type has a male predominance.

Etiology

Cleft lip is due to hypoplasia of the mesenchymal tissues with subsequent failure of fusion. There is a strong genetic component; the risk is highest in children with affected first-degree relatives. Monozygotic twins are affected with only 60% concordance, suggesting other nongenomic factors. Environmental factors during gestation also increase risk, including drugs (phenytoin, valproic acid, thalidomide), maternal alcohol and tobacco use, dioxins and other herbicides, and possibly high altitude. Chromosomal and nonchromosomal syndromes are associated with clefting, as are specific genes in some families.

Clinical Manifestations and Treatment

Cleft lip can be unilateral or bilateral and associated with cleft palate and defects of the alveolar ridge and dentition. When present, palatal defects allow direct communication between the nasal and oral cavities, creating problems with speech and feeding. Management includes squeeze-bottle feedings, special nipples, nipples with attached shields to seal the palate, and gastrostomy in severe cases. Surgical closure of the cleft lip is usually done by 3 months of age. Closure of the palate follows, usually before 1 year of age. Missing teeth are replaced by prostheses. Cosmetic results are often good, but they depend on the severity of the defect.

Complications

Speech is nasal as a result of the cleft palate. Surgical treatment is effective, but it sometimes does not restore palatal function completely. Speech therapy or, occasionally, the use of a speech-assisting appliance may help. Frequent episodes of otitis media are common, as are defects of teeth and the alveolar ridge.

THRUSH

Epidemiology

Oropharyngeal *Candida albicans* infection, or thrush, is common in healthy neonates. The organism may be acquired in the birth canal or from the environment. Persistent infection

is common in breast-fed infants as a result of colonization or infection of the mother's nipples. Thrush in older patients can occur but should suggest the possibility of an immunodeficiency, broad-spectrum antibiotic or inhaled steroid use, or diabetes.

Clinical Manifestations

Thrush is easily visible as white plaques, often with a “fuzzy” appearance, on oral mucous membranes. When scraped with a tongue depressor, the plaques are difficult to remove and the underlying mucosa is inflamed and friable. Clinical diagnosis is usually adequate but may be confirmed by fungal culture or potassium hydroxide smear. Oropharyngeal candidiasis is sometimes painful (especially if associated with esophagitis) and can interfere with feeding.

Treatment

Thrush is treated with topical nystatin or an azole antifungal agent such as fluconazole. When the mother's breasts are infected and painful, consideration should be given to treating the mother at the same time. Because thrush is commonly self-limited in newborns, withholding therapy in asymptomatic infants and treating only persistent or severe cases is a reasonable approach.

PEARLS FOR PRACTITIONERS

See *The Digestive System: Pearls for Practitioners* at the end of this section.

CHAPTER 128

Esophagus and Stomach

GASTROESOPHAGEAL REFLUX

Etiology and Epidemiology

Gastroesophageal reflux (GER) is defined as the effortless retrograde movement of gastric contents upward into the esophagus or oropharynx. **Physiologic GER** (“spitting up”) is normal in infants. Nearly half of all infants are reported to spit up between 2 and 4 months of age. Infants who regurgitate meet the criteria for physiologic GER so long as they maintain adequate nutrition and have no signs of respiratory complications or esophagitis. Contributing factors of infantile GER include liquid diet; horizontal body position; short, narrow esophagus; small, noncompliant stomach; frequent, relatively large-volume feedings; and an immature lower esophageal sphincter (LES). As infants grow, they spend more time upright, eat more solid foods, develop a longer and larger diameter esophagus, have a larger and more compliant stomach, and experience lower caloric needs per unit of body weight. As a result, most infants stop spitting up by 9–12 months of age.

Gastroesophageal reflux disease (GERD) occurs when GER leads to troublesome symptoms or complications such as poor growth, pain, or breathing difficulties. GERD occurs in a minority of infants but is often implicated as the cause of fussiness. GERD is seen in fewer than 5% of older children.

In older children, normal protective mechanisms against GER include antegrade esophageal motility, tonic contraction of the LES, and the geometry of the gastroesophageal junction. Abnormalities that cause GER in older children and adults include reduced tone of the LES, transient relaxations of the LES, esophagitis (which impairs esophageal motility), increased intraabdominal pressure, cough, respiratory difficulty (asthma or cystic fibrosis), and hiatal hernia.

Clinical Manifestations

The presence of GER is easy to observe in an infant who spits up. In older children, the refluxate is usually kept down by reswallowing, but GER may be suspected by associated symptoms, such as heartburn, cough, epigastric abdominal pain, dysphagia, wheezing, aspiration pneumonia, hoarse voice, failure to thrive, and recurrent hiccoughs or belching. In severe cases of esophagitis, there may be laboratory evidence of anemia and hypoalbuminemia secondary to esophageal bleeding and inflammation.

When esophagitis develops as a result of acid reflux, esophageal motility and LES function are impaired further, creating a cycle of reflux and esophageal injury.

Laboratory and Imaging Studies

A clinical diagnosis is often sufficient in children with classic effortless regurgitation and no complications. Diagnostic studies are indicated if there are persistent symptoms or complications or if other symptoms suggest the possibility of GER in the absence of regurgitation. A child with recurrent pneumonia, chronic cough, or apneic spells without overt emesis

may have occult GER. A **barium upper gastrointestinal (GI) series** helps to rule out gastric outlet obstruction, malrotation, or other anatomic contributors to GER. Because of the brief nature of the examination, a negative barium study does *not* rule out GER, nor does it rule it in as it is normal to have some reflux into the esophagus many times per day. A **24-hour esophageal pH probe monitoring** uses a pH electrode placed transnasally into the distal esophagus, with continuous recording of esophageal pH. Data typically are gathered for 24 hours and analyzed for the number and temporal pattern of acid reflux events. **Esophageal impedance monitoring** records the migration of electrolyte-rich gastric fluid in the esophagus. **Endoscopy** is useful to evaluate for esophagitis, esophageal stricture, and anatomic abnormalities.

Treatment

In otherwise healthy young infants, no treatment is necessary. For infants with complications of GER, an H₂ blocker or proton pump inhibitor may be offered (Table 128.1), but these have shown little benefit in infants with uncomplicated GER and/or fussiness. Prokinetic drugs, such as metoclopramide, occasionally are helpful by enhancing gastric emptying and increasing LES tone, but they are seldom effective and may lead to complications. When severe symptoms persist despite medication, or if life-threatening aspiration is present, surgical intervention may be required. Fundoplication procedures, such as the Nissen operation, are designed to enhance the antireflux anatomy of the LES. In children with a severe neurologic defect who cannot tolerate oral or gastric tube feedings, placement of a feeding jejunostomy may be considered as an alternative to fundoplication. In older children, lifestyle changes should

TABLE 128.1 Treatment of Gastroesophageal Reflux

THERAPIES	COMMENTS
CONSERVATIVE THERAPIES	
Towel on caregiver's shoulder	Cheap, effective; useful only for physiologic reflux
Thickened feedings	Reduces number of episodes, enhances nutrition
Smaller, more frequent feedings	Can help some; be careful not to <i>underfeed</i> child
Avoidance of tobacco smoke and alcohol	Always a good idea; may help reflux symptoms
Abstaining from caffeine	Inexpensive, offers some benefit
Positional therapy—upright in seat, elevate	Prone positioning with head of crib or bed up is helpful, but <i>not</i> for young infants because of risk of SIDS
Weight loss when indicated	Increased weight (especially abdominal) increases intraabdominal pressure, leading to reflux
MEDICAL THERAPY	
Proton pump inhibitor	Effective medical therapy for heartburn and esophagitis
H ₂ -receptor antagonist	Reduces heartburn, less effective for healing esophagitis
Metoclopramide	Enhances stomach emptying and LES tone; real benefit is often minimal
SURGICAL THERAPY	
Nissen or other fundoplication procedure	For life-threatening or medically unresponsive cases
Feeding jejunostomy	Useful in child requiring tube feeds; delivering feeds downstream eliminates GERD

GERD, Gastroesophageal reflux disease; LES, lower esophageal sphincter; SIDS, sudden infant death syndrome.

be discussed, including cessation of smoking, weight loss, not eating or exercising before bed, and limiting intake of caffeine, carbonation, and high-fat foods. If lifestyle changes are ineffective in reducing symptoms, proton pump inhibitor therapy is effective in reducing symptoms and supports healing.

EOSINOPHILIC ESOPHAGITIS

Etiology and Epidemiology

This chronic immune-mediated disorder is characterized by infiltration of eosinophils into the mucosa of the esophagus. It is thought to be triggered by non-IgE-mediated allergic reactions to ingested foods or aeroallergens. Eosinophilic esophagitis (EoE) may have a familial component; no specific gene has yet been identified. Incidence appears to be increasing with estimated prevalence of more than 50 per 100,000 children. It is more common in males than females and in patients with history of atopy.

Clinical Manifestations

The presentation of EoE often varies with age. In young children, it may present with oral aversion, vomiting, and failure to thrive. In school-age children, it may present with vague abdominal pain or vomiting. In adolescents and adults, it presents with dysphagia and food impactions. These symptoms are attributed to the inflammatory response in the esophagus leading to edema and poor esophageal motility.

Laboratory and Imaging Studies

Diagnosis requires multilevel esophageal biopsies via flexible endoscopy with the finding of more than 15 eosinophils per high-power field (Fig. 128.1). Treatment with high-dose proton pump inhibitor therapy is recommended to exclude the possibility that findings are secondary to severe acidic esophageal injury or by evaluating for acid reflux by pH probe testing. Proton pump responsive esophageal eosinophilia (PPI-REE) is a subset of EoE that has histologic response to high-dose proton pump inhibitor therapy. Gross findings at endoscopy may include normal appearance, esophageal linear furrowing, trachealization, and eosinophilic abscesses (Fig. 128.2). A barium study may reveal a food impaction in an acutely symptomatic patient or esophageal stricture in someone with chronic disease.

Treatment and Prognosis

Exposure to identified causative antigens needs to be eliminated. Identification can be difficult, as typical allergy testing (skin prick, radioallergosorbent test [RAST], and immunocap assays) only identifies IgE-mediated antigens. Atopic patch testing may be more reliable but is not standardized and can be difficult to perform. One approach is to eliminate from the diet cow's milk, soy, wheat, eggs (*four-food elimination diet*) or additionally peanuts and fish/shellfish (*six-food elimination diet*), as these are the most common causative dietary antigens. Alternatively, eliminating the most common allergen first (cow's milk) can be effective for a number of patients. Repeat endoscopies are often necessary to document efficacy of these eliminations. An elemental diet can also be used and is very

FIGURE 128.1 Histologic image of eosinophilic esophagitis. Note the large number of eosinophils within the lamina propria.

FIGURE 128.2 Endoscopic picture of eosinophilic esophagitis. White plaques on the surface are collections of eosinophils (eosinophilic abscesses). Linear furrowing is also seen.

effective, but it often requires either nasogastric or gastrostomy administration because of its poor palatability.

Systemic glucocorticoids can decrease symptoms, but long-term use is discouraged due to concerns for potential complications. Swallowed “topical” glucocorticoids administered via a metered-dose inhaler (fluticasone) or mixed as a slurry (budesonide) have shown benefit. *Candida* esophagitis or oral thrush are the most common side effects.

Endoscopy can be used to relieve food impactions and to dilate esophageal strictures secondary to EoE. The prognosis for EoE is largely unknown. Symptoms tend to wax and wane over time.

Complications

Failure to thrive or weight loss may be seen due to difficulty in eating. Food impactions are a common complication in the older child and may require endoscopic removal. Chronic

inflammation of the esophagus can predispose to esophageal strictures.

ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA

Etiology and Epidemiology

The esophagus and trachea develop in close proximity to each other during weeks 4–6 of fetal life. Defects in the mesenchyme separating these two structures result in a tracheoesophageal fistula (TEF), often in association with other anomalies (renal, heart, spine, limbs). This defect occurs in about 1 in 3,000 live births. TEF is not thought to be a genetic defect.

Clinical Manifestations

The most common forms of TEF occur with esophageal atresia; the “H-type” TEF without atresia is uncommon, as is esophageal atresia without TEF (Fig. 128.3). Associated defects include the VACTERL association—vertebral anomalies (70%), anal atresia (imperforate anus) (50%), cardiac anomalies (30%), TEF (70%), renal anomalies (50%), and limb anomalies (polydactyly, forearm defects, absent thumbs, syndactyly) (70%). A single-artery umbilical cord is often present. Infants with esophageal atresia have a history of polyhydramnios, exhibit drooling, and have mucus and saliva bubbling from the nose and mouth. Patients with a TEF are vulnerable to aspiration pneumonia. When TEF is suspected, the first feeding should be delayed until a diagnostic study is performed.

Laboratory and Imaging Studies

The simplest test for TEF is to gently attempt to place a 10 F or larger tube via the mouth into the stomach. The passage of the tube is blocked at the level of the atresia. A chest x-ray reveals

the tube coiled in the esophageal pouch. Air can be injected through the tube to outline the atretic pouch. Barium should not be used because of extreme risk of aspiration, but a tiny amount of dilute water-soluble contrast agent can be given carefully, then suctioned when the defect is clearly shown.

Treatment and Prognosis

The treatment of TEF is surgical. The fistula is divided and ligated. The esophageal ends are approximated and anastomosed. In some cases, primary anastomosis cannot be performed because of a long gap between the proximal and distal esophagus. Various techniques have been described to treat this problem, including pulling up the stomach, elongating the esophagus by myotomy, and simply delaying esophageal anastomosis and providing continuous suction to the upper pouch while allowing for growth.

Complications

The surgically reconstructed esophagus is not normal and is prone to poor motility, GER, anastomotic stricture, recurrent fistula, and leakage. The trachea also is malformed; tracheomalacia and wheezing are common.

ESOPHAGEAL FOREIGN BODIES

Etiology and Epidemiology

Young children often place nonfood items in the mouth. When these items are swallowed, they may become lodged in the esophagus at the thoracic inlet or at the LES. The most common objects are coins. Smaller coins may pass harmlessly into the stomach, where they rarely cause symptoms. Other common esophageal foreign bodies include food items, small toys or toy parts, button batteries, and other small household items.

FIGURE 128.3 Various types of tracheoesophageal fistulas (TEF) with relative frequency (%).

Children with a prior history of esophageal atresia or with poor motility secondary to GER or EoE are more prone to food impactions, which seldom occur in the normal esophagus.

Clinical Manifestations

Some children are asymptomatic, but most exhibit some degree of drooling, food refusal, or chest discomfort. Older children usually can point to the region of the chest where they feel the object to be lodged. Respiratory symptoms tend to be minimal, but cough or wheezing may be present, especially when the esophagus is completely blocked by a large object, such as a piece of meat, which presses on the trachea.

Diagnosis

Plain chest and abdominal radiographs should be taken when foreign body ingestion is suspected. Metallic objects are easily visualized. A plastic object often can be seen if the child is given a small amount of dilute x-ray contrast material to drink, although endoscopy is probably safer and more definitive.

Treatment

Endoscopy is ultimately necessary in most cases to remove a retained esophageal foreign body. Various devices can be used to remove the object, depending on its size, shape, and location. Coins usually are grasped with special-purpose forceps and removed. Nets, baskets, and snares also are available. Whenever objects that may threaten the airway are being recovered, endoscopy should be performed with endotracheal intubation and under general anesthesia. Removal is usually not necessary if the object is small and located in the stomach, as it will most likely pass without complication. Endoscopy is emergent for removal of any esophageal foreign body if the patient has airway compromise. Due to high risk of complications, emergent removal is required for esophageal button batteries or multiple magnets.

Complications

Sharp objects may lacerate or perforate the esophagus; smooth objects present for a long time also may result in perforation due to ulceration. Corrosive objects, such as zinc-containing pennies and button batteries, can cause considerable local tissue injury and esophageal perforation. Magnets can lead to perforation and fistula formation when they connect between adjacent loops of bowel.

CAUSTIC INJURIES AND PILL ULCERS

Etiology and Epidemiology

In adolescents, caustic ingestion injuries are usually the result of suicide attempts. In toddlers, ingestion of household cleaning products typically is accidental. Injurious agents include drain cleaners, toilet bowl cleaners, dishwasher and laundry detergents, and powerful bleaching agents. Childproof lids for commercial products offer some protection but have not eliminated the problem. Lye-based drain cleaners, especially liquid products, cause the worst injuries because they are swallowed easily and liquefy tissue rapidly. Full-thickness burns can occur in seconds. Granular products are less likely to cause esophageal injury during accidental exposures because they burn the

tongue and lips and often are expelled before swallowing. Less caustic agents, such as bleach and detergents, cause less serious injury. **Pill ulcers** occur when certain medications (tetracyclines and nonsteroidal antiinflammatory drugs [NSAIDs]) are swallowed without sufficient liquids, allowing prolonged direct contact of the pill with the esophageal mucosa.

Clinical Manifestations

Caustic burns cause immediate and severe mouth pain. The child cries out, drools, spits, and usually drops the container immediately. Burns of the lips and tongue are visible almost immediately. These burns clearly indicate the possibility of esophageal involvement, although esophageal injury can occur in the absence of oral burns. Symptoms may not be present; further evaluation by endoscopy usually is indicated with any significant history of caustic ingestion. Pill injury causes severe chest pain and often prominent odynophagia and dysphagia.

Laboratory and Imaging Studies

A chest x-ray should be obtained to rule out aspiration and to inspect for mediastinal air. The child should be admitted to the hospital and given intravenous (IV) fluids until endoscopy. The true extent of burns may not be endoscopically apparent immediately, but delayed endoscopy can increase the risk of perforation. Most endoscopists perform the initial endoscopy soon after injury, when the patient has been stabilized. The extent of injury and severity of the burn should be carefully determined. Risk of subsequent esophageal strictures is related to the degree of burn and whether the injury is circumferential.

Treatment

A nasogastric tube can be placed over a guide wire at the time of the initial endoscopy to provide a route for feeding and to stent the esophagus. Systemic steroid use has not been found to be beneficial in reducing stricture formation. Broad-spectrum antibiotics should be prescribed if infection is suspected.

Complications

Esophageal strictures, if they occur, usually develop within 1–2 months and can be treated with endoscopic dilation. There is a risk of perforation during dilation. When esophageal destruction is severe, surgical reconstruction of the esophagus using stomach or intestine may be necessary.

PYLORIC STENOSIS

Etiology and Epidemiology

Pyloric stenosis is an acquired condition caused by hypertrophy and spasm of the pyloric muscle, resulting in gastric outlet obstruction. It occurs in 6–8 per 1,000 live births, has a 5:1 male predominance, and is more common in first-born children. Its cause is unknown.

Clinical Manifestations

Infants with pyloric stenosis typically begin vomiting during the first weeks of life, but onset may be delayed. The emesis becomes increasingly frequent and forceful as time passes. Vomiting differs from spitting up because of its extremely

FIGURE 128.4 Pyloric stenosis. Note the huge, gas-filled stomach extending across the midline, with minimal air in the intestine downstream. (Courtesy Warren Bishop, MD.)

forceful and often projectile nature. The vomited material never contains bile because the gastric outlet obstruction is proximal to the duodenum. This feature differentiates pyloric stenosis from most other obstructive lesions of early childhood. Affected infants are ravenously hungry early in the course of the illness but become more lethargic with increasing malnutrition and dehydration. The stomach becomes massively enlarged with retained food and secretions, and gastric **peristaltic waves** are often visible in the left upper quadrant. A hypertrophied pylorus (the “olive”) may be palpated. As the illness progresses, very little of each feeding is able to pass through the pylorus, and the child becomes progressively thinner and more dehydrated.

Laboratory and Imaging Studies

Repetitive vomiting of purely gastric contents results in loss of hydrochloric acid; the classic laboratory finding is a **hypochloremic, hypokalemic metabolic alkalosis** with elevated blood urea nitrogen (BUN) secondary to dehydration. Jaundice with unconjugated hyperbilirubinemia may also occur. Plain abdominal x-rays typically show an enlarged stomach and diminished or absent gas in the intestine (Fig. 128.4). Ultrasound examination shows marked elongation and thickening of the pylorus (Fig. 128.5). A barium upper GI series also may be obtained whenever doubt about the diagnosis exists; this shows a “string sign” caused by barium moving through an elongated, constricted pyloric channel.

Treatment

Treatment of pyloric stenosis includes IV fluid and electrolyte resuscitation followed by surgical pyloromyotomy. Before surgery, dehydration and hypochloremic alkalosis must be corrected, generally with an initial normal saline fluid bolus followed by infusions of half-normal saline

FIGURE 128.5 Ultrasound image of infant with pyloric stenosis. Large, fluid-filled stomach (S) is seen at right, with an elongated, thickened pylorus. The length of the pylorus is marked by the red arrows; the wall thickness is marked by the yellow arrows.

containing 5% dextrose and potassium chloride when urine output is observed. In pyloromyotomy (often by laparoscope), the pyloric muscle is incised longitudinally to release the constriction.

PEPTIC DISEASE

Etiology and Epidemiology

Acid-related injury can occur in the esophagus, stomach, or duodenum. Table 128.2 lists risk factors for **peptic ulcer disease** in children. *Helicobacter pylori* is responsible for more than half of ulcers in the stomach and duodenum in adults. *H. pylori* plays a significant but lesser role in childhood ulcer disease. Risk factors for acquisition of *H. pylori* are low socioeconomic status and poor sanitation, with the highest incidence in developing countries. **Nonulcer dyspepsia** includes upper abdominal symptoms (pain, bloating, nausea, early satiety) in the absence of gastric or duodenal ulceration. Nonulcer dyspepsia is *not* associated with *H. pylori* infection. GER (see Chapter 128) allows acidic gastric contents to injure the esophagus, resulting in **esophagitis**. Esophagitis is characterized by retrosternal and epigastric burning pain and is best diagnosed by endoscopy. It can range from minimal, with only erythema and microscopic inflammation on biopsy, to superficial erosions and, finally, to frank ulceration.

Clinical Manifestations

Typical symptoms are listed in Table 128.3. The presence of recurrent burning epigastric and retrosternal pain is a risk

factor for esophagitis. With duodenal ulcers, pain typically occurs several hours after meals and often awakens patients at night. Eating tends to relieve the pain. Gastric ulcers differ in that pain is commonly aggravated by eating, resulting in weight loss. GI bleeding from either can occur. Many patients report symptom relief with antacids or acid blockers.

Laboratory and Imaging Studies

Endoscopy can be used to diagnose the underlying condition. Empiric therapy with H₂ blockers or proton pump inhibitors can be used but may delay diagnosis of conditions such as *H. pylori*. For patients with chronic epigastric pain, the possibilities of inflammatory bowel disease, anatomic abnormality such as malrotation, pancreatitis, and biliary disease should be ruled out by appropriate testing when suspected (see Chapter 126 and Table 128.3 for recommended studies). Testing for *H. pylori* can be performed by biopsy during endoscopy with use of a urease test or presence histologically on tissue. If endoscopy is not done, noninvasive tests for infection can be done with reasonable accuracy with *H. pylori* fecal antigen and ¹³C urea breath tests.

Treatment

If *H. pylori* is present in association with ulcers, it should be treated with a multidrug regimen, such as omeprazole-clarithromycin-metronidazole (or amoxicillin). Other proton pump inhibitors may be substituted when necessary. Bismuth compounds are effective against *H. pylori* and can be considered in addition to the abovementioned therapies. In North America, only the subsalicylate salt is available, the use of which raises some concerns about Reye syndrome and potential salicylate toxicity. Tetracycline is useful in adults but should be avoided in children less than 8 years of age. In the absence of *H. pylori*, esophagitis and peptic ulcer disease are treated with a proton pump inhibitor, which yields higher rates of healing than H₂-receptor antagonists. Gastric and duodenal ulcers heal in 4–8 weeks in at least 80% of patients. Esophagitis requires several months of proton pump inhibitor treatment for optimal healing.

TABLE 128.3 Peptic Disorders, Symptoms, and Clinical Investigation

SYNDROME AND ASSOCIATED SYMPTOMS	CLINICAL INVESTIGATIONS
ESOPHAGITIS	
Retrosternal and epigastric location	Endoscopy
Burning pain	Therapeutic trial of acid-blocker therapy
Sensation of regurgitation	pH probe study
Dysphagia, odynophagia	
NONULCER DYSPEPSIA	
Upper abdominal location	Endoscopy
Fullness	Therapeutic trial of acid-blocker therapy
Bloating	Upper GI series to ligament of Treitz—rule out malrotation
Nausea	CBC, ESR, amylase, lipase, abdominal ultrasound
PEPTIC ULCER DISEASE	
“Alarm” symptoms	Endoscopy—mandatory with alarm symptoms
Weight loss	Test for <i>Helicobacter pylori</i>
Hematemesis	CBC, ESR, amylase, lipase, abdominal ultrasound
Melena, heme-positive stools	
Chronic vomiting	
Microcytic anemia	
Nocturnal pain	
Other symptoms—same as for esophagitis and nonulcer dyspepsia	

CBC, Complete blood count; ESR, erythrocyte sedimentation rate; GI, gastrointestinal.

CYCLIC VOMITING SYNDROME

Etiology and Epidemiology

Cyclic vomiting syndrome (CVS) presents with intermittent episodes of prolonged nausea and vomiting with periods of health in between. It can occur at any age but is diagnosed most frequently in preschool to school-age children. It is thought to be a migraine variant; many patients have a positive family history of migraines, and some with CVS will eventually develop migraine headaches. Triggers to an episode often include viral illnesses, lack of sleep, stressful or exciting events (holidays, birthdays, vacations), physical exhaustion, and menses.

Clinical Manifestations

Episodes can start at any time but will often start in the early morning hours. Episodes are similar to each other in timing and duration. Repetitive vomiting can last hours to days. Patients can also have abdominal pain, diarrhea, and headaches. Those affected are typically pale, listless, and prefer to be left alone. They may have photo- or phonophobia.

Laboratory and Imaging Studies

There are no specific tests for CVS, which is diagnosed based on the history and the exclusion of other disorders. Diagnoses that should be considered include malrotation with

intermittent volvulus, uteropelvic junction (UPJ) obstruction, EoE, intracranial mass lesions, and metabolic disorders. Rome IV criteria for diagnosis are outlined in [Table 126.5](#).

Treatment

For the acute episode, supportive treatment includes hydration; dark, quiet environment; and antiemetics such as ondansetron. In addition, abortive therapy using antimigraine medications such as triptans or antiemetics such as ondansetron can be used. For those with frequent or prolonged episodes, prophylactic therapy should be considered, such as cyproheptadine, tricyclic antidepressants, β blockers, or topiramate.

PEARLS FOR PRACTITIONERS

See *The Digestive System: Pearls for Practitioners* at the end of this section.

CHAPTER 129

Intestinal Tract

MALROTATION

Etiology and Epidemiology

During early fetal life, the midgut is attached to the yolk sac and loops outward into the umbilical cord. Beginning at around 10 weeks of gestation, the bowel re-enters the

abdomen and rotates counterclockwise around the superior mesenteric artery until the cecum arrives in the right lower quadrant. The duodenum rotates behind the artery and terminates at the **ligament of Treitz** in the left upper quadrant. The base of the mesentery becomes fixed along a broad attachment posteriorly, running from the cecum to the ligament of Treitz (Fig. 129.1A). When rotation is incomplete or otherwise abnormal, “malrotation” is present. Incomplete rotation occurs when the cecum fails to move behind the mesenteric artery; this results in an extremely narrow mesenteric root (see Fig. 129.1B) that makes the child susceptible to midgut **volvulus**, causing intestinal obstruction or mesenteric artery occlusion and intestinal infarction (Fig. 129.2). It is also common for abnormal mesenteric attachments (Ladd bands) to extend from the cecum across the duodenum, causing partial obstruction.

Clinical Manifestations

About 60% of children with malrotation present with symptoms of bilious vomiting during the first month of life. The remaining 40% present later in infancy or childhood. The emesis initially may be due to obstruction by Ladd bands without volvulus. When midgut volvulus occurs, the venous drainage of the gut is impaired; congestion results in ischemia, pain, tenderness, and often bloody emesis and stools. The bowel undergoes ischemic necrosis, and the child may appear septic. Physicians must be alert to the possibility of volvulus in patients with vomiting, fussiness, abdominal pain, or shock.

FIGURE 129.1 (A) Normal rotation of the midgut. Note the long axis of mesenteric attachment (*line*). (B) Midgut malrotation. Note the narrow mesentery, which predisposes to volvulus, and the presence of Ladd bands extending across the duodenum from the abnormally elevated cecum. (From Donellan WJ, ed. *Abdominal Surgery of Infancy and Childhood*. Luxembourg: Harwood Academic; 1996:43/6, 43/8.)

FIGURE 129.2 Malrotation with volvulus. Midgut is twisted around the mesentery, with an area of darker, ischemic intestine visible. (Courtesy Robert Soper, MD.)

Laboratory and Imaging Studies

Plain abdominal x-rays generally show evidence of obstruction. Abdominal ultrasound may show evidence of malrotation. An upper gastrointestinal (GI) series shows the absence of a typical duodenal “C-loop,” with the duodenum instead remaining on the right side of the abdomen. Abnormal placement of the cecum on follow-through (or by contrast enema) confirms the diagnosis. Laboratory studies are nonspecific, showing evidence of dehydration, electrolyte loss, or evidence of sepsis. A decreasing platelet count is a common indicator of bowel ischemia.

Treatment

Treatment is surgical. The bowel is untwisted, and Ladd bands and other abnormal membranous attachments are divided. The mesentery is spread out and flattened against the posterior wall of the abdomen by moving the cecum to the left side of the abdomen. Sutures may be used to hold the bowel in position, but postoperative adhesions tend to hold the mesentery in place, resulting in a broad attachment and eliminating the risk of recurrent volvulus. Necrotic bowel is resected and, at times, results in short gut syndrome.

INTESTINAL ATRESIA

Etiology and Epidemiology

Congenital partial or complete blockage of the intestine is a developmental defect that occurs in about 1 in 1,500 live births. Atresia occurs in several forms (Fig. 129.3). One or more segments of bowel may be missing completely, there may be varying degrees of obstruction caused by webs or stenosis, or there may be obliteration of the lumen in cordlike bowel remnants. The end result is obstruction with upstream dilation of the bowel and small, disused intestine distally. When obstruction is complete or high grade, bilious vomiting and abdominal distention are present in the newborn period. In lesser cases, as in “windsock” types of intestinal webs, the obstruction is partial, and symptoms are more subtle. Duodenal atresia is associated with other anomalies in more than half of infants. Down syndrome is the most common associated disorder, but it can also be associated with biliary, cardiac, renal, or vertebral

anomalies. Jejunal and ileal atresia can be seen in meconium ileus secondary to cystic fibrosis.

Clinical Manifestations

Intestinal atresia presents with a history of polyhydramnios, abdominal distention, and bilious vomiting in the neonatal period. If intestinal perforation is present, peritonitis and sepsis may develop.

Laboratory and Imaging Studies

Plain abdominal x-rays may localize the area of atresia and identify evidence of perforation, such as free air or calcifications typical of meconium peritonitis. Duodenal atresia appears as a double-bubble sign (gas in the stomach and enlarged proximal duodenum), with no gas distally. Atresias of the distal intestine are characterized by longer segments of dilated, air-filled bowel. Contrast studies are helpful if plain films are not sufficient. Atresia may be a complication of **meconium ileus** associated with cystic fibrosis. Laboratory evaluation for **cystic fibrosis** (see Chapter 137) is indicated in cases of small bowel atresia. A complete blood count, serum electrolytes, liver functions, and amylase should be measured to identify dehydration, pancreatitis, and other complications.

Treatment

The treatment of intestinal atresia is surgical, but surgery must be preceded by adequate hemodynamic stabilization of the patient. Intravenous (IV) fluids, nasogastric suction, and broad-spectrum antibiotics should be given.

OTHER CONGENITAL DISORDERS

Gastroschisis is an abdominal wall defect, not involving the umbilicus, through which intestinal contents have herniated. In contrast to omphalocele, the bowel is not covered by peritoneum or amniotic membrane. As a result, prolonged contact with the amniotic fluid typically causes a thick, exudative covering (a “peel”) on the exposed bowel. Gastroschisis is not associated with extraintestinal anomalies, but segments of intestinal atresia are common. After surgical reduction of the defect, return of normal bowel function may be slow and require prolonged parenteral nutrition for infants with long atretic segments (short-bowel syndrome) and infants with a thick peel.

Omphalocele is an abdominal wall defect through the umbilicus caused by failure of the intestine to return to the abdomen during fetal life. The bowel remains within the umbilical cord and is covered by peritoneum and amniotic membranes. This defect is associated with other congenital anomalies, especially cardiac defects, **Beckwith-Wiedemann syndrome**, and intestinal complications. Treatment is surgical closure, which sometimes must be performed in stages to fit the bowel into a congenitally small abdominal cavity.

Anorectal malformations, including imperforate anus and its variants, are embryologic defects recognized at birth by the absence of a normal anal opening. Evaluation of these infants should include observation for emergence of meconium from the urethra or fistulas on the perineum. A urinary catheter should be placed if urinary distention is present. In low

FIGURE 129.3 Types of intestinal atresia. (A) Internal web; (B) cordlike remnant connecting proximal and distal bowel; (C) interrupted bowel with V-shaped mesenteric defect; (D) “apple peel” atresia with surviving bowel spiraling around a marginal artery; (E) multiple atresias. (From Grosfeld JL, Ballantine TVN, Shoemaker R. Operative management of intestinal atresia based on pathologic findings. *J Pediatr Surg.* 1979;14:368–375.)

lesions, a fistulous opening that drains meconium is present on the perineum. Low lesions commonly are associated with fistulization between the bowel and bladder, vagina, or urethra. Lateral plain x-rays show the level of the defect and show gas in the bladder caused by a fistula. Initial treatment is a colostomy to divert the fecal flow, with subsequent reconstruction. The internal sphincter muscle is functionally absent in high lesions, and continence after repair is difficult to achieve. All children with imperforate anus require magnetic resonance imaging (MRI) of the lumbosacral spinal cord because of high incidence of tethered spinal cord. Urologic dysfunction is common and should be evaluated.

Hirschsprung disease is a motility defect caused by failure of ganglion cell precursors to migrate into the distal bowel during fetal life. The aganglionic distal segment does not exhibit normal motility and is functionally obstructed secondary to spasm. In 75% of cases, the involved segment is limited to the rectosigmoid; total colonic involvement is seen in 8%. Rarely, long segments of small bowel also are aganglionic. “Ultrashort” segment involves only a few centimeters of distal rectum. About 95% of normal infants pass stool spontaneously by 24 hours of age; 95% of infants with Hirschsprung disease do not. Symptoms of distal bowel obstruction occur with distention and bilious vomiting. If the diagnosis is not made quickly, **enterocolitis** can result, associated with a high rate of mortality. Diagnosis is based on examination and one or more diagnostic studies. Abdominal distention is present in most

cases. Digital rectal examination reveals an empty rectum that clenches around the examiner’s finger, giving the impression of an elongated sphincter. When the finger is withdrawn, a powerful gush of retained stool is often expelled. A deep **rectal biopsy** specimen obtained surgically or by using a suction biopsy instrument is required for diagnosis. When no ganglion cells are shown in the submucosal plexus, accompanied by nerve trunk hyperplasia, the diagnosis is certain. **Barium enema** and **anorectal manometry** may be used before biopsy, but false-negative and false-positive results can occur. Therapy is surgical. When the bowel is markedly distended or inflamed, an initial colostomy usually is performed above the aganglionic segment, followed weeks later by one of several definitive repair procedures. The transanal pull-through excises the aganglionic bowel and creates a primary colorectal anastomosis without laparotomy. This procedure can be considered in patients with uncomplicated involvement limited to the rectosigmoid region.

Meckel diverticulum is a remnant of the fetal omphalomesenteric duct and is an outpouching of the distal ileum present in 1–2% of the population. Although most diverticula are asymptomatic throughout life, some cause significant, painless GI bleeding. Ectopic gastric tissue within the diverticulum causes ulceration of mucosa in the adjacent ileum. Meckel diverticulum may be a lead point for intussusception or may enable twisting (volvulus) of neighboring bowel around its vascular supply. Diverticulitis mimics appendicitis. Diagnosis

may be made in most cases by technetium scan (Meckel scan), which labels the acid-producing mucosa. Because not all diverticula are seen, ultrasound, barium enteroclysis, or video capsule endoscopy may be useful. When the level of suspicion is high, surgical or laparoscopic investigation is warranted. The treatment is surgical excision.

INFLAMMATORY BOWEL DISEASE

Epidemiology and Etiology

The peak incidence of inflammatory bowel disease (IBD) in children is in the second decade of life, but it may occur at any age. IBD includes Crohn disease (CD), which can involve any part of the gut, and ulcerative colitis (UC), which affects only the colon. The incidence of IBD is increasing, especially in industrialized countries, for reasons that are unclear. It is more common in northern latitudes. IBD is uncommon in tropical and Third World countries but is becoming more prevalent. It is more common in Jewish than in other ethnic populations. Genetic factors play a role in susceptibility, with significantly higher risk if there is a family history of IBD. Having a first-degree relative with IBD increases the risk about 30-fold. Susceptibility has been linked to some human leukocyte antigen (HLA) subtypes, and linkage analysis has identified multiple other susceptibility loci on several chromosomes. Environmental factors (not yet identified) also seem to play a role because there is often nonconcordance among monozygotic twins. Dietary and infectious triggers have been proposed but not yet proven. Smoking increases the risk as well as the severity of CD and decreases the risk for UC.

Very early-onset IBD occurring under the age of 2 years is rare and represents a wide etiologic spectrum including congenital immune defects and other inflammatory disorders. IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) and IPEX-like syndromes are the prototype disorders often associated with extraintestinal manifestations such as cytopenias, eczema, and eosinophilia.

Clinical manifestations depend on the region of involvement. UC involves only the colon, whereas CD can include the entire gut from mouth to anus. **Colitis** from either condition results in diarrhea; blood and mucus in the stool; urgency; and *tenesmus*, a sensation of incomplete emptying after defecation. When colitis is severe, the child often awakens from sleep to pass stool. **Toxic megacolon** is a life-threatening complication characterized by fever, abdominal distention and pain, massively dilated colon, anemia, and low serum albumin owing to fecal protein losses. Symptoms of colitis always are present in UC and usually suggest the diagnosis early in its course. Extraintestinal manifestations of UC occur in a few patients and may include primary sclerosing cholangitis, arthritis, uveitis, and pyoderma gangrenosum (Table 129.1).

Symptoms can be subtle in CD. **Small bowel involvement** in CD is associated with loss of appetite, crampy postprandial pain, poor growth, delayed puberty, fever, anemia, and lethargy. Symptoms may be present for some time before the diagnosis is made. Severe CD with fibrosis may cause partial or complete small bowel obstruction. Perineal abnormalities, including skin tags and fistulas, are another feature distinguishing CD from UC. Other extraintestinal manifestations of CD include arthritis, erythema nodosum, and uveitis.

TABLE 129.1 Comparison of Crohn Disease and Ulcerative Colitis

FEATURE	CROHN DISEASE	ULCERATIVE COLITIS
Malaise, fever, weight loss	Common	Sometimes
Rectal bleeding	Sometimes	Usual
Abdominal mass	Common	Rare
Abdominal pain	Common	Common
Perianal disease	Common	Rare
Ileal involvement	Common	None (except for backwash ileitis)
Strictures	Common	Unusual
Fistula	Common	Very rare
Skip lesions	Common	Not present
Transmural involvement	Usual	Not present
Crypt abscesses	Variable	Usual
Intestinal granulomas	Common	Rarely present
Risk of cancer*	Increased	Greatly increased
Erythema nodosum	Common	Less common
Mouth ulceration	Common	Rare
Osteopenia at onset	Yes	No
Autoimmune hepatitis	Rare	Yes
Sclerosing cholangitis	Rare	Yes

*Colonic cancer, cholangiocarcinoma, lymphoma in Crohn disease.

Laboratory and Imaging Studies

Blood tests should include complete blood count, albumin, erythrocyte sedimentation rate, and C-reactive protein (Table 129.2). Anemia and elevated platelet counts are typical. Serologic testing for IBD may be considered but is not recommended for screening due to poor sensitivity. Elevated fecal calprotectin or positive lactoferrin testing indicates intestinal inflammation. These tests have a high negative predictive value but are not specific to IBD. Genetic testing is available for many causes of very early-onset IBD (e.g., *FOXP3* for IPEX).

In patients with suspected IBD, upper endoscopy and colonoscopy are recommended. Colonoscopic findings in UC include diffuse carpeting of the distal or entire colon with tiny ulcers and loss of haustral folds. Within the involved segment, no skip areas are present. In CD, ulcerations tend to be much larger and deeper with a linear, branching, or aphthous appearance; skip areas are usually present. **Upper endoscopy** cannot evaluate the jejunum and ileum but is more sensitive than contrast studies in identifying proximal CD involvement. Other methods to detect small bowel involvement include **video capsule endoscopy**; upper GI series with small bowel follow-through; computed tomography (CT) scanning, which can detect small bowel disease as well as abscesses; and **MR enterography**, which has the advantage of no radiation and good sensitivity for finding active bowel disease.

TABLE 129.2 Diagnostic Studies for Inflammatory Bowel Disease	
STUDIES	INTERPRETATION
BLOOD TESTS	
CBC with WBC differential	Anemia, elevated platelets suggest IBD
ESR	Elevated in many, but not all, IBD patients
C-reactive protein	Elevated in many, but not all, IBD patients
Albumin	May be low in IBD due to fecal loss
ASCA	Found in about 50% of CD patients and few UC patients
Atypical p-ANCA	Found in most UC patients and few CD patients
Anti-OmpC	Found in some UC and CD patients, rare in non-IBD
Anti-C Bir1	Found in about 50% of CD patients
STOOL STUDIES	
Fecal calprotectin and lactoferrin	Elevated in IBD and can differentiate from functional disorders
IMAGING STUDIES	
Upper GI series with SBFT	Evaluate for ileal and jejunal CD
CT scan	Used to detect abscess, small bowel involvement
Magnetic resonance enterography	Used to detect bowel thickening, inflammation, and strictures as well as abscesses and fistulas
ENDOSCOPY	
Upper endoscopy	Evaluate for CD of esophagus, stomach, and duodenum; obtain tissue for histologic diagnosis
Colonoscopy	Show presence or absence of colitis and terminal ileal CD; obtain tissue for histology
Video capsule endoscopy	Emerging role in diagnosis of small bowel CD, more sensitive than upper GI series with SBFT

Anti-OmpC, Antibody to outer membrane protein C; *ASCA*, anti-*Saccharomyces cerevisiae* antibody; *atypical p-ANCA*, atypical perinuclear staining by antineutrophil cytoplasmic antibody; *CBC*, complete blood count; *CD*, Crohn disease; *CT*, computed tomography; *ESR*, erythrocyte sedimentation rate; *GI*, gastrointestinal; *IBD*, inflammatory bowel disease; *SBFT*, small bowel follow-through; *UC*, ulcerative colitis; *WBC*, white blood cell.

Treatment

Ulcerative Colitis

UC is treated with aminosalicylate drugs, which deliver **5-aminosalicylic acid** (5-ASA) to the distal gut. Because it is rapidly absorbed, pure 5-ASA (mesalamine) must be specially packaged in coated capsules or pills or taken as a suppository to be effective in the colon. Other aminosalicylates (sulfasalazine, olsalazine, and balsalazide) use 5-ASA covalently linked to a carrier molecule. Sulfasalazine is the least expensive, but side effects resulting from its sulfapyridine component are common.

When aminosalicylates alone cannot control the disease, steroid therapy may be required to induce remission. Whenever possible, steroids should not be used for long-term therapy. An immunosuppressive drug, such as **6-mercaptopurine** or **azathioprine**, is useful to spare excessive steroid use in difficult cases. More potent immunosuppressives, such as cyclosporine or anti-tumor necrosis factor (TNF) agents such as infliximab, may be used in more severe or recalcitrant cases. Other biologic therapies are being used (such as the anti-integrin vedolizumab or JAK kinase inhibitor tofacitinib) but are not yet Food and Drug Administration approved in the pediatric patient who have failed anti-TNF therapy. Surgical colectomy with ileoanal anastomosis is an option for unresponsive severe disease or electively to end chronic symptoms and to reduce the risk of colon cancer, which is increased in patients with UC.

Crohn Disease

Systemic steroids or exclusive formula-based enteral nutrition is used to induce remission in CD. To avoid the need for repetitive steroid therapy, immunomodulator drugs such as azathioprine, 6-mercaptopurine, or methotrexate are often started soon after diagnosis; however, anti-TNF therapies are being used more frequently due to their efficacy and safety profile. Other biologic agents (such as vedolizumab and the anti-IL12/23 drug ustekinumab) are being used but not yet approved in the pediatric patient. Exclusive enteral nutrition may also be an effective therapy for CD. Patients take formula as their sole source of nutrition for months as a steroid-sparing therapy. Other diets such as the specific carbohydrate diet continue to be studied as a possible therapy. As with UC, surgery is sometimes necessary usually because of obstructive symptoms (strictures), abscess, fistulas, or severe, unremitting symptoms. Because surgery is not curative in CD, its use must be limited, and the length of bowel resection must be minimized.

CELIAC DISEASE

Etiology and Epidemiology

Celiac disease is an injury to the mucosa of the small intestine caused by the ingestion of **gluten** (a protein component) from wheat, rye, barley, and related grains. In its severe form, celiac disease causes malabsorption and malnutrition. The availability of more sensitive and specific serologic testing has revealed many patients with few or no GI symptoms but may have extraintestinal manifestations and who have early, attenuated, or latent disease. Incidence of celiac disease is estimated at 1%. The disease is seen in association with type 1 diabetes, autoimmune thyroiditis, Addison disease, Turner syndrome, and trisomy 21.

Clinical Manifestations

Symptoms can begin at any age when gluten-containing foods are given. Diarrhea, abdominal bloating, failure to thrive, irritability, decreased appetite, and ascites caused by hypoproteinemia are classic. Children may be minimally symptomatic or may be severely malnourished. Constipation is found in a few patients. A careful inspection of the child's growth curve and evaluation for reduced subcutaneous fat and abdominal

distention are crucial. Celiac disease should be considered in any child with chronic abdominal complaints, short stature, poor weight gain, or delayed puberty. Extraintestinal manifestations include osteopenia, arthritis or arthralgias, ataxia, dental enamel defects, elevated liver enzymes, nutritional anemias, dermatitis herpetiformis, and erythema nodosum.

Laboratory and Imaging Studies

Serologic markers include antiendomysial, deamidated anti-gliadin, and tissue transglutaminase IgA antibodies. Because IgA deficiency may be associated with celiac disease, total serum IgA also must be measured to document the accuracy of these tests. In the absence of IgA deficiency, either test yields a sensitivity and specificity of 95%. An endoscopic **small bowel biopsy** is essential to confirm the diagnosis and should be performed while the patient is still ingesting gluten. The biopsy specimen shows various degrees of villous atrophy (short or absent villi), mucosal inflammation, crypt hyperplasia, and increased numbers of intraepithelial lymphocytes. When there is any question about response to treatment, a repeat biopsy specimen may be obtained several months later; however, the antibodies should decrease with exclusion of gluten in the diet over time. Other laboratory studies should be performed to rule out complications, including complete blood count, calcium, phosphate, vitamin D, iron, total protein and albumin, and liver function tests. Mild elevations of the transaminases are common and should normalize with dietary therapy.

Treatment

Treatment consists of complete elimination of gluten from the diet. Consultation with a dietitian experienced in celiac disease is helpful, as is membership in a celiac disease support group. Lists of prepared foods that contain hidden gluten are particularly important for patients to use. Starchy foods that are safe include rice, soy, tapioca, buckwheat, potatoes, and (pure) oats. Many resources also are available via the Internet to help families cope with the large changes in diet that are required. Most patients respond clinically within a few weeks with weight gain, improved appetite, and improved sense of well-being. Histologic improvement lags behind clinical response, requiring several months to normalize.

MILK AND SOY PROTEIN INTOLERANCE (ALLERGIC COLITIS)

See Chapter 34.

INTUSSUSCEPTION

Etiology and Epidemiology

Intussusception is the “telescoping” of a segment of proximal bowel (the intussusceptum) into downstream bowel (the intussusciptum). Most cases occur in infants 1–2 years old; in this age group, nearly all cases are idiopathic. Viral-induced lymphoid hyperplasia may produce a lead point in these children. In older children, the proportion of cases caused by a pathologic lead point increases. In young children, **ileocolonic** intussusception is common; the ileum invaginates into

the colon, beginning at or near the ileocecal valve. When pathologic lead points are present, the intussusception may be ileoileal, jejunoileal, or jejunojejunal.

Clinical Manifestations

An infant with intussusception has sudden onset of crampy abdominal pain; the infant’s knees draw up, and the infant cries out and exhibits pallor with a colicky pattern occurring every 15–20 minutes. Feedings are refused. As the intussusception progresses and obstruction becomes prolonged, bilious vomiting becomes prominent, and the dilated, fatigued intestine generates less pressure and less pain. As the intussuscepted bowel is pulled further and further into the downstream intestine by motility, the mesentery is pulled with it and becomes stretched and compressed. The venous outflow from the intussusceptum is obstructed, leading to edema, weeping of fluid, and congestion with bleeding. Third space fluid losses and “currant jelly” stools result. Another unexpected feature of intussusception is **lethargy**. Between episodes of pain, the infant is glassy-eyed and groggy and appears to have been sedated. A sausage-shaped mass caused by the swollen, intussuscepted bowel may be palpable in the right upper quadrant or epigastrium.

Laboratory and Imaging Studies

The diagnosis depends on the direct demonstration of bowel-within-bowel. A simple way of showing this is by abdominal ultrasound. If the ultrasound is positive, or if good visualization has not been achieved, a pneumatic or contrast enema under fluoroscopy is indicated. This is a potentially useful way to both identify and **treat** intussusception. Air and barium can show the intussusception quickly and, when administered with controlled pressure, usually can reduce it completely. The success rate for pneumatic reduction is higher than for hydrostatic reduction with barium and approaches 90% if done when symptoms have been present for less than 24 hours. The pneumatic enema has the additional advantages over barium of not preventing subsequent radiologic studies and having no risk of causing barium peritonitis if perforation occurs. Nonoperative reduction should not be attempted if the patient is unstable or has evidence of pre-existing perforation or peritonitis.

Treatment

Therapy must begin with placement of an IV catheter and a nasogastric tube. Before radiologic intervention is attempted, the child must have adequate **fluid resuscitation** to correct the often severe dehydration caused by vomiting and third space losses. Ultrasound may be performed before the fluid resuscitation is complete. Surgical consultation should be obtained early as the surgeon may prefer to be present during nonoperative reduction. If pneumatic or hydrostatic reduction is successful, the child should be admitted to the hospital for overnight observation of possible recurrence (risk is 5–10%). If reduction is not complete, emergency surgery is required. The surgeon attempts gentle manual reduction but may need to resect the involved bowel after failed radiologic reduction because of severe edema, perforation, a pathologic lead point (polyp, Meckel diverticulum), or necrosis.

APPENDICITIS

Etiology and Epidemiology

Appendicitis is the most common surgical emergency in childhood. The prevalence of appendicitis varies by age with the peak in the second decade but may occur at any age. Appendicitis begins with obstruction of the lumen, most commonly by fecal matter (fecalith), but appendiceal obstruction also can occur secondary to hyperplasia of lymphoid tissue associated with viral infections or, rarely, the presence of neoplastic tissue, such as an appendiceal carcinoid tumor. Trapped bacteria proliferate and begin to invade the appendiceal wall, inducing inflammation and secretion. The obstructed appendix becomes engorged, its blood supply is compromised, and it finally ruptures. The entire process is rapid, with appendiceal rupture usually occurring within 48 hours of the onset of symptoms.

Clinical Manifestations

Classic appendicitis begins with **visceral pain**, localized to the periumbilical region. Nausea and vomiting occur soon after, triggered by the appendiceal distention. As the inflammation begins to irritate the parietal peritoneum adjacent to the appendix, **somatic pain** fibers are activated, and the pain localizes to the right lower quadrant. Examination of the patient reveals a tender right lower quadrant. Voluntary guarding is present initially, progressing to rigidity, then to rebound tenderness with rupture and peritonitis. These classic findings may not be present, especially in young children or if the appendix is retrocecal, covered by omentum, or in another unusual location. Clinical prediction rules have been developed for the diagnosis of appendicitis. The Alvarado/MANTRELS rule is scored by 1 point for each of the following: migration of pain to the right lower quadrant, anorexia, nausea/vomiting, rebound pain, temperature of at least 37.3°C, and white blood cell (WBC) shift to greater than 75% neutrophils; 2 points are given for each of tenderness in the right lower quadrant and leukocytosis greater than 10,000/ μL . Children with a score of 4 or less are unlikely to have appendicitis; a score of 7 or greater increases the likelihood that the patient has appendicitis. When classic history and physical examination findings are present, the patient is taken to the operating room. When doubt exists, imaging is helpful to rule out complications (right lower quadrant abscess, liver disease) and other disorders, such as mesenteric adenitis and ovarian or fallopian tube disorders. If the evaluation is negative and some doubt remains, the child should be admitted to the hospital for close observation and serial examinations.

Laboratory and Imaging Studies

The history and examination are often enough to make the diagnosis, but laboratory and imaging studies are helpful when the diagnosis is uncertain (Table 129.3). A WBC count greater than 10,000/ mm^3 is found in 89% of patients with appendicitis and 93% with perforated appendicitis. This criterion is met by 62% of abdominal pain patients without appendicitis. Urinalysis is done to rule out urinary tract infection, and x-rays of the chest or the kidney-ureter-bladder (KUB) rule out lower lobe pneumonia masquerading as abdominal pain. Amylase, lipase, and liver enzymes are done to look for pancreatic or liver and gallbladder disease. The plain abdominal x-ray may reveal a calcified fecalith, which strongly suggests

TABLE 129.3 Diagnostic Studies in Suspected Appendicitis

the diagnosis. When these studies are inconclusive, imaging is indicated with an abdominal ultrasound or CT scan, which may reveal the presence of an enlarged, thick-walled appendix with surrounding fluid. A diameter of more than 6 mm is considered diagnostic.

Treatment

Treatment of appendicitis is usually surgical. Laparoscopic appendectomy is curative if performed before perforation. With perforation, a course of postoperative IV antibiotics is required. Broad-spectrum coverage is necessary to cover the mixed bowel flora. In low-risk patients with nonperforated appendicitis and no fecalith, some centers have a nonsurgical approach and use high-dose broad-spectrum IV antibiotics in a hospital setting.

PEARLS FOR PRACTITIONERS

See *The Digestive System: Pearls for Practitioners at the end of this section.*

CHAPTER 130

Liver Disease

CHOLESTASIS**Etiology and Epidemiology**

Cholestasis is defined as reduced bile flow and is characterized by elevation of the conjugated, or direct, bilirubin fraction. This condition must be distinguished from physiologic neonatal jaundice, in which the direct bilirubin is never elevated (see [Chapter 62](#)). Neonatal jaundice that is secondary to unconjugated hyperbilirubinemia is the result of immature hepatocellular excretory function or hemolysis, which increases the production of bilirubin. When direct bilirubin is elevated, many potentially serious disorders must be considered ([Fig. 130.1](#), [Table 130.1](#)). Emphasis must be placed on the rapid diagnosis of treatable and potentially lethal

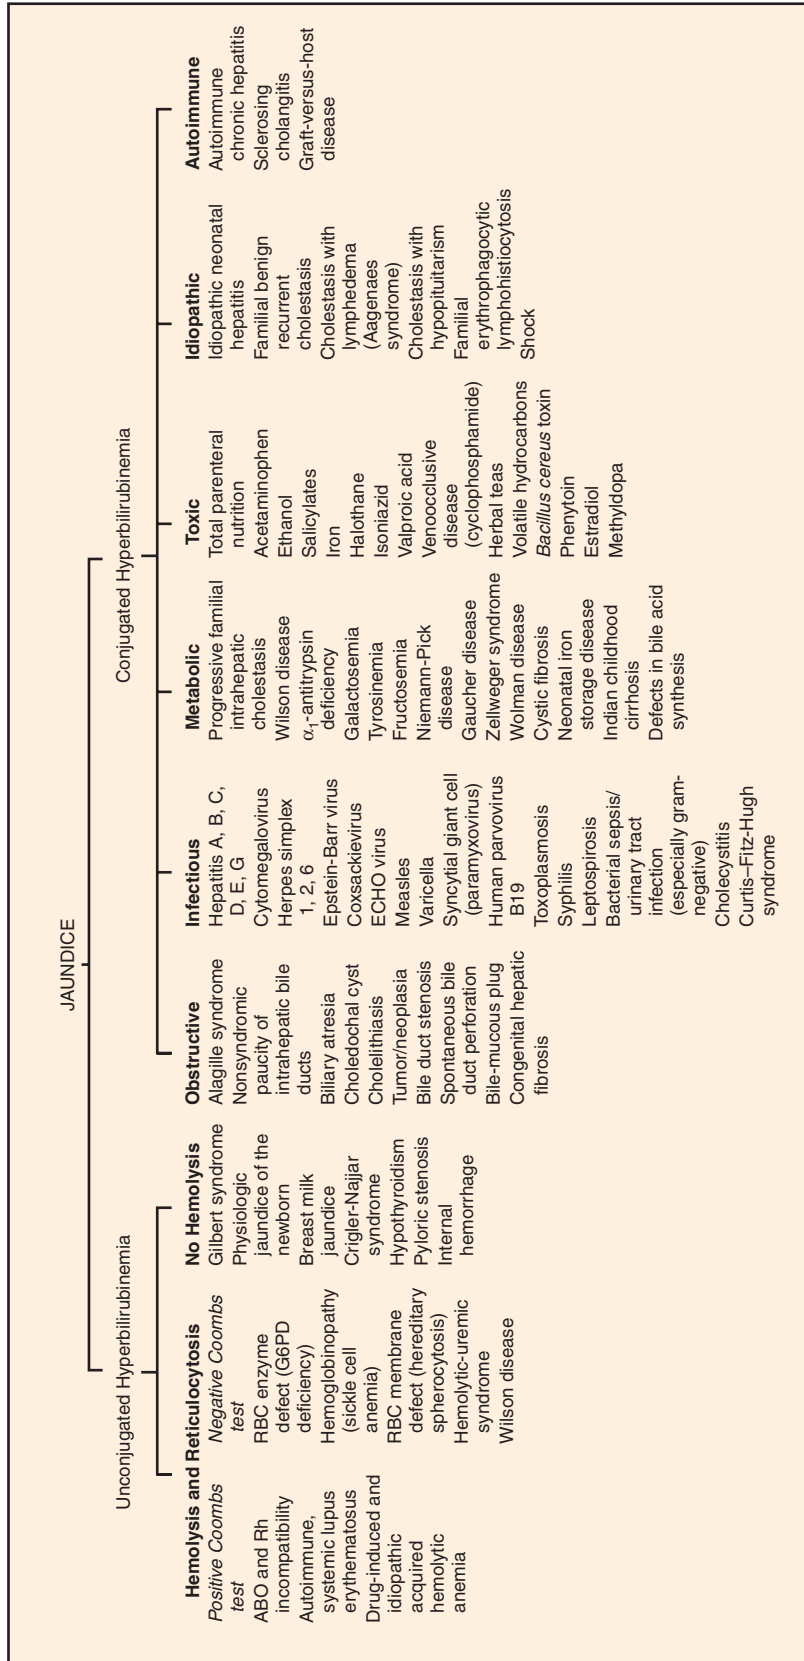

FIGURE 130.1 Differential diagnosis of jaundice in childhood. G6PD, Glucose-6-phosphate dehydrogenase; RBC, red blood cell; GALD, gestational alloimmune liver disease (neonatal hemochromatosis).

TABLE 130.1 Differential Diagnosis of Conjugated Hyperbilirubinemia in Infants

OBSTRUCTIVE/ANATOMIC DISORDERS	
Biliary atresia	Niemann-Pick disease
Choledochal cyst	Beta-oxidation defects
Caroli disease (cystic dilatation of intrahepatic ducts)	Gaucher disease
Congenital hepatic fibrosis	DISORDERS OF BILE ACID SYNTHESIS AND METABOLISM
Neonatal sclerosing cholangitis	Primary Enzyme Deficiencies
Bile duct stenosis	3 β -hydroxy- Δ 5-C27-steroid dehydrogenase/isomerase
Spontaneous bile duct perforation	Δ 4-3-oxosteroid 5 β -reductase
Anomalous choledocho-pancreatico-ductal junction	Oxysterol 7 α -hydroxylase
Cholelithiasis	Secondary
Inspissated bile or mucous	Zellweger syndrome (cerebrohepatorenal syndrome)
Mass or neoplasia	Infantile Refsum disease
INFECTIONS	Smith-Lemli-Opitz syndrome
Bacterial (gram negative) sepsis	Other enzymopathies
Urinary tract infection	Mitochondrial disorders (respiratory chain)
Listeriosis	Intrahepatic Cholestasis
Syphilis	Alagille syndrome (arteriohepatic dysplasia)
Toxoplasmosis	Nonsyndromic paucity of intrahepatic bile ducts
Tuberculosis	Progressive familial intrahepatic cholestasis (PFIC)
Cytomegalovirus	Type 1: Byler disease
Herpesvirus (herpes simplex, herpes zoster, human herpesvirus 6)	Type 2: Defect in the bile salt export pump
Rubella virus	Type 3: Defect in canalicular phospholipid transporter
Hepatitis B virus	Benign recurrent intrahepatic cholestasis
HIV	Greenland familial cholestasis (Nielsen syndrome)
Coxsackievirus	North American Indian cirrhosis
Echovirus	Hereditary cholestasis with lymphedema (Aagaens syndrome)
Parvovirus B19	Toxin or Drug Related
Adenovirus	Cholestasis associated with total parenteral nutrition
Measles	Chloral hydrate
METABOLIC DISORDERS	Home remedies/herbal medicines
α ₁ -antitrypsin deficiency	Venoocclusive disease
Cystic fibrosis	Miscellaneous
Citrin deficiency	Idiopathic neonatal hepatitis
ENDOCRINE DISORDERS	GALD
Panhypopituitarism	Autoimmune hemolytic anemia with giant cell hepatitis
Hypothyroidism	Shock or hypoperfusion (including cardiac disease)
DISORDERS OF CARBOHYDRATE METABOLISM	Intestinal obstruction
Galactosemia	Langerhans cell histiocytosis
Hereditary fructose intolerance (fructosemia)	Neonatal lupus erythematosus
Glycogen storage disease type IV	Dubin-Johnson syndrome
DISORDERS OF AMINO ACID METABOLISM	North American Indian childhood cirrhosis
Tyrosinemia	Trisomies (18, 21)
Hypermethioninemia	Congenital disorders of glycosylation
DISORDERS OF LIPID METABOLISM	Kabuki syndrome
Wolman disease	Donahue syndrome (leprechaunism)
Cholesterol ester storage disease	Arthrogryposis, cholestatic pigmentary disease, renal dysfunction syndrome
Farber disease	Familial hemophagocytic lymphohistiocytosis

GALD, Gestational alloimmune liver disease (neonatal hemochromatosis)

Modified from Balistreri WF. Liver disease in infancy and childhood. In: Schiff ER, Sorrell MF, Maddrey WC, eds. Schiff's Diseases of the Liver. 8th ed. Philadelphia: Lippincott-Raven; 1999:1370; Suchy FJ. Approach to the infant with cholestasis. In: Suchy FJ, Sokol RJ, Balistreri WF, eds. Liver Disease in Children. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2001:188.

disorders, especially biliary atresia, sepsis, urinary tract infection, hemophagocytic or histiocytic syndromes, and treatable metabolic disorders, such as galactosemia or tyrosinemia.

Clinical Manifestations

The jaundice of **extrahepatic biliary atresia** (biliary atresia) usually is not evident immediately at birth but develops in the first week or two of life. The reason is that extrahepatic bile ducts are usually present at birth but are then destroyed by an idiopathic inflammatory process. Aside from jaundice, these infants do not initially appear ill. The liver injury progresses rapidly to cirrhosis; symptoms of portal hypertension with splenomegaly, ascites, muscle wasting, and poor weight gain are evident by a few months of age. If surgical drainage is not performed successfully early in the course (ideally by 2 months), progression to liver failure is inevitable.

Idiopathic neonatal hepatitis is defined as inflammation of the liver, occurring in infancy, without an identifiable cause. It is characterized clinically by an ill-appearing infant with an enlarged liver and jaundice. This diagnosis can only be made after thorough testing for identifiable infectious, anatomic, and metabolic/genetic causes of neonatal cholestasis have been performed and are negative (see later). If liver biopsy is performed, the presence of hepatocyte giant cells is characteristic. Hepatobiliary scintigraphy typically shows slow hepatic uptake with eventual excretion of isotope into the intestine. These infants have a good prognosis overall, with spontaneous resolution occurring in most.

α_1 -antitrypsin deficiency presents with clinical findings indistinguishable from neonatal hepatitis. Only about 10–20% of all infants with the genetic defect exhibit neonatal cholestasis. Of these affected infants, about 20–30% develop chronic liver disease, which may result in cirrhosis and liver failure. Life-threatening α_1 -antitrypsin deficiency occurs in only 3–5% of affected pediatric patients. α_1 -antitrypsin deficiency is the leading metabolic disorder requiring liver transplantation.

Alagille syndrome is characterized by chronic cholestasis with the unique liver biopsy finding of *paucity of bile ducts* in the portal triads. Associated abnormalities in some (syndromic) types include peripheral pulmonic stenosis or other cardiac anomalies; hypertelorism; unusual facies with deep-set eyes, prominent forehead, and a pointed chin; butterfly vertebrae; and a defect of the ocular limbus (*posterior embryotoxon*). Cholestasis is variable but is usually lifelong and associated with hypercholesterolemia and severe pruritus. Progression to end-stage liver disease is uncommon early in life. Liver transplantation sometimes is performed electively to relieve severe and uncontrollable pruritus. Alternative surgical treatments to prevent intestinal reabsorption of pruritus-inducing bile acids can also be effective. These include partial or complete drainage to an ostomy and bypass of the terminal ileum, the location of most bile acid reabsorption.

Laboratory and Imaging Studies

The laboratory approach to diagnosis of a neonate with cholestatic jaundice is presented in Table 130.2. Noninvasive studies may aid a rapid diagnosis. Early imaging studies are performed to evaluate for biliary obstruction and other anatomic lesions that may be surgically treatable. When necessary to rule out biliary atresia or to obtain prognostic

TABLE 130.2 Laboratory and Imaging Evaluation of Neonatal Cholestasis

EVALUATION	RATIONALE
INITIAL TESTS	
Total and direct bilirubin	Elevated direct fraction confirms cholestasis
AST, ALT	Hepatocellular injury
GGT	Biliary obstruction/injury
RBC galactose-1-phosphate uridylyltransferase	Galactosemia
α_1 -antitrypsin level and phenotype	α_1 -antitrypsin deficiency
Urinalysis and urine culture	Urinary tract infection can cause cholestasis in neonates
Blood culture	Sepsis can cause cholestasis
Serum amino acids	Aminoacidopathies
Urine organic acids	Organic acidurias
Very-long-chain fatty acids	Zellweger syndrome, peroxisomal disorders
Carnitine profile	Mitochondrial and fatty acid oxidation disorders
Sweat chloride or CF mutation analysis	Cystic fibrosis
Urine culture for cytomegalovirus	Congenital cytomegalovirus infection
GENETIC TESTING	
Rapidly advancing genetic diagnosis capabilities can identify Alagille syndrome, progressive familial cholestasis syndromes, α -1-AT deficiency, familial HLH, and bile acid synthesis disorders. Some laboratories offer PCR-based testing for most or all of these in a single panel.	
INITIAL IMAGING STUDY	
Abdominal ultrasound	Choledochal cyst, gallstones, mass lesion, Caroli disease
SECONDARY IMAGING STUDY	
Hepatobiliary scintigraphy	Evaluate for biliary atresia
Pathology	Liver; salivary gland (GALD)
Percutaneous liver biopsy	Biliary atresia, idiopathic giant cell hepatitis, α_1 -antitrypsin deficiency

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; CF, cystic fibrosis; GALD, gestational alloimmune liver disease; GGT, γ -glutamyltransferase; HLH, hemophagocytic lymphohistiocytosis; RBC, red blood cell.

information, liver biopsy can be very helpful; surgical exploration is a final option (Fig. 130.2). When cholestasis persists, biliary atresia has been ruled out, and routine testing fails to yield a diagnosis, genetic testing for rare etiologies should be considered.

Treatment

Treatment of extrahepatic biliary atresia is the surgical **Kasai procedure**, in which the fibrotic extrahepatic bile duct remnant is removed and replaced with a Roux-en-Y loop of

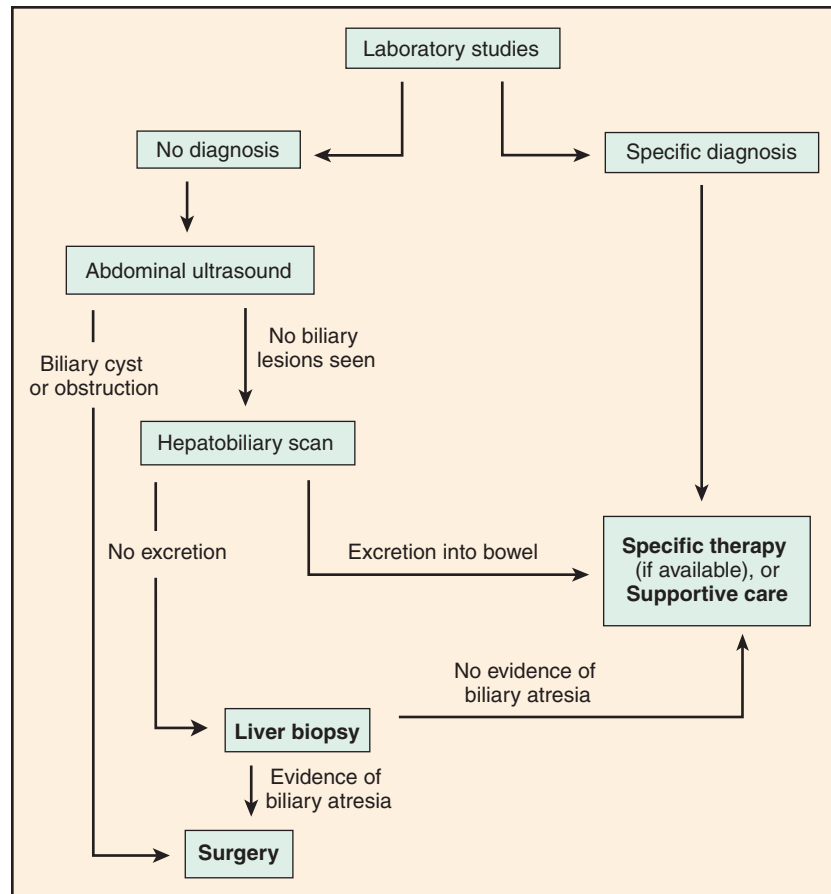

FIGURE 130.2 Flow chart for evaluation of neonatal cholestasis.

jejunum. This operation must be performed before 2 months of age to have the best chance of success. Even so, the success rate is low, and many children require liver transplantation. Some metabolic causes of neonatal cholestasis are treatable by dietary manipulation (galactosemia) or medication (tyrosinemia); all affected patients require supportive care. This includes fat-soluble vitamin supplements (vitamins A, D, E, and K) and formula containing medium-chain triglycerides, which can be absorbed without bile salt-induced micelles. Choleric agents, such as ursodeoxycholic acid, may improve bile flow in some conditions.

VIRAL HEPATITIS

See Chapter 113.

FULMINANT LIVER FAILURE

Etiology and Epidemiology

Fulminant liver failure is defined as severe liver disease with onset of hepatic encephalopathy within 8 weeks after initial symptoms, in the absence of chronic liver disease. Etiology includes viral hepatitis, metabolic disorders, autoimmune hepatitis, ischemia, neoplastic disease, and toxins, but in ~50% no etiology is identified (Table 130.3).

Clinical Manifestations

Liver failure is a multisystem disorder with complex interactions among the liver, kidneys, vascular structures, gut, central nervous system (CNS), and immune function. Hepatic encephalopathy is characterized by varying degrees of impairment (Table 130.4). Respiratory compromise occurs as severity of the failure increases and requires early institution of ventilatory support. Hypoglycemia resulting from impaired glycogenolysis and gluconeogenesis must be prevented. Renal function is impaired, and frank renal failure, or **hepatorenal syndrome**, may occur. This syndrome is characterized by low urine output, azotemia, and low urine sodium content. Ascites develops secondary to hypoalbuminemia and disordered regulation of fluid and electrolyte homeostasis. Increased risk of infection occurs and may cause death. Esophageal varices may cause significant hemorrhage, whereas hypersplenism from portal hypertension may produce thrombocytopenia and other cytopenias.

Laboratory and Imaging Studies

Coagulation tests and serum albumin are used to follow hepatic synthetic function. These tests are confounded by administration of blood products and clotting factors. Vitamin K should be administered to maximize the liver's ability to synthesize factors II, VII, IX, and X. In addition to monitoring

liver biopsy may be indicated to ascertain the nature and degree of injury and estimate the likelihood of recovery. In the presence of coagulopathy, biopsy must be done using a transjugular or surgical approach.

Treatment

Because of the life-threatening and complex nature of this condition, management must be carried out in an intensive

TABLE 130.5 Treatment of Fulminant Liver Failure

Hepatic encephalopathy	Avoid sedatives Lactulose via nasogastric tube—start with 1–2 mL/kg/day, adjust dose to yield several loose stools per day Rifaximin or neomycin Enemas if constipated Mechanical ventilation if stage III or IV
Coagulopathy	Administer intravenous vitamin K Fresh frozen plasma only if active bleeding, monitor coagulation studies frequently Platelet transfusions as required
Hypoglycemia	Intravenous glucose supplied with $\geq 10\%$ dextrose solution, electrolytes as appropriate
Ascites	Restrict fluid intake to 50–60% maintenance Restrict sodium intake to 0.5–1 mEq/kg/day Monitor central venous pressure to maintain adequate intravascular volume (avoid renal failure)
Renal failure	Maintain adequate intravascular volume, give albumin if low Diuretics Vasoconstrictors Dialysis or hemofiltration Exchange transfusion Liver transplantation

care unit at a liver transplant center. Treatment of acute liver failure is supportive; the definitive lifesaving therapy is liver transplantation. Supportive measures are listed in Table 130.5. Efforts are made to treat metabolic derangements, avoid hypoglycemia, support respiration, minimize hepatic encephalopathy, and support renal function.

CHRONIC LIVER DISEASE

Etiology and Epidemiology

Chronic liver disease in childhood is characterized by the development of cirrhosis and its complications and by progressive hepatic failure. Causative conditions may be congenital or acquired. Major congenital disorders leading to chronic disease include biliary atresia, tyrosinemia, untreated galactosemia, and α_1 -antitrypsin deficiency. In older children, hepatitis B or C virus, autoimmune hepatitis, Wilson disease, primary sclerosing cholangitis, cystic fibrosis, and biliary obstruction secondary to choledochal cyst are leading causes.

Clinical Manifestations

Chronic liver disease is characterized by the consequences of portal hypertension, impaired hepatocellular function, and cholestasis. **Portal hypertension** caused by cirrhosis results in risk of gastrointestinal bleeding, ascites, and reduced hepatic blood flow. Blood entering the portal vein from the splenic and mesenteric veins is diverted to collateral circulation that bypasses the liver, enlarging these previously tiny vessels in the esophagus, stomach, and abdomen. **Esophageal varices** are particularly prone to bleed, but bleeding also can occur from

hemorrhoidal veins, engorged gastric mucosa, and gastric varices. **Ascites** develops as a result of weeping of a high-pressure ultrafiltrate from the surfaces of the viscera and is at risk of becoming infected (spontaneous bacterial peritonitis); ascites can often be massive and interfere with patient comfort and respiration. The spleen enlarges secondary to impaired splenic vein outflow, causing excessive scavenging splenic entrapment of platelets and white blood cells; this increases the patient's susceptibility to bleeding and infection.

Impaired hepatocellular function is associated with coagulopathy unresponsive to vitamin K, low serum albumin, elevated ammonia, and **hepatic encephalopathy**. The diversion of portal blood away from the liver via collateral circulation worsens this process. Malaise develops and contributes to poor nutrition, leading to muscle wasting and other consequences.

Chronic cholestasis causes debilitating pruritus and deepening jaundice. The reduced excretion of bile acids impairs absorption of fat calories and fat-soluble vitamins, which contributes to the poor nutritional state. Deficiency of vitamin K impairs production of clotting factors II, VII, IX, and X and increases the risk of bleeding. Vitamin E deficiency leads to hematologic and neurologic consequences unless corrected.

Laboratory and Imaging Studies

Laboratory studies include specific tests for diagnosis of the underlying illness and testing to monitor the status of the patient. Children presenting for the first time with evidence of chronic liver disease should have a standard investigation (Table 130.6). Monitoring should include coagulation tests, electrolytes and renal function testing, complete blood count with platelet count, transaminases, alkaline phosphatase, and γ -glutamyltransferase at appropriate intervals. Frequency of testing should be tailored to the pace of the patient's illness. Ascites fluid can be tested for infection by culture and cell count and generally is found to have an albumin concentration lower than that of serum.

Treatment

Treatment of chronic liver disease is complex. Supportive care for each of the many problems encountered in these patients is outlined in Table 130.7. Ultimately, survival depends on the availability of a donor liver and the patient's candidacy for transplantation. When transplantation is not possible or is delayed, palliative procedures, such as portosystemic shunts to treat portal hypertension, can be considered. The transjugular intrahepatic portosystemic shunt is an expandable stent placed between the hepatic vein and a branch of the portal vein within the hepatic parenchyma. This procedure is performed using catheters inserted via the jugular vein and is entirely nonsurgical. All portosystemic shunts carry increased risk of hepatic encephalopathy.

SELECTED CHRONIC HEPATIC DISORDERS

Wilson Disease

Wilson disease is characterized by abnormal storage of copper in the liver, leading to hepatocellular injury, CNS dysfunction, and hemolytic anemia. It is an autosomal recessive trait caused by mutations in the *ATP7B* gene. The encoded protein

TABLE 130.6 Laboratory and Imaging Investigation of Chronic Liver Disease	
METABOLIC TESTING	AST, ALT, GGT, alkaline phosphatase
Serum α_1 -antitrypsin level	Total and direct bilirubin
α_1 -antitrypsin phenotype if low serum level	Serum cholyglycine or bile acids
Serum ceruloplasmin	Serum cholesterol

Ascites	Abdominal distention, shifting dullness and fluid wave, respiratory compromise, spontaneous bacterial peritonitis	Abdominal ultrasound, diagnostic paracentesis; measure ascites fluid albumin (and serum albumin), cell count, WBC differential, culture fluid in blood culture bottles	Restrict sodium intake to 0.5–1 mEq/kg/day, restrict fluids, monitor renal function, treat peritonitis and portal hypertension. Central portosystemic shunt may be required.
Nutritional compromise	Muscle wasting, fat-soluble vitamin deficiencies, poor or absent weight gain, fatigue	Coagulation studies, serum albumin, 25-hydroxyvitamin D level, vitamin E level, vitamin A level	Fat-soluble vitamin supplements: vitamins A, D, E, and K; use water-soluble form of vitamins. Supplemental feedings—nasogastric or parenteral if necessary.
Hepatic encephalopathy	Irritability, confusion, lethargy, somnolence, coma	Serum ammonia	Lactulose orally or via nasogastric tube, avoid narcotics and sedatives, liver transplantation

*May also have peptic ulcerations.

CBC, Complete blood count; TIPSS, transjugular intrahepatic portosystemic shunt; WBC, white blood cell.

of this gene functions as an adenosine triphosphate (ATP)-driven copper pump. The **diagnosis** is made by identifying low serum levels of ceruloplasmin, elevated 24-hour urine copper excretion, the presence of Kayser-Fleischer rings in the iris, evidence of hemolysis, and elevated hepatic copper content. In any single patient, one or more of these measures may be normal. **Clinical presentation** varies but seldom occurs before age 3 years. Neurologic abnormalities may predominate, including tremor, decline in school performance, worsening handwriting, and psychiatric disturbances. Hemolytic anemia may be the first noted symptom. Hepatic presentations include appearance of jaundice, spider hemangiomas, portal hypertension and its consequences, and fulminant hepatic failure. **Treatment** consists of administration of copper-chelating drugs (penicillamine or trientine), with monitoring of urine copper excretion at intervals. Zinc salts often replace chelating agents after chelation therapy has successfully reduced excessive body copper stores. Adequate therapy must be continued for life to prevent liver and CNS deterioration. Patients whose initial presentation is with severe liver disease may require immediate transplantation.

Autoimmune Hepatitis

Immune-mediated liver injury may be primary or occur in association with other autoimmune disorders, such as inflammatory bowel disease or systemic lupus erythematosus. **Diagnosis** is made on the basis of elevated serum total IgG and the presence of an autoantibody, most commonly antinuclear, anti-smooth muscle, or anti-liver-kidney microsomal antibody (see Table 130.6). Liver biopsy specimens show the presence of a plasma cell-rich portal infiltrate with piecemeal necrosis. **Treatment** consists of corticosteroids initially, usually with the addition of an immunosuppressive drug after remission is achieved. Steroids are tapered gradually as tolerated to minimize glucocorticoid side effects. Many patients require lifelong immunosuppressive therapy, but some may be able to stop medications after several years under careful monitoring for recurrence.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is characterized by the presence of macrovesicular fatty change in hepatocytes on biopsy. When accompanied by evidence of hepatic inflammation, the diagnosis is termed NASH (non-alcoholic steatohepatitis). Varying degrees of inflammation and portal fibrosis may be present. This disorder chiefly occurs in obese children, sometimes in association with insulin-resistant (type 2) diabetes and hyperlipidemia. Children with marked obesity, with or without type 2 diabetes, who have elevated liver enzymes and no other identifiable liver disease are likely to have this condition. NASH can progress to cirrhosis. Treatment is weight loss and exercise. Efforts should be made to control blood glucose and hyperlipidemia and promote weight loss. In general, the rate of progression to end-stage liver disease is slow.

PEARLS FOR PRACTITIONERS

See *The Digestive System: Pearls for Practitioners* at the end of this section.

CHAPTER 131

Pancreatic Disease

PANCREATIC INSUFFICIENCY

Etiology and Epidemiology

The cause of inadequate pancreatic digestive function in 95% of cases is **cystic fibrosis** (see Chapter 137). The defect in *CFTR* chloride channel function results in thick secretions in the lungs, intestines, pancreas, and bile ducts. In the pancreas, there is destruction of pancreatic function, often before birth. Some mutations result in less severe defects in *CFTR* function and later onset of lung disease and pancreatic insufficiency. Less common causes of pancreatic insufficiency are *Shwachman-Diamond* syndrome and *Pearson* syndrome in developed countries and severe malnutrition in developing countries.

Clinical Manifestations

Children with pancreatic exocrine insufficiency have multiple bulky, foul-smelling stools each day, usually with visible oil or fat. They typically have voracious appetites because of massive malabsorption of calories from fat, complex carbohydrates, and proteins. Failure to thrive is uniformly present if diagnosis and treatment are not accomplished rapidly. It is important to distinguish children with malabsorption due to pancreatic disease from children with intestinal disorders that interfere with digestion or absorption. Appropriate testing should be performed to rule out conditions such as celiac disease and inflammatory bowel disease if any doubt about the state of pancreatic sufficiency exists.

Laboratory and Imaging Studies

Direct testing of pancreatic function by sampling aspirated pancreatic juice after secretin stimulation is not routine and is technically difficult. Stools can be tested for the presence of maldigested fat, which usually indicates poor fat digestion. Measuring fecal fat can give either a qualitative assessment of fat absorption (fecal Sudan stain) or a semiquantitative measurement (72-hour fecal fat determination) of fat maldigestion. Another way to assess pancreatic function is to test for the presence of pancreatic enzymes in the stool. Of these, measuring **fecal elastase-1** by immunoassay seems to be the most accurate method of assessment. Depressed fecal elastase-1 concentration correlates well with the presence of pancreatic insufficiency. Imaging studies, such as ultrasound and computed tomography (CT), cannot accurately assess pancreatic function, but they may reveal evidence of injury or other alterations of the gland (such as fatty change) suggesting functional impairment.

Treatment

Replacement of missing pancreatic enzymes is the best available therapy. Pancreatic enzymes are available as capsules containing enteric-coated microspheres. The coating on these spheres is designed to protect the enzymes from gastric acid degradation. For children unable to swallow capsules, the

contents may be sprinkled on a spoonful of soft food, such as applesauce. Excessive use of enzymes must be avoided because high doses (>6,000 U/kg/meal) can cause colonic fibrosis. In infants, typical dosing is 2,000–4,000 U of lipase/120 mL of formula. In children younger than 4 years old, 1,000 U/kg/meal is given. For older children, 500 U/kg/meal is usual. This dose may be adjusted upward as required to control steatorrhea, but a dose of 2,500 U/kg/meal should not be exceeded. Use of H₂-receptor antagonists or proton pump inhibitors can increase the efficacy of pancreatic enzymes by enhancing their release from the microspheres and reducing inactivation by acid.

ACUTE PANCREATITIS

Etiology and Epidemiology

The exocrine pancreas produces numerous proteolytic enzymes, including trypsin, chymotrypsin, and carboxypeptidase. These are produced as inactive proenzymes to protect the pancreas from autodigestion. Trypsin is activated after leaving the pancreas by enterokinase, an intestinal brush border enzyme. After activation, trypsin cleaves other proteolytic proenzymes into their active states. Protease inhibitors found in pancreatic juice inhibit early activation of trypsin, and the presence of self-digestion sites on the trypsin molecule allows for feedback by self-inactivation. Pancreatitis occurs when digestive enzymes are activated inside the pancreas, causing injury. Triggers for acute pancreatitis differ between adults and children. In the adult patient, most episodes are related to alcohol abuse or gallstones. In children, most cases are idiopathic, with some due to physical injury, medications, or viral infection. There are other rare causes listed in Table 131.1.

Clinical Manifestations

Acute pancreatitis presents with relatively rapid onset of pain, usually in the epigastric region. The pain may radiate to the back and is nearly always aggravated by eating. The patient moves frequently to find a position of comfort. Nausea and vomiting occur in most cases. Pain is typically continuous and quite severe, usually requiring narcotics. Severe pancreatitis can lead to hemorrhage, visible as ecchymoses in the flanks (Grey Turner sign) or periumbilical region (Cullen sign). Rupture of pancreatic ducts can lead to development of a pancreatic pseudocyst, characterized by persistent severe pain, tenderness, and a palpable mass. With necrosis and fluid collections, patients experiencing severe pancreatitis are prone to infectious complications, and the clinician must be alert for fever and signs of sepsis.

Laboratory and Imaging Studies

The diagnosis of acute pancreatitis is based on two of the following three criteria: abdominal pain consistent with the disease (severe epigastric pain typically), serum amylase and/or lipase greater than three times the upper limit of normal, and/or characteristic findings on imaging. Acute pancreatitis can be difficult to diagnose. Pancreatic enzymes are released into the blood during pancreatic injury. Nonspecific elevations of the enzymes are common. As acute pancreatitis progresses, the amylase level tends to decline faster than lipase, making the

latter a good choice for diagnostic testing late in the course of the disease.

Because enzyme levels are not 100% sensitive or specific, imaging studies are important for the diagnosis of pancreatitis. In acute pancreatitis, edema is present in all but the mildest cases. Ultrasound can detect this edema and should be performed early as part of the overall diagnostic approach. If overlying bowel gas obscures the pancreas, a CT scan allows complete visualization of the gland. CT scans should be done with oral and intravenous (IV) contrast agents to facilitate interpretation. Ultrasound and CT also can be used to monitor for the development, progression, and resolution of **pseudocysts** and for evidence of ductal dilation secondary to obstruction. The other important reason to perform imaging studies early in the course of pancreatitis is to rule out gallstones; the liver, gallbladder, and common bile duct all should be visualized. Magnetic resonance cholangiopancreatography (MRCP) is superior to CT to detect anatomic variants causing pancreatitis, as it allows the best visualization of pancreatic and biliary ducts.

Treatment

There are no proven specific therapies for acute pancreatitis. If a predisposing etiology is found, such as a drug reaction or a gallstone obstructing the sphincter of Oddi, this should be specifically treated. Fluid resuscitation is necessary because of vomiting and third space losses. Pain relief should be provided as required. Oral, nasogastric, or nasojejunal feedings can begin early if tolerated, and both shorten hospital course and improve outcome. If early enteral feeding is not possible, parenteral nutrition should be considered. Antibiotics should be considered if the patient is febrile, has extensive pancreatic necrosis, or has laboratory evidence of infection. A broad-spectrum antibiotic, such as imipenem, is considered the best choice.

CHRONIC PANCREATITIS

Etiology and Epidemiology

Chronic pancreatitis is defined as recurrent or persistent attacks of pancreatitis, which have resulted in irreversible morphologic changes in pancreatic structure. These include scarring of the ducts with irregular areas of narrowing and dilation (beading), fibrosis of parenchyma, and loss of acinar and islet tissue. Pancreatic exocrine insufficiency and diabetes mellitus may result from unremitting chronic pancreatitis. Most patients have discrete attacks of acute symptoms occurring repeatedly, but chronic pain may be present. The causes of chronic pancreatitis include hereditary pancreatitis and milder phenotypes of cystic fibrosis associated with pancreatic sufficiency. Familial disease is often caused by one of several known mutations in the trypsinogen gene. These mutations favor intraglandular activation or loss of feedback inhibition of trypsinogen. Genetic testing is readily available for these mutations. Genetic testing for cystic fibrosis must include screening for the less common mutations associated with pancreatic sufficiency. Less commonly, hereditary pancreatitis results from mutations in the *SPINK1* gene, which codes for pancreatic trypsin inhibitor, and *PRSS1*, a mutation of cationic trypsinogen, or *CTRC*, a mutation in chymotrypsin C.

Clinical Manifestations

Children with chronic pancreatitis initially present with recurring attacks of acute pancreatitis. Injury to the pancreatic ducts predisposes these children to continued attacks owing to scarring of small and large pancreatic ducts, stasis of pancreatic secretions, stone formation, and inflammation. Loss of pancreatic exocrine and endocrine tissue over time can lead to exocrine and endocrine deficiency. More than 90% of the pancreatic mass must be destroyed before exocrine deficiency becomes clinically apparent; this is a late complication that does not occur in all cases. Chronic pain is a serious problem in most affected individuals.

Laboratory and Imaging Studies

Laboratory diagnosis of chronic pancreatitis is similar to acute pancreatitis, but with more severe loss of pancreatic tissue it becomes less likely that the patient presents with elevation of amylase or lipase. The diagnosis of chronic pancreatitis requires demonstration of chronic injury on imaging studies. Plain abdominal x-rays may show pancreatic calcifications. CT scan or magnetic resonance imaging (MRI) may show fibrosis, glandular atrophy, and ductal strictures. MRCP can demonstrate details of ductular structure and is commonly performed before considering direct ductal imaging via endoscopic retrograde cholangiopancreatography (ERCP), in which dye is injected directly into the pancreatic and common bile ducts. When an accessible dominant ductal stricture or other obstruction of pancreatic discharge is found, ERCP does offer the possibility of therapeutic intervention. Diagnostic testing for the etiology of chronic pancreatitis should include genetic testing for hereditary pancreatitis and cystic fibrosis and sweat chloride determination.

Treatment

Treatment is largely supportive. Potential but unproven therapies include the use of daily pancreatic enzyme supplements, octreotide (somatostatin) to abort early attacks, low-fat diets, and daily antioxidant therapy. Care must be taken that extreme diets do not result in nutritional deprivation. Interventional ERCP to dilate large strictures and remove stones and surgical pancreatic drainage procedures to decompress dilated pancreatic ducts by creating a side-to-side pancreaticojejunostomy may have some value.

PEARLS FOR PRACTITIONERS

See *The Digestive System: Pearls for Practitioners* at the end of this section.

CHAPTER 132

Peritonitis

ETIOLOGY AND EPIDEMIOLOGY

The peritoneum consists of a single layer of mesothelial cells that covers all intraabdominal organs. The portion that covers the abdominal wall is derived from the underlying somatic structures and is innervated by somatic nerves. The portion covering the viscera is derived from visceral mesoderm and is innervated by nonmyelinated visceral afferents. Inflammation

of the peritoneum, or peritonitis, usually is caused by infection but may result from exogenous irritants introduced by penetrating injuries or surgical procedures, radiation, and endogenous irritants such as meconium. Infectious peritonitis can be an acute complication of intestinal inflammation and perforation, as in appendicitis, or it can occur secondary to contamination of pre-existing ascites associated with renal, cardiac, or hepatic disease. In this setting, when there is no other intraabdominal source, it is referred to as **spontaneous bacterial peritonitis**. Spontaneous bacterial peritonitis is usually due to pneumococcus and less often to *Escherichia coli*.

CLINICAL MANIFESTATIONS

Peritonitis is characterized on examination by marked abdominal tenderness. Rebound tenderness also generally is quite pronounced. The patient tends to move very little owing to intense peritoneal irritation and pain. Fever is not always present, and absence of fever should not be regarded as contradictory to the diagnosis. Patients who are taking corticosteroids for an underlying condition, such as nephrotic syndrome, are likely to have little fever and reduced tenderness.

LABORATORY AND IMAGING STUDIES

Blood tests should focus on identifying the nature of the inflammation and its underlying cause. An elevated white blood cell count, erythrocyte sedimentation rate, and C-reactive protein suggest infection. In children older than 5 years, appendicitis is the leading cause. Total serum protein, albumin, and urinalysis should be ordered to rule out nephrotic syndrome. Liver function tests should be performed to rule out chronic liver disease causing ascites. The best way to diagnose suspected peritonitis is to sample the peritoneal fluid with a needle or catheter (paracentesis). Peritoneal fluid in spontaneous bacterial peritonitis has a high neutrophil count of greater than 250 cells/mm³. Other tests that should be run on the peritoneal fluid include amylase (to rule out pancreatic ascites), culture, albumin, and lactate dehydrogenase concentration. For culture, a large sample of fluid should be placed into aerobic and anaerobic blood culture bottles immediately on obtaining the sample.

Appendicitis may be identified by ultrasound or computed tomography scan. When other intraabdominal emergencies are suspected, such as midgut volvulus, meconium ileus, peptic disease, or any other condition predisposing to intestinal perforation, specific testing should be performed.

TREATMENT

Peritonitis caused by an intraabdominal surgical process, such as appendicitis or a penetrating wound, must be managed surgically. Spontaneous bacterial peritonitis should be treated with a broad-spectrum antibiotic with good coverage of resistant pneumococcus and enteric bacteria. Cefotaxime is generally effective as initial therapy while awaiting culture and sensitivity results. Anaerobic coverage with metronidazole should be added whenever a perforated viscus is suspected.

PEARLS FOR PRACTITIONERS

CHAPTER 126

Digestive System Assessment

- Take a careful history and perform a thorough but focused physical examination, using your findings to form a diagnostic hypothesis and plan.
- Surgical emergencies, such as bowel obstruction or appendicitis, must be identified rapidly in children with acute abdominal pain. Common distinguishing characteristics include pain that is accompanied by vomiting, tenderness, abdominal wall rigidity, or guarding.
- Extraintestinal disorders (lower lobe pneumonia, pyelonephritis) may produce abdominal pain.
- When evaluating recurrent abdominal pain, a complete work-up must include not only a medical evaluation, but also assessment of functional impairment, such as missing school, and consideration of psychosocial factors influencing the pain.
- Recurrent abdominal pain is seen in 10% of school-age children and is often functional.
- For patients with emesis, remember to distinguish between true vomiting (forceful retching, preceded usually by nausea) from regurgitation (effortless, usually no nausea) when considering the differential diagnosis.
- Emesis in a neonate suggests a gastrointestinal (GI) obstruction such as pyloric stenosis or volvulus; an inborn error of metabolism should be considered in the presence of acidosis, hypoglycemia, or hyperammonemia.
- When treating a patient with significant GI bleeding, focus on fluid resuscitation and tissue oxygenation/perfusion as your first priority.
- Acute diarrhea is often due to viral gastroenteritis (rotavirus, norovirus). Dysentery often presents with fever, pain, and diarrhea with blood and mucus.
- Painless large volume rectal bleeding in a 2-year-old would suggest a Meckel diverticulum; older patients may also have a polyp.

CHAPTER 127

Oral Cavity

- Many systemic disorders affect the oral cavity, which careful examination can demonstrate. Examples include Peutz-Jeghers syndrome, Crohn disease, gastroesophageal reflux disease (GERD), Addison disease, and leukemia.
- Deciduous teeth erupt in a predictable sequence and age. Significant delayed eruption may be associated with hypothyroidism, Down syndrome, and other disorders.
- Cleft lip and palate are common birth defects; combined cleft lip and palate is more common in males and isolated cleft palate is more likely to be associated with other congenital malformations.

CHAPTER 128

Esophagus and Stomach

- As many as half of infants will have physiologic reflux. The majority of infants do not benefit from acid reduction therapy.
- Gastroesophageal reflux disease occurs when there are complications of reflux such as poor growth, esophagitis, abdominal or chest pain, or respiratory problems.
- Reflux cannot be diagnosed based on imaging as this is only a snapshot in time. Upper GI series evaluates for anatomic abnormalities.
- In an older child who has not improved with lifestyle changes, a trial with a proton pump inhibitor is recommended.
- Eosinophilic esophagitis should be considered in children with poor feeding or growth, chronic abdominal pain or vomiting, and in children with dysphagia or recurrent food impactions. Treatment includes dietary changes or topical glucocorticoid therapy.
- A neonate with poor feeding and drooling with a nasogastric tube on x-ray coiled in the neck most likely has a tracheoesophageal fistula.
- Button batteries in the esophagus must be removed emergently. Two or more ingested magnets should be removed as soon as possible due to risk of perforation.
- Infants with pyloric stenosis develop hypochloremic, hypokalemic metabolic alkalosis.
- The diagnosis of pyloric stenosis may be made with abdominal ultrasonography.
- *Helicobacter pylori* cannot be reliably tested by blood tests. Urea breath hydrogen testing, endoscopy with biopsies, and fecal antigen testing can be considered.
- Cyclic vomiting syndrome is a migraine variant that leads to repeated bouts of repetitive vomiting over hours to days.

CHAPTER 129

Intestinal Tract

- Bile-stained emesis in an infant may suggest a volvulus.
- Intestinal malrotation may lead to a volvulus with subsequent intestinal infarction.
- Passage of first meconium after 24 hours of life should raise suspicion for Hirschsprung disease.
- Hirschsprung disease is diagnosed by suction or full thickness rectal biopsy.
- Duodenal atresia is associated with trisomy 21 and prematurity. There may also be polyhydramnios.
- Suspect Crohn disease in a child with poor growth, delayed puberty, fatigue, and abdominal pain. Initial testing may show anemia, thrombocytosis, elevated sedimentation rate and C-reactive protein, and hypoalbuminemia, but can be normal.

- Fecal calprotectin is a marker of intestinal inflammation. Normal fecal calprotectin makes inflammatory bowel disease diagnosis unlikely.
- Recommended serologic testing for celiac disease is the tissue transglutaminase antibody immunoglobulin A (IgA). Confirmation by duodenal biopsy is recommended prior to initiating a gluten-free diet.
- Celiac disease is associated with type 1 diabetes, thyroiditis, Turner syndrome, and trisomy 21.
- Intussusception is a cause of acute colicky abdominal pain in toddlers; there may also be rectal bleeding and intestinal obstruction.
- The diagnosis of intussusception is suggested by abdominal ultrasonography but confirmed and treated by barium or air enema.
- Appendicitis can occur at any age but is most common in adolescents and young adults.
- Periumbilical pain followed by nausea followed by right lower quadrant pain is suggestive of appendicitis.

CHAPTER 130

Liver Disease

- Infants with jaundice that persists beyond a few weeks of life should have both total and direct (conjugated) bilirubin measured to ensure that cholestasis is not missed.
- Cholestasis in infants requires prompt investigation to identify treatable causes such as biliary atresia, choledochal cyst, and certain disorders of metabolism.
- Neonatal giant cell hepatitis may be due to cytomegalovirus (CMV), herpes simplex, or syphilis.
- α_1 -antitrypsin deficiency may present as neonatal hepatitis.
- Alagille syndrome presents with chronic cholestasis due to paucity of bile ducts and is associated with itch, butterfly vertebra, triangular facies, congenital heart disease, and ocular posterior embryotoxon. Work-up of hepatitis in children requires consideration of more than just the classic hepatitis viruses and should include evaluation for autoimmune hepatitis, Wilson disease, and biliary obstruction, as well as measures of liver function.
- Wilson disease is associated with low serum ceruloplasmin and elevated 24-hour urine copper.

- Consultation with a major referral center should be sought for any child with acute severe hepatitis or chronic hepatitis.

CHAPTER 131

Pancreatic Disease

- Fecal elastase is the preferred test for pancreatic insufficiency.
- Cystic fibrosis is the most common cause of pancreatic insufficiency.
- The diagnosis of acute pancreatitis is based on symptoms of severe epigastric abdominal pain and tenderness, increase of amylase and/or lipase more than three times the upper limit of normal, and/or imaging findings of pancreatic inflammation.
- Complications of pancreatitis include shock, pancreatic pseudocyst formation, and pancreatic abscess.
- Patients with pancreatitis may feed abnormally if tolerated.
- In patients with recurrent pancreatitis, consider hereditary disorders such as cystic fibrosis or familial pancreatitis involving mutations in *CFTR*, *PRSS1*, *SPINK1*, or *CTRC*.

CHAPTER 132

Peritonitis

- When peritonitis is suspected, appropriate laboratory and imaging studies should be ordered to reveal underlying conditions, such as appendicitis.
- Nephrotic syndrome, heart failure, and chronic liver disease are associated with an increased risk of spontaneous bacterial peritonitis due to chronic presence of ascites.
- Spontaneous bacterial peritonitis is most commonly caused by *Streptococcus pneumoniae* or by *Escherichia coli*.
- Paracentesis is required to accurately diagnose peritonitis.
- Analysis of ascites fluid obtained with a needle should include culture, cell count with differential, amylase, albumin, and lactate dehydrogenase.

THE RESPIRATORY SYSTEM

BreAnna Kinghorn | Erin W. MacKintosh | Susan G. Marshall

CHAPTER 133

Respiratory System Assessment

ANATOMY OF THE RESPIRATORY SYSTEM

Air enters the **nose** and passes over the large surface area of the **nasal turbinates**, which warm, humidify, and filter the inspired air. Secretions draining from the paranasal sinuses are carried to the **pharynx** by the mucociliary action of the ciliated respiratory epithelium. Enlarged lymphoid tissue can obstruct airflow through the nasopharynx (adenoids) or the posterior pharynx (tonsils).

The **epiglottis** protects the larynx during swallowing by deflecting material toward the esophagus (Fig. 133.1). The **arytenoid cartilages**, which assist in opening and closing the vocal folds, are less prominent in children than in adults. The opening formed by the vocal folds (the **glottis**) is V shaped, with the apex of the V being anterior. Below the vocal folds, the walls of the **subglottic space** converge toward the cricoid portion of the trachea. In children under 3 years of age, the cricoid ring is the narrowest portion of the airway. In older children and adults it is the glottis. C-shaped cartilage, extending approximately 320 degrees around the airway circumference, supports the **trachea** and **mainstem bronchi**. The posterior wall of the trachea is membranous, allowing airway caliber to change during inspiration and expiration. Beyond the lobar bronchi, cartilaginous support of the airways becomes discontinuous but persists until the terminal **bronchioles**. Airway formation and branching is complete at birth, although length and caliber continue to increase until final adult height is achieved.

The right lung has three lobes (upper, middle, lower) and comprises approximately 55% of the total lung volume. The left lung has two lobes (upper, lower); the inferior division of the left upper lobe, the **lingula**, is analogous to the right middle lobe. The **lung parenchyma**, where gas exchange occurs, is composed of the respiratory bronchioles, alveolar ducts, and alveoli. **Oxygen** (O₂) and **carbon dioxide** (CO₂) must traverse alveolar and capillary membranes and the **interstitium** to maintain adequate oxygenation and ventilation to meet metabolic demands.

The pediatric lung has tremendous capacity for growth. A full-term infant has approximately 25 million alveoli; an adult nearly 300 million alveoli. The growth of new alveoli occurs during the first 2 years of life and is complete by 8 years of age. After this time, lung volume increases primarily by increase in alveolar dimensions, with new alveoli rarely formed.

PULMONARY PHYSIOLOGY

Pulmonary Mechanics

The major function of the lungs is to exchange O₂ and CO₂ between the atmosphere and the blood. The anatomy of the airways, mechanics of the respiratory muscles and rib cage, nature of the alveolar-capillary interface, pulmonary circulation, tissue metabolism, and neuromuscular control of ventilation all influence gas exchange.

Air enters the lungs when intrathoracic pressure is less than atmospheric pressure. Negative intrathoracic pressure is generated by contraction and lowering of the **diaphragm** during normal inspiration. The accessory muscles of inspiration (**external intercostal**, **scalene**, and **sternocleidomastoid muscles**) are not used during quiet breathing but are recruited during exercise or in disease states to raise and enlarge the rib cage. Exhalation is normally passive, but with active exhalation the **abdominal** and **internal intercostal muscles** are recruited.

During normal breathing at rest, lung volumes are usually in the midrange of inflation (Fig. 133.2). **Tidal volume** (TV) is the amount of air inspired with each *relaxed* breath. The volume of gas retained in the lung at the end of a *relaxed* exhalation is the **functional residual capacity** (FRC). This gas volume maintains exchange of O₂ between breaths. **Total lung capacity** (TLC) is the volume of gas in the lungs at the end of *maximal* inhalation, and **residual volume** (RV) is the volume of gas left in the lungs at the end of a *maximal* exhalation. **Vital capacity** (VC) is the maximal amount of air that can be forcibly expelled from the lungs and is the difference between TLC and RV.

Airway resistance is influenced by the diameter and length of the conducting airways, the viscosity of gas, and the nature of the airflow. During quiet breathing, airflow in the smaller airways is laminar (streamlined). At higher flow rates, turbulent flow increases resistance. Resistance is inversely proportional to the fourth power of the radius of the airway, so relatively small changes in airway diameter can result in large changes in airway resistance. Excessive airway secretions, bronchospasm, mucosal edema, stenosis, foreign bodies, loss of airway wall integrity (bronchiectasis), and airway compression may all produce symptomatic increases in airway resistance. Diseases that impact airway resistance, particularly lower airway resistance, fall into the category of **obstructive airways disease**.

Lung compliance (change in volume for a given change in pressure) is a measure of the ease with which the lung can be inflated. Processes that decrease lung compliance (surfactant deficiency, pulmonary fibrosis, pulmonary edema) may lead to **restrictive lung disease**. Restrictive lung disease can also

result from respiratory muscle weakness, pleural disease (effusion, inflammation, or mass), thoracic stiffness (scoliosis), and abdominal distention.

Respiratory Gas Exchange

Alveolar ventilation is defined as the exchange of CO_2 between the alveoli and ambient air. Normally, about 30% of each tidal breath fills the conducting airways (**anatomic dead space**). Because the anatomic dead space is relatively constant, increasing the TV generally increases the efficacy of ventilation. Conversely, if TV decreases, then the dead space:TV ratio increases and alveolar ventilation decreases.

Gas exchange depends on **alveolar ventilation**, **pulmonary capillary blood flow**, and the **diffusion** of gases across the alveolar-capillary membrane. Exchange of CO_2 is determined

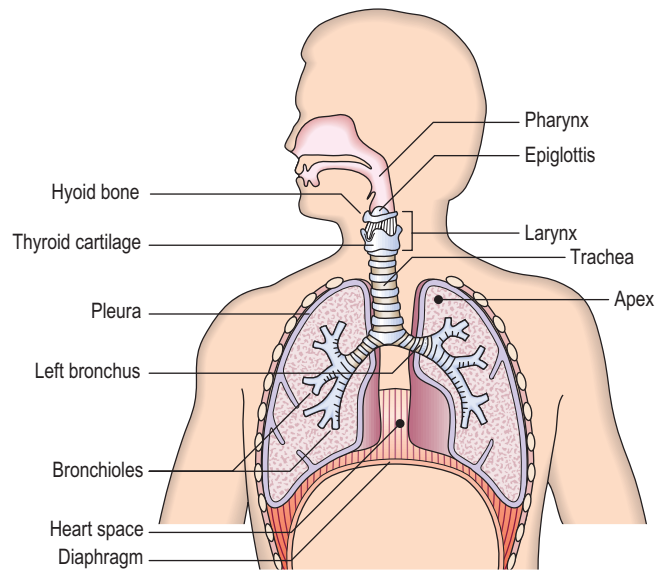

FIGURE 133.1 Anatomy of the respiratory tract. (From Wallace WAH. The respiratory tract. In: Cross SS, ed. *Underwood's Pathology: A Clinical Approach*. 7th ed. Philadelphia: Elsevier; 2019 [fig 14.1].)

by alveolar ventilation, whereas the exchange of O_2 is influenced primarily by the regional matching of ventilation (V) with pulmonary blood flow (Q) (V/Q matching). V/Q matching is maintained, in part, by **hypoxic pulmonary vasoconstriction** (local constriction of the pulmonary vessels in areas that are underventilated). There are five causes of **hypoxemia** (Table 133.1). Disorders resulting in **V/Q mismatching** (such as pneumonia and atelectasis) are the most common causes of hypoxemia in children.

Lung Defense Mechanisms

The lungs are constantly exposed to particles and infectious agents. The **nose** is the primary filter for large particles. Particles less than $10\mu\text{m}$ in diameter may reach the trachea and bronchi and deposit on the mucosa. Particles less than $1\mu\text{m}$ may reach the alveoli. **Ciliated epithelium** lining the airways from the larynx to the bronchioles continuously propels a thin layer of mucus toward the mouth. **Alveolar macrophages**

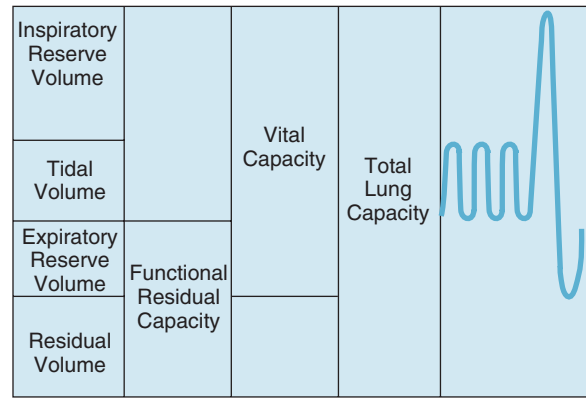

FIGURE 133.2 Lung volumes and capacities. Vital capacity and its subdivisions can be measured by spirometry, but calculation of residual volume requires measurement of functional residual capacity by body plethysmography, helium dilution, or nitrogen washout. (From Andreoli TE, Bennett JC, Carpenter CJ, et al., eds. *Cecil Essentials of Medicine*. 4th ed. Philadelphia: WB Saunders; 1997:127.)

TABLE 133.1 Causes of Hypoxemia				
CAUSE	EXAMPLE(S)	PaO_2	PaCO_2	PaO_2 IMPROVES WITH SUPPLEMENTAL OXYGEN
Ventilation-perfusion mismatch	Asthma Bronchopulmonary dysplasia Pneumonia Atelectasis	↓	Normal, ↓, or ↑	Yes
Hypoventilation	Apnea Narcotic overdose Neuromuscular disease	↓	↑	Yes
Extrapulmonary shunt	Cyanotic heart disease	↓	Normal or ↑	No
Intrapulmonary shunt	Pulmonary arteriovenous malformation Atelectasis	↓	Normal or ↑	No
Low FIO_2	High altitude	↓	↓	Yes
Diffusion defect	Scleroderma Hepatopulmonary syndrome Pulmonary fibrosis	↓	Normal	Yes

FIO_2 , Fraction of inspired oxygen; PaCO_2 , arterial partial pressure of carbon dioxide; PaO_2 , arterial partial pressure of oxygen.

and **polymorphonuclear cells** engulf particles and pathogens that have been opsonized by locally secreted immunoglobulin A (IgA) antibodies or transudated serum antibodies.

Cough is a critically important mechanism for protecting the lungs from infection. It may be voluntary or generated by reflex irritation of the nose, sinuses, pharynx, larynx, trachea, bronchi, or bronchioles. Cough is a rapid, forceful expiration intended to clear the airways of debris and secretions. Effective cough requires the ability to (1) inhale to near TLC, (2) close and open the glottis, and (3) contract abdominal muscles to forcibly exhale. Loss of the ability to cough, as with neuromuscular weakness, results in poor secretion clearance and predisposes to atelectasis and pneumonia. Persistent cough suggests chronic irritation at any of these sites due to infectious (e.g., chronic bronchitis), allergic (e.g., postnasal drip, asthma), or chemical (e.g., inhalation or aspiration) triggers.

HISTORY

Common respiratory complaints in children include cough, labored or noisy breathing, chest pain, and exercise intolerance. The complete respiratory history includes **onset**, **duration**, and **frequency** of symptoms. It is important to obtain information concerning severity (hospitalizations, missed school days) and pattern (acute, chronic, or intermittent), including factors leading to worsening or improvement. Exposure to others with respiratory illness and **environmental factors** (such as pet dander, tobacco smoke, or chemical fumes) should be reviewed. For infants, a **feeding history** should be obtained, including questions of coughing or choking with eating or drinking. Information regarding growth history and nutritional status during infancy and childhood may also contribute to diagnosis. Family history should include questions about asthma and atopy, immune deficiencies, cystic fibrosis, or other chronic respiratory diseases.

A thorough history focused on the factors mentioned is essential in determining the underlying etiology of cough. Morning cough may be due to the accumulation of excessive secretions during the night from sinusitis, allergic rhinitis, or bronchial infection. Nighttime cough is a hallmark of asthma and can also be caused by gastroesophageal reflux disease or postnasal drip. Cough with exercise is highly suggestive of exercise-induced asthma/bronchospasm. Habit cough can masquerade as organic disease but should disappear when children are distracted or during sleep. Paroxysmal cough (especially associated with cyanosis) suggests pertussis, whereas a repetitive, staccato cough occurs in chlamydial infections in infants. A harsh, brassy, seal-like cough suggests croup, tracheomalacia, or psychogenic (habit) cough. Sudden onset of cough after a choking episode suggests foreign body aspiration.

PHYSICAL EXAMINATION

Clothing should be removed from the upper half of the child's body so the thorax may be inspected while maintaining modesty for adolescents. It is optimal to observe the respiratory pattern, rate, and work of breathing while the child is quiet, noting the shape and symmetry of the chest wall and the anteroposterior (AP) diameter.

Any factor that impairs respiratory mechanics is likely to increase the **respiratory rate**. However, nonrespiratory causes

of tachypnea include fever, pain, and anxiety. Respiratory rates vary with age (Table 133.2).

It is important to observe the respiratory **pattern** and **degree of effort** (work of breathing). Abnormal respiratory patterns are detailed in Table 133.3. Increased work of breathing can be described as inspiratory (**nasal flaring**; intercostal, supraclavicular, or subcostal **retractions**) or expiratory (use of **abdominal muscles to actively exhale**). Causes of increased work of breathing during inspiration include extrathoracic airway obstruction (laryngomalacia, croup, subglottic stenosis) and/or decreased pulmonary compliance (e.g., pneumonia, pulmonary edema). Increased expiratory work of breathing usually indicates intrathoracic airway narrowing

TABLE 133.2 Normal Respiratory Rates by Age

AGE	RESPIRATORY RATE (BREATHS PER MINUTE)
Birth–9 mo	30–60
9 mo–2yr	24–40
2–5yr	20–36
5–12yr	14–26
12yr–adult	12–20

TABLE 133.3 Abnormal Breathing Patterns

PATTERN	FEATURES	CAUSES
Tachypnea	Respiratory rate > normal for age	Restrictive physiology, fever, increased metabolic demands, stress
Bradypnea	Respiratory rate < normal for age	Sleep, sedating medications, CNS injury, metabolic alkalosis
Hyperpnea	Increased depth of breathing, normal rate	Stress, exercise, metabolic acidosis
Periodic breathing	Brief pauses (<10sec) followed by rapid, shallow breaths	Normal variant for preterm and term infants, prominent in sleep
Kussmaul respiration	Increased rate, increased tidal volume, regular deep respiration	Metabolic acidosis, especially diabetic ketoacidosis, uremia
Cheyne-Stokes respiration	Cyclic pattern of waxing and waning of depth of breathing interposed with apnea	CNS injury (brainstem), elevated intracranial pressure, heart failure, uremia
Biot respiration	Rapid, deep respiration followed by apnea	CNS injury or infection
Apneustic respiration	Long inspiration with short or staccato expiration	Brainstem lesion
Agonal respiration	Slow rate, variable tidal volume	Shock, sepsis, or asphyxia

CNS, Central nervous system.

DISEASE PROCESS	MEDIASTINAL DEVIATION	CHEST MOTION	VOCAL FREMITUS	PERCUSSION	BREATH SOUNDS	ADVENTITIOUS SOUNDS	VOICE SIGNS
Consolidation	No	Reduced over area	Increased	Dull	Bronchial or reduced	None or crackles	Egophony* Pectoriloquy†
Bronchospasm	No	Hyperexpansion with limited motion	Normal or decreased	Hyperresonant	Normal to decreased	Wheezes, crackles	Normal to decreased
Atelectasis	Shift toward affected side	Reduced over area	Decreased	Dull	Reduced	None or crackles	None
Pneumothorax	With tension: shift to the opposite side	Reduced over PMI	None	Resonant	None	None	None
Pleural effusion	If large: shift to opposite side	Reduced over area	None or reduced	Dull	None	Egophony Friction rub	Muffled
Interstitial process	No	Reduced	Normal to increased	Normal	Normal	Inspiratory crackles	None

*In egophony, e sounds like a (may be a sign of consolidation but also is associated with moderate-sized pleural effusions).

†In pectoriloquy, words/voice sounds clearer over the affected site (associated with consolidation and cavitory lesions).

PMI, Point of maximum impulse.

Modified from Andreoli TE, Bennett JC, Carpenter CJ, et al., eds. Cecil Essentials of Medicine. 4th ed. Philadelphia: WB Saunders; 1997:115.

(e.g., asthma, tracheomalacia). **Grunting** (forced expiration against a partially closed glottis) is often seen in small children with respiratory distress but may also be a manifestation of pain.

When attempting to determine the cause of a respiratory complaint, it is useful to auscultate over all potential sites of pathology, including the nose and mouth, neck, large airways (central chest and back), and all lobes of both lungs (anterior and posterior, upper and lower, as well as lateral chest wall).

Stridor is a harsh, monophonic sound caused by a partially obstructed large airway, more commonly heard on inspiration and localized to the neck. **Wheezing** is produced by partial obstruction of the smaller lower airways, more commonly heard during exhalation and localized to the chest. Wheezes can be monophonic and low-pitched (usually from large, central airways) or high-pitched and musical (from small peripheral airways). Secretions in the intrathoracic airways may produce wheezing but more commonly result in irregular sounds called **rhonchi**. Fluid or secretions in small airways may produce sounds characteristic of crumpling cellophane (**crackles** or **rales**). Having the child take a deep breath and exhale forcefully will accentuate many abnormal lung sounds. **Decreased, absent, or asymmetric breath sounds** may be due to atelectasis, lobar consolidation (pneumonia), thoracic mass, or a pleural effusion. Observation of respiratory rate, work of breathing, and chest wall motion, combined with percussion and auscultation, help to identify intrathoracic disease (Table 133.4).

Digital clubbing (Fig. 133.3) is seen in cystic fibrosis and in other, less common chronic pulmonary diseases (such as interstitial lung disease). It is not associated with asthma, so its presence should heighten concern for other diagnoses. Clubbing may also be present in nonpulmonary chronic diseases (cardiac, gastrointestinal, or hematologic) or, rarely, as a familial trait.

FIGURE 133.3 Clubbing of the fingers. There is increased curvature and loss of nail angle. This child has cystic fibrosis. (From Lissauer T, Clayden G, eds. *Illustrated Textbook of Pediatrics*. 4th ed. London: Mosby; 2012 [fig 2.6a].)

DIAGNOSTIC MEASURES

Imaging Techniques

Chest radiographs are useful in assessing respiratory disease in children. In addition to determining lung abnormalities, they provide information about the bony thorax (rib or vertebral abnormalities), the heart (cardiomegaly, pericardial effusion), and the great vessels (right aortic arch/vascular rings, rib notching). Chest radiographs should be obtained in both the posteroanterior (PA) and lateral projections and, if possible, following a full inspiration. Estimation of lung hyperinflation based on a single PA view is unreliable; flattened diaphragms and an increased AP diameter on lateral projection are better indicators of hyperinflation. Increased density on chest radiograph may represent *blood, water, mucus, or tissue*. **Expiratory** and **decubitus views** may be useful to detect partial bronchial obstruction due to an aspirated foreign body because the

affected lung or lobe does not deflate on exhalation. Decubitus films can also help to differentiate pleural effusion from alveolar infiltrate.

A **barium esophagram** may be valuable in diagnosing disorders of esophageal motility, vascular rings (esophageal compression), tracheoesophageal fistulas, and, to a lesser extent, gastroesophageal reflux. When evaluating for a tracheoesophageal fistula, contrast material must be instilled under pressure via a catheter with the distal tip situated in the esophagus (see Chapter 128). A **video fluoroscopic swallow study (VFSS)** can be used to diagnose swallowing disorders (dysphagia).

Computed tomography (CT) of the chest is the imaging tool of choice for evaluating masses, interstitial lung disease, and bronchiectasis, as well as delineating pleural from parenchymal lesions. CT scans with intravenous contrast provide excellent information about the pulmonary vasculature and great vessels, are useful for characterizing congenital pulmonary malformations, and can detect pulmonary embolism. The speed of current CT scanners makes it possible to scan most children without sedating them; however, sedation may be required in infants and toddlers to decrease motion artifact. **Magnetic resonance imaging (MRI)**, useful in visualizing cardiac and great vessel anatomy and mediastinal lesions, is less useful for evaluation of pulmonary parenchymal lesions. **Ultrasonography** can be used to delineate some intrathoracic masses and is the imaging procedure of choice for assessing size and character of parapneumonic effusion/empyema. It is also useful for assessing diaphragmatic motion in small children.

Measures of Respiratory Gas Exchange

A properly performed **arterial blood gas** analysis provides information about the effectiveness of both oxygenation and ventilation. As arterial samples are difficult to obtain, capillary and venous blood samples are more commonly used. Capillary or venous samples should not be used to assess oxygenation. The partial pressure of carbon dioxide (PCO_2) from a capillary sample is similar to that from arterial blood. The PCO_2 in venous samples is approximately 6 mm Hg higher than arterial PCO_2 .

There are both respiratory and metabolic causes of acidosis (see Chapter 37). In the presence of an alkalosis or acidosis, respiratory compensation (altering PCO_2 to maintain a normal pH) can occur within minutes, but renal compensation (altering the serum bicarbonate level) may not be complete for several days. Since both the respiratory and metabolic compensation are incomplete, pH will remain on the side of the primary insult (whether acidosis or alkalosis).

Pulse oximetry measures the O_2 saturation of hemoglobin by measuring the blood absorption of two or more wavelengths of light. It is noninvasive, easy to use, and reliable. Because of the shape of the oxyhemoglobin dissociation curve, O_2 saturation does not decrease much until the partial pressure of oxygen (PO_2) reaches approximately 60 mm Hg. Pulse oximetry may not accurately reflect true O_2 saturation when abnormal hemoglobin is present (carboxyhemoglobin, methemoglobin), when perfusion is poor, or if no light passes through to the photodetector (nail polish).

The measurement of PCO_2 is accomplished most reliably by blood gas analysis. However, there are noninvasive monitors that record exhaled PCO_2 (**end-tidal CO_2**), which is representative of alveolar PCO_2 . End-tidal PCO_2 measurements are

most commonly used in intubated and mechanically ventilated patients, but some devices can measure PCO_2 at the nares. **Transcutaneous electrodes** can be used to monitor PCO_2 at the skin surface but are less reliable. Noninvasive techniques of CO_2 measurement are best suited for detecting trends rather than for providing absolute values.

Pulmonary Function Testing

Measurement of lung volumes and airflow rates using **spirometry** is important in assessing pulmonary disease. Most children above 6 years of age can perform spirometry. The patient inhales to TLC and then forcibly exhales until no more air can be expelled. During the forced expiratory maneuver, **forced vital capacity (FVC)**, **forced expired volume in the first second (FEV_1)**, and **forced expiratory flow (FEF)** rates are measured. These are compared to predicted values based on patient age, gender, and race, but rely mostly on height. Severity of disease is quantified by calculated percentage of predicted values. The **peak expiratory flow rate (PEFR)** can be obtained with a simple hand-held device and may be useful for home monitoring of older children with asthma; however, it is *highly dependent on patient effort*, and values must be interpreted with caution. Measurement of TLC, FRC, and RV require **body plethysmography**. Helium dilution can also measure TLC and RV by determining the magnitude of dilution of inhaled helium in the air within the lung but may underestimate air trapping.

Abnormal results on pulmonary function testing can be used to categorize **obstructive** (low flow rates and/or increased RV) or a **restrictive lung disease** (low FVC and TLC, with relative preservation of flow rates). When the FEV_1 is decreased to a greater extent than the FVC ($FEV_1:FVC$ ratio <80%), obstructive lung disease is diagnosed. The mean midexpiratory flow rate ($FEF_{25-75\%}$) is a more sensitive measure of small airway disease than the FEV_1 but is also more variable. Spirometry can detect reversible airway obstruction characteristics of asthma when a significant improvement in FEV_1 (>12%) or in $FEF_{25-75\%}$ (>25%) following inhalation of a bronchodilator is measured. **Inhalation challenge tests** using methacholine, histamine, or cold, dry air are used to assess airway hyperreactivity but require sophisticated equipment and special expertise and should only be performed in a pulmonary function laboratory with experienced technicians.

Endoscopic Evaluation of the Airways

Endoscopic evaluation of the upper airways (**nasopharyngoscopy**) is performed with a flexible fiberoptic nasopharyngoscope to assess adenoid size, patency of the nasal passages, and abnormalities of the glottis. It is especially useful in evaluating stridor and assessing vocal cord motion/function and does not require sedation. Endoscopic evaluation of the subglottic space and intrathoracic airways can be done with either a flexible or rigid bronchoscope under anesthesia. **Flexible bronchoscopy** is useful in identifying dynamic or static airway abnormalities (stenosis, malacia, endobronchial lesions, or excessive secretions) and to obtain airway samples for culture (**bronchoalveolar lavage**). **Rigid bronchoscopy** is the method of choice for removing foreign bodies from the airways and performing other interventions, such as airway dilation. Transbronchial biopsies are rarely performed in children.

Examination of Sputum

Sputum specimens may be useful in evaluating lower respiratory tract infections but are difficult to obtain in children. Specimens containing large numbers of squamous epithelial cells or heavily contaminated with upper airway secretions may yield misleading results. Sputum in patients with lower respiratory tract bacterial infections often contains polymorphonuclear leukocytes and one predominant organism on culture. If sputum cannot be obtained, then bronchoalveolar lavage may be necessary for microbiologic diagnosis in selected situations. In patients with cystic fibrosis (CF) who are unable to expectorate sputum, specially processed throat cultures are used as surrogates for lower airway cultures.

Lung Biopsy

When less invasive methods fail to provide diagnoses in patients with pulmonary disease, a lung biopsy may be required. Concern for childhood interstitial lung disease, atypical infection (especially in an immunocompromised host), and evaluation of a mass/malformation are the most common indications for biopsy. CT-guided **needle biopsy** performed by an interventional radiologist is an option if limited histology is needed and the lesion is amenable to percutaneous approach (e.g., fungal nodules). Either a **thoracoscopic procedure** or a **thoracotomy** is preferred if thorough histologic evaluation is desired.

THERAPEUTIC MEASURES

Oxygen Administration

Any child in respiratory distress should be treated with **supplemental oxygen** at a concentration sufficient to maintain *acceptable* O_2 saturation levels. Normal O_2 saturation is greater than 95%; however, lower saturations may be appropriate in certain clinical scenarios, such as preterm birth or congenital heart disease. It is not necessary to achieve 100% saturation. Patients requiring supplemental O_2 should be monitored with pulse oximetry, intermittently or continuously, or with arterial blood gas measurements of PO_2 to allow titration to the lowest

required O_2 concentration. The actual fraction of inspired oxygen (FI_{O_2}) delivered to the patient can be quite variable and is affected by the delivery device used, device position, the child's size, and respiratory pattern.

For long-term administration of O_2 , a **nasal cannula** is the most widely used device, as it enables patients to eat and speak unhindered by the O_2 delivery system. **Humidified high flow nasal cannula** (HFNC) allows the provider to deliver greater flow rates of blended gas at a specific FI_{O_2} . Though its use began in neonates as an alternative to continuous positive airway pressure (CPAP), it is now commonly used across the pediatric age spectrum. Depending on the size of the patient, the type of cannula and device used, HFNC can deliver modest positive pressure, relieve dyspnea, and purge CO_2 from anatomic dead space to improve alveolar ventilation in addition to providing oxygenation. There are very limited options for provision of HFNC outside the hospital at this time. Supplemental O_2 may also be delivered by a variety of mask systems including a **simple mask** (delivers O_2 in L/min), a **Venturi mask** (blends to a specific FI_{O_2}), and a **non-rebreather mask** with reservoir that can provide nearly 100% O_2 .

Aerosol Therapy

Therapeutic agents such as bronchodilators, corticosteroids, and antibiotics can be delivered to the lower respiratory tract by **dry powder inhaler** (DPI), **metered-dose inhaler** (MDI), or **nebulizer**. All of these devices are designed to generate small particles that can bypass the filtering action of the upper airway and deposit in the lower airways. Many factors influence drug deposition including patient technique, device used, age of the child, and breathing pattern. Nebulizers should be used with a face mask (infants) or mouthpiece (children and teens) to minimize loss of drug to ambient air. Plastic holding chambers (**spacers**) are available for all ages and should always be used with MDIs. DPIs require a single rapid, deep inhalation for optimal drug delivery, which is difficult for children under 6 years of age. MDIs and nebulizers are equally effective in delivering medications only if the technique is correct, so it is important to review this frequently and carefully with families (Fig. 133.4).

FIGURE 133.4 Inhaled drug delivery in children. (A) Proper use of a nebulizer with mouthpiece, and (B) metered-dose inhaler with spacer and face mask. (A, From Hopper T. *Mosby's Pharmacy Technician*. 2nd ed. St Louis: Mosby; 2007 [fig 25.7]; B, From Hockenberry MJ, Wilson D, eds. *Wong's Essentials of Pediatric Nursing*. 8th ed. St Louis: Mosby; 2009 [fig 23.5].)

Chest Physiotherapy and Airway Clearance Techniques

When disease processes impair normal ciliary and cough function, **airway clearance therapy** may help maintain airway patency and secretion mobilization. Most methods work by moving secretions toward the central airways, from which they can be expectorated. **Chest percussion** or **pneumatic vests** are often used in young or neurologically impaired children; whereas older children can operate hand-held devices that generate expiratory back-pressure and vibration (*TheraPEP*, *Flutter*, *Acapella*, and *Aerobika*). Pneumatic (therapy) vests may also be used in older children and adolescents, especially those with CF. Children who are too weak to generate an effective cough benefit from the use of a mechanical insufflation-exsufflation device (CoughAssist), used in conjunction with chest physiotherapy. Chest physiotherapy is generally not beneficial for patients with asthma or pneumonia, and its effectiveness in patients with atelectasis has not been clearly established.

Intubation

If the upper airway is obstructed or mechanical ventilation is needed, it may be necessary to provide the patient with an **artificial airway**. This is best done by placing an endotracheal tube via the mouth or nose into the trachea (**intubation**). **Endotracheal tubes** can damage the larynx and the airways if the tubes are of improper size and are not carefully maintained. The cricoid ring is the narrowest segment of a child's airway and is completely surrounded by cartilage, which makes it vulnerable to damage and subglottic stenosis. If the pressure created by the tube against the airway mucosa exceeds capillary filling pressure, mucosal ischemia develops, leading to necrosis. Therefore a small air leak should always be maintained around the endotracheal tube to minimize the risk of mucosal damage. No clear guidelines are available regarding how long pediatric patients can be intubated without sustaining airway damage or when conversion to tracheostomy is indicated.

Intubation alters the physiology of the respiratory tract in many ways, not all of which are beneficial. It interferes with the humidification, warming, and filtration of inspired air and stimulates secretion production. Providing adequate humidification of inspired air and appropriate suctioning of the tube reduce the probability of occlusion by secretions. In addition to endotracheal tubes, the **laryngeal mask airway (LMA)** can be used to provide mechanical ventilation. This device consists of a tube with a soft mask at the distal end that is placed over the larynx, creating a seal without the trachea being instrumented. Although less invasive, the LMA is less secure, so it is generally limited to procedural anesthesia.

Tracheostomy

Tracheostomy is the surgical placement of an artificial airway into the trachea below the larynx. Congenital or acquired upper airway obstruction (see [Chapter 135](#)) is the most common indication for tracheostomy in children. In addition, if prolonged mechanical ventilation is required, elective tracheostomy can be performed to increase patient comfort and facilitate nursing care. Many children with tracheostomy tubes can be cared for at home, provided the caregivers are

well trained and adequately equipped. The tracheostomy tube can hamper the ability to phonate. More importantly, it can become occluded with secretions, leading to life-threatening airway obstruction; therefore the child must be monitored carefully at all times.

Mechanical Ventilation

Patients who are unable to maintain adequate gas exchange may require **mechanical ventilation**. Most modes of mechanical ventilation involve inflation of the lungs with gas using positive pressure. The inspiratory phase is active (air is pushed in), and exhalation is passive.

Mechanical ventilation often requires an artificial airway, although it can be provided *noninvasively* via nasal or full face masks. **Noninvasive ventilation** is particularly useful in patients with obstructive sleep apnea and neuromuscular disease who require support only part of the day or night, but it can also be used to assist ventilation continuously for patients in acute respiratory failure from a variety of causes.

No method of mechanical ventilation truly simulates natural breathing. All methods have their drawbacks and potential complications. Positive pressure is transmitted to the entire thorax and may impede venous return to the heart. The airways and lung parenchyma may be damaged by inflation pressures and high concentrations of inspired O₂. In general, inflation pressures should be limited to those necessary to provide sufficient lung expansion for adequate ventilation and the prevention of atelectasis. Pressure-cycled and volume-cycled ventilators (conventional ventilation) are the most widely used modalities in pediatrics. High-frequency jet ventilation and high-frequency oscillatory ventilation are used often in neonatology and may be used in patients with severe lung disease who are failing conventional mechanical ventilation.

PEARLS FOR PRACTITIONERS

See *The Respiratory System: Pearls for Practitioners* at the end of this section.

CHAPTER 134

Control of Breathing

Ventilation is controlled primarily by **central chemoreceptors** located in the medulla that respond to intracellular pH and PCO_2 levels (Fig. 134.1). To a lesser extent, ventilation is modulated by **peripheral receptors** located in the carotid and aortic bodies, which respond predominantly to PO_2 . The central receptors are quite sensitive. Small acute changes in PaCO_2 normally result in significant changes in **minute ventilation**. The ventilatory drive is not increased when the PCO_2 is chronically elevated, as the intracellular pH returns to normal levels following compensatory increases in the serum bicarbonate level. The peripheral receptors do not stimulate ventilation until the PaO_2 decreases to approximately 60 mm Hg (compared to normal PaO_2 of 100 mm Hg at sea level). These receptors become important in patients with chronic PaCO_2 elevation who may have a blunted ventilatory response to CO_2 .

The output of the central respiratory center also is modulated by reflex mechanisms. Full lung inflation temporarily inhibits inspiratory effort in infants (**Hering-Breuer reflex**) through vagal afferent fibers. Other reflexes from the airways and intercostal muscles may influence the depth and frequency of respiratory efforts (see Fig. 134.1).

APNEA

Etiology

Apnea is defined as the cessation of airflow due to either lack of respiratory effort (**central apnea**) or upper airway obstruction (**obstructive apnea**) (Table 134.1). Central apnea is more common in infants, and obstructive apnea, especially during sleep, is more common in older children.

Central apnea lasting less than 10 seconds is common in healthy infants and can be present in normal children during sleep, especially after a sigh breath. Central pauses

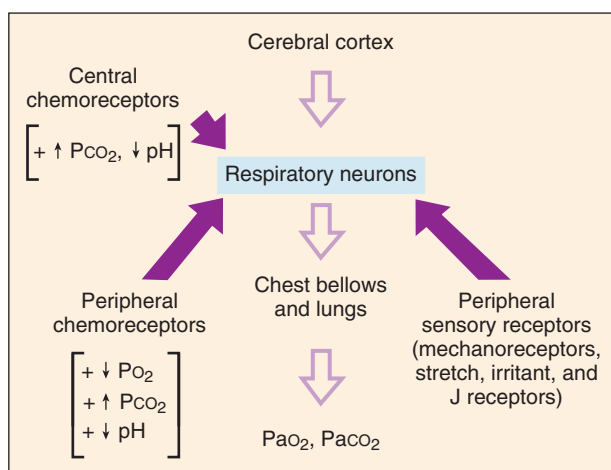

FIGURE 134.1 Schematic representation of the respiratory control system. The respiratory neurons in the brainstem receive information from the chemoreceptors, peripheral sensory receptors, and cerebral cortex. This information is integrated, and the resulting neural output is transmitted to the diaphragms and lungs. The sign denotes stimulation of the receptor. (From Andreoli TE, Bennett JC, Carpenter CJ, et al., eds. *Cecil Essentials of Medicine*. 4th ed. Philadelphia: WB Saunders; 1997:171.)

lasting longer than 15–20 seconds are considered abnormal. Premature infants can have **apnea of prematurity**, which consists of recurrent apneic episodes that are often of central origin, although they can be mixed central/obstructive. Apnea of prematurity should resolve by 44 weeks postconceptional age. Central apnea outside of infancy is a rare occurrence and warrants evaluation.

Congenital central hypoventilation syndrome (**CCHS**) is a rare genetic disorder in which there is profound loss of respiratory control during sleep leading to primary central apnea, hypercarbia, and hypoxemia. Individuals with CCHS have a defect in the **PHOX2B** gene, which is necessary for autonomic nervous system development. Infants with CCHS typically have respiratory difficulties within the first several weeks of life although it can also present later in childhood. Some **PHOX2B** mutation types are associated with an increased risk of Hirschsprung disease and neural crest tumors (neuroblastoma). Other genetic syndromes associated with abnormal central respiratory control include Rett, Joubert, and Prader-Willi syndromes and tuberous sclerosis complex. Secondary causes of central apnea and hypoventilation are more common and include medications impairing central respiratory drive (narcotics), increased intracranial pressure, central nervous system (CNS) tumors, myelomeningocele and/or Arnold-Chiari malformation, and mitochondrial/metabolic disorders.

Breath holding spells are a form of apnea occurring when a young child is awake, usually triggered by emotional stress. Breath holding spells typically occur in children under 3 years of age during periods of agitation or crying and can be associated with cyanosis and loss of consciousness. The return of spontaneous breathing usually occurs quickly. Most breath holding spells are benign and lessen over time, but seizures and disorders of central respiratory control should be considered.

Obstructive sleep apnea syndrome (OSA) affects 2–3% of young children with peak prevalence at 2–8 years of age. It is caused by complete or partial upper airway obstruction during sleep. Control of breathing is usually preserved, although infants and others with immature respiratory control may have obstructive and central apnea together. Restless sleep, behavioral problems, and inattention/hyperactivity are more common in young children than the classic adult findings of daytime hypersomnolence and loud snoring. Some

TABLE 134.1		Categories of Apnea		
DISEASE	RISK FACTORS	MECHANISM	SIGNS	TREATMENT
Apnea of prematurity	Prematurity (<36 wk corrected gestational age)	Immature central control, upper airway obstruction	Apnea, bradycardia	Caffeine, HFNC, CPAP, intubation
Central apnea/hypoventilation	CCHS, Arnold-Chiari malformation	Abnormal central control	Apnea	Mechanical ventilation or BiPAP
Obstructive sleep apnea	Obesity, adenotonsillar hypertrophy, Pierre Robin sequence, Down syndrome, cerebral palsy	Upper airway obstruction due to excess tissue, loss of pharyngeal tone, or crowded anatomy	Snoring, restless sleep, poor school performance, behavior problems, mouth breathing	Adenotonsillectomy, CPAP or BiPAP, uvulopalatoplasty, tracheostomy
Breath holding spells		Prolonged expiratory apnea; reflex anoxic seizures	Cyanosis, syncope, brief tonic-clonic movements after cyanosis	Reassurance; condition is self-limiting. Must exclude seizure disorder

BiPAP, Bilevel positive airway pressure; CCHS, congenital central hypoventilation syndrome; CPAP, continuous positive airway pressure; HFNC, high flow nasal cannula.

children experience poor somatic growth due to interruption of normal growth hormone production during deep sleep. A small subset can have significant hypoxemia and hypercarbia leading to morning headaches and, if untreated, pulmonary hypertension and cor pulmonale. Not all children who snore have OSA, and not all children who have OSA snore. Thus, when the diagnosis is in question, it should be confirmed with a polysomnogram (PSG).

PSG is the only definitive test for evaluation of obstructive and central sleep apnea. It involves continuous recording of electroencephalogram (EEG) and electrooculogram for sleep staging, oronasal airflow and pressure, audible snore, chest and abdominal wall excursion, leg and chin electromyogram, electrocardiogram, pulse oximetry, and capnography. The most commonly reported metric from a PSG is the **apnea-hypopnea index** (AHI) or number of times in an hour of sleep that the child has cessation or reduction of airflow of a significant magnitude to negatively affect oxygenation or sleep stage. An AHI less than 1 is the generally accepted norm for pediatric patients, although the decision to treat often hinges on the severity of daytime impairment. Measured AHI is typically worse in rapid eye movement (REM) sleep and when the child is supine, so an ideal study captures all sleep stages and positions.

Adenotonsillar hypertrophy is the most common cause of OSA in young children, with peak age 2–5 years. Other risk factors for OSA include obesity, premature birth, craniofacial differences, trisomy 21, and neuromuscular diseases. The decision to treat is dependent on severity of daytime and nighttime symptoms, as well as likelihood of spontaneous resolution with time, which is affected by obesity, ethnicity, and age at time of diagnosis. OSA may improve with treatment of underlying respiratory conditions such as allergic rhinitis or asthma. Targeted treatment of OSA starts with determining whether the child will benefit from adenotonsillectomy. If surgical intervention is not indicated or fails to alleviate the problem, then the use of continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) via mask interfaces can be used to distend the upper airway during sleep. This requires a well-fitted nasal mask, which may not be well tolerated in young children. Supplemental oxygen can blunt hypoxemia in milder cases of OSA but does not alter obstruction and sleep fragmentation. In extreme cases, especially those associated with craniofacial abnormalities or hypotonia, tracheostomy may be indicated.

BRIEF RESOLVED UNEXPLAINED EVENTS

A **brief resolved unexplained event** (BRUE) is defined as a short (<1 minute), self-limited episode with one or more of the following features: (1) cyanosis or pallor, (2) absent or irregular breathing, (3) change in tone, or (4) altered level of responsiveness in an infant under 1 year of age. Importantly, BRUE differs from the previously used diagnostic term *apparent life-threatening event* (ALTE) in that it includes only episodes with cyanosis (not rubor) and/or altered responsiveness and does not include caregiver perception of the event as “life threatening.” The label BRUE should be used only when no other explanation for the event is identified on detailed history and physical examination. Historical data suggests that a cause could be identified in more than 50% of ALTE events, thus the new category of BRUE is quite small. History and

exam should focus on the most common identifiable causes of abnormal breathing episodes in infancy including gastroesophageal reflux, CNS pathology (seizures, intracranial bleeding from accidental or nonaccidental trauma), and infection (respiratory syncytial virus [RSV], pertussis, and serious bacterial infections). Cardiovascular events (arrhythmia) and metabolic derangements are among diagnoses that may not be recognized on initial history and examination; however, these are quite uncommon.

Infants over 2 months of age and born at term or born at more than 32 weeks gestation and currently 45 weeks gestational age who experience a single, brief (<1 minute), self-limited (no cardiopulmonary resuscitation [CPR] required) BRUE are considered at *low risk* for undiagnosed serious condition or repeat event. An electrocardiogram and pertussis screening may be considered in this low-risk group. Additional diagnostic tests (e.g., metabolic panel, complete blood count, imaging, PSG, and EEG) and hospital admission for cardiorespiratory monitoring are not recommended. Offering parents infant CPR instruction and attempting to alleviate anxiety surrounding the event are recommended. There is currently no consensus on evaluation and management of the high-risk infant with BRUE. Careful history and physical examination should be used to guide differential diagnosis and assessment. Cardiorespiratory monitoring for 12–24 hours in the hospital can provide more detailed information on respiratory and cardiac patterns while allowing time to gather additional history and perform repeat examinations.

Of note, PSG in infants previously categorized as ALTE generally show nonspecific differences compared to control groups, thus it is not considered a useful tool for diagnosis unless clinical suspicion of OSA is high. PSG, home oximetry, and home cardiorespiratory monitoring are not helpful in predicting risk or preventing sudden infant death syndrome (SIDS) so should not be recommended for this purpose.

SUDDEN INFANT DEATH SYNDROME

Etiology and Epidemiology

SIDS is defined as the *unexpected* death of an infant younger than 1 year of age in which the cause remains *unexplained* after autopsy, death scene investigation, and review of clinical history. The risk of SIDS is higher in male, premature, and low birthweight infants; infants born to impoverished mothers; and mothers who smoke cigarettes or use illicit drugs. The risk of SIDS is increased three- to fivefold in siblings of infants who have died of SIDS and is highest during the winter. SIDS is rare before 4 weeks or after 6 months of age and is most common between 2 and 4 months. The incidence of SIDS has decreased dramatically since the 1980s, largely as a result of the **back-to-sleep** campaign and modifications to infant sleep environments.

A variety of unproven mechanisms have been proposed to explain SIDS. Current theories for a predisposition to SIDS include cellular brainstem abnormalities and maturational delay related to neural or cardiorespiratory control. Prone (chest down) position during sleep and exposure to maternal smoking both alter heart rate variability and arousal response, which may contribute to the risk of SIDS. A portion of SIDS deaths may be due to prolongation of the Q-T interval, abnormal CNS control of respiration, and CO₂ rebreathing from sleeping face down (especially in soft bedding). Importantly, there is no association between BRUE/ALTE and SIDS.

Differential Diagnosis

Sudden unexpected infant death (SUID) is a term to describe any sudden and unexpected death occurring in the first year of life without an obvious cause before further investigation; this term includes those deaths caused by SIDS as well as those with subsequently identified explanation. See Table 134.2 for the differential diagnosis of SUIDs, including SIDS.

Prevention

SIDS is associated with prone position during sleep, especially with soft bedding, excessive bundling, and bed sharing. There has been a significant decline in SIDS with the back-to-sleep program and avoiding soft bedding. Thus all parents should be instructed to place their infants in the supine position (on their backs/chest up) unless there are medical contraindications. All loose, soft bedding should be excluded from sleep space, and parents who share beds with their infants should be counseled on the risks, especially if consuming alcohol or sedating medications. Counseling for cessation of maternal cigarette smoking, both during and after pregnancy, is recommended. Breast-feeding, pacifier use, and sharing a room (in separate beds) have been identified as protective. Though there are many commercial devices marketed for prevention,

such as sleep positioners and home oximeters, none have been proven to reduce SIDS risk.

PEARLS FOR PRACTITIONERS

See *The Respiratory System: Pearls for Practitioners at the end of this section.*

CHAPTER 135

Upper Airway Obstruction

ETIOLOGY

Upper airway obstruction (UAO), which is defined as blockage of any part of the airway located above the thoracic inlet, ranges from nasal obstruction due to the common cold to life-threatening obstruction of the larynx or upper trachea. In children, nasal obstruction is usually more of a nuisance than a danger because the mouth can serve as an airway, but it may be a serious problem for neonates, who breathe predominantly through the nose. The differential diagnosis of airway obstruction varies with patient age and can be subdivided into **supraglottic**, **glottic**, and **subglottic** causes (Tables 135.1, 135.2, and 135.3).

TABLE 135.1 Age-Related Differential Diagnosis of Sub-Acute Upper Airway Obstruction

NEWBORN

Choanal atresia
 Rhinitis neonatorum
 Micrognathia (Pierre Robin syndrome, Treacher Collins syndrome, DiGeorge syndrome)
 Macroglossia (Beckwith-Wiedemann syndrome, hypothyroidism, Pompe disease, trisomy 21)
 Pharyngeal collapse
 Laryngeal web
 Vocal cord paralysis/paresis (idiopathic, birth trauma or central nervous system pathology)
 Congenital subglottic stenosis
 Nasal encephalocele

INFANT

Chronic or recurrent rhinitis (infection, acid reflux, irritant)
 Laryngomalacia (most common)
 Subglottic stenosis (congenital or acquired [e.g., after intubation])
 Laryngeal web or cyst
 Laryngeal papillomatosis
 Airway hemangioma
 Vascular rings/slings

TODDLER

Chronic or recurrent rhinitis (infection, allergy, irritant)
 Hypertrophied tonsils and adenoids (most common)
 Spasmodic croup
 Laryngeal papillomatosis
 Vascular rings/slings

OLDER CHILDREN

Chronic or recurrent rhinitis (infection, allergic, irritants)
 Hypertrophied tonsils and adenoids (most common)
 Paradoxical vocal fold movement
 Infectious mononucleosis

TABLE 135.2 Common Causes of Acute Upper Airway Obstruction

DIAGNOSIS	AGE	HISTORY	EXAM	IMAGING AND LABS	TREATMENT
INFECTIOUS					
Croup (<i>parainfluenza</i> and other viruses)	6 mo–3yr	Fever, URI	Nontoxic, stridor, barky cough, hoarse	Steeple sign	Aerosolized epinephrine, systemic steroids, cool mist
Epiglottitis (<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> ; respiratory viruses)	2–6yr	High fever, rapid onset, no cough, unable to swallow	Toxic, agitated, tripod sitting, drooling, stridor	Thumb sign Leukocytosis	Intubation, antibiotics
Bacterial tracheitis (<i>Staphylococcus aureus</i> , <i>Moraxella catarrhalis</i>)	Any age	High fever, rapid onset, sore throat, no URI symptoms	Toxic, anxious, ±stridor, ±cough	Ragged tracheal border Leukocytosis	Intubation, antibiotics
Retropharyngeal abscess (<i>S. aureus</i> , group A strep, oral anaerobes)	<6yr	Fever, insidious onset, sore throat, no URI/cough	Moderately toxic, drooling, arched neck, inflamed pharynx	Thickened retropharyngeal space Leukocytosis	Antibiotics, surgical drainage
Peritonsillar abscess (group A strep, oral anaerobes)	>8yr	Fever, sudden worsening, sore throat, trismus	Moderately toxic, “hot potato” voice, drooling, asymmetric tonsil swelling	Imaging not needed Leukocytosis	Antibiotics, surgical drainage
NONINFECTIOUS					
Angioedema	Any age	No fever, sudden onset, urticarial, facial swelling, ± allergen exposure	Nontoxic (unless anaphylaxis), ± stridor, hoarse, facial edema	Steeple sign	Aerosolized or intramuscular epinephrine, systemic steroids, antihistamines
Spasmodic croup	6 mo–6yr	Sudden onset, no fever/URI, recurrent, often nocturnal	Nontoxic, ± stridor, hoarse, barky cough	Often normal	Aerosolized epinephrine, antihistamines, antacids, systemic steroids
Foreign body	6 mo–5yr	Sudden onset, cough and choke	Nontoxic, anxious, stridor, aphonic, brassy cough	Radiopaque object may be seen	Rigid bronchoscopy

URI, Upper respiratory tract infection (with coryza, sneezing).

TABLE 135.3 Differentiating Supraglottic from Subglottic Causes of Acute Airway Obstruction

FEATURE	SUPRAGLOTTIC OBSTRUCTION	SUBGLOTTIC OBSTRUCTION
Common clinical syndromes	Epiglottitis, peritonsillar and retropharyngeal abscess	Croup, angioedema, foreign body, bacterial tracheitis
Stridor	Quiet	Loud
Voice	Muffled	Hoarse
Dysphagia	Yes	No
Tripod or arching posture	Yes	No
Barking cough	No	Yes
Toxic	Yes	No, unless tracheitis
Trismus	Some	No
Drooling	Yes	No

Modified from Davis H, Gartner JC, Galvis AG, et al. Acute upper airway obstruction: Croup and epiglottitis. *Pediatr Clin North Am.* 1981;28:859–880.

CLINICAL MANIFESTATIONS

UAO is more pronounced during inspiration because the negative pressure generated collapses the upper airway, increasing resistance and turbulent airflow that creates an inspiratory

noise. Children with UAO may have increased inspiratory work of breathing manifested by **suprasternal retractions**. The respiratory noise most commonly associated with UAO is **stridor**, a harsh sound caused by the vibration of the airway

structures. Stridor often decreases during sleep because of lower inspiratory flow rates, and increases during feeding, excitement, and agitation because of higher flow rates. Occasionally stridor may also be present on exhalation. Hoarseness or aphonia with stridor suggests **vocal cord** involvement. **Stertor** is a low-pitched sound like a snore and suggests implosion of pharyngeal soft tissue structures.

DIAGNOSTIC STUDIES

Radiographic evaluation of a child with stridor is rarely helpful. On anteroposterior (AP) views of the neck taken with the head in extension, the subglottic space should be symmetrical with diameter continuing to increase down to the midtrachea. Asymmetry suggests subglottic stenosis or a mass lesion, whereas tapering suggests subglottic edema. However, these findings may be subtle. In the child with stertor or snoring, lateral views of the neck and nasopharynx may provide information about tonsil or adenoid hypertrophy. Computed tomography (CT) scans of the upper airway can help delineate the site of the obstruction when soft tissue mass (e.g., tonsillar abscess) is suspected, but may require sedation in younger children. Flexible nasopharyngoscopy/laryngoscopy, which can be done without sedation, is extremely useful in assessing airway patency, the presence of adenoid tissue or vocal cord and other airway lesions, and laryngomalacia.

DIFFERENTIAL DIAGNOSIS

Choanal Stenosis (Atresia)

Choanal stenosis/atresia is a congenital problem presenting in the neonatal period. It may be bilateral or unilateral and is relatively rare. Neonates are generally obligate nose breathers, so obstruction of nasal passages can cause significant respiratory distress, especially when feeding. Crying bypasses the obstruction because crying infants breathe through the mouth. Inability to easily pass a small catheter through the nostrils should raise the suspicion of choanal atresia. The diagnosis is confirmed by CT scan and by inspecting the area directly with a flexible nasopharyngoscope. An oral airway may be useful in the short term, but the definitive treatment is surgery.

Croup (Laryngotracheobronchitis)

See Chapter 107.

Epiglottitis

See Chapter 107.

Bacterial Tracheitis

See Chapter 107.

Laryngomalacia

Etiology

Laryngomalacia is due to exaggerated collapse of the glottic structures, especially the epiglottis and arytenoid cartilages, during inspiration. It is the most common cause of stridor in infants. It may be due to decreased muscular tone of the larynx and surrounding structures or immature cartilaginous

structures. It usually does not result in significant respiratory distress, but occasionally it is severe enough to cause apnea, hypoventilation, hypoxemia, and difficulty feeding.

Clinical Manifestations

The primary sign of laryngomalacia is **inspiratory stridor** with little or no expiratory component. The stridor is typically loudest when the infant is feeding or active and decreases when the infant is relaxed or placed prone, or when the neck is flexed. Any condition that increases upper airway inflammation will exacerbate laryngomalacia, including viral respiratory infections, dysphagia (swallowing dysfunction), and gastroesophageal reflux. Laryngomalacia normally peaks by 3–5 months of age and resolves between 6 and 12 months of age. However, occasionally it can persist in otherwise normal children up until 24 months of age, and even longer in children with underlying conditions, especially those with neurologic diseases affecting control of upper airway muscles (such as cerebral palsy).

Diagnostic Studies

In many infants with presumed laryngomalacia, the diagnosis can be tentatively established by history and physical examination. If the patient follows the typical course for laryngomalacia, then no further work-up is necessary. However, to firmly establish the diagnosis, which is important in more severe or atypical cases, the patient should undergo flexible nasopharyngoscopy to assess the patency and dynamic movement (collapse) of the larynx and surrounding structures. This procedure can also identify vocal cord abnormalities and airway lesions above the vocal cords.

Treatment

In most cases, no therapy is required for laryngomalacia. The infant should be observed closely during times of respiratory infection for evidence of respiratory compromise. Medical management for moderate to severe laryngomalacia can include acid suppression for those infants with suspected gastroesophageal reflux, feeding therapy, and optimization of nutritional status. Infants with severe laryngomalacia resulting in hypoventilation, hypoxia, or growth failure may benefit from a surgical procedure (e.g., supraglottoplasty) or, in extreme cases, a tracheostomy to bypass the upper airway.

Subglottic Stenosis

Etiology

Subglottic stenosis is the narrowing of the portion of the trachea immediately below the vocal cords. It may be congenital but more often is acquired. Endotracheal intubation, especially prolonged or repeated intubation required in some premature infants, can lead to inflammation and scarring of the subglottic space.

Clinical Manifestations

Subglottic stenosis can present as stridor that is **biphasic** (on both inspiration and expiration) but usually more prominent on inspiration. With increasing respiratory effort, the stridor becomes louder. Very small infants may not be able to breathe with enough force to generate a sound. Subglottic stenosis may also be associated with a barking cough similar to that noted with croup. Respiratory infections can cause subglottic edema, exacerbating the clinical manifestations of subglottic stenosis.

Diagnostic Studies

Definitive diagnosis requires endoscopic evaluation, either by flexible or rigid bronchoscopy.

Treatment

Mild subglottic stenosis can be managed conservatively and may improve sufficiently with airway growth alone. More severe cases require surgical intervention. Depending on the nature of the lesion, endoscopic laser treatment may be effective. Other surgical options include tracheoplasty and cricoid split procedures. A tracheostomy tube may be required to bypass the subglottic space until the airway is patent enough to allow adequate airflow.

Mass Lesions

Upper airway mass lesions are relatively uncommon. The most common laryngeal tumor in childhood is the **hemangioma**, which usually presents before 6 months of age and is often able to be treated medically (see Chapter 194). Definitive diagnosis requires endoscopy. If the obstruction is severe, a tracheostomy tube may be needed until the lesion spontaneously involutes or improves with therapy.

Laryngeal webs are either the result of failed recanalization of the glottic airway in utero or secondary to airway trauma (intubation, traumatic injury, prior surgical manipulation), whereas **laryngeal cysts** typically occur as a consequence of airway trauma. Laryngeal webs can present during infancy with a weak or high-pitched cry with respiratory distress. Both laryngeal webs and laryngeal cysts can produce biphasic stridor and are best identified by bronchoscopy. **Foreign body** should be considered in any infant or child capable of ingesting small objects who develops acute onset of stridor.

Juvenile laryngeal papillomatosis is a rare condition of benign tumors caused by human papillomavirus 6 (HPV-6) and HPV-11 acquired at birth from maternal genital warts. Clinical manifestations usually start in infancy and include biphasic stridor and hoarse voice/cry. The lesions are most commonly located in the larynx, but they can spread distally into the trachea, large bronchi, and even to the lung parenchyma. Treatment options, which are limited and rarely curative, include laser therapy and interferon. Tracheostomy may be required to ensure an adequate airway but should be avoided if possible as there is risk of seeding of the distal airways with tumor.

Vocal Cord Paralysis

Etiology

Vocal cord paralysis is an important cause of laryngeal dysfunction. Paralysis may be unilateral or bilateral and is more often caused by damage to the recurrent laryngeal nerve than by a central lesion. The left recurrent laryngeal nerve passes around the aortic arch and is more susceptible to damage than the right laryngeal nerve. Peripheral nerve injury may be caused by trauma (neck traction during delivery of infants or thoracic surgical procedures) and mediastinal lesions. Central causes include Arnold-Chiari malformation (meningomyelocele), hydrocephalus, and intracranial hemorrhage.

Clinical Manifestations

Vocal cord paralysis presents as biphasic stridor and alterations in voice and cry, including a weak cry (in infants), hoarseness, and aphonia. Children with vocal cord paralysis are at risk for

aspiration, often manifested as coughing/choking with drinking and coarse airway sounds audibly and by auscultation.

Treatment and Prognosis

Patients with traumatic injury to the recurrent laryngeal nerve often have spontaneous improvement over time, usually within 3–6 months. If the paralyzed vocal cord has not recovered within 1 year of the injury, then it is likely to be permanently damaged. In some cases, injection of biocompatible material into a paralyzed vocal cord can reposition the cord to improve phonation and airway protection. Patients with vocal cord paralysis resulting in severe airway obstruction and aspiration may require tracheostomy tube placement. Patients with vocal cord paralysis are at higher risk for descending aspiration and should be evaluated by a videofluoroscopic swallow study (VFSS) to assess safety for oral feeding.

Adenoidal and Tonsillar Hypertrophy

Etiology

The most common cause of chronic UAO in children is hypertrophy of the adenoids and tonsils. Adenoidal and tonsillar hyperplasia may be aggravated by recurrent infection, allergy, and inhaled irritants.

Clinical Manifestations

The signs of adenoidal and tonsillar hypertrophy are mouth breathing, snoring, and, in some patients, obstructive sleep apnea (see Chapter 134). The eustachian tubes enter the nasopharynx at the choanae and can be obstructed by enlarged adenoids, predisposing to recurrent or persistent otitis media.

Diagnostic Studies

Adenoidal hypertrophy is assessed by a lateral radiograph of the nasopharynx or by flexible nasopharyngoscopy.

Treatment

If the adenoids or tonsils are large and thought to be significantly contributing to UAO, then the most effective treatment is removal. Because the adenoids are not a discrete organ but rather consist of lymphoid tissue, regrowth is possible, especially in preschool children. Refractory OSA is less common after adenotonsillectomy than adenoidectomy or tonsillectomy alone.

PEARLS FOR PRACTITIONERS

See *The Respiratory System: Pearls for Practitioners at the end of this section.*

CHAPTER 136

Lower Airway, Parenchymal, and Pulmonary Vascular Diseases

ETIOLOGY

There are many causes of lower airway diseases (Table 136.1). Lower airway diseases often result in airway obstruction. The most common lower airway disease in children is **asthma**, which results in variable and recurring symptoms, diffuse

TABLE 136.1 Causes of Wheezing in Childhood

ACUTE
Asthma
Exercise-induced asthma
Hypersensitivity reactions
Infection (e.g., bronchiolitis)
Inhalation of irritant gases or particulates
Descending aspiration
Foreign body (airway or esophageal)
Aspiration of gastric contents (ascending aspiration)
CHRONIC OR RECURRENT
Asthma (see under acute)
Hypersensitivity reactions, allergic bronchopulmonary aspergillosis (seen only in children with either asthma or cystic fibrosis)
Vocal cord dysfunction
Recurrent aspiration/swallowing dysfunction (dysphagia)
Retained foreign body
Gastroesophageal reflux
Bronchopulmonary dysplasia
Bronchitis, bronchiectasis
Cystic fibrosis
Primary ciliary dyskinesia
Bronchiolitis obliterans
Pulmonary edema (congestive heart failure)
Bronchomalacia/tracheomalacia
Vascular ring
Pulmonary artery dilatation (absent pulmonary valve)
Bronchial or pulmonary cysts/masses
Lymph nodes (tuberculosis, lymphoma)
Endobronchial masses/tumors (carcinoid)
Bronchial or tracheal stenosis
Cardiomegaly

bronchial obstruction from airway inflammation, and hyperresponsiveness of bronchial smooth muscle leading to airway constriction. Virus-induced wheezing episodes are common, especially in children under 3 years of age. Wheezing that is localized to one area of the chest suggests focal airway obstruction (foreign body aspiration or extrinsic compression).

CLINICAL MANIFESTATIONS

A wheeze is a continuous sound that is produced by vibration of airway walls and generally has a more musical quality than does stridor. In contrast to upper airway obstruction, obstruction below the thoracic inlet causes more wheezing on expiration than on inspiration. Intrathoracic pressure is increased relative to atmospheric pressure during exhalation, which collapses the intrathoracic airways and accentuates airway narrowing on expiration. Expiratory airflow through obstructed intrathoracic airways leads to wheeze, prolonged expiratory phase, and increased abdominal work of breathing. In patients with chronic airway infection (e.g., cystic fibrosis), the bronchi become permanently damaged and dilated (bronchiectasis). Patients with bronchiectasis have episodes of cough, often productive of purulent sputum, and may have inspiratory crackles.

DIAGNOSTIC STUDIES

When asthma is suspected, empiric trials of therapy (bronchodilators, short courses of oral corticosteroids, long-term use of inhaled corticosteroids) are useful in arriving at a diagnosis. In children older than 6 years, pulmonary function tests (spirometry) can assess airflow obstruction and response to bronchodilators. **Radiographic evaluation** is not needed with each episode of wheezing, but those with significant respiratory distress, fever, history consistent with foreign body aspiration, or focal auscultatory findings should have posteroanterior (PA) and lateral chest radiographs obtained. Generalized **hyperinflation**, indicated by flattening of the diaphragms and an increased anteroposterior (AP) chest diameter, suggests diffuse obstruction of the small airways. Localized hyperinflation, especially on expiratory views, suggests localized bronchial obstruction (foreign body or an anatomic anomaly). Dysphagia leading to aspiration and airway inflammation can present with persistent wheezing. This is best assessed with a **videofluoroscopic swallowing study**. Gastroesophageal reflux may aggravate asthma and may lead to wheezing in very young children, especially if it is associated with aspiration. Infants with persistent wheezing despite empiric treatment with asthma therapy may benefit from an airway evaluation with **flexible bronchoscopy**.

DIFFERENTIAL DIAGNOSIS

Asthma

See Chapter 78.

Tracheomalacia

Etiology

Tracheomalacia is a floppy trachea due to lack of structural integrity of the tracheal wall (Fig. 136.1). The tracheal cartilaginous rings normally extend through an arc of approximately 320 degrees, maintaining rigidity of the trachea during changes in intrathoracic pressure. With tracheomalacia, the cartilaginous rings may not extend as far around the circumference (leaving the membranous posterior trachea wider than usual), may be completely absent, or may be present but damaged. These abnormalities can result in excessive collapse of the trachea, most pronounced during expiration. Tracheomalacia is the most common congenital tracheal abnormality and may be congenital (tracheoesophageal fistula or bony dysplasia syndromes) or acquired (long-term mechanical ventilation). Tracheomalacia must be differentiated from extrinsic tracheal compression by masses or vascular structures. Localized

FIGURE 136.1 Normal tracheal anatomy (A) and tracheomalacia (B) showing loss of anterior tracheal ring integrity and collapse of the tracheal posterior wall membrane. (Courtesy Anne & Robert H. Lurie Children's Hospital of Chicago.)

tracheomalacia may persist after the trachea has been relieved of extrinsic compression.

Clinical Manifestations

With tracheomalacia, the tracheal collapse may only be apparent during forced exhalation or with cough. It is commonly aggravated by respiratory infections. The airway collapse causes a harsh, monophonic wheeze compared to the polyphonic wheeze more often seen in asthma. Secretions may be retained behind the segment of malacia, predisposing to infection. Infants with severe tracheomalacia may completely collapse the trachea during agitation, resulting in cyanotic episodes that resemble breath holding spells. The voice is normal, as is inspiratory effort. In older children, the hallmark sign is a brassy, barking cough due to the vibration of the tracheal walls. The expiratory noises of tracheomalacia are often mistakenly ascribed to asthma or bronchiolitis, and the barking cough is often misdiagnosed as croup.

Treatment

Infants with mild to moderate tracheomalacia usually require no intervention. Tracheomalacia improves with airway growth as the lumen increases in diameter and the tracheal wall becomes more firm. The treatment of older symptomatic children is geared toward treating the precipitating cause for cough and providing supportive care. Chest physiotherapy is essential to improve mucociliary clearance, and antibiotics are often necessary to treat concurrent infection.

Children, especially infants, with severe tracheomalacia may require tracheostomy tubes to administer continuous positive airway pressure (CPAP), which serves to stent open the airway. Custom-length tracheostomy tubes are used to bypass the site of collapse. Surgical techniques such as slide tracheoplasty may benefit short segments of severe malacia. Aortopexy has been used to limit anterior collapse but does not treat posterior tracheal membrane collapse. Historically, surgically placed airway stents have been problematic in children because airway stents may erode and migrate, do not grow with children, and serve as a source of fixed stenosis and obstruction. Newer absorbable airway external splints and internal stents with three-dimensional printing technology are under active investigation for treatment of severe pediatric tracheomalacia.

Tracheoesophageal Fistula

See Chapter 128.

Extrinsic Tracheal Compression

Compression of the trachea by vascular structures or masses can cause significant respiratory compromise. Tracheal compression by aberrant great vessels (aorta, innominate artery) may cause wheezing, stridor, cough, and dyspnea. Incomplete vascular rings are often asymptomatic and incidentally found, but anterior tracheal compression can occur from an **anomalous innominate artery** that arises more distally than normal from the aortic arch. This usually results in mild respiratory symptoms. Surgical correction is rarely necessary. Complete vascular rings, which compress the esophagus posteriorly and the trachea anteriorly, include the double aortic arch and a right aortic arch with a persistent ligamentum arteriosum (most common). Both lesions have right-sided aortic arches, which may be visible on chest radiograph. In addition to respiratory symptoms, complete vascular rings

may cause dysphagia as a result of esophageal compression. The diagnosis of vascular anomalies can often be made by a barium swallow, which identifies the esophageal compression (Fig. 136.2). Bronchoscopy will identify a pulsatile compression of the airway, but the diagnostic procedures of choice are a computed tomography (CT) angiogram of the chest and great vessels or magnetic resonance angiogram (MRA). Definitive treatment of vascular rings requires surgical repair. Other causes of extrinsic tracheal compression include enlarged mediastinal lymph nodes (tuberculosis), mediastinal masses (teratoma, lymphoma, thymoma, germ cell tumors), and, rarely, cystic hygromas.

Foreign Body Aspiration

Epidemiology

Aspiration of foreign bodies into the trachea and bronchi is relatively common. The majority of children who aspirate foreign bodies are under 3 years of age. Patients with developmental delay or with older siblings are at increased risk. Because the right mainstem bronchus takes off at a less acute angle than the left mainstem bronchus, foreign bodies tend to lodge in right-sided airways. Some foreign bodies, especially nuts, can also lodge more proximally in the larynx or subglottic space, totally occluding the airway. Many foreign bodies are not radiopaque, which makes them difficult to detect radiographically. The most common foreign bodies aspirated by young children are food (especially nuts) and small toys. In younger children, coins and button batteries more often lodge in the esophagus than in the airways. Button batteries can cause esophageal erosion and be life threatening. Older children have been known to aspirate rubber balloons, which also can be life threatening.

FIGURE 136.2 Vascular ring. Indentation of the posterior esophagus seen on barium swallow, lateral view. This child had a double aortic arch.

Clinical Manifestations

Many children who aspirate foreign bodies have clear histories of choking, witnessed aspiration, or physical or radiographic evidence of foreign body aspiration. However, a proportion of patients have a negative history because the aspiration went unrecognized. Physical findings observed with acute foreign body aspiration may include cough, localized wheezing, unilateral absence of breath sounds, stridor, and, rarely, bloody sputum.

Most foreign bodies are small and quickly expelled, but some may remain in the lung for long periods of time and may come to medical attention because of persistent cough, sputum production, or recurrent unilateral pneumonia. Foreign body aspiration should be in the differential diagnosis of patients with persistent wheezing unresponsive to bronchodilator therapy, persistent atelectasis, recurrent or persistent pneumonia, or chronic cough without another explanation. Foreign bodies may also lodge in the esophagus and compress the trachea, thus producing respiratory symptoms. Therefore esophageal foreign bodies should be included in the differential diagnosis of infants or young children with persistent cough, stridor, or wheezing, particularly if dysphagia is present.

Diagnostic Studies

Radiographic studies will reveal the presence of radiopaque objects and can also identify focal air trapping, especially on expiratory views or decubitus films. Many foreign bodies are not radiopaque. Thus, when foreign body aspiration is suspected, expiratory or lateral decubitus chest radiographs may identify air trapping on the affected, dependent side. If history or exam is suggestive of foreign body aspiration, the patient should undergo bronchoscopy. Flexible bronchoscopy can be used to locate an aspirated foreign body and may be useful when the presentation is not straightforward, but foreign body removal is best performed via rigid bronchoscopy.

Prevention

Common foods, including peanuts or other nuts, popcorn, uncooked carrots, or any foods difficult to break into small pieces, are at risk to be aspirated by infants and children, particularly before molar teeth have erupted. Older siblings should be counseled to keep small toys separate and not present younger children with small parts.

Bronchiolitis

See Chapter 109.

Bronchopulmonary Dysplasia

See Chapter 61.

Congenital Lung Anomalies

Congenital lobar emphysema (congenital lobar overinflation) consists of hyperinflation of one or more lobes of the lung. This overdistention may cause severe respiratory distress in the neonatal period due to compression of surrounding normal lung tissue, but it can also be asymptomatic and remain undiagnosed for years. Radiographically, it may be mistaken for a pneumothorax. Lobectomy may be required if respiratory

distress is severe or progressive, but if the patient is asymptomatic then surgical resection may not be indicated.

Congenital pulmonary airway malformations (CPAMs) are a spectrum of lesions arising during early lung development with histologic appearance ranging from simplified bronchial to complex cystic alveolar tissue, connected to the tracheobronchial tree. They are often first identified on antenatal ultrasound, and after birth can be inconspicuous on chest radiograph. CPAMs are nonfunctioning lung tissue and can have hybrid features of **pulmonary sequestration** (presence of systemic circulation connections). Although CPAM lesions can be stand-alone lesions, a substantial proportion of pulmonary sequestrations are hybrid CPAM lesions. Sequestrations without hybrid features are separate from the tracheobronchial tree and are classified as intrapulmonary (located in a normal lobe without its own pleura) and extrapulmonary (outside normal lung). CPAMs and sequestrations can coexist with other chest lesions including **congenital diaphragmatic hernia**. Sequestration is also associated with **Scimitar syndrome** (partial anomalous pulmonary venous return). Symptomatic neonates with respiratory distress, large lesions, or family history of features concerning for malignancy require further imaging. Although large malformations can cause neonatal respiratory distress, many are asymptomatic. Chest CT with contrast is the diagnostic test of choice (Fig. 136.3) but may be delayed if the child is asymptomatic with close clinical follow-up for symptom development. Surgical resection is curative, but risk of infection or malignancy is not completely understood in these children. Conservative management with observation is a reasonable option for families with low risk.

Pulmonary hypoplasia, or a relative decrease in number and size of alveoli, may be the result of bronchopulmonary dysplasia or due to congenital differences such as congenital heart disease, trisomy 21, **congenital diaphragmatic hernia** (see Chapter 61), or unilateral congenital absence of a pulmonary artery. Alveolar growth occurs after birth, predominantly up to 3 years, but has been documented beyond 8 years of age.

FIGURE 136.3 Congenital pulmonary airway malformation. Coronal (A) and axial (B) computed tomography images of a right lower lobe congenital pulmonary airway malformation in a child who presented with recurrent pneumonias. The entire left lung and upper and middle lobes of the right lung are normal.

Primary Ciliary Dyskinesia

Etiology

Primary ciliary dyskinesia (PCD) is a heterogeneous, usually recessive genetic disorder of motile cilia and is characterized by a diverse array of clinical features, including chronic/recurrent upper and lower respiratory tract infections, laterality defects (including *situs inversus totalis* [*SIT*] and heterotaxy), and male infertility. This disorder affects approximately 1 in 15,000–20,000 live births, although the actual incidence may be higher because of a limited ability to definitively diagnose affected patients.

Clinical Manifestations

The clinical features of PCD reflect defective motile cilia function in the respiratory tract, sinuses, middle ear, and reproductive tract, as well as laterality defects. Early pediatric PCD clinical features include (1) history of unexplained neonatal respiratory distress, with supplemental oxygen requirement for more than 24 hours in term infants, (2) early-onset, year-round wet cough, (3) early onset, year-round nasal congestion, and (4) laterality defects. Patients develop progressive bronchiectasis that is universal by adulthood and can lead to end-stage lung disease. Cilia dysfunction in embryonic nodal cells can result in laterality defects and congenital heart disease. Other clinical manifestations include impaired growth, recurrent middle ear effusions with associated hearing loss, chronic sinusitis, nasal polyps, male infertility, and decreased female fertility.

Genotype-phenotype relationships are emerging in PCD, particularly regarding variability in severity and progression of lung disease. Patients with a distinct ultrastructural defect (inner dynein arm defect with microtubular disorganization), which is usually linked to mutations in *CCDC39* and *CCDC40*, typically present earlier in life, have worse pulmonary function by both functional and structural assessment (spirometry and CT scans), and poorer nutritional status compared to similar-aged patients with ODA defects.

Diagnostic Studies

PCD diagnosis has historically relied on a combination of clinical features and ultrastructural analysis of respiratory cilia by electron microscopy, obtained from scrapings/biopsy of nasal or airway epithelium. Results may be difficult to interpret as chronic infection and inflammation may also lead to ultrastructural abnormalities in nasal cilia. The most common ciliary ultrastructural defect is the absence of outer dynein arms (ODA). However, a third of affected individuals have normal ciliary ultrastructure. The measurement of nasal nitric oxide is the most sensitive and specific diagnostic test for PCD, and a low nasal nitric oxide level (<77 nL/min) is consistent with PCD. PCD is usually autosomal recessive; however, it has been associated with X-linked cri du chat syndrome and other overlapping ciliopathies. Currently 50 genes have been identified to explain approximately 75% of cases. High-speed videomicroscopy assesses ciliary beat frequency and pattern but requires specialized equipment, and, currently, there is an absence of standardized reporting methods.

Treatment

Treatment is geared toward treating infections and improving clearance of respiratory secretions. High-resolution chest CT scans are useful to confirm and monitor bronchiectasis.

Surveillance cultures help identify organisms involved and guide antibiotic therapy. Chest physiotherapy and prompt treatment of bacterial infections are helpful, but the course of the lower airway disease tends to be slowly progressive. Inhaled hypertonic saline improves cough clearance and has been shown to improve lung function. Antiinflammatory antibiotics, such as low-dose macrolides, may reduce the number of exacerbations per year. Sinus surgical procedures are often done to manage chronic sinusitis, but their benefit is questionable. Most children require placement of pressure equalization (PE) tubes for management of recurrent otitis media. Multidisciplinary care with pulmonology, otolaryngology, audiology, respiratory therapy, and nutrition is recommended.

Pneumonia

See Chapter 110.

Pulmonary Edema

Etiology

Pulmonary edema is the seepage of fluid into the alveolar and interstitial spaces. Capillary hydrostatic forces and interstitial osmotic pressures tend to push fluid into the air spaces, whereas plasma osmotic pressures and tissue mechanical forces tend to move fluid away from the air spaces. Under normal circumstances, the sum of these forces favors absorption, so the alveolar and interstitial spaces remain dry. Fluid entering the alveoli is normally removed by pulmonary lymphatics. Pulmonary edema forms when transcapillary fluid flux exceeds lymphatic drainage. Reduced left ventricular function leads to pulmonary venous hypertension and increased capillary hydrostatic pressure, and fluid moves into the interstitial space and alveoli. Fluid initially enters the interstitial space around the terminal bronchioles, alveoli, and arterioles (**interstitial edema**), causing increased lung stiffness and premature closure of bronchioles on expiration. If the process continues, fluid then enters the alveoli, further reducing compliance and resulting in **intrapulmonary shunting** (alveolar units that are perfused but not ventilated). Decreased ventilation (hypercarbia) is a late finding.

Pulmonary edema is most commonly due to heart failure from left ventricular or biventricular dysfunction. Pulmonary hypertension (PH) and associated cor pulmonale (right ventricular dysfunction) do not usually cause pulmonary edema, as the increased vascular resistance is proximal to the capillary bed. Increased capillary permeability, seen in disease states such as sepsis and acute respiratory distress syndrome, can lead to pulmonary edema. Pulmonary edema may also occur with excessive swings in intrathoracic pressure, as seen after tracheal foreign body aspiration or severe obstruction from hypertrophied tonsils and adenoids (**postobstructive pulmonary edema**). Pulmonary edema may also be present in conditions with decreased serum oncotic pressure (hypoalbuminemia); after administration of large volumes of intravenous (IV) fluids, especially if there is capillary injury; with ascent to high altitude (**high-altitude pulmonary edema**); and after central nervous system injury (**neurogenic pulmonary edema**).

Clinical Manifestations

The clinical manifestations of pulmonary edema are **dyspnea**, tachypnea, and cough (can occur with frothy, pink-tinged

sputum). As the edema worsens, there is increased work of breathing and hypoxemia; diffuse inspiratory crackles can be heard on auscultation.

Diagnostic Studies

Chest radiographs may reveal diffuse hazy infiltrates, classically in a perihilar pattern, but these findings may be obscured by underlying lung disease. Interstitial edema (**Kerley B lines**) may be seen, especially at the lung bases.

Treatment and Prognosis

Treatment and prognosis depend on the cause of the pulmonary edema and response to therapy. Patients should be positioned in an upright posture and given supplemental O₂. Diuretic therapy and rapidly acting IV inotropic agents may be helpful in cardiogenic pulmonary edema. CPAP or intubation with positive pressure ventilation using high positive end-expiratory pressures (PEEP) may be required.

Acute Respiratory Distress Syndrome

See Chapter 39.

Pulmonary Arterial Hypertension and Cor Pulmonale

Etiology

PH is defined as a mean pulmonary artery pressure of 20 mm Hg or higher in children over 3 months of age at sea level. Pediatric PH is categorized into five groups based on the World Health Organization classification, similar to adult PH. Group 1 is pulmonary arterial hypertension (PAH) due to diseases within veins and small pulmonary muscular arteries such as persistent PH of the newborn, congenital heart disease (including those with excessive pulmonary blood flow due to left-to-right cardiac shunting), exposure to various drugs (e.g., cocaine, amphetamines), and **idiopathic pulmonary arterial hypertension** (IPAH, previously called primary PH). Hereditary IPAH is also in this group and has been linked with the bone morphogenetic receptor-2 (*BMPR2*) gene. Group 2 is caused by dysfunction of the left heart such as valvular disease. Group 3 is secondary to lung disease or chronic hypoxia, including upper airway obstruction resulting in obstructive sleep apnea and hypoxemia. In Group 4, PH is secondary to chronic pulmonary thromboembolism. Group 5 includes PH of unclear but multifactorial diseases, including some autoimmune diseases and metabolic diseases. The Panama classification is a new pediatric-specific system that includes 10 categories to capture the heterogeneity of pulmonary hypertensive vascular disease from the fetus to adolescent (e.g., perinatal pulmonary vascular maladaptation, multifactorial pulmonary hypertensive vascular disease in congenital malformation syndromes, diffuse pediatric lung disease). This classification system is promising but has yet to be tested and validated for utility and accuracy.

Prolonged PH may lead to irreversible changes in the intima and media of the pulmonary arterioles. PH strains the right side of the heart, which leads to hypertrophy and dilation of the right ventricle. Altered structure and/or function of the right heart from PH is known as **cor pulmonale**. The most common causes of cor pulmonale in children are chronic lung diseases, especially severe bronchopulmonary dysplasia

and severe, untreated obstructive sleep apnea (with chronic hypoxia).

Clinical Manifestations and Diagnostic Studies

PAH should be suspected with developmental anatomic abnormalities or historical exposures (e.g., congenital heart disease, bronchopulmonary dysplasia, congenital diaphragmatic hernia, prolonged hypoxemia). Exertional dyspnea and unexplained syncope are presenting symptoms. In addition to the other physical findings associated with pulmonary and cardiac diseases, an accentuated pulmonary component of the second heart sound may be heard. Definitive diagnosis is made by cardiac catheterization, but echocardiography may confirm the presence of right ventricular hypertrophy, ventricular dysfunction, interventricular septal flattening, and tricuspid insufficiency, which can be used to estimate the pulmonary artery pressures. Cardiac magnetic resonance imaging can be useful in diagnosis and to assess changes in ventricular function and size. Lung biopsy may be considered for children with PAH suspected of diffuse lung disease, pulmonary venoocclusive disease, or vasculitis.

Treatment and Prognosis

Treatment should focus on the underlying condition of known causes of PH, such as lung volume optimization in persistent PH of the newborn, or therapy with diuretics and salt/fluid restriction in heart failure. In all conditions of PH and PAH, the relief of hypoxemia with supplemental O₂ therapy can be therapeutic as a pulmonary vasodilator. Medications for pulmonary vasodilation such as short-term inhaled nitric oxide may be helpful in some patients. Continuous infusions of prostacyclin may be helpful, both acutely and chronically, and is available in inhaled, subcutaneous, and IV forms. Endothelium antagonists may be beneficial. Unfortunately, many patients with the idiopathic form of PAH have progressive courses, and lung or heart-lung transplantation may be the only treatment option.

Pulmonary Hemorrhage

Etiology

Pulmonary hemorrhage is a rare but potentially life-threatening condition in children. It can be due to bleeding from the airways (hemangiomas, bronchial vessel bleeds) or from diffuse capillary bleeding (alveolar hemorrhage). Alveolar hemorrhage is usually due to diffuse capillary disruption/inflammation.

Clinical Manifestations

The presentation of pulmonary hemorrhage is variable with a spectrum of asymptomatic radiographic abnormalities to life-threatening respiratory failure. **Hemoptysis**, although experienced by most children with pulmonary hemorrhage, can be absent in a third of individuals. It is important to rule out extrapulmonary sources of bleeding, including hematemesis and bleeding from the nasopharynx or mouth, as these are more common than true pulmonary hemorrhage. In addition to hemoptysis, the presenting signs and symptoms of pulmonary hemorrhage include cough, wheeze, shortness of breath, pallor, fatigue, cyanosis, and fever. Episodic pulmonary hemorrhage frequently manifests as recurrent respiratory symptoms associated with pulmonary infiltrates on chest radiographs.

Symptomatic **airway hemorrhage** may result in significant hemoptysis with few radiographic changes, whereas **alveolar bleeding** often causes profound respiratory symptoms, hypoxemia, diffuse infiltrates on radiographs, and minimal hemoptysis. Some patients experience a localized bubbling sensation in the chest, which may be helpful in differentiating local from diffuse sources of pulmonary bleeding. Physical examination findings may include locally or diffusely decreased breath sounds, cyanosis, and crackles on auscultation.

The **differential diagnosis** of pulmonary hemorrhage includes alveolar and airway bleeding. Airway bleeding can be due to airway hemangiomas, pulmonary arteriovenous malformations (e.g., hereditary hemorrhagic telangiectasia), and bronchial artery collaterals, which develop in some patients with chronic lung infections (e.g., cystic fibrosis). The causes of alveolar (capillary) bleeding can be divided into immune-mediated and non-immune-mediated categories. Immune-mediated causes include antineutrophil cytoplasmic autoantibodies (ANCA)-associated vasculitides, isolated pulmonary capillaritis, antiglomerular basement membrane disease, drug-induced vasculitis, and other connective tissue diseases. Nonimmune mediated causes include idiopathic pulmonary hemosiderosis, clotting disorders, infection, inhalation injury, and cardiac conditions associated with elevated pulmonary venous and capillary pressures (Table 136.2). Alveolar

hemorrhage following bone marrow transplant can occur from immune-mediated causes and from complications of diffuse alveolar damage. Rarely, a previously well infant will present with life-threatening acute alveolar hemorrhage. Often no cause is found, and, once the acute episode resolves, the infant returns to normal. Most of these infants never have a second bleeding episode. **Idiopathic pulmonary hemosiderosis** is a rare disorder characterized by recurrent alveolar bleeding, iron-deficiency anemia, and hemosiderin-laden macrophages in the lung, which can be identified microscopically with the use of special iron-staining techniques in bronchoalveolar lavage or lung biopsy specimens. Although the term *hemosiderosis* is sometimes used interchangeably with pulmonary hemorrhage, it is a pathologic finding that results from bleeding anywhere in the lung, airway, pharynx, nasopharynx, or mouth leading to hemosiderin accumulation in the lung.

Diagnostic Studies

It is important to perform a thorough upper airway examination to rule out epistaxis. Sometimes this requires nasopharyngoscopy. If extrapulmonary sources of bleeding have been excluded, then a chest radiograph, CT angiogram of the chest, bronchoscopy, echocardiogram, and evaluation for rheumatologic/autoimmune diseases follow, especially to consider antiglomerular basement membrane disease, granulomatosis with polyangiitis, Henoch-Schönlein purpura, and systemic lupus erythematosus. Approximately one-third of children with hemoptysis will have a normal chest radiograph, and additional diagnostic evaluation is warranted.

Treatment

The management of acute episodes of pulmonary bleeding includes the administration of supplemental O₂, blood transfusions, and, often with acute alveolar hemorrhages, mechanical ventilation with PEEP to tamponade the bleeding. Treatment is directed toward the underlying disorders and providing supportive care. In bronchial arterial bleeding, arteriography with vessel embolization has been shown to be successful.

Pulmonary Embolism

Etiology

Pulmonary embolism (PE) is rare in children. When it occurs, it is often associated with indwelling central venous catheters, oral contraceptives, or hypercoagulable states. Other risk factors, such as trauma, surgery, immobilization, systemic lupus erythematosus, systemic infection, and cancer, may lead to deep vein thromboses (DVTs) and pulmonary embolism.

Clinical Manifestations

In the distensible pulmonary vascular bed, small emboli may be asymptomatic unless they are infected (septic emboli). Large emboli may cause acute dyspnea, pleuritic chest pain, cough, and hemoptysis. Tachypnea, tachycardia, and hypoxia are common, as are nonspecific ST-segment and T-wave changes on the electrocardiogram (ECG). The P₂ heart sound may be increased. Unilateral calf swelling may be present in the setting of DVT.

Diagnostic Studies

Imaging plays an important role in the evaluation and management of acute PE. The diagnostic approach in children

CARDIOVASCULAR DISORDERS
Heart failure with pulmonary edema Pulmonary hypertension with Eisenmenger syndrome Mitral stenosis Venoocclusive disease Arteriovenous malformation (Osler-Weber-Rendu syndrome) Pulmonary embolism Portal vein obstruction
PULMONARY DISORDERS
Bronchogenic cyst Bronchopulmonary sequestration Pneumonia (bacterial, mycobacterial, fungal, parasitic, or viral) Bronchiectasis (cystic fibrosis, primary ciliary dyskinesia, immunodeficiency, retained foreign body) Tracheobronchitis Lung abscess Tumor (adenoma, carcinoid, hemangioma, metastasis) Trauma (contusion, laceration)
IMMUNE DISORDERS
Henoch-Schönlein purpura Pulmonary capillaritis Idiopathic pulmonary hemosiderosis Antiglomerular basement membrane disease (Goodpasture disease) Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis) Systemic lupus erythematosus Polyarteritis nodosa
OTHER CONDITIONS/FACTORS
Coagulopathy (Von Willebrand factor) Toxic inhalation (nitrogen dioxide, pesticides, crack cocaine) Post-bone marrow transplantation Catamenial hemoptysis (females)

differs somewhat from the approach in adults in that D-dimer testing and clinical prediction tools lack utility in the diagnosis of PE in children. CT pulmonary angiography (CTPA) is the current standard of care and provides accurate diagnosis with rapid turnaround time. CT also provides information on other potential causes of acute chest pain. Chest radiograph has limited utility, occasionally showing findings of PE or infarction, but is useful in evaluating other potential causes of chest pain. Ventilation-perfusion scans may reveal defects in perfusion without matching ventilation defects, but they are difficult to perform in young children. Catheter pulmonary angiography is no longer used for diagnosis and is used only for interventional management. Doppler or compression ultrasonography can be useful in assessing patients for lower extremity DVTs. Children with pulmonary embolism without an obvious cause should be evaluated for hypercoagulable states, the most common of which is factor V Leiden.

Treatment

The patient should be anticoagulated, usually with low-molecular-weight heparin or unfractionated heparin. Although rare, if pulmonary embolism is extensive and hemodynamically compromising, catheter-directed thrombolytic agents such as tissue plasminogen activator should be considered. All patients should receive supplemental O₂, and it is important to treat the predisposing factors.

See The Respiratory System: Pearls for Practitioners at the end of this section.

CHAPTER 137

Cystic Fibrosis

ETIOLOGY AND EPIDEMIOLOGY

Cystic fibrosis (CF) is a life-shortening autosomal recessive disorder that affects over 70,000 individuals worldwide. Although found predominantly in people of European descent, CF is reported among all races and ethnicities. The gene for CF, located on the long arm of chromosome 7, encodes for the **cystic fibrosis transmembrane conductance regulator (CFTR)**, a chloride channel located on the apical surface of epithelial cells. CFTR is important for the proper movement of salt and water across cell membranes and maintaining the appropriate composition of various secretions, especially in the airways, liver, and pancreas. The most common mutation is a deletion of three base pairs resulting in the absence of phenylalanine at the 508 position (Phe508del, F508del). Nearly 2,000 mutations of the *CFTR* gene have been identified to date.

The secretory and absorptive characteristics of epithelial cells are affected by abnormal CFTR, resulting in the clinical manifestations of CF. The altered chloride ion conductance in the sweat gland results in excessively high sweat sodium and chloride levels. This is the basis for the **sweat chloride test**, which is still the standard diagnostic test for this disorder. It is positive (elevated sweat chloride ≥ 60 mEq/L) in 99% of patients with CF. Abnormal airway secretions make the airway

more prone to colonization with bacteria. Defects in CFTR may also reduce the function of airway defenses and promote bacterial adhesion to the airway epithelium. This ultimately leads to chronic airway infections and eventually to bronchial damage (bronchiectasis).

CLINICAL MANIFESTATIONS

CF is a chronic progressive disease that can present with protein and fat malabsorption (failure to thrive, hypoalbuminemia, steatorrhea), liver disease (cholestatic jaundice), or chronic respiratory infection (Table 137.1). Many infants in the United States are currently diagnosed by newborn screening (available in all 50 states and the District of Columbia since 2010). Older children have traditionally presented with pulmonary manifestations such as chronic cough, poorly controlled asthma, and chronic respiratory infections, but recurrent pancreatitis, **nasal polyps**, and chronic sinusitis can also be presenting manifestations. **Digital clubbing** is common in patients with CF, even in those without significant lung disease.

The respiratory epithelium of patients with CF exhibits marked impermeability to chloride and an excessive

TABLE 137.1 Complications of Cystic Fibrosis

RESPIRATORY COMPLICATIONS

Bronchiectasis, bronchitis, bronchiolitis, pneumonia
Hemoptysis
Pneumothorax
Nasal polyps
Sinusitis
Cor pulmonale (associated with chronic hypoxemia)
Respiratory failure
Atypical mycobacterial infection
Allergic bronchopulmonary aspergillosis

GASTROINTESTINAL COMPLICATIONS

Pancreatic insufficiency
Meconium ileus/peritonitis (infants)
Intestinal atresia (infants)
Distal intestinal obstruction syndrome (non-neonatal obstruction)
Rectal prolapse
Fibrosing colonopathy (strictures)
Recurrent pancreatitis
Hepatic cirrhosis (portal hypertension, esophageal varices, hypersplenism)
Neonatal obstructive jaundice
Hepatic steatosis
Gastroesophageal reflux
Cholelithiasis
Growth failure (malabsorption)
Fat-soluble vitamin deficiency states (vitamins A, K, E, D)
Cystic fibrosis-related diabetes
Malignancy (rare)

OTHER COMPLICATIONS

Diabetes
Infertility
Delayed puberty
Dehydration–heat exhaustion
Electrolyte disturbances (hyponatremic hypochloremic metabolic alkalosis)
Hypertrophic osteoarthropathy–arthritis
Pseudotumor cerebri
Digital clubbing

reabsorption of sodium. This leads to thicker airway secretions, resulting in airway obstruction and impaired mucociliary transport. This, in turn, leads to endobronchial colonization with bacteria, especially *Staphylococcus aureus* and *Pseudomonas aeruginosa*. Chronic bronchial infection results in **persistent or recurrent cough** that is often productive of sputum, especially in older children. Pulmonary infections with *P. aeruginosa*, *Burkholderia cepacia*, and other organisms are difficult to treat and may be associated with accelerated clinical deterioration. Allergic bronchopulmonary aspergillosis (ABPA) is a hypersensitivity reaction to *Aspergillus* in the CF airways. It causes airway inflammation/obstruction and aggravates CF lung disease. The treatment for ABPA is systemic corticosteroids (prednisone) and antifungal agents (itraconazole). Minor hemoptysis is usually due to airway infection, but major hemoptysis is often caused by bleeding from bronchial artery collateral vessels in damaged/chronically infected portions of the lung. Pneumothoraces can occur in patients with advanced lung disease. Chronic airway infection leads to airway obstruction and bronchiectasis and, eventually, to pulmonary insufficiency and premature death. The median age of survival is currently over 45 years, with some patients now living into their 80s.

Ninety percent of patients with CF are born with **exocrine pancreatic insufficiency**. The inspissation of mucus and subsequent destruction of the pancreatic ducts result in the inability to excrete pancreatic enzymes into the intestine. This leads to malabsorption of proteins, sugars (to a lesser extent), and especially fat. Fat malabsorption manifests clinically as **steatorrhea** (large, foul-smelling stools), deficiencies of fat-soluble vitamins (A, D, E, and K), and failure to thrive. Protein malabsorption can present early in infancy as hypoproteinemia and peripheral edema. Approximately 10% of patients with CF are born with intestinal obstruction caused by inspissated meconium (**meconium ileus**). In older patients, intestinal obstruction may result from thick inspissated mucus in the intestinal lumen (**distal intestinal obstruction syndrome [DIOS]**). In adolescent or adult patients, progressive pancreatic damage can lead to enough islet cell destruction to cause insulin deficiency. This initially presents as glucose intolerance, but true diabetes that requires insulin therapy (**CF-related diabetes**) may develop. The failure of the sweat ducts to conserve sodium and chloride may lead to hyponatremia and hypochloremic metabolic alkalosis, especially in infants. Inspissation of mucus in the reproductive tract leads to reproductive dysfunction in both males and females. In males, congenital absence of the vas deferens and azoospermia are nearly universal. In females, secondary amenorrhea is often present as a result of chronic illness and reduced body weight. Fertility can be diminished by malnutrition and abnormal cervical mucus, but women with CF can conceive.

All infants with a positive newborn screen and/or with meconium ileus should be evaluated for CF. The diagnosis of CF should be seriously considered in any infant presenting with failure to thrive, cholestatic jaundice, chronic respiratory symptoms, or electrolyte abnormalities (hyponatremia, hypochloremia, metabolic alkalosis). CF should be in the differential diagnosis of children with chronic respiratory or gastrointestinal symptoms, especially if there is digital clubbing. Any child with nasal polyps, especially those younger than 12 years, should be evaluated for CF. All siblings of patients with CF should also be evaluated.

DIAGNOSTIC STUDIES

Readily available commercial DNA tests detect many CF mutations, but because there are nearly 2,000 identified mutations (and some of unknown clinical significance), DNA analysis will not detect all cases of CF. All U.S. states have newborn screening for CF, based either on elevated immunoreactive trypsinogen (IRT) levels or DNA tests, identifying the majority of infants with CF, but there are both false-positive and false-negative results. Therefore the diagnostic test of choice is still the sweat test. Indications for performing a **sweat test** are listed in Table 137.2. The following criteria should be met to establish the diagnosis of CF:

- The presence of one or more typical clinical features of CF (chronic pulmonary disease, characteristic gastrointestinal and nutritional abnormalities, salt loss syndromes, or obstructive azoospermia) AND
- Two elevated sweat chloride tests performed at an accredited CF Foundation–certified laboratory (positive if the value is ≥ 60 mEq/L, borderline if 30–59 mEq/L, and negative if < 30 mEq/L, with adequate sweat collection) OR
- Two mutations known to cause CF identified by DNA analysis OR
- A characteristic abnormality in ion transport across nasal epithelium demonstrated in vivo (nasal potential difference testing)

TABLE 137.2 Indications for Sweat Testing

RESPIRATORY

Chronic or recurrent cough
 Chronic or recurrent pneumonia
 Recurrent bronchiolitis or bronchitis
 Recurrent wheezing/difficult to control asthma
 Recurrent or persistent atelectasis
 Bronchiectasis
 Hemoptysis
Pseudomonas aeruginosa in the respiratory tract (if not explained by other factors [e.g., tracheostomy or prolonged intubation])

GASTROINTESTINAL

Meconium ileus
 Neonatal intestinal obstruction (meconium plug, atresia)
 Steatorrhea, malabsorption
 Hepatic cirrhosis in childhood (including any manifestations such as esophageal varices or portal hypertension)
 Cholestatic jaundice in infancy
 Pancreatitis
 Rectal prolapse
 Fat-soluble vitamin deficiency states (A, D, E, K)
 Hypoproteinemia, hypoalbuminemia, peripheral edema unexplained by other causes
 Prolonged, direct-reacting neonatal jaundice

MISCELLANEOUS

Positive newborn screen (sweat testing performed after 2wk of age and > 2 kg if asymptomatic)
 Digital clubbing
 Failure to thrive
 Family history of cystic fibrosis (e.g., in sibling or cousin)
 Salty taste of skin (typically noted by parent on kissing affected child—from salt crystals formed after evaporation of sweat)
 Hyponatremic hypochloremic alkalosis in infants
 Nasal polyps
 Recurrent sinusitis
 Azoospermia
 Absent vas deferens

For those identified by positive newborn screening or because a sibling has CF, positive sweat chloride testing or the presence of known disease-causing DNA mutations are the only criteria required for diagnosis, as clinical symptoms may not be manifested early in life.

Although the sweat test is both specific and sensitive for CF, it is subject to technical problems with both false-positive and false-negative results (Table 137.3). Cutoff diagnostic measurements evolve as more disease-causing DNA mutations are identified. Other supportive tests include the measurement of bioelectrical potential differences across nasal epithelium (not widely available) and measurement of fecal elastase levels. Low fecal elastase levels indicate exocrine pancreatic insufficiency. CF genotyping done by commercial laboratories identifies approximately 95% of patients with CF, but there are mutations that are not identified by standard testing. Not all mutations in CFTR are considered disease causing, and some have uncertain prognostic consequences. Some infants identified by newborn screening with borderline sweat tests and mutations of uncertain consequence are considered to have CFTR-related metabolic syndrome (CRMS). Older children that present with atypical clinical features and borderline sweat tests may be considered nonclassic CF or mild variant CF.

Identification of carriers (heterozygotes) and prenatal diagnosis of children with the F508del and other common mutations is offered at most medical centers. Prenatal testing techniques can identify more than 90% of carriers. Prenatal detection of a known CF genotype may be accomplished by amniocentesis or chorionic villus sampling.

TREATMENT

The treatment of CF is multifactorial. Most maintenance therapies are directed toward the gastrointestinal and pulmonary complications. Presently, there is no effective single cure for CF. Precision therapies, known as CFTR modulators, target genotype-specific functional defects of the CFTR protein. Ivacaftor, the first CFTR modulator approved by the U.S. Food and Drug Administration (FDA), is a small molecule

potentiator that improves CFTR function in a small group of CF individuals who have an abnormal gating mechanism of their CFTR protein, contributing to sustained health improvements including lung function. The second FDA-approved medication is a combination of ivacaftor and lumacaftor, approved for individuals with two copies of the most common CFTR mutation, F508del. It has been associated with a modest but significant improvement in lung function, improved body mass index, and a decrease in hospitalizations for pulmonary exacerbations. The third FDA-approved medication is a combination of ivacaftor and tezacaftor, which has considerably fewer drug interactions compared to lumicaftor-ivacaftor. The triple-drug combination elexacaftor-tezacaftor-ivacaftor is an important new therapy for individuals who have at least one F508del mutation, which includes approximately 85% of people with CF. Elexacaftor-tezacaftor-ivacaftor demonstrated improvement in lung function and symptom-related quality of life, and decreased sweat chloride, compared to dual-therapy tezacaftor-ivacaftor. As of mid-2021, it is approved for adults and children 6 years of age and older. Clinical trials are underway studying both triple-drug therapy in younger children and next-generation CFTR modulators.

Treatment with CFTR modulator therapy does not preclude management of pulmonary complications. Management of pulmonary exacerbations is directed toward facilitating clearance of secretions from the airways and minimizing the effects of chronic bronchial infection. Airway secretion clearance techniques (**chest physiotherapy**) help remove mucus from the airways, and aerosolized DNase and 7% hypertonic saline, both delivered by nebulizer, decrease the viscosity of mucus. **Antibiotic therapy** is important in controlling chronic infection. Monitoring pulmonary bacterial flora via airway cultures and providing aggressive therapy with appropriate antibiotics (oral, aerosolized, and intravenous [IV]) help to slow the progression of lung disease. Patients often require 2- to 3-week courses of high-dose IV antibiotics and aggressive chest physiotherapy to treat pulmonary exacerbations. Antibiotics are selected based on organisms identified by sputum culture. If patients are unable to provide sputum, then a throat culture for CF pathogens can be used to direct therapy. Common infecting organisms include *P. aeruginosa* and *S. aureus*.

Exocrine pancreatic insufficiency is treated with enteric-coated pancreatic enzyme capsules, which contain lipase and proteases. Patients with CF are encouraged to follow high-calorie diets, often with the addition of nutritional supplements. Even with optimal pancreatic enzyme replacement, stool losses of fat and protein may be high. Fat should not be withheld from the diet, even when significant steatorrhea exists. Rather, pancreatic enzyme doses should be titrated to optimize fat absorption, although there is a limit to the doses that should be used. Lipase dosages exceeding 2,500 U/kg per meal are concerning because they have been associated with **fibrosing colonopathy**. Fat-soluble vitamins (A, D, E, and K) are recommended, preferably in a water-miscible form.

Newborns with **meconium ileus** may require surgical intervention, but some can be managed with contrast (Gastrografin) enemas. Intestinal obstruction in CF patients beyond the neonatal period is often due to DIOS, which may need to be treated with courses of oral laxatives (polyethylene glycol) or, in more refractory cases, with Gastrografin enemas. Pancreatic enzyme dosage adjustment, adequate hydration, and dietary fiber may help prevent recurrent episodes. Patients

TABLE 137.3 Causes of False-Positive and False-Negative Results on Sweat Testing

FALSE POSITIVE
Adrenal insufficiency
Eczema
Ectodermal dysplasia
Nephrogenic diabetes insipidus
Hypothyroidism
Fucosidosis
Mucopolysaccharidosis
Dehydration
Malnutrition
Poor technique/inadequate sweat collection
Type I glycogen storage disease
Panhypopituitarism
Pseudohypoaldosteronism
Hypoparathyroidism
Prostaglandin E ₁ administration
FALSE NEGATIVE
Edema
Poor technique/inadequate sweat collection

with CF-related diabetes are treated with insulin, primarily to improve nutrition and prevent dehydration, as ketoacidosis is rare. Although transaminase elevation is common in patients with CF, only 1–3% of patients have progressive cirrhosis resulting in portal hypertension. Cholestasis may be treated with the bile salt ursodeoxycholic acid. Portal hypertension and esophageal varices due to cirrhosis of the liver are managed, when necessary, with portal vein shunting procedures or liver transplantation. Patients with symptomatic sinus disease and nasal polyps not responding to medical management may require surgical intervention.

The management of CF is complex and is best coordinated by medical teams at accredited CF centers. More than 50% of the CF population are now adults, highlighting the importance of a successful transition of pediatric patients to adult centers. As with other severe chronic diseases, management of CF patients requires a multidisciplinary team working with patients and their families to maintain an optimistic, comprehensive, and aggressive approach to treatment.

PEARLS FOR PRACTITIONERS

See The Respiratory System: Pearls for Practitioners at the end of this section.

CHAPTER 138

Chest Wall and Pleura

Thoracic scoliosis, when it is severe (curve >50 – 60 degrees), can be associated with chest wall deformity and limitation of chest wall movement (see Chapter 202). This, in turn, can lead to decreased lung volumes (restrictive lung disease), ventilation-perfusion mismatching, hypoventilation, and even respiratory failure (see Chapter 39). Surgical correction of scoliosis may prevent further loss of lung function, but it rarely improves pulmonary function beyond presurgical levels. **Neuromuscular weakness** and hypotonia of the chest wall are also common causes of respiratory failure (see Chapter 39), and are classically associated with restrictive lung disease and hypoventilation. The differential diagnoses for weakness and hypotonia are extensive (see Chapter 182 in prior edition).

PECTUS EXCAVATUM AND CARINATUM

Pectus Excavatum

Sternal concavity (**pectus excavatum**), a common chest wall deformity in children, is usually not associated with significant pulmonary compromise. Patients with pectus excavatum generally come to medical attention because of concerns over the appearance of the chest. Occasionally, if severe, it may result in restrictive lung disease, obstructive defects, and/or decreased cardiac function. Adolescents with pectus excavatum may complain of exercise intolerance. Routine spirometry is often normal but may show decreased vital capacity consistent with restrictive lung disease. The main reason for surgical correction is generally to improve appearance (cosmetic reasons), although in some cases surgical repair is justified to improve cardiac function and exercise tolerance.

Pectus Carinatum

Pectus carinatum is an abnormality of chest wall shape in which the sternum bows out. Though pectus carinatum does not cause abnormal pulmonary function, underlying pulmonary disease may contribute to the deformity. It can be observed after cardiac surgery performed via midsternal approach. Surgical correction of this condition is rarely indicated but occasionally is done for cosmetic purposes.

PNEUMOTHORAX

Etiology

Pneumothorax, which is the accumulation of air in the pleural space, may result from external trauma or from leakage of air from the lungs or airways. **Spontaneous primary pneumothorax** (no underlying cause) occurs in teenagers and young adults, more commonly in tall, thin males and smokers. Factors predisposing to **secondary pneumothorax** (underlying cause identified) include barotrauma from mechanical ventilation, asthma, cystic fibrosis, trauma to the chest, and severe necrotizing pneumonia.

Clinical Manifestations

The most common signs and symptoms of pneumothorax are chest and shoulder pain and dyspnea. If the pneumothorax is caused by air that enters the pleural space during inspiration and cannot escape, mediastinal shift and functional lung compression may occur, resulting in **tension pneumothorax** with severe respiratory distress and hemodynamic changes (reduced venous return to the heart). Subcutaneous emphysema may result when the air leak communicates with the mediastinum. Physical findings associated with pneumothorax include decreased breath sounds on the affected side, a tympanic percussion note, and evidence of mediastinal shift (deviation of the point of maximal impact [PMI] and trachea away from the side of the pneumothorax). If the pneumothorax is small, there may be few or no clinical findings. However, the patient's clinical condition can deteriorate rapidly if the pneumothorax expands, especially if the air in the pleural space is under pressure (**tension pneumothorax**). This is a life-threatening condition that can result in death if the pleural space is not decompressed by evacuation of the pleural air.

Diagnostic Studies

The presence of a pneumothorax can usually be confirmed by upright chest radiographs. Computed tomography (CT) scans are generally not necessary unless chest x-rays suggest the need for further evaluation. When indicated, CT scans of the chest can be useful in quantifying the size of pneumothoraces, for differentiating air within the lung parenchyma (cystic lung disease) from air in the pleural space, and for identifying subpleural blebs that may be present in spontaneous recurrent pneumothoraces. In infants, transillumination of the chest wall may be of some use in making a rapid diagnosis of pneumothorax.

Treatment

The type of intervention depends on the size of the pneumothorax and the nature of the underlying disease. Small pneumothoraces ($<20\%$ of thorax occupied with pleural air) may

not require intervention as they often resolve spontaneously. Inhaling high concentrations of supplemental O₂ may enhance reabsorption of pleural air by washing out nitrogen from the blood. Larger pneumothoraces and any tension pneumothorax require immediate drainage of the air, preferably via chest tube. In an emergency, a simple needle aspiration may suffice, although placement of a chest tube is often required for resolution. In patients with recurrent or persistent pneumothoraces, sclerosing the pleural surfaces to obliterate the pleural space (pleurodesis) may be necessary. This can be done either chemically, by instilling talc or sclerosis agents (doxycycline) through the chest tube, or mechanically, by surgical abradement. Surgical approaches, such as open thoracotomy and **video-assisted thoracoscopic surgery (VATS)**, enable visualization of the pleural space and resection of pleural blebs, when indicated. Airline travel and spirometry may be restricted for a period of time (≥ 2 weeks) following radiographic resolution of the pneumothorax to minimize risk of recurrence.

PNEUMOMEDIASTINUM

Pneumomediastinum results from the dissection of air from the pulmonary parenchyma into the mediastinum. It is usually a mild, self-limited process that does not require aggressive intervention. The most common causes in children are severe forceful coughing and acute asthma exacerbations. Common symptoms are chest pain and dyspnea. There are often no physical findings, although a crunching noise over the sternum can sometimes be appreciated on auscultation, and subcutaneous emphysema may be detected about the neck. The diagnosis is confirmed by chest radiograph, and treatment is directed toward the underlying lung disease.

PLEURAL EFFUSION

Etiology

Fluid accumulates in the pleural space when the local hydrostatic forces that are pushing fluid out of the vascular space exceed the oncotic forces that are drawing fluid back into the vascular space. Pleural effusions can be transudates (intact membrane but abnormal hydrostatic or oncotic forces) or exudates (decreased integrity of the membrane due to

inflammatory processes or impaired lymphatic drainage). There are relatively few causes of transudates, the most common being congestive heart failure and hypoproteinemia states, whereas the causes of exudates are numerous. Almost any pulmonary inflammatory process can result in pleural fluid accumulation. Among the most common causes of exudates are infection (e.g., tuberculosis, bacterial pneumonia), collagen vascular diseases (e.g., systemic lupus erythematosus), and malignancy. Chylous pleural effusions (elevated triglyceride levels) are seen with thoracic duct injury and abnormalities of lymphatic drainage (lymphangiomatosis, lymphangiectasia). Bacterial pneumonia can lead to an accumulation of pleural fluid (**parapneumonic effusion**). When this fluid is purulent or infected, then it is called an **empyema**, although often the terms *parapneumonic effusion* and *empyema* are used interchangeably. Parapneumonic effusion/empyema is the most common reason for effusion in children. Upright and decubitus chest radiograph (Fig. 138.1) can be useful for identifying parapneumonic effusion; however, chest ultrasound or CT is necessary for accurate estimates of fluid volume and organization (loculation) if surgical drainage is being considered. Most parapneumonic effusions are due to pneumonia caused by *Streptococcus pneumoniae*, group A streptococci, or *Staphylococcus aureus*.

Clinical Manifestations

Small pleural effusions may be asymptomatic but will cause dyspnea and tachypnea if they are large enough to compress lung tissue. Effusions due to infection are usually associated with fever, malaise, poor appetite, pleuritic chest pain, and splinting. Physical findings include tachypnea, decreased breath sounds, dullness to percussion, and decreased tactile fremitus. Large effusions may occupy more than half the hemithorax and cause a mediastinal shift away from the affected side, compromising respiratory status, particularly in young children.

Diagnostic Studies

The presence of pleural fluid can often be confirmed by chest radiograph. In addition to anteroposterior and lateral projections, a decubitus view should be done to assess for layering

FIGURE 138.1 Parapneumonic effusion. (A) Posterior-anterior chest radiograph showing dense opacification of the right hemithorax. (B) On decubitus view, some of the density forms a horizontal layer indicating that there is pleural fluid in addition to pneumonia.

of fluid. Chest ultrasonography is useful for confirming the presence of the effusion and quantifying its size. CT scans of the chest can help differentiate pleural fluid from parenchymal lesions and pleural masses. Both ultrasonography and CT scans can determine whether parapneumonic effusions contain loculations (fibrous strands that compartmentalize the effusion).

The analysis of pleural fluid is useful in differentiating a transudate from an exudate. Routine tests on pleural fluid such as cell count, pH, protein, lactate dehydrogenase, and glucose characterize the effusions. Triglyceride levels, cytology, hematocrit, gram and acid-fast bacilli stain, culture, and adenosine deaminase levels can be useful in diagnosing chylous, malignant, and tuberculous effusions (Table 138.1). However, the yield of pleural fluid cultures is low. Transudative pleural effusions have a low specific gravity (<1.015) and protein content, low lactate dehydrogenase activity, and a low white blood cell (WBC) count with few polymorphonuclear cells. In contrast, exudates are characterized by high specific gravity and high

protein (>3 g/dL) and lactate dehydrogenase levels. They may also have a low pH (<7.2), low glucose level (<40 mg/dL), and a high WBC count with many lymphocytes or polymorphonuclear leukocytes.

Treatment

Therapy is directed at the underlying condition causing the effusion and at relief of the mechanical consequences of the fluid collection. For small effusions, especially if they are transudates, no pleural drainage is required. Large effusions that are causing respiratory compromise should be drained with a **chest tube**. Approaches to parapneumonic effusions vary widely. Small effusions can be managed conservatively with intravenous antibiotics alone. For medium-sized effusion without respiratory compromise, the decision to trial empiric antibiotic therapy alone or proceed straight to drainage depends on regional expertise and practice patterns. With parapneumonic effusions/empyema, simple drainage with a chest tube alone is often not sufficient because the fluid may be thick and loculated. In such cases, pleural drainage is best achieved with either the administration of fibrinolytic agents via chest tubes or VATS. Both fibrinolytic therapy via chest tubes and VATS can reduce morbidity and length of hospital stay for complicated effusions.

TABLE 138.1 Pleural Fluid Analysis	
EXUDATIVE EFFUSION BY LIGHT TRADITIONAL CRITERIA	
Pleural fluid protein/serum protein ratio >0.5 OR Pleural fluid LDH/serum LDH ratio >0.6 OR Pleural fluid LDH >two-thirds the upper limits of laboratory's normal serum LDH	
CHYLOTHORAX	
Triglycerides >110 mg/dL	
TUBERCULOUS

PEARLS FOR PRACTITIONERS

CHAPTER 133

Respiratory System Assessment

- Airway branching is complete at birth; alveolar number increases through childhood.
- Resistance increases with reduction of airway diameter, leading to obstructive lung disease.
- Pulmonary compliance is reduced when lungs, pleura, or chest wall become stiff, leading to restrictive lung disease.
- Ventilation-perfusion (V/Q) mismatch is the most common cause of hypoxemia in children.
- A chest radiograph can provide valuable information about parenchymal, pleural, and airway disease and is recommended as first-line imaging for most patients with respiratory complaints.
- Spirometry is the pulmonary function test of choice for diagnosing asthma and other obstructive lung diseases; body plethysmography is needed to confirm restrictive lung disease.
- Flexible bronchoscopy is useful for evaluation of airway anatomy and obtaining lower respiratory samples; rigid bronchoscopy is required for foreign body removal.

CHAPTER 134

Control of Breathing

- Ventilation and oxygenation are regulated by central and peripheral chemoreceptors, with signal origin in the deep brainstem.
- Central apnea is more likely secondary (drugs, central nervous system tumor, or trauma) than primary (genetic syndrome).
- Apnea of prematurity should resolve by 44 weeks postmenstrual age.
- A brief resolved unexplained event (BRUE) is defined as a short (<1 minute), self-limited episode with cyanosis or pallor, irregular breathing, change in tone, or altered level of responsiveness occurring in an infant younger than 1 year.
- The risk of sudden infant death syndrome (SIDS) is associated with preterm birth, maternal smoking, prone sleep position, and overinsulation.
- Obstructive sleep apnea is most commonly caused by adenotonsillar hypertrophy in children.
- Polysomnogram is the diagnostic test of choice for obstructive and central apnea.

CHAPTER 135

Upper Airway Obstruction

- Upper airway obstruction at the level of the glottis or subglottis produces stridor, typically worse when the child is awake and active.
- The most common cause of *noninfectious* stridor in infants is laryngomalacia.
- The most common cause of *infectious* stridor in infants and young children is croup (laryngotracheobronchitis).
- Upper airway obstruction at the level of the pharynx is usually due to soft tissue collapse or enlargement, leading to mouth breathing and snoring that is typically worse during sleep.
- The most common cause of *noninfectious* soft tissue upper airway obstruction in young children is adenotonsillar hypertrophy.
- Common infectious causes of soft tissue upper airway obstruction include retropharyngeal abscess and peritonsillar abscess.

CHAPTER 136

Lower Airway, Parenchymal, and Pulmonary Vascular Diseases

- The most common cause of lower airway disease in children is asthma, a clinical disease of variable and recurring symptoms with airway inflammation and bronchial hyperresponsiveness.

- A wheeze is a continuous sound produced by small airway narrowing and is most pronounced on exhalation.
- Tracheomalacia is the most common tracheal abnormality, can be congenital or acquired, and often improves with growth.
- Vascular rings can be complete or incomplete, causing extrinsic tracheal compression, leading to wheezing, stridor, cough, or dyspnea.
- Foreign body aspiration typically occurs in children 1–4 years of age, often with nonradiopaque material such as food (e.g., nuts).
- Primary ciliary dyskinesia (PCD) is a heterogenous, typically autosomal recessive, disorder of motile cilia with clinical features of neonatal respiratory distress, year-round productive cough, year-round nasal congestion, chronic sinusitis, chronic otitis media, and laterality defects. Late clinical manifestations include bronchiectasis and end-stage lung disease.
 - PCD diagnosis is multifactorial and involves compatible clinical phenotype, evaluation for cilia defects on electron microscopy, nasal nitric oxide testing, and genetic analysis.
- Pulmonary hypertension may lead to irreversible pulmonary vascular changes that strain the right heart and lead to cor pulmonale.
 - Cor pulmonale is commonly caused by chronic lung disease, particularly severe bronchopulmonary dysplasia and untreated severe obstructive sleep apnea.
- Hemoptysis from pulmonary sources can occur from airway hemorrhage or alveolar bleeding.

CHAPTER 137

Cystic Fibrosis

- Cystic fibrosis (CF) is an autosomal recessive genetic disorder.
- The gene for CF encodes for a polypeptide, the cystic fibrosis transmembrane conductance regulator (CFTR), a chloride channel located on the apical surface of epithelial cells.
 - Defects in the CFTR gene result in abnormal movement of salt and water across cell membranes leading to thick secretions impacting multiple organ systems.
- Clinical manifestations of CF in children include chronic cough, recurrent pulmonary infections, failure to thrive, poor growth and weight gain, recurrent sinusitis, nasal polyposis, steatorrhea, recurrent pancreatitis, and rectal prolapse.
- Common pathogens in CF sputum are *Staphylococcus aureus* and *Pseudomonas aeruginosa*.
- Sweat chloride testing is the diagnostic test of choice and confirms diagnosis with newborn screening, genetic testing, and clinical symptoms.
- Management of CF includes enhancing airway clearance, medications to decrease mucus viscosity, treating airway infections, and improving nutritional status with pancreatic enzyme replacement therapy and nutritional supplements.
- Newer therapies are genotype specific and improve the function of CFTR protein for many individuals with CF.

CHAPTER 138

Chest Wall and Pleura

- Severe thoracic scoliosis can lead to chest wall deformity that limits lung volumes and causes restrictive lung disease.
- Pectus excavatum (sternal concavity) and pectus carinatum (sternal extrusion) are common chest wall deformities that are typically not associated with significant pulmonary compromise.
- Pneumothorax is an accumulation of air in the pleural space that can occur spontaneously from leakage of air from the lung or airways.
- Pleural effusions can be transudative (e.g., heart failure) or exudative (e.g., infection/empyema).
- Parapneumonic effusion in children is commonly associated with infection from *Streptococcus pneumoniae*, group A streptococci, or *Staphylococcus aureus*.

THE CARDIOVASCULAR SYSTEM

Daniel S. Schneider

CHAPTER 139

Cardiovascular System Assessment

HISTORY

A **maternal history** of medication, drug or alcohol use, or excessive smoking may contribute to cardiac and other systemic findings. The **prenatal history** may reveal a maternal infection early in pregnancy (possibly teratogenic) or later in pregnancy (causing myocarditis or myocardial dysfunction in infants). Infants with heart failure exhibit poor **growth**, with weight being more significantly affected than height and head circumference.

Heart failure may present with fussiness, **fatigue**, or **diaphoresis** with feeds. **Tachypnea** without significant dyspnea may be present. Older children with heart failure may have easy fatigability, **shortness of breath** on exertion, and, sometimes, orthopnea. Not keeping up with other children during play or exercise is a sign of **exercise intolerance**. Heart failure may be misdiagnosed as recurrent pneumonia, bronchitis, wheezing, or asthma.

A history of a **heart murmur** is important, but many well children have a normal or innocent murmur at some time in their lives. Other cardiac symptoms include cyanosis, palpitations, chest pain, syncope, and near-syncope. A review of systems assesses for possible systemic diseases or congenital malformation syndromes that may cause cardiac abnormalities (Tables 139.1 and 139.2). Current and past medication use as well as history of drug use is important. **Family history** should be reviewed for hereditary diseases, early atherosclerotic heart disease, congenital heart disease, sudden unexplained deaths, thrombophilia, rheumatic fever, hypertension, and hypercholesterolemia.

PHYSICAL EXAMINATION

A complete cardiovascular examination starts in the supine position and includes evaluation in sitting and standing positions, when possible. **Inspection** is supplemented by **palpation** and **auscultation** to provide a complete examination.

The examination starts with vital signs. The normal **heart rate** varies with age and activity. Newborn resting heart rates are approximately 120 beats per minute, slightly higher in infants 3–6 months of age, and then gradually declining through adolescence to near 80 beats per minute. The range

of normal for any given age is approximately 30 beats per minute above or below the average. Tachycardia may be a manifestation of anemia, dehydration, shock, heart failure, or dysrhythmia. Bradycardia can be a normal finding in patients with high vagal tone (athletes) but may be a manifestation of atrioventricular block. The **respiratory rate** of infants is best assessed while the infant is quiet. Respiratory rate may be increased when there is a left-to-right shunt or pulmonary venous congestion.

Normal **blood pressure** also varies with age. A properly sized cuff should have a bladder width that is at least 40% and a length that is 80–100% of the arm circumference. Initially, blood pressure in the right arm is measured. If elevated, measurements in the left arm and legs are indicated to evaluate for possible coarctation of the aorta. The **pulse pressure** is determined by subtracting the diastolic pressure from the systolic pressure. It is normally below 50 mm Hg or half the systolic pressure, whichever is less. A wide pulse pressure may be seen with aortopulmonary connections (patent ductus arteriosus [PDA], truncus arteriosus, arteriovenous malformations), aortic insufficiency, or relative intravascular volume depletion (anemia, vasodilation with fever or sepsis). A narrow pulse pressure is seen with pericardial tamponade, aortic stenosis, and heart failure.

Inspection includes general appearance, nutritional status, circulation, and respiratory effort. Many chromosomal abnormalities and syndromes associated with cardiac defects have dysmorphic features or failure to thrive (see Table 139.2). Skin color must be assessed for **cyanosis** and pallor. Central cyanosis (tongue, lips) is associated with arterial desaturation; isolated peripheral cyanosis (hands, feet) is associated with normal arterial saturation and increased peripheral extraction of oxygen. Perioral cyanosis is a common finding, especially in pale infants or when infants and toddlers become cold. Chronic arterial desaturation results in **clubbing** of the fingernails and toenails. Inspection of the chest may reveal asymmetry or a prominent left precordium, suggesting chronic cardiac enlargement.

After inspection, **palpation** of pulses in all four extremities, the precordial activity, and the abdomen is performed. Pulses are assessed for rate, regularity, intensity, symmetry, and timing between upper and lower extremities. A good pedal pulse with normal right arm blood pressure effectively rules out coarctation of the aorta. The precordium should be assessed for apical impulse, **point of maximum impulse**, hyperactivity, and presence of a **thrill**. Abdominal palpation assesses liver and spleen size. The liver size provides an assessment of intravascular volume and is enlarged with systemic venous congestion. The spleen may be enlarged with infective endocarditis.

SYSTEMIC DISEASE	CARDIAC COMPLICATIONS
Hunter-Hurler syndrome	Valvular insufficiency, heart failure, hypertension
Duchenne dystrophy	Cardiomyopathy, heart failure
Pompe disease	Short PR interval, cardiomegaly, heart failure, arrhythmias
Kawasaki disease	Coronary artery aneurysm, thrombosis, myocardial infarction, myocarditis
Marfan syndrome	Aortic and mitral insufficiency, dissecting aortic aneurysm
Juvenile rheumatoid arthritis	Pericarditis
Systemic lupus erythematosus	Pericarditis, Libman-Sacks endocarditis, congenital AV block
Lyme disease	Arrhythmias, myocarditis, heart failure
Graves disease (hyperthyroidism)	Tachycardia, arrhythmias, heart failure
Tuberous sclerosis	Cardiac rhabdomyoma
Neurofibromatosis	Pulmonic stenosis, coarctation of aorta

AV, Atrioventricular.

Auscultation is the most important part of the cardiovascular examination but should supplement what already has been found by inspection and palpation. Systematic listening in a quiet room allows assessment of each portion of the cardiac cycle. In addition to heart rate and regularity, the heart sounds, clicks, and murmurs need to be timed and characterized.

Heart Sounds

S₁ is associated with closure of the mitral and tricuspid valves, is usually single, and is best heard at the lower left sternal border (LLSB) or apex (Fig. 139.1). Although it can normally be split, if a split **S₁** is heard, the possibility of an ejection click or, much less commonly, an **S₄** should be considered. **S₂** is associated with closure of the aortic and pulmonary valves. It should normally be split with inspiration and be single with exhalation. Abnormalities of splitting and intensity of the pulmonary component are associated with significant anatomic and physiologic abnormalities (Table 139.3). **S₃** is heard in early diastole and is related to rapid ventricular filling. It is best heard at the LLSB or apex and may be a normal sound, but a loud **S₃** is abnormal and heard in conditions with dilated ventricles. **S₄** occurs late in diastole just before **S₁**; it is best heard at the LLSB/apex and is associated with decreased ventricular compliance. It is rare and is always abnormal.

Clicks

A click implies a valvular abnormality or dilated great artery. It may be ejection or midsystolic in timing and may or may not be associated with a murmur. A midsystolic click is associated with mitral valve prolapse. **Ejection clicks** occur early in systole. Pulmonary ejection clicks are best heard at the left upper sternal border and vary in intensity with respiration. Aortic

SYNDROME	CARDIAC FEATURES
Trisomy 21 (Down syndrome)	Endocardial cushion defect, VSD, ASD, PDA
Trisomy 18	VSD, ASD, PDA, PS
Trisomy 13	VSD, ASD, PDA, dextrocardia
XO (Turner syndrome)	Coarctation of aorta, aortic stenosis
CHARGE association (coloboma, heart, atresia choanae, retardation, genital and ear anomalies)	TOF, aortic arch and conotruncal anomalies*
22q11 (DiGeorge) syndrome	Aortic arch anomalies, conotruncal anomalies*
VACTERL association [†] (vertebral, anal, cardiac, tracheoesophageal, radial, renal, limb anomalies)	VSD
Marfan syndrome	Dilated and dissecting aorta, aortic valve regurgitation, mitral valve prolapse
William syndrome	Supravalvular aortic stenosis, peripheral pulmonary stenosis
Infant of diabetic mother	Hypertrophic cardiomyopathy, VSD, conotruncal anomalies
Asplenia syndrome	Complex cyanotic heart lesions, anomalous pulmonary venous return, dextrocardia, single ventricle, single AV valve
Polysplenia syndrome	Azygos continuation of inferior vena cava, pulmonary atresia, dextrocardia, single ventricle
Fetal alcohol syndrome	VSD, ASD
Fetal hydantoin syndrome	TGA, VSD, TOF

*Conotruncal—tetralogy of Fallot, pulmonary atresia, truncus arteriosus, transposition of great arteries.

[†]VACTERL association is also known as VATER association, in which the limb anomalies are not included.

ASD, Atrial septal defect; AV, atrioventricular; PDA, patent ductus arteriosus; PS, pulmonic stenosis; TGA, transposition of great arteries; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

clicks are often louder at the apex, left midsternal border, or right upper sternal border and do not vary with respiration.

Murmurs

Murmur evaluation should determine timing, duration, location, intensity, radiation, and frequency or pitch of the murmur. The timing determines a murmur's significance and can be used to develop a differential diagnosis (see Fig. 139.1). Murmurs should be classified as **systolic**, **diastolic**, or **continuous**. Most murmurs are systolic and can be divided further into systolic ejection murmurs or holosystolic (also called pansystolic or regurgitant) murmurs. **Ejection murmurs** are crescendo-decrescendo with a short time between **S₁** and the onset of the murmur (isovolumic contraction). Systolic

FIGURE 139.1 Timing of heart murmurs. AV, Atrioventricular.

TABLE 139.3 Abnormal Second Heart Sound	
SINGLE S_2	
Pulmonary hypertension (severe) One semilunar valve (aortic atresia, pulmonary atresia, truncus arteriosus) Malposed great arteries (d-TGA, l-TGA) Severe aortic stenosis	
WIDELY SPLIT S_2	
Increased flow across valve (ASD, PAPVR) Prolonged flow across valve (pulmonary stenosis) Electrical delay (right bundle branch block) Early aortic closure (severe mitral regurgitation)	
PARADOXICALLY SPLIT S_2	
Severe aortic stenosis	
ABNORMAL INTENSITY OF P_2	
Increased in pulmonary hypertension Decreased in severe pulmonary stenosis, tetralogy of Fallot	

ASD, Atrial septal defect; d-TGA, dextro-transposition of the great arteries; l-TGA, levo-transposition of the great arteries; PAPVR, partial anomalous pulmonary venous return.

ejection murmurs require the ejection of blood from the ventricle and may occur with aortic stenosis, pulmonary stenosis, atrial septal defects (ASDs), and coarctation of the aorta. **Holosystolic murmurs** have their onset with S_1 . The murmur has a plateau quality and may be heard with ventricular septal defects (VSDs) and mitral or tricuspid regurgitation. A *late regurgitant* murmur may be heard after a midsystolic click in mitral valve prolapse.

TABLE 139.4 Heart Murmur Intensity	
GRADE	DESCRIPTION
Grade I	Very soft, heard in quiet room with cooperative patient
Grade II	Easily heard but not loud
Grade III	Loud but no thrill
Grade IV	Loud with palpable thrill
Grade V	Loud with thrill, audible with stethoscope at 45-degree angle
Grade VI	Loud with thrill, audible with stethoscope off chest 1 cm

Murmurs are often heard along the path of blood flow. Ejection murmurs usually are best heard at the base of the heart, whereas holosystolic murmurs are louder at the LLSB and apex. Pulmonary ejection murmurs radiate to the back and axilla. Aortic ejection murmurs radiate to the neck. The **intensity** or loudness of a heart murmur is assessed as grade I through VI (Table 139.4). The **frequency** or pitch of a murmur provides information regarding the pressure gradient. The higher the pressure gradient across a narrowed area (valve, vessel, or defect), the faster the flow and higher the frequency of the murmur. Low-frequency murmurs imply low-pressure gradients and mild obstruction or less restriction to flow.

Diastolic murmurs are much less common than systolic murmurs and should be considered abnormal. Early diastolic murmurs occur when there is regurgitation through the aortic

or pulmonary valve. Mid-diastolic murmurs are caused by increased flow (ASD, VSD) or anatomic stenosis across the mitral or tricuspid valves.

Continuous murmurs are heard when there is flow through the entire cardiac cycle and are abnormal with one common exception, the **venous hum**. A PDA is the most common abnormal continuous murmur. Continuous murmurs can also be heard with coarctation of the aorta when collateral vessels are present.

Normal or **innocent murmurs** are common, occurring in at least 80% of normal infants and children and are heard most often during the first 6 months of life, from 3–6 years of age, and in early adolescence. They have also been called benign, functional, vibratory, and flow murmurs. Characteristic findings of innocent murmurs include the quality of the sound, a lack of significant radiation, and a significant alteration in the intensity of the murmur with positional changes (Table 139.5). Most important, the cardiovascular history and examination are otherwise normal. The presence of symptoms, including failure to thrive or dysmorphic features, should make one more cautious about diagnosing a *normal* murmur. Diastolic, holosystolic, late systolic, and continuous (except for the venous hum) murmurs and the presence of a thrill are not normal.

MURMUR	CLINICAL FEATURES	USUAL AGE WHEN HEARD
Still murmur/ vibratory murmur	Systolic ejection murmur LLSB or between LLSB and apex Grades I–III/VI Vibratory, musical quality Intensity decreases in upright position	3–6 yr
Venous hum	Continuous murmur Infraclavicular region (right > left) Grades I–III/VI Louder with patient in upright position Changes with compression of jugular vein or turning head	3–6 yr
Carotid bruit	Systolic ejection murmur Neck, over carotid artery Grade I–III/VI	Any age
Adolescent ejection murmur	Systolic ejection murmur LUSB Grade I–III/VI Usually softer in upright position Does not radiate to back	8–14 yr
Normal peripheral pulmonary stenosis murmur	Systolic ejection murmur Axilla and back, LUSB/ RUSB Grade I–III/VI Harsh, short, high frequency	Newborn–6 mo

LLSB, Left lower scapular border; LUSB, left upper scapular border; RUSB, right upper scapular border.

LABORATORY AND IMAGING TESTS

Pulse Oximetry

Mild desaturation that is not clinically apparent may be the only early finding in complex congenital heart defects. Measurement of pulse oximetry in the right arm and a lower extremity may allow diagnosis of complex congenital heart disease including a ductal-dependent lesion in which desaturated blood flows right to left across a PDA to perfuse the lower body. By improving early diagnosis and management, the now routine pulse oximetry screening of newborns prior to discharge has resulted in decreased morbidity and mortality from critical congenital heart disease.

Electrocardiography

The 12-lead electrocardiogram (ECG) provides information about the **rate**, **rhythm**, **depolarization**, and **repolarization** of the cardiac cells and the size and wall thickness of the chambers. It should be assessed for rate, rhythm, axis (P wave, QRS, and T wave), intervals (PR, QRS, QTc) (Fig. 139.2), and voltages (left atrial, right atrial, left ventricular, right ventricular) adjusted for the child's age.

The **P wave** represents atrial depolarization. A criterion for right atrial enlargement is an increase of the amplitude of the P wave, reflected best in lead II. The diagnosis of left atrial enlargement is made by prolongation of the second portion of the P wave, exhibited best in the chest leads.

The **PR interval**, measured from the beginning of the P wave to the beginning of the QRS complex, increases with age. Conduction time is shortened when the conduction velocity is increased (glycogen storage disease) or when the atrioventricular node is bypassed (Wolff-Parkinson-White syndrome). A prolonged PR interval usually indicates slow conduction through the atrioventricular node. Diseases in the atrial myocardium, the bundle of His, or the Purkinje system may also contribute to prolonged PR intervals.

The **QRS complex** represents ventricular depolarization. A greater ventricular volume or mass causes a greater magnitude of the complex. The proximity of the right ventricle to the chest surface accentuates that ventricle's contribution to the complex. Changes in the normal ECG occur with age. Normative data for each age group must be known to make a diagnosis from the ECG.

FIGURE 139.2 Nomenclature of electrocardiogram waves and intervals.

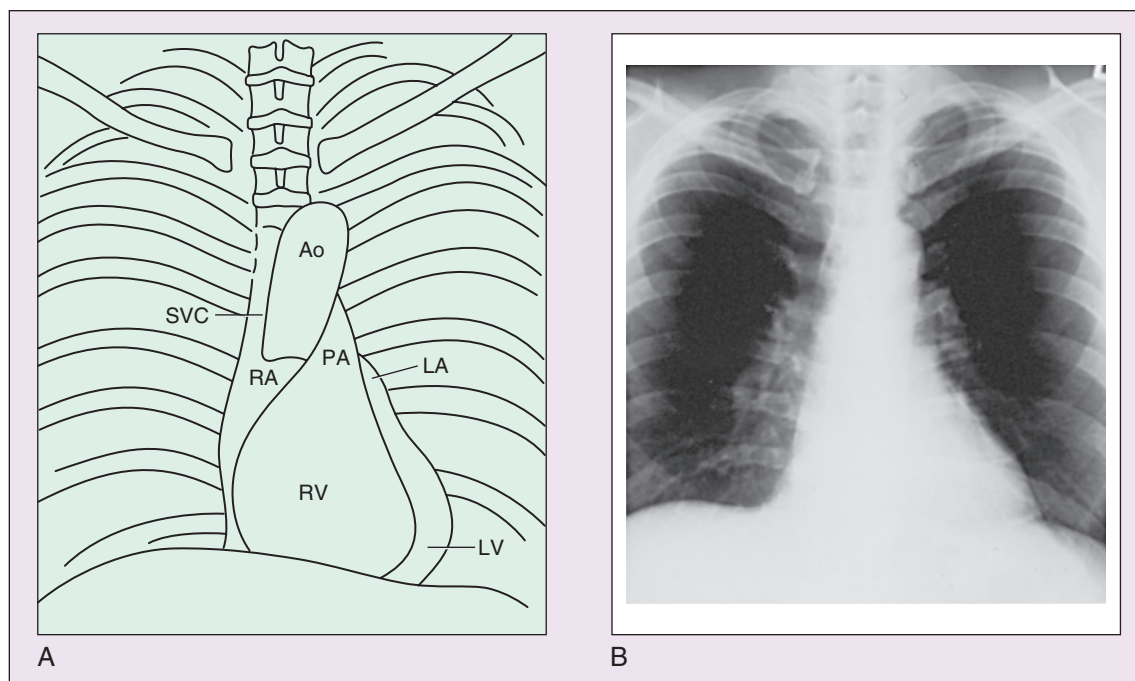

FIGURE 139.3 (A) Parts of the heart whose outlines can be identified on a routine chest x-ray. (B) Routine posteroanterior x-ray of the normal cardiac silhouette. Ao, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (From Andreoli TE, Carpenter CCJ, Plum F, et al., eds. *Cecil Essentials of Medicine*. 2nd ed. Philadelphia: WB Saunders; 1990.)

The **QT interval** is measured from the beginning of the QRS complex to the end of the T wave. The corrected QT interval (corrected for rate) should be less than 0.45 second ($QTc = QT \sqrt{\text{preceding R to R interval}}$). The interval may be prolonged in children with hypocalcemia or severe hypokalemia. It is also prolonged in a group of children at risk for severe ventricular arrhythmias and sudden death (**prolonged QT syndrome**). Drugs such as quinidine and erythromycin may prolong the QT interval.

Chest Radiography

A systematic approach to reading a chest radiograph includes assessment of extracardiac structures, the shape and size of the heart, and the size and position of the pulmonary artery and aorta (Fig. 139.3). Assessment of the location and size of the heart and **cardiac silhouette** may suggest a cardiac defect. On a good inspiratory film, the cardiothoracic ratio should be less than 55% in infants under 1 year of age and less than 50% in older children and adolescents. An enlarged heart may be due to an increased volume load (left-right shunt) or due to myocardial dysfunction (dilated cardiomyopathy). The shape of the heart may suggest specific congenital heart defects. The most common examples are the *boot-shaped* heart seen with tetralogy of Fallot, the *egg-on-a-string* seen with dextroposed transposition of the great arteries, and the “snowman” seen with supracardiac total anomalous pulmonary venous return. The chest x-ray can aid in the assessment of **pulmonary blood flow**. Defects associated with left-to-right shunting have increased pulmonary blood flow (*shunt vascularity*) on x-ray. Right-to-left shunts have decreased pulmonary blood flow.

Echocardiography

Echocardiography has become the most important noninvasive tool in the diagnosis and management of cardiac disease,

FIGURE 139.4 Four-chamber echocardiogram of an atrial septal defect. The defect margins are identified by the two arrows. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

providing a full anatomic evaluation in most congenital heart defects (Fig. 139.4). Physiologic data on the direction of blood flow can be obtained with the use of pulsed, continuous wave, and color flow Doppler. Imaging from multiple views provides an assessment of spatial relationships. Three-dimensional (3D) and four-dimensional (4D) imaging now allows reconstruction

of the heart and manipulation of the images to provide more detail, especially with regard to valve structure and function. Prenatal or fetal echocardiography can diagnose congenital heart disease by 18 weeks of gestation and allows for delivery of the infant at a tertiary care hospital, improving the timeliness of therapy. Many congenital heart defects now are surgically repaired based on the echocardiogram without need for cardiac catheterization.

Transesophageal echocardiography (TEE) provides better imaging when transthoracic imaging is inadequate. It is used intraoperatively to assess results and cardiac function after surgery. TEE and intracardiac echocardiography are used to guide interventional catheterization and radiofrequency ablation of dysrhythmias.

Cardiac Catheterization

Cardiac catheterization is performed in patients who need additional anatomic information or precise hemodynamic information before operating or establishing a management plan. Pressures, oxygen saturations, and oxygen content are measured in each chamber and blood vessel entered (Fig. 139.5). This information is used to calculate systemic and pulmonary blood flow and resistance. Angiography is performed by injecting contrast material into selected sites to define anatomy and supplement noninvasive information. An increasing percentage of cardiac catheterizations are done to perform an intervention, including balloon dilation of stenotic valves and vessels, ballooning and stenting of stenotic lesions, closure of collateral vessels by coil embolization, and device closure of PDAs, secundum ASDs, patent foramen ovales, and muscular VSDs. Catheterization with electrophysiologic studies allows for precise mapping of the electrical activity, can assess the risk of abnormal heart rhythms, and, often, is done in anticipation of radiofrequency ablation of the site of a dysrhythmia.

FIGURE 139.5 The normal heart. Circled values are oxygen saturations. Ao, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Cardiac Computed Tomography/Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are often used to provide additional structural and functional information in congenital and acquired heart disease. They are especially helpful in providing 3D anatomy and when visualizing extracardiac structures (aortic arch, pulmonary artery and vein anatomy and relationships). While CT can often be performed without sedation, MRI frequently requires sedation; both imaging modalities have strengths and weaknesses regarding the information provided.

PEARLS FOR PRACTITIONERS

See *The Cardiovascular System: Pearls for Practitioners* at the end of this section.

CHAPTER 140

Syncope

ETIOLOGY

Syncopal events are characterized by a transient loss of consciousness and muscle tone that, by history, does not suggest other altered states of consciousness. Presyncope or near-syncope has many or all of the prodromal symptoms without loss of consciousness. Syncopal events are relatively common (Table 140.1) and are most commonly due to autonomic dysfunction. The frequency of episodes, amount of stress, and functional impairment caused by syncopal events vary. Most syncopal events are relatively benign but can represent a serious cardiac condition that may lead to death (see Table 140.1). The differential diagnosis for typical syncopal events includes seizure, metabolic cause (hypoglycemia), hyperventilation, atypical migraine, and breath holding.

CLINICAL MANIFESTATIONS

Typical syncopal events usually occur in the upright position or are related to changing position. Syncopal events may be associated with anxiety, pain, blood drawing or the sight of blood, fasting, a hot environment, or crowded places. The patient often appears pale. A prodrome, consisting of dizziness, lightheadedness, nausea, diaphoresis, visual changes (blacking out), or possibly palpitations, warns the patient and often prevents injury. Unconsciousness lasts for less than 1 minute. A return to normal consciousness occurs relatively quickly. Most of these syncopal episodes are vasovagal or neurocardiogenic in origin. The physical examination is normal.

DIAGNOSTIC STUDIES

Syncopal episodes may require no more than reassurance to the patient and family. If the episodes have a significant impact on daily activities, further evaluation may be indicated. An electrocardiogram (ECG) should be obtained with attention to the QTc and PR intervals (see Chapter 139). Although reassurance and increasing fluid and salt intake may be adequate to treat most cases of syncopal events, medical management is sometimes indicated.

TABLE 140.1 Syncope and Dizziness: Etiology

DIAGNOSIS	HISTORY	SIGNS/ SYMPTOMS	DESCRIPTION	HEART RATE/BLOOD PRESSURE	DURATION	POSTSYNCOPE	RECURRENCE
Neurocardiogenic (vasodepressor)	At rest	Pallor, nausea, visual changes	Brief ± convulsion	↓/↓	<1 min	Residual pallor, sweaty, hot; recurs if child stands	Common
OTHER VAGAL							
Micturition	Postvoiding	Pallor, nausea	Brief; convulsions rare	↓/↓	<1 min		(+)
Hair grooming	Standing getting hair done or ears touched	Pallor, nausea, visual changes, lightheaded	Brief		<1 min	Residual pallor, sweaty, hot, can recur if stands too soon	(+)
Cough (deglutition)	Paroxysmal cough	Cough	Abrupt onset	May not change	<5 min	Fatigue or baseline	(+)
Carotid sinus	Tight collar, turned head	Vague, visual changes	Sudden onset, pallor	Usually ↓/↓	<5 min	Fatigue or baseline	(+)
CARDIAC SYNCOPE							
LVOT obstruction	Exercise	±Chest pain, SOB	Abrupt during or after exertion, pallor	↑/↓	Any duration	Fatigue, residual pallor, and sweating	(+)
Pulmonary hypertension	Any time, especially exercise	SOB	Cyanosis and pallor	↑/↓	Any duration	Fatigue, residual cyanosis	(+)
Myocarditis	Post-viral infection exercise	SOB, chest pain, palpitations	Pallor	↑/↓	Any duration	Fatigue	(+)
Tumor or mass	Recumbent, paroxysmal	SOB±chest pain	Pallor	↑/↓	Any duration	Baseline	(+)
Coronary artery disease	Exercise	SOB±chest pain	Pallor	↑/↓	Any duration	Fatigue, chest pain	(+)
Dysrhythmia	Any time	Palpitations± chest pain	Pallor	↑ or ↑/↓	Usually <10min	Fatigue or baseline	(+)

LVOT, Left ventricular outflow tract; SOB, shortness of breath; ±, with or without; (+), yes but not consistent or predictable.

CHAPTER 141

Chest Pain

ETIOLOGY

Chest pain in the pediatric patient often generates a significant amount of patient and parental concern. Although chest pain is rarely cardiac in origin in children, common knowledge about atherosclerotic heart disease raises concerns about a child experiencing chest pain. Most diagnosable chest pain in

childhood is musculoskeletal in origin. However, a significant amount remains idiopathic. Knowledge of the complete differential diagnosis is necessary to make an accurate assessment (Table 141.1).

CLINICAL MANIFESTATIONS

Assessment of a patient with chest pain includes a thorough history to determine activity at the onset; the location, radiation, quality, and duration of the pain; what makes the pain better and worse during the time that it is present; and any associated symptoms. A family history and assessment of how much anxiety the symptom is causing are important and often revealing. A careful general physical examination should focus on the chest wall, heart, lungs, and abdomen. A history of chest pain associated with exertion, syncope, or palpitations or acute onset associated with fever suggests a cardiac etiology.

TABLE 141.1 Differential Diagnosis of Pediatric Chest Pain

Somatization disorders
Depression

AS, Aortic stenosis; HOCM, hypertrophic obstructive cardiomyopathy; PS, pulmonary stenosis.

Cardiac causes of chest pain are generally ischemic, inflammatory, or arrhythmic in origin.

DIAGNOSTIC STUDIES

Tests rarely are indicated based on the history. A chest x-ray, electrocardiogram (ECG), 24-hour Holter monitoring, echocardiogram, and exercise stress testing may be obtained based on history and examination. Referral to a pediatric cardiologist is based on the history, physical examination findings, family history, and, frequently, the level of anxiety in the patient or family members regarding the pain.

PEARLS FOR PRACTITIONERS

See *The Cardiovascular System: Pearls for Practitioners at the end of this section.*

CHAPTER 142

Dysrhythmias

ETIOLOGY AND DIFFERENTIAL DIAGNOSIS

Cardiac dysrhythmias or abnormal heart rhythms are uncommon in pediatrics but may be caused by infection and inflammation, structural lesions, metabolic abnormalities, and intrinsic conduction abnormalities (Table 142.1). Many pediatric dysrhythmias are normal variants that do not require treatment or even further evaluation.

Sinus rhythm originates in the sinus node and has a normal axis P wave (upright in leads I and aVF) preceding each QRS complex. Because normal rates vary with age, sinus bradycardia and sinus tachycardia are defined based on age. **Sinus arrhythmia** is a common finding in children and represents a normal variation in the heart rate associated with breathing. The heart rate increases with inspiration and decreases with expiration, producing a recurring pattern on the electrocardiogram (ECG) tracing. Sinus arrhythmia is normal and does not require further evaluation or treatment.

TABLE 142.1 Etiology of Dysrhythmias

DRUGS
Intoxication (cocaine, tricyclic antidepressants, and others) Antiarrhythmic agents (proarrhythmic agents [quinidine]) Sympathomimetic agents (caffeine, theophylline, ephedrine, and others) Digoxin
INFECTION AND POSTINFECTION
Myocarditis Lyme disease Endocarditis Diphtheria Guillain-Barré syndrome Rheumatic fever
METABOLIC-ENDOCRINE
Electrolyte disturbances ($\downarrow K^+$, $\downarrow Ca^{2+}$, $\downarrow Mg^{2+}$) Cardiomyopathy Thyrotoxicosis Uremia Pheochromocytoma Porphyria Mitochondrial myopathies
STRUCTURAL LESIONS
Congenital heart defects Ventricular tumor Ventriculotomy Arrhythmogenic right ventricle (dysplasia)
OTHER CAUSES
Adrenergic-induced Prolonged QT interval Maternal systemic lupus erythematosus Idiopathic Central venous catheter

Atrial Dysrhythmias

A **wandering atrial pacemaker** is a change in the morphology of the P waves with variable PR interval and normal QRS complex. This is a benign finding, requiring no further evaluation or treatment.

Premature atrial contractions are relatively common prenatally and in infants. A premature P wave, usually with an abnormal axis consistent with its ectopic origin, is present. The premature atrial activity may be blocked (no QRS following it), conducted normally (normal QRS present), or conducted aberrantly (a widened, altered QRS complex). Premature atrial contractions are usually benign and, if present around the time of delivery, usually disappear during the first few weeks of life.

Atrial flutter and **atrial fibrillation** are uncommon dysrhythmias in pediatrics and usually present after surgical repair of complex congenital heart disease. They may also be seen in patients with myocarditis or in association with drug toxicity.

Supraventricular tachycardia (SVT) is the most common symptomatic dysrhythmia in pediatric patients. The rhythm has a rapid, regular rate with a narrow QRS complex. SVT in infants is often 280–300 beats per minute with slower rates for older children and adolescents. The tachycardia has an abrupt onset and termination. In a child with a structurally normal heart, most episodes are relatively asymptomatic other than a pounding heartbeat. If there is structural heart disease or

the episode is prolonged (>12 hours), there may be an alteration in the cardiac output and development of symptoms of heart failure. Although most patients with SVT have structurally normal hearts and normal baseline ECGs, some children have Wolff-Parkinson-White syndrome or preexcitation as the cause of the dysrhythmia.

Ventricular Dysrhythmias

Premature ventricular contractions (PVCs) are less common than premature atrial contractions in infancy but more common in older children and adolescents (Table 142.2). The premature beat is not preceded by a P wave, and the QRS complex is wide and bizarre. If the heart is structurally normal, and the PVCs are singleton, uniform in focus, and disappear with increased heart rate, they are usually benign and require no treatment. Any deviation from the presentation (history of syncope or a family history of sudden death) requires further investigation and possibly treatment with antiarrhythmic medications.

Ventricular tachycardia, defined as three or more consecutive PVCs, is also relatively rare in pediatric patients. Although there are multiple causes of ventricular tachycardia, it usually is a sign of serious cardiac dysfunction or disease. Rapid-rate ventricular tachycardia results in decreased cardiac output and cardiovascular instability. Treatment in

TABLE 142.2 Dysrhythmias in Children

TYPE	ELECTROCARDIOGRAM CHARACTERISTICS	TREATMENT
Supraventricular tachycardia	Rate usually >220 beats/min (range, 180–320 beats/min); abnormal atrial rate for age; P waves may be present and are related to QRS complex; normal, narrow QRS complexes unless aberrant conduction is present	Increase vagal tone (bag of ice water to face, Valsalva maneuver), adenosine, digoxin, sotalol, electrical cardioversion if acutely ill, catheter ablation
Atrial flutter	Atrial rate usually 300 beats/min, with varying degrees of block; sawtooth flutter waves	Digoxin, sotalol, cardioversion
Premature ventricular contraction	Premature, wide, unusually shaped QRS complex, with large inverted T wave	None if normal heart and if premature ventricular contractions disappear on exercise; lidocaine, procainamide
Ventricular tachycardia	>3 premature ventricular beats; AV dissociation; fusion beats, blocked retrograde AV conduction; sustained if >30sec; rate 120–240 beats/min	Lidocaine, amiodarone, procainamide, propranolol, cardioversion
Ventricular fibrillation	No distinct QRS complex or T waves; irregular undulations with varied amplitude and contour, no conducted pulse	Nonsynchronized cardioversion
Complete heart block	Atria and ventricles have independent pacemakers; AV dissociation; escape-pacemaker is at atrioventricular junction if congenital	Awake rate <55 beats/min in neonate or <40 beats/min in adolescent, or hemodynamic instability requires permanent pacemaker
First-degree heart block	Prolonged PR interval for age	Observe, obtain digoxin level if on therapy
Mobitz type I (Wenckebach) second-degree heart block	Progressive lengthening of PR interval until P wave is not followed by conducted QRS complex	Observe, correct underlying electrolyte or other abnormalities
Mobitz type II second-degree heart block	Sudden nonconduction of P wave with loss of QRS complex without progressive PR interval lengthening	Consider pacemaker
Sinus tachycardia	Rate <240 beats/min	Treat cause (fever), remove sympathomimetic drugs

AV, Atrioventricular.

TABLE 142.3 Classification of Drugs for Antiarrhythmia

CLASS	ACTION	EXAMPLE(S)
I	Depression of phase of depolarization (velocity of upstroke of action potential); sodium channel blockade	
Ia	Prolongation of QRS complex and QT interval	Quinidine, procainamide, disopyramide
Ib	Significant effect on abnormal conduction	Lidocaine, mexiletine, phenytoin, tocainide
Ic	Prolongation of QRS complex and PR interval	Flecainide, propafenone, moricizine?
II	β blockade; slowing of sinus rate; prolongation of PR interval	Propranolol, atenolol, acebutolol
III	Prolongation of action potential; prolongation of PR, QT intervals, QRS complex; sodium and calcium channel blockade	Bretylium, amiodarone, sotalol
IV	Calcium channel blockade; reduction in sinus and AV node pacemaker activity and conduction; prolongation of PR interval	Verapamil and other calcium channel blocking agents

AV, Atrioventricular.

symptomatic patients is synchronized cardioversion. Medical management with lidocaine or amiodarone may be appropriate in a conscious asymptomatic patient. Complete evaluation of the etiologic picture is necessary, including electrophysiologic study.

Heart Block

First-degree heart block is the presence of a prolonged PR interval. It is asymptomatic and, when present in otherwise normal children, requires no evaluation or treatment. **Second-degree heart block** is when some, but not all, of the P waves are followed by a QRS complex. Mobitz type I (also known as Wenckebach) is characterized by a progressive prolongation of the PR interval until a QRS complex is dropped. It is often seen during sleep, usually does not progress to other forms of heart block, and does not require further evaluation or treatment in otherwise normal children. Mobitz type II is present when the PR interval does not change, but a QRS is intermittently dropped. This form may progress to complete heart block and may require pacemaker placement. **Third-degree heart block**, whether congenital or acquired, is present when there is no relationship between atrial and ventricular activity. The ventricular rate is much slower than the atrial rate. **Congenital complete heart block** is associated with maternal collagen vascular disease (such as systemic lupus erythematosus or Sjögren syndrome) or congenital heart disease. The acquired form most often occurs after cardiac surgery but may be secondary to infection, inflammation, or drugs.

TREATMENT

Most atrial dysrhythmias require no intervention. Treatment of SVT depends on presentation and symptoms. Acute treatment of SVT in infants usually consists of **vagal maneuvers**, such as the application of cold (ice bag) to the face. Intravenous (IV) **adenosine** usually converts the dysrhythmia because the atrioventricular node forms a part of the re-entry circuit in most patients with SVT. In patients with cardiovascular compromise at the time of presentation, **synchronized cardioversion** is indicated using 1–2 J/kg. In patients with palpitations, it is important to document heart rate and rhythm during their symptoms before considering therapeutic options. The frequency, length, and associated symptoms during the episodes,

as well as what is required to convert the rhythm, determine the need for ongoing treatment. Some patients require only education regarding the dysrhythmia and follow-up. Ongoing pharmacologic management with a β blocker is usually the first choice when treatment is needed. Some practitioners still use digoxin for management of SVT, but it is contraindicated in patients with Wolff-Parkinson-White syndrome. Additional antiarrhythmic medications are sometimes needed depending on the mechanism of the SVT. In patients who are symptomatic or for those not wanting to take daily medications, **radiofrequency ablation** may be performed.

A variety of antiarrhythmic agents are used to treat ventricular dysrhythmias that require intervention (Table 142.3). Management of third-degree heart block depends on the ventricular rate and presence of symptoms. Treatment, if needed, often requires placement of a pacemaker.

PEARLS FOR PRACTITIONERS

See *The Cardiovascular System: Pearls for Practitioners* at the end of this section.

CHAPTER 143

Acyanotic Congenital Heart Disease

ETIOLOGY AND EPIDEMIOLOGY

Congenital heart disease (CHD) is the most common congenital disorder in newborns and occurs in 8 per 1,000 births. Of newborns born with CHD, 25% have critical CHD requiring surgical or catheter-based intervention in the first year of life. The spectrum of lesions ranges from asymptomatic to fatal. Although most cases of CHD are multifactorial, some lesions are associated with chromosomal disorders, single gene defects, teratogens, or maternal metabolic disease (see [Table 139.2](#)).

CHDs can be divided into three pathophysiologic groups ([Table 143.1](#)):

1. Left-to-right shunts
2. Right-to-left shunts
3. Obstructive, stenotic lesions

TABLE 143.1 Classification of Congenital Cardiac Defects

STENOTIC	SHUNTING		MIXING
	RIGHT→LEFT	LEFT→RIGHT	
Aortic stenosis	Tetralogy	Patent ductus arteriosus	Truncus
Pulmonary stenosis	Transposition	Ventricular septal defect	TAPVR
Coarctation of the aorta	Tricuspid atresia	Atrial septal defect	HLH

HLH, Hypoplastic left heart syndrome; TAPVR, total anomalous pulmonary venous return.

FIGURE 143.1 Ventricular septal defect. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Acyanotic CHD includes left-to-right shunts resulting in an increase in pulmonary blood flow (patent ductus arteriosus [PDA], ventricular septal defect [VSD], atrial septal defect [ASD]), and obstructive lesions (aortic stenosis, pulmonary stenosis, coarctation of the aorta), which usually have normal pulmonary blood flow.

VENTRICULAR SEPTAL DEFECT

Etiology and Epidemiology

The ventricular septum is a complex structure that can be divided into four components. The largest component is the **muscular septum**. The inlet or posterior septum comprises **endocardial cushion tissue**. The subarterial or **supracristal septum** comprises conotruncal tissue. The **membranous septum** is below the aortic valve and is relatively small. VSDs occur when any of these components fails to develop normally (Fig. 143.1). VSD, the most common congenital heart defect, accounts for 25% of all congenital heart disease. **Perimembranous VSDs** are the most common of all VSDs (67%).

Although the location of the VSD is important prognostically and in approach to repair, the amount of flow crossing a VSD depends on the size of the defect and the pulmonary

vascular resistance. Large VSDs are not symptomatic at birth because the pulmonary vascular resistance is normally elevated at this time. As the pulmonary vascular resistance decreases over the first 6–8 weeks of life, the amount of shunt increases, and symptoms may develop.

Clinical Manifestations

Small VSDs with little shunt are often asymptomatic but have a high-frequency, loud murmur. Moderate to large VSDs result in pulmonary overcirculation and heart failure. The typical physical finding with a VSD is a **pansystolic murmur**, usually heard best at the lower left sternal border. There may be a thrill. Large shunts increase flow across the mitral valve causing a **mid-diastolic murmur** at the apex. The splitting of S_2 and intensity of P_2 depend on the pulmonary artery pressure.

Imaging Studies

Electrocardiogram (ECG) and chest x-ray findings depend on the size of the VSD. Small VSDs usually have normal studies. Larger VSDs cause volume overload to the left side of the heart, resulting in ECG findings of left atrial and ventricular enlargement and hypertrophy. A chest x-ray may reveal cardiomegaly, enlargement of the left ventricle, an increase in the pulmonary artery silhouette, and increased pulmonary blood flow. Pulmonary hypertension due to either increased flow or increased pulmonary vascular resistance may lead to right ventricular enlargement and hypertrophy. Echocardiography provides the location and size of the defect as well as hemodynamic information regarding the magnitude of the shunt (left heart enlargement) and right heart/pulmonary artery pressure (flow velocity across the defect).

Treatment

Approximately one-third of all VSDs close spontaneously. Small VSDs usually close spontaneously and, if they do not close, surgical closure may not be required. Initial treatment for moderate to large VSDs includes **diuretics** with some practitioners using **digoxin** and/or **afterload reduction**. Continued poor growth or pulmonary hypertension despite therapy requires closure of the defect. Most VSDs are closed surgically, but some VSDs, especially muscular defects, can be closed with **devices** placed at cardiac catheterization.

ATRIAL SEPTAL DEFECT

Etiology and Epidemiology

During the embryologic development of the heart, a septum grows toward the endocardial cushions to divide the atria. Failure of septal growth or excessive reabsorption of tissue leads to ASDs (Fig. 143.2). ASDs represent approximately 10% of all congenital heart defects. A secundum defect, with the hole in the region of the foramen ovale, is the most common ASD. A **primum ASD**, located inferiorly in the septum near the crux of the heart, may be part of a complete atrioventricular canal defect or may be present with an intact ventricular septum. The least common ASD is the **sinus venosus defect**, which may be associated with anomalous pulmonary venous return.

FIGURE 143.2 Atrial septal defect. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Clinical Manifestations

The pathophysiology and amount of shunting depend on the size of the defect and the relative compliance of the both ventricles. Even with large ASDs and significant shunts, infants and children are rarely symptomatic. A prominent **right ventricular impulse** at the left lower sternal border (LLSB) often can be palpated. A soft (grade I or II) **systolic ejection murmur** in the region of the right ventricular outflow tract and a **fixed split S₂** (due to overload of the right ventricle with prolonged ejection into the pulmonary circuit) are often audible. A larger shunt may result in a mid-diastolic murmur at the LLSB as a result of the increased volume passing across the tricuspid valve.

Imaging Studies

ECG and chest x-ray findings reflect the **increased blood flow** through the right atrium, right ventricle, pulmonary arteries, and lungs. The ECG may show **right axis deviation** and **right ventricular enlargement**. A chest radiograph may show cardiomegaly, right atrial enlargement, and a prominent pulmonary artery. Echocardiography demonstrates the location and size of the defect as well as the magnitude of the shunt (right heart size).

Treatment

Medical management is rarely indicated. If a significant shunt is still present at around 3 years of age, closure is usually recommended. Many secundum ASDs can be closed with an ASD **closure device** in the catheterization laboratory. Primum and sinus venosus defects require **surgical closure**.

PATENT DUCTUS ARTERIOSUS

Etiology and Epidemiology

The ductus arteriosus allows blood to flow from the pulmonary artery to the aorta during fetal life. Failure of the normal closure of this vessel results in a PDA (Fig. 143.3). With falling pulmonary vascular resistance after birth, left-to-right

FIGURE 143.3 Patent ductus arteriosus. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

shunting of blood and increased pulmonary blood flow occur. Excluding premature infants, PDAs represent approximately 5–10% of congenital heart disease.

Clinical Manifestations

Symptoms depend on the amount of pulmonary blood flow. The magnitude of the shunt depends on the size of the PDA (diameter, length, and tortuosity) and the pulmonary vascular resistance. Small PDAs are asymptomatic; moderate to large shunts can produce the symptoms of heart failure as the pulmonary vascular resistance decreases.

The physical examination findings depend on the size of the shunt. A **widened pulse pressure** is often present as a result of the runoff of blood into the pulmonary circulation during diastole. A **continuous, machine-like murmur** can be heard at the left infraclavicular area, radiating along the pulmonary arteries and often well heard over the left side of the back. Larger shunts with increased flow across the mitral valve may result in a mid-diastolic murmur at the apex and a **hyperdynamic precordium**. Splitting of S₂ and intensity of P₂ depend on the pulmonary artery pressure.

Imaging Studies

ECG and chest x-ray findings are normal with small PDAs. Moderate to large shunts may result in a **full pulmonary artery silhouette** and **increased pulmonary vascularity**. ECG findings vary from normal to evidence of left ventricular hypertrophy. If pulmonary hypertension is present, there is also right ventricular hypertrophy. Echocardiography demonstrates the size and anatomy of the PDA as well as hemodynamic information regarding the magnitude of the shunt (left heart size) and pulmonary artery pressure (flow velocity across the PDA).

Treatment

Spontaneous closure of a PDA after a few weeks of age is uncommon in full-term infants. Moderate and large PDAs

FIGURE 143.4 Atrioventricular canal defects. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

may be managed initially with **diuretics**, but they eventually require closure. Elective closure of small, hemodynamically insignificant PDAs is controversial. Most PDAs can be closed in the catheterization laboratory by either **coil embolization** or a PDA **closure device**.

ENDOCARDIAL CUSHION DEFECT

Etiology and Epidemiology

Endocardial cushion defects, also referred to as **atrioventricular canal defects** or atrioventricular septal defects, may be complete (Fig. 143.4), partial, or transitional. Abnormal development of the endocardial cushion tissue results in failure of the septum to fuse with the endocardial cushion; this results in **abnormal atrioventricular valves** as well. The complete defect results in a primum ASD, a posterior or inlet VSD, and a common atrioventricular valve with anterior and posterior bridging leaflets. Partial and transitional defects have two separate atrioventricular valves, usually with a “cleft” in the anterior leaflet of the left-sided valve. In addition to left-to-right shunting at both levels, there may be **atrioventricular valve insufficiency**.

Clinical Manifestations

The symptoms of heart failure usually develop as the pulmonary vascular resistance decreases over the first 6–8 weeks of life. Symptoms may be earlier and more severe with significant atrioventricular valve insufficiency. Pulmonary hypertension is present due to the increased pulmonary blood flow, and pulmonary vascular obstructive disease may develop early, especially in patients with trisomy 21. The presence of murmurs varies depending on the amount of shunting at both atrial and ventricular levels. If there is a large VSD component, S_2 will be single. Growth is usually poor. This is the most common congenital heart defect in children with trisomy 21.

Imaging Tests

The diagnosis usually is made with echocardiography. A chest radiograph reveals cardiomegaly with enlargement

of all chambers and the presence of **increased vascularity**. An ECG reveals **left axis deviation** and **combined ventricular hypertrophy** and may show combined atrial enlargement.

Treatment

Initial management includes diuretics. Some practitioners use afterload reduction for treatment of heart failure but, ultimately, surgical repair of the defect is required.

PULMONARY STENOSIS

Etiology

Pulmonary stenosis accounts for approximately 10% of all congenital heart disease and can be **valvular**, **subvalvular**, or **supravalvular** in nature. Pulmonary stenosis results from the failure of the development, in early gestation, of the three leaflets of the valve, insufficient resorption of infundibular tissue, or insufficient canalization of the peripheral pulmonary arteries.

Clinical Manifestations

Symptoms depend on the degree of obstruction present. Mild pulmonary stenosis is asymptomatic. Moderate to severe stenosis results in **exertional dyspnea** and easy **fatigability**. Newborns with severe stenosis may be more symptomatic and even cyanotic because of right-to-left shunting at the atrial level.

Pulmonary stenosis causes a systolic ejection murmur at the second left intercostal space, which radiates to the back. A thrill may be present. S_2 may be widely split with a quiet pulmonary component. With more severe pulmonary stenosis, an impulse at the lower left sternal border results from **right ventricular hypertrophy**. Valvular stenosis may result in a **click** that varies with respiration. Worsening stenosis causes an increase in the duration of the murmur and a higher frequency of the sound. The systolic ejection murmurs of **peripheral pulmonary stenosis** are heard distal to the site of obstruction in the pulmonary circulation, including radiation to the axillae and back.

Imaging Tests

ECG and chest x-ray findings are normal in mild stenosis. Moderate to severe stenosis results in **right axis deviation** and **right ventricular hypertrophy**. The heart size is usually normal on chest x-ray, although **dilation of the main pulmonary artery** may be seen. Echocardiography provides assessment of the site of stenosis, degree of hypertrophy, valve morphology, as well as an estimate of the pressure gradient.

Treatment

Valvular pulmonary stenosis usually does not progress, especially if it is mild. **Balloon valvuloplasty** is often successful in reducing the gradient to acceptable levels for more significant or symptomatic stenosis. **Surgical repair** is required if balloon valvuloplasty is unsuccessful or when subvalvular (muscular) stenosis is present.

AORTIC STENOSIS

Etiology and Epidemiology

Valvular, subvalvular, or supravalvular aortic stenosis represents approximately 5% of all congenital heart disease. Lesions result from failure of development of the three leaflets or failure of resorption of tissue around the valve.

Clinical Manifestations

Mild to moderate obstructions cause no symptoms. More severe stenosis results in easy fatigability, exertional chest pain, and syncope. Infants with critical aortic stenosis may present with symptoms of heart failure.

A **systolic ejection murmur** is heard at the right second intercostal space along the sternum and radiating into the neck. The murmur increases in length and becomes higher in frequency as the degree of stenosis increases. With valvular stenosis, a **systolic ejection click** often is heard, and a thrill may be present at the right upper sternal border or in the suprasternal notch. The aortic component of S_2 may be decreased in intensity.

Imaging Studies

ECG and chest x-ray findings are normal with mild degrees of stenosis. **Left ventricular hypertrophy** develops with moderate to severe stenosis and is detected on the ECG and chest x-ray. **Dilation** of the ascending aorta or aortic knob due to an intrinsic aortopathy may be seen on chest radiographs. Echocardiography shows the site of stenosis, valve morphology, and the presence of left ventricular hypertrophy, and it allows an estimate of the pressure gradient.

Treatment

The degree of aortic stenosis frequently progresses with growth and age. Aortic insufficiency often develops or progresses. Serial follow-up with echocardiography is indicated. **Balloon valvuloplasty** is usually the first interventional procedure for significant stenosis. It is not as successful as pulmonary balloon valvuloplasty and has a higher risk of significant valvular insufficiency. **Surgical management** is necessary when balloon valvuloplasty is unsuccessful or significant valve insufficiency develops.

COARCTATION OF THE AORTA

Etiology and Epidemiology

Coarctation of the aorta occurs in approximately 10% of all congenital heart defects. It is almost always **juxtaductal** in position. During development of the aortic arch, the area near the insertion of the ductus arteriosus fails to develop correctly, resulting in a narrowing of the aortic lumen.

Clinical Manifestations

Timing of presentation depends on the severity of obstruction and associated cardiac defects. Infants presenting with coarctation of the aorta frequently have a hypoplastic aortic arch, abnormal aortic valves, and VSDs. They may be dependent on a PDA to provide descending aortic flow and may present with a differential oxygen saturation between the right arm and leg

on newborn screening. Symptoms develop when the aortic ampulla of the ductus closes with classic age of presentation at approximately 2 weeks of age. Less severe obstruction causes no symptoms in infancy.

Symptoms, including poor feeding, respiratory distress, and shock, may develop before 2 weeks of age. Classically, the **femoral pulses** are weaker and delayed compared with the right radial pulse. The blood pressure in the lower extremities is lower than that in the upper extremities. However, if cardiac function is poor, these differences may not be as apparent until appropriate resuscitation is accomplished. In this situation, there may be no murmur, but an S_3 is often present.

Older children presenting with coarctation of the aorta are usually asymptomatic. There may be a history of **leg discomfort** with exercise, headache, or epistaxis. Decreased or absent lower extremity pulses, **hypertension** (upper extremity), or a murmur may be present. The murmur is typically best heard in the left interscapular area of the back. If significant collaterals have developed, continuous murmurs may be heard throughout the chest. An abnormal aortic valve is present approximately 50% of the time, causing a systolic ejection click and systolic ejection murmur of aortic stenosis.

Imaging Studies

The ECG and chest x-ray show evidence of right ventricular enlargement and hypertrophy in infantile coarctation with marked **cardiomegaly** and **pulmonary edema**. In older children, the ECG and chest x-ray usually show left ventricular hypertrophy and a mildly enlarged heart. **Rib notching** may also be seen in older children (>8 years of age) with large collaterals. Echocardiography shows the site and degree of coarctation, the presence of left ventricular hypertrophy, and the aortic valve morphology and function.

Treatment

Management of an infant presenting with cardiac decompensation includes intravenous infusion of **prostaglandin E₁** (chemically opens the ductus arteriosus), inotropic agents, diuretics, and other supportive care. **Balloon angioplasty** has been done, especially in critically ill infants, but **surgical repair** of the coarctation is most commonly performed. Ballooning and stenting of older patients with coarctation has become more accepted as primary therapy, but surgical repair remains a common form of management.

PEARLS FOR PRACTITIONERS

See *The Cardiovascular System: Pearls for Practitioners at the end of this section.*

CHAPTER 144

Cyanotic Congenital Heart Disease

Cyanotic congenital heart disease occurs when some of the systemic venous return crosses from the right side of the heart

to the left and returns to the body without going through the lungs (**right-to-left shunt**). **Cyanosis**, the visible sign of this shunt, occurs when approximately 5 g/100 mL of reduced hemoglobin is present in systemic blood. Thus a polycythemic patient appears cyanotic with a higher oxygen saturation than a normocythemic patient. A patient with anemia requires a higher percentage of reduced hemoglobin (lower saturation) for the recognition of cyanosis.

The most common cyanotic congenital heart defects are the five *Ts*:

1. Tetralogy of Fallot
2. Transposition of the great arteries
3. Tricuspid atresia
4. Truncus arteriosus
5. Total anomalous pulmonary venous return

Other congenital heart defects that allow complete mixing of systemic and pulmonary venous return can present with cyanosis depending on the amount of pulmonary blood flow that is present. Many cyanotic heart lesions present in the neonatal period (Table 144.1).

TETRALOGY OF FALLOT

Etiology and Epidemiology

Tetralogy of Fallot is the most common cyanotic congenital heart defect, representing about 10% of all congenital heart defects (Fig. 144.1). There are four structural defects: **ventricular septal defect (VSD)**, **pulmonary stenosis**, **overriding aorta**, and **right ventricular hypertrophy**. Tetralogy of Fallot is due to abnormal septation of the truncus arteriosus into the aorta and pulmonary artery that occurs early in gestation (3–4 weeks). The VSD is large, and the pulmonary stenosis is most commonly subvalvular or infundibular. It may also be

valvular, supravalvular, or, frequently, a combination of levels of obstruction.

Clinical Manifestations

Infants initially may be acyanotic. A **pulmonary stenosis murmur** is the usual initial abnormal finding. The amount of right-to-left shunting at the VSD (and the degree of cyanosis) increases as the degree of pulmonary stenosis increases. With increasing severity of pulmonary stenosis, the murmur becomes shorter and softer. In addition to varying degrees of cyanosis and a murmur, a **single S₂** and **right ventricular impulse** at the left sternal border are typical findings.

Hypoxic (Tet) spells are less commonly seen than in the past because of early surgical repair but do still occur. During a spell, the child typically becomes restless and agitated and may cry inconsolably. An ambulatory toddler may squat. Hyperpnea occurs with gradually increasing cyanosis and loss of the murmur. In severe spells, prolonged unconsciousness and convulsions, hemiparesis, or death may occur. Independent of hypoxic spells, patients with unrepaired tetralogy of Fallot are at increased risk for cerebral thromboembolism and cerebral abscesses resulting, in part, from their right-to-left intracardiac shunt.

Imaging Studies

The electrocardiogram (ECG) usually has **right axis deviation** and **right ventricular hypertrophy**. The classic chest x-ray finding is a **boot-shaped heart** created by the small main pulmonary artery and upturned apex secondary to right ventricular hypertrophy. Echocardiography shows the anatomic features, including the anatomic level and quantification of

TABLE 144.1 Categories of Presenting Symptoms and Signs in the Neonate

SYMPTOM/SIGN	PHYSIOLOGIC CATEGORY	ANATOMIC CAUSE	LESION
Cyanosis with respiratory distress	Increased pulmonary blood flow	Transposition	d-Transposition with or without associated lesions
Cyanosis without respiratory distress	Decreased pulmonary blood flow	Right heart obstruction	Tricuspid atresia Ebstein anomaly Pulmonary atresia Pulmonary stenosis Tetralogy of Fallot
Hypoperfusion	Poor cardiac output	Left heart obstruction	Total anomalous pulmonary venous return with obstruction Aortic stenosis Hypoplastic left heart syndrome
	Poor cardiac function	Normal anatomy	Cardiomyopathy Myocarditis
Respiratory distress with desaturation (not visible cyanosis)	Bidirectional shunting	Complete mixing	Truncus arteriosus AV canal Complex single ventricle (including heterotaxias) without pulmonary stenosis
Respiratory distress with normal saturation	Left-to-right shunting	Simple intracardiac shunt	ASD VSD PDA Aortopulmonary window AVM

ASD, Atrial septal defect; AV, atrioventricular; AVM, arteriovenous malformation; PDA, patent ductus arteriosus; VSD, ventricular septal defect.

FIGURE 144.1 Tetralogy of Fallot. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

pulmonary stenosis. Coronary anomalies, most commonly a left anterior descending coronary artery arising from the right coronary artery and crossing the anterior surface of the right ventricular outflow tract, are present in 5% of patients with tetralogy of Fallot.

Treatment

The natural history of tetralogy of Fallot is progression of pulmonary stenosis and cyanosis. Treatment of hypoxic spells consists of oxygen administration (although of minimal value given that worsening cyanosis is due to lack of pulmonary blood flow) and placing the child in the knee-chest position (to increase venous return). Traditionally, morphine sulfate was given (to relax the pulmonary infundibulum and for sedation). The use of ketamine is often beneficial (sedation, increases systemic vascular resistance [SVR], and can be given intramuscularly). If necessary, the SVR can be increased acutely through the administration of an α -adrenergic agonist (phenylephrine). The occurrence of a cyanotic spell is an indication to proceed with surgical repair.

Complete surgical repair with VSD closure and removal or patching of the pulmonary stenosis can be performed in infancy. Occasionally, **palliative shunt surgery** between the subclavian artery and pulmonary artery is performed for complex forms of tetralogy of Fallot and more complete repair is done at a later time. **Subacute bacterial endocarditis prophylaxis** is indicated until 6 months after complete repair unless there is a residual VSD. Prophylaxis is then continued as long as there is a residual VSD.

TRANSPOSITION OF THE GREAT ARTERIES

Etiology and Epidemiology

Although dextroposed transposition of the great arteries (dTGA) represents only about 5% of congenital heart defects, it is the most common cyanotic lesion to present in the newborn period (Fig. 144.2). TGA is ventriculoarterial discordance secondary to abnormalities of septation of the truncus arteriosus. In dTGA, the aorta arises from the right

FIGURE 144.2 Transposition of the great vessels. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

ventricle, anterior and to the right of the pulmonary artery, which arises from the left ventricle. This results in desaturated blood returning to the right side of the heart and being pumped back out to the body, while well-oxygenated blood returning from the lungs enters the left side of the heart and is pumped back to the lungs. Without mixing of the two circulations, death occurs quickly. Mixing can occur at the atrial (patent foramen ovale/atrial septal defect [ASD]) or less commonly at the ventricular (VSD) level. The presence of a patent ductus arteriosus (PDA) increases pulmonary blood flow and will improve mixing if adequate intracardiac communication is present.

Clinical Manifestations

A history of **cyanosis** is always present, although it depends on the amount of mixing. **Quiet tachypnea** and a **single S₂** are typically present. If the ventricular septum is intact, there may be no murmur.

Children with transposition and a large VSD have improved intracardiac mixing and less cyanosis. They may present with signs of heart failure. The heart is hyperdynamic, with palpable left and right ventricular impulses. A loud VSD murmur is heard. S₂ is single.

Imaging Studies

ECG findings typically include **right axis deviation** and **right ventricular hypertrophy**. The chest x-ray reveals **increased pulmonary vascularity**, and the cardiac shadow is classically an **egg on a string** created by the narrow superior mediastinum. Echocardiography shows the transposition of the great arteries, the sites and amount of mixing, and any associated lesions.

Treatment

Initial medical management includes **prostaglandin E₁** to maintain ductal patency and increase pulmonary blood flow and return. If significant hypoxia persists on prostaglandin

FIGURE 144.3 Tricuspid atresia with ventricular septal defect. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium.

therapy, a **balloon atrial septostomy** improves mixing between the two circulations. Complete surgical repair is most often an **arterial switch**. The arterial switch usually is performed within the first 2 weeks of life, when the left ventricle can still maintain systemic pressure.

TRICUSPID ATRESIA

Etiology and Epidemiology

Tricuspid atresia accounts for approximately 2% of all congenital heart defects (Fig. 144.3). The absence of the tricuspid valve results in a **hypoplastic right ventricle**. All systemic venous return must cross the atrial septum into the left atrium. A PDA or VSD is necessary for pulmonary blood flow and survival.

Clinical Manifestations

Infants with tricuspid atresia are usually **severely cyanotic** and have a **single S₂**. If a VSD is present, there may be a murmur. A diastolic murmur across the mitral valve may be audible. Frequently there is no significant murmur.

Imaging Studies

The ECG shows **left ventricular hypertrophy** and a **superior QRS axis** (between 0 and -90 degrees). The chest x-ray reveals a normal or mildly enlarged cardiac silhouette with **decreased pulmonary blood flow**. Echocardiography shows the anatomy, associated lesions, and source of pulmonary blood flow.

Treatment

Management initially depends on the presence of a VSD and the amount of antegrade blood flow to the lungs. If there is no VSD, or it is small, prostaglandin E₁ maintains pulmonary blood flow until surgery. Surgery is staged with an initial subclavian artery-to-pulmonary shunt (**Blalock-Taussig procedure**) typically followed by a two-stage procedure: **bidirectional cavopulmonary shunt (bidirectional Glenn)** and

FIGURE 144.4 Truncus arteriosus. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Fontan procedure. These surgeries direct systemic venous return directly to the pulmonary arteries.

TRUNCUS ARTERIOSUS

Etiology and Epidemiology

Truncus arteriosus occurs in less than 1% of all cases of congenital heart disease (Fig. 144.4). It results from the failure of septation of the truncus during the first 3–4 weeks of gestation. A single arterial trunk arises from the heart with a large VSD immediately below the truncal valve. The pulmonary arteries arise from the single arterial trunk either as a single vessel that divides or individually from the arterial trunk to the lungs.

Clinical Manifestations

Varying degrees of cyanosis depend on the amount of pulmonary blood flow. If not diagnosed at birth, the infant may develop signs of heart failure as pulmonary vascular resistance decreases. The signs then include tachypnea, difficulty feeding, and poor growth. Peripheral pulses are usually bounding as a result of the diastolic runoff into the pulmonary arteries. A single S₂ is due to the single valve. There may be a systolic ejection click, and there is often a **systolic murmur** at the left sternal border.

Imaging Studies

ECG findings include **combined ventricular hypertrophy** and **cardiomegaly**. A chest x-ray usually reveals **increased pulmonary blood** and may show displaced pulmonary arteries. Echocardiography defines the anatomy, including the VSD, truncal valve function, and origin of the pulmonary arteries.

Treatment

Medical management is usually needed and includes **anticongestive medications**. **Surgical repair** includes VSD closure and placement of a conduit between the right ventricle and pulmonary arteries.

FIGURE 144.5 Total anomalous pulmonary venous return. AO, Aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

TOTAL ANOMALOUS PULMONARY VENOUS RETURN

Etiology and Epidemiology

Total anomalous pulmonary venous return accounts for about 1% of congenital heart disease (Fig. 144.5). Disruption of the development of normal pulmonary venous drainage during the third week of gestation results in one of four abnormalities. All of the pulmonary veins fail to connect to the left atrium and return abnormally via the right side of the heart. They may have **supracardiac**, **infracardiac**, **cardiac**, or **mixed drainage**. An atrial-level communication is required for systemic cardiac output and survival.

Clinical Manifestations

The most important determinant of presentation is the presence or absence of **obstruction** to the pulmonary venous drainage. Infants without obstruction have minimal cyanosis and may be asymptomatic. There is a hyperactive **right ventricular impulse** with a **widely split S₂** (owing to increased right ventricular volume) and a **systolic ejection murmur** at the left upper sternal border. There is usually a mid-diastolic murmur at the lower left sternal border from the increased flow across the tricuspid valve. Growth is relatively poor. Infants with **obstruction** present with cyanosis, marked tachypnea and dyspnea, and signs of right-sided heart failure including hepatomegaly. The obstruction results in little, if any, increase in right ventricular volume, so there may be no murmur or changes in S₂.

Imaging Studies

For infants without obstruction, the ECG is consistent with right ventricular volume overload. Cardiomegaly with increased pulmonary blood flow is seen on chest x-ray. Infants with obstructed veins have right axis deviation and right ventricular hypertrophy on ECG. On chest x-ray, the heart is normal or mildly enlarged with varying degrees of pulmonary edema that can appear similar to hyaline membrane disease or pneumonia.

FIGURE 144.6 Hypoplastic left side of the heart. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PDA, patent ductus arteriosus; RA, right atrium; RV, right ventricle.

Echocardiography shows the volume-overloaded right side of the heart, right-to-left atrial level shunting, and common pulmonary vein site of drainage and degree of obstruction.

Treatment

At **surgery**, the common pulmonary vein is opened into the left atrium, and there is ligation of any vein or channel that had been draining the common vein.

HYPOPLASTIC LEFT HEART SYNDROME

Etiology and Epidemiology

Hypoplastic left heart syndrome accounts for 1% of all congenital heart defects (Fig. 144.6) but is the most common cause of death from cardiac defects in the first month of life. Hypoplastic left heart syndrome occurs when there is failure of normal development of the mitral or aortic valve. A small left ventricle that is unable to support normal systemic circulation is a central finding, regardless of etiology. Associated degrees of hypoplasia of the ascending aorta and aortic arch are present. Left-to-right shunting occurs at the atrial level pre- and postnatally.

Clinical Manifestations

The newborn is dependent on right-to-left shunting at the ductus arteriosus for systemic blood flow. As the ductus arteriosus constricts, the infant becomes critically ill with signs and symptoms of heart failure from excessive pulmonary blood flow and obstruction of systemic blood flow. Pulses are diffusely weak or absent. S₂ is single and loud. There is usually no heart murmur. Cyanosis may be minimal, but **low cardiac output** gives a grayish color to the cool, mottled skin.

Imaging Studies

ECG findings include **right ventricular hypertrophy** with **decreased left ventricular forces**. The chest x-ray reveals

TABLE 144.2 Extracardiac Complications of Cyanotic Congenital Heart Disease

PROBLEM	ETIOLOGY	THERAPY
Polycythemia	Persistent hypoxia	Phlebotomy
Relative anemia	Nutritional deficiency	Iron replacement
CNS abscess	Right-to-left shunting	Antibiotics, drainage
CNS thromboembolic stroke	Right-to-left shunting or polycythemia	Phlebotomy
Gingival disease	Polycythemia, gingivitis, bleeding	Dental hygiene
Gout	Polycythemia, diuretic agents	Allopurinol
Arthritis, clubbing	Hypoxic arthropathy	None
Pregnancy	Poor placental perfusion, poor ability to increase cardiac output	Bed rest
Infectious disease	Associated asplenia, DiGeorge syndrome	Antibiotics
	Fatal RSV pneumonia with pulmonary hypertension	Ribavirin, RSV immune globulin
Growth	Failure to thrive, increased oxygen consumption, decreased nutrient intake	Treat heart failure; correct defect early
Psychosocial adjustment	Limited activity, peer pressure; chronic disease, multiple hospitalizations, cardiac surgical techniques	Counseling

CNS, Central nervous system; RSV, respiratory syncytial virus.

cardiomegaly (with right-sided enlargement) and pulmonary venous congestion or pulmonary edema. Echocardiography shows the small left side of the heart, the degree of stenosis of the aortic and mitral valves, the hypoplastic ascending aorta, and the adequacy of left-to-right atrial flow and right-to-left ductal flow.

Treatment

Medical management includes **prostaglandin E₁** to open the ductus arteriosus, correction of acidosis, and ventilatory and blood pressure support as needed. **Surgical repair** is staged with the first surgery (Norwood procedure) done during the newborn period. Subsequent procedures create a systemic source for the pulmonary circulation (bidirectional Glenn and Fontan procedures), leaving the right ventricle to supply systemic circulation. There have been many modifications to all three stages of the repair. Prognosis for survival has improved significantly over the past 2 decades.

COMPLICATIONS OF CONGENITAL HEART DISEASE

Extracardiac complications are summarized in Table 144.2.

PEARLS FOR PRACTITIONERS

See *The Cardiovascular System: Pearls for Practitioners at the end of this section.*

CHAPTER 145

Heart Failure

ETIOLOGY AND EPIDEMIOLOGY

The force generated by the cardiac muscle fiber depends on its contractile status and basal length, which is equivalent to

the preload. As the preload (fiber length, left ventricular filling pressure, or volume) increases, myocardial performance (stroke volume and wall tension) increases up to a point (the normal Starling curve). The relationship is the **ventricular function curve** (Fig. 145.1). Alterations in the contractile state of the muscle lower the relative position of the curve but retain the relationship of fiber length to muscle work. The cardiac output equals stroke volume times the heart rate; thus heart rate is another important determinant of cardiac work. Additional factors also affect cardiac performance (Table 145.1).

Heart failure occurs when the heart is unable to pump blood at a rate commensurate with metabolic needs (inadequate oxygen delivery). It may be due to a change in **myocardial contractility** that results in low cardiac output or to **abnormal loading conditions** being placed on the myocardium. The abnormal loading conditions may be **afterload** (pressure overload, such as with aortic stenosis, pulmonary stenosis, or coarctation of the aorta) or **preload** (volume overload, such as in ventricular septal defect [VSD], patent ductus arteriosus [PDA], or valvular insufficiency). Volume overload is the most common cause of heart failure in children.

The age of presentation is helpful in creating the differential diagnosis (Table 145.2). In the first weeks of life, excessive afterload being placed on the myocardium is most common. Heart failure presenting around 2 months of age is usually due to increasing left-to-right shunts that become apparent as the pulmonary vascular resistance decreases. Acquired heart disease, such as myocarditis and cardiomyopathy, can present at any age.

CLINICAL MANIFESTATIONS

Heart failure presents in infants as poor feeding, failure to thrive, tachypnea, and diaphoresis with feeding. Older children may present with shortness of breath, easy fatigability, and edema. The physical examination findings depend on whether pulmonary venous congestion, systemic venous

FIGURE 145.1 Ventricular function curve illustrating the effect of inotropic agents or arterial vasodilators. In contrast to diuretics, the effect of digitalis or arterial vasodilator therapy in a patient with heart failure is movement onto another ventricular function curve, which is intermediate between the normal and the depressed curves. When the patient's ventricular function moves from A to B by the administration of one of these agents, the left ventricular end-diastolic pressure may also decrease because of improved cardiac function; further administration of diuretics or venodilators may shift the function further to the left along the same curve from B to C and eliminate the risk of pulmonary edema. A vasodilating agent that has arteriolar and venous dilating properties (e.g., nitroprusside) would shift this function directly from A to C. If this agent shifts the function from A to D because of excessive venodilation or the administration of diuretics, the cardiac output may decrease too much, even though the left ventricular end-diastolic pressure would be normal (10 mm Hg) for a normal heart. Left ventricular end-diastolic pressures of 15–18 mm Hg are usually optimal in the failing heart to maximize cardiac output, but to avoid pulmonary edema. (From Andreoli TE, Carpenter CCJ, Griggs RC, et al., eds. *Cecil Essentials of Medicine*. 5th ed. Philadelphia: Saunders; 2001.)

congestion, or both are present. Tachycardia, a gallop rhythm, and thready pulses may be present with either cause. If left-sided failure is predominant, tachypnea, orthopnea, wheezing, and pulmonary edema are seen. Hepatomegaly, edema, and distended neck veins are signs of right-sided failure.

IMAGING STUDIES

The absence of cardiomegaly on a chest x-ray usually rules out the diagnosis of heart failure. An echocardiogram assesses the

heart chamber sizes, measures myocardial function, and diagnoses congenital heart defects when present.

TREATMENT

Initial treatment is directed at improving myocardial function and optimizing preload and afterload. Diuretics, inotropic support, and, often, **afterload reduction** are employed (Table 145.3). Long-term therapy usually consists of diuretics

followed by afterload reduction. Long-term therapy with **β blockers** also may be beneficial, although this remains somewhat controversial in pediatric patients. Spironolactone is usually added to the medical regimen because of its effect on cardiac remodeling.

PEARLS FOR PRACTITIONERS

See The Cardiovascular System: Pearls for Practitioners at the end of this section.

TABLE 145.3 Treatment of Heart Failure	
THERAPY	MECHANISM
GENERAL CARE	
Rest	Reduces cardiac output
Oxygen	Improves oxygenation in the presence of pulmonary edema
Sodium, fluid restrictions	Decreases vascular congestion; decreases preload
DIURETICS	
Furosemide	Salt excretion at ascending loop of Henle; reduces preload; afterload reduces with control of hypertension; may also cause venodilation
Combination of distal tubule and loop diuretics	Greater sodium excretion
INOTROPIC AGENTS	
Digitalis	Inhibits membrane Na^+ , K^+ -ATPase and increases intracellular Ca^{2+} ; improves cardiac contractility, increases myocardial oxygen consumption
Dopamine	Releases myocardial norepinephrine plus a direct effect on β -receptor, may increase systemic blood pressure; at low infusion rates, dilates renal artery, facilitating diuresis
Dobutamine	β_1 -receptor agent; often combined with dopamine
Milrinone	Phosphodiesterase 3 inhibitor with positive inotropic properties and decreases vascular resistance/afterload
AFTERLOAD REDUCTION	
Hydralazine	Arteriolar vasodilator
Nitroprusside	Arterial and venous relaxation; venodilation reduces preload
Captopril/enalapril	Inhibition of angiotensin-converting enzyme; reduces angiotensin II production
OTHER MEASURES	
Mechanical counterpulsation	Improves coronary flow, afterload
Transplantation	Removes diseased heart
Extracorporeal membrane oxygenation	Bypasses heart
Carvedilol	β -blocking agent

CHAPTER 146

Rheumatic Fever

ETIOLOGY AND EPIDEMIOLOGY

Although uncommon in the United States, *acute* rheumatic fever remains an important preventable cause of cardiac disease. It is most common in children 6–15 years of age. It is due to an immunologic reaction that is a delayed sequela of group A β -hemolytic streptococcal infections of the pharynx. A family history of rheumatic fever and lower socioeconomic status are additional factors.

CLINICAL MANIFESTATIONS

Acute rheumatic fever is diagnosed using the clinical and laboratory findings of the **revised Jones criteria** (Table 146.1). The presence of either two **major criteria** or one major and two **minor criteria**, along with evidence of an antecedent **streptococcal infection**, confirm a diagnosis of acute rheumatic fever. The infection often precedes the presentation of rheumatic fever by 2–6 weeks. Streptococcal antibody tests, such as the antistreptolysin O titer, are the most reliable laboratory evidence of prior infection.

Arthritis is the most common major manifestation. It usually involves the large joints and is migratory. Arthralgia cannot be used as a minor manifestation if arthritis is used as a major manifestation. **Carditis** occurs in about 50% of patients. Tachycardia, a new murmur (mitral or aortic regurgitation), pericarditis, cardiomegaly, and signs of heart failure are evidence of carditis. **Erythema marginatum**, a serpiginous, non-pruritic, and evanescent rash, is uncommon, occurs on the trunk, and is brought out by warmth. **Subcutaneous nodules** are seen predominantly with chronic or recurrent disease. They are firm, painless, nonpruritic, mobile nodules found on the extensor surfaces of the large and small joints, the scalp, and the spine. **Chorea** (Sydenham chorea or St. Vitus dance) consists of neurologic and psychiatric signs. It also is uncommon and often presents long after the infection.

TREATMENT AND PREVENTION

Management of acute rheumatic fever consists of **benzathine penicillin** to eradicate the β -hemolytic streptococcus, anti-inflammatory therapy with **salicylates**, and **bed rest**. Additional supportive therapy for heart failure or chorea may be necessary. **Long-term penicillin prophylaxis**, preferably with intramuscular benzathine penicillin G, 1.2 million U every 28 days, is required. Oral regimens for prophylaxis generally are not as

TABLE 146.1 Major Jones Criteria for Diagnosis of Acute Rheumatic Fever	
SIGN	COMMENTS
Polyarthrititis	Common; swelling, limited motion, tender, erythema Migratory; involves large joints but rarely small or unusual joints, such as vertebrae
Carditis	Common; pancarditis, valves, pericardium, myocardium Tachycardia greater than explained by fever; new murmur of mitral or aortic insufficiency; Carey-Coombs mid-diastolic murmur; heart failure
Chorea (Sydenham disease)	Uncommon; manifests long after infection has resolved; more common in females; antineuronal antibody positive
Erythema marginatum	Uncommon; pink macules on trunk and proximal extremities, evolving to serpiginous border with central clearing; evanescent, elicited by application of local heat; nonpruritic
Subcutaneous nodules	Uncommon; associated with repeated episodes and severe carditis; located over extensor surface of elbows, knees, knuckles, and ankles, or scalp and spine; firm, nontender

*Minor criteria include fever (temperatures of 101–102°F [38.2–38.9°C]), arthralgias, previous rheumatic fever, leukocytosis, elevated erythrocyte sedimentation rate/C-reactive protein, and prolonged PR interval.

†One major and two minor, or two major, criteria with evidence of recent group A streptococcal disease (e.g., scarlet fever, positive throat culture, or elevated antistreptolysin O or other antistreptococcal antibodies) strongly suggest the diagnosis of acute rheumatic fever.

effective. The prognosis of acute rheumatic fever depends on the degree of permanent cardiac damage. Cardiac involvement may resolve completely, especially if it is the first episode and the prophylactic regimen is followed. The severity of cardiac involvement worsens with each recurrence of rheumatic fever.

CHAPTER 147

Cardiomyopathies

ETIOLOGY

A cardiomyopathy is an intrinsic disease of the heart muscle and is not associated with other forms of heart disease (Table 147.1). There are three types of cardiomyopathy based on anatomic and functional features:

1. Dilated
2. Hypertrophic
3. Restrictive

Dilated cardiomyopathies are the most common. They are often idiopathic, but they may be due to infection (echovirus or coxsackie B virus) or be postinfectious, familial, or secondary to systemic disease or to cardiotoxic drugs. Hypertrophic cardiomyopathies are usually familial with autosomal dominant inheritance but may occur sporadically. Restrictive cardiomyopathies are rare; they may be idiopathic or associated with systemic disease (Table 147.2).

TABLE 147.2 Anatomic and Functional Features of Cardiomyopathies

FEATURE	DILATED	HYPERTROPHIC	RESTRICTIVE
Etiology	Infectious Metabolic Toxic Idiopathic	Sporadic Inherited (autosomal dominant)	Infiltrative (amyloidosis, sarcoidosis) Noninfiltrative (idiopathic, familial) Storage disease (hemochromatosis, Fabry disease) Endomyocardial disease
Hemodynamics	Decreased systolic function	Diastolic dysfunction (impaired ventricular filling)	Diastolic dysfunction (impaired ventricular filling)
Treatment	Positive inotropes Diuretics Afterload reduction β blockers Antiarrhythmics Anticoagulants Cardiac transplantation	β blockers Calcium channel blockers	Diuretics Anticoagulants Cardiac transplantation

CLINICAL MANIFESTATIONS

Dilated cardiomyopathies result in enlargement of the left ventricle only or of both ventricles. Myocardial contractility is variably decreased. Children with dilated cardiomyopathy present with signs and symptoms of inadequate cardiac output and **heart failure**. Tachypnea and tachycardia are present on examination. Peripheral pulses are often weak because of a **narrow pulse pressure**. Rales may be audible on auscultation. The heart sounds may be muffled, and an S_3 is often present. Concurrent infectious illness may result in circulatory collapse and shock in children with dilated cardiomyopathies.

Hypertrophic cardiomyopathy is initially difficult to diagnose. Infants, but not older children, frequently present with signs of heart failure. Sudden death may be the initial presentation in older children. Dyspnea, fatigue, chest pain, syncope or near-syncope, and palpitations may be present. A murmur is heard in more than 50% of children referred after identification of an affected family member. Restrictive cardiomyopathies are relatively rare in pediatrics. Presenting symptoms usually include dyspnea exacerbated by a respiratory illness, syncope, hepatomegaly, and an S_4 heart sound on examination.

IMAGING STUDIES

Cardiomegaly usually is seen on chest radiographs for all three types of cardiomyopathies. The electrocardiogram (ECG) in dilated cardiomyopathy may have nonspecific ST-T-wave changes and left ventricular hypertrophy. ECG evidence of right ventricular hypertrophy is present in 25% of children with cardiomyopathy. The ECG with hypertrophic cardiomyopathy is universally abnormal, but changes are nonspecific. Primary hypertrophic cardiomyopathy is associated with a prolonged QT interval. Children with restrictive cardiomyopathies may show atrial enlargement on the ECG. Echocardiography features vary by type of cardiomyopathy. Dilated cardiomyopathies result in left atrial and ventricular dilation and depressed contractility. Asymmetric septal hypertrophy and left ventricular outflow tract obstruction are seen in hypertrophic cardiomyopathies. Massive atrial dilation is seen in restrictive cardiomyopathies. Endomyocardial biopsy specimens, obtained while the patient is hemodynamically

stable, identify histologic type and allow tests for mitochondrial or infiltrative diseases.

TREATMENT

Supportive therapy, including **diuretics**, **inotropic medications**, and **afterload reduction**, is provided for all three types of cardiomyopathy. If a specific etiology can be identified, treatment is directed at the etiology. Symptomatic therapy with close monitoring and follow-up is crucial. Because of the high mortality rate associated with all forms of cardiomyopathy, **cardiac transplantation** must be considered.

PEARLS FOR PRACTITIONERS

See The Cardiovascular System: Pearls for Practitioners at the end of this section.

CHAPTER 148

Pericarditis

ETIOLOGY AND EPIDEMIOLOGY

Pericarditis is inflammation of the parietal and visceral surfaces of the pericardium. It is most often viral in origin, with many viruses identified as causative agents. A bacterial etiology is rare but causes a much more serious and symptomatic pericarditis. *Staphylococcus aureus* and *Streptococcus pneumoniae* are the most likely bacterial causes. Pericarditis is associated with collagen vascular diseases, such as rheumatoid arthritis, and is seen with uremia (Table 148.1). **Postpericardiotomy syndrome** is a relatively common form of pericarditis that follows heart surgery.

CLINICAL MANIFESTATIONS

The symptoms of pericarditis (Table 148.2) depend on the amount of fluid in the pericardial space and how fast it accumulates. A small effusion usually is well tolerated. A large

effusion may be well tolerated if it accumulates slowly. The faster the fluid accumulates, the sooner the patient is hemodynamically compromised and develops symptoms.

IMAGING AND LABORATORY STUDIES

Echocardiography is the most specific and useful diagnostic test for detection of pericardial effusions. A chest x-ray may reveal cardiomegaly. A large effusion creates a rounded, globular cardiac silhouette. The electrocardiogram (ECG) may show tachycardia, elevated ST segments, reduced QRS voltage, or electrical alternans (variable QRS amplitude). The causative organism may be identified through viral titers, antistreptolysin O (ASO) titers, or diagnostic testing of the pericardial fluid.

TREATMENT

Pericardiocentesis is indicated for the treatment of hemodynamically significant effusions and to determine the etiology of the pericarditis. Additional treatment is directed at the specific etiology. There is no specific treatment for viral pericarditis other than **antiinflammatory medications**.

PEARLS FOR PRACTITIONERS

CHAPTER 139

Cardiovascular System Assessment

- Rate of growth is one of the most valuable and objective signs of cardiovascular health.
 - In infants with heart failure, weight gain is more significantly affected than height and head circumference.
- Cardiovascular vital signs vary with age, and one needs to know or have a resource for “normal” for all age groups to be able to recognize/diagnose abnormal.
- Blood pressure should be routinely taken in the right arm and, if elevated, then taken in all four extremities.
 - The presence of a normal right arm blood pressure and normal pedal pulses effectively rules out coarctation of the aorta.
- Peripheral cyanosis (hands, feet, perioral), also known as acrocyanosis, is common in infants and needs to be differentiated from central cyanosis (tongue, lips).
- Murmurs are “noisy blood flow” and are very common in pediatric patients. They may be normal (innocent) or abnormal.
 - The timing of the murmur is most important in determining the significance of the murmur and developing a differential diagnosis.
 - Diastolic murmurs, holosystolic murmurs, continuous murmurs (with the exception of the venous hum), and murmurs with a palpable thrill are abnormal murmurs.
 - To be a normal (innocent) murmur, the cardiovascular history and remainder of the cardiovascular exam must be normal.
- A normal heart size on chest radiograph virtually rules out heart failure; however, a large heart is not diagnostic of heart failure.
- Echocardiography is the most important noninvasive tool in the diagnosis and management of congenital heart disease with electrocardiogram (ECG), chest x-ray, cardiac catheterization, and computed tomography (CT)/magnetic resonance imaging (MRI) providing additional information.
- Mild desaturation that is not clinically apparent may be the only early finding in complex congenital heart defects. Routine measurement of pulse oximetry in the right arm and a lower extremity after delivery may allow diagnosis of congenital heart disease.

CHAPTER 140

Syncope

- Syncope is the transient loss of consciousness and muscle tone and is typically associated with an upright position, prodromal symptoms, pale appearance, and brief loss of consciousness with rapid return to normal state of consciousness.
- Syncope occurring during exercise or with associated cardiac symptoms should be considered atypical until more extensively evaluated.

CHAPTER 141

Chest Pain

- Chest pain is common in pediatrics but is rarely cardiac in origin.
- Up to one-third of all pediatric chest pain is idiopathic, with musculoskeletal chest pain being the most common cause of diagnosable chest pain.

CHAPTER 142

Dysrhythmias

- The most common symptomatic dysrhythmia in pediatrics is supraventricular tachycardia.
- Sinus arrhythmia is common in children and represents a normal variation in heart rate with respiration.

CHAPTER 143

Acyanotic Congenital Heart Disease

- Congenital heart defects occur in about 1% of births and include a wide spectrum of defects from asymptomatic to fatal lesions.
- Ventricular septal defect (VSD) is the most common congenital heart defect.
 - The amount of shunting at a VSD depends on the size of the defect and the pulmonary vascular resistance.
 - Large shunts result in excessive pulmonary blood flow (congestive heart failure), typically presenting with tachypnea, fatigue, and diaphoresis with feeding and poor weight gain.

- Atrial septal defects (ASDs) rarely cause symptoms in childhood.
 - The amount of shunting across an ASD depends on the size of the defect and the relative compliance of the ventricles.
 - In addition to a systolic ejection murmur from increased flow across the pulmonary valve, a widely split S₂ that does not vary with respiration is the classic exam finding associated with an ASD.
- A patent ductus arteriosus (PDA) results in volume overload of the left heart; the shunting is dependent on the size of the PDA and the pulmonary vascular resistance.
- The most common congenital heart defect in children with trisomy 21 is the endocardial cushion defect, which is also called atrioventricular canal defect or atrioventricular septal defect.
- Symptoms and management of pulmonary stenosis and aortic stenosis depend on the severity of the stenosis.
 - Pulmonary valve stenosis is rarely progressive; aortic valve stenosis is usually progressive.
- Coarctation of the aorta usually occurs in the juxtaductal region.
- Symptoms and presentation depend on the severity of the obstruction and associated congenital heart defects.

CHAPTER 144

Cyanotic Congenital Heart Disease

- Clinical cyanosis occurs when more than 5 g/100 mL of reduced hemoglobin is present in the systemic blood.
- The cyanotic congenital heart defects are the five *T*s: tetralogy of Fallot, transposition of the great arteries, tricuspid atresia, truncus arteriosus, and total anomalous pulmonary venous return.
- Tetralogy of Fallot is the most common cyanotic congenital heart defect. The degree of cyanosis and the murmur depend on the amount of pulmonary stenosis.
- Transposition of the great arteries is the most common cyanotic lesion to present in the newborn period.
- Congenital heart defects with a functionally single ventricle, such as tricuspid atresia and hypoplastic left heart syndrome (HLHS) require a staged surgical repair.
 - Survival of patients with HLHS—the most common cause of death from a cardiac defect in the first month of life—has

improved dramatically with staged surgical and aggressive medical management.

CHAPTER 145

Heart Failure

- Both the most common causes and the clinical manifestations of congestive heart failure vary with age of presentation.
- Diseases/issues that impact preload, afterload, and contractility can all result in worsening cardiac performance and heart failure.
- Treatment of heart failure often includes diuresis, inotropic support, and afterload reduction.

CHAPTER 146

Rheumatic Fever

- Rheumatic fever remains an important, preventable cause of cardiac disease worldwide. Diagnosis of rheumatic fever is made using the clinical and laboratory findings of the revised Jones criteria.

CHAPTER 147

Cardiomyopathies

- There are three types of cardiomyopathy: dilated (most common), hypertrophic, and restrictive.
- Supportive therapy, including diuretics, inotropic medications, and afterload reduction, are used in all three types.
- Cardiac transplantation must be considered due to the high mortality rate seen in all forms of cardiomyopathy.

CHAPTER 148

Pericarditis

- Pericarditis is inflammation of the parietal and visceral surfaces of the pericardium and is most often viral in origin.
 - The severity of symptoms depends on the amount of fluid present in the pericardial space and the rapidity with which the fluid accumulated.

HEMATOLOGY

Amanda M. Brandow | Brian R. Branchford | J. Paul Scott

CHAPTER 149

Hematology Assessment

HISTORY

A detailed history of the onset, severity, progression, associated symptoms, presence of systemic complaints, and exacerbating factors is crucial to the diagnosis of a blood disorder. In many blood disorders, a **detailed pedigree** identifying a pattern of inheritance can point to the diagnosis.

PHYSICAL EXAMINATION AND COMMON MANIFESTATIONS

The physical examination of patients with blood disorders first focuses on hemodynamic stability. Acute episodes of anemia may be life threatening, presenting with impairment of perfusion and cognitive status. Two common findings of anemia include **pallor** and **jaundice**. The presence of **petechiae**, **purpura**, or deeper sites of **bleeding**, including generalized hemorrhage, indicates abnormalities of platelets, coagulation factors, or both. **Growth parameters** point to whether anemia is an acute or chronic process. Severe types of anemia, thrombocytopenia, and pancytopenia often are associated with congenital anomalies and a pattern of growth delay. Organ system involvement (especially **hepatosplenomegaly** and **lymphadenopathy**) or systemic illness points to a generalized disorder as the cause for hematologic abnormalities (Table 149.1).

INITIAL DIAGNOSTIC EVALUATION

Diagnosis of pediatric blood disorders requires a detailed knowledge of normal hematologic values that vary according to age and, after puberty, according to sex (Table 149.2). Directed by the history, physical examination, and screening laboratory studies, specific diagnostic testing can confirm the diagnosis.

DEVELOPMENTAL HEMATOLOGY

Hematopoiesis begins by 3 weeks of gestation with **erythropoiesis** in the yolk sac. By 2 months of gestation, the primary site of hematopoiesis migrates to the liver. By 5–6 months of gestation, the process shifts from the liver to the bone marrow. An extremely premature infant may have significant **extramedullary hematopoiesis** due to limited bone marrow hematopoiesis. During infancy, virtually all marrow cavities are

actively hematopoietic, and the proportion of hematopoietic to stromal elements is quite high. As a child grows, hematopoiesis moves to the central bones of the body (vertebrae, sternum, ribs, and pelvis), and the marrow is gradually replaced with fat. Hemolysis or marrow damage may lead to marrow repopulation of cavities where hematopoiesis previously had ceased or may delay the shift of hematopoiesis. Hepatosplenomegaly in patients with chronic hemolysis may signify extramedullary hematopoiesis. When a patient with cytopenia(s) is being evaluated, a **bone marrow examination** provides valuable information about processes that lead to underproduction of circulating cells. In addition, bone marrow infiltration by neoplastic elements or storage cells often occurs in concert with infiltration in the spleen, liver, and lymph nodes.

The hematopoietic cells consist of the following:

1. Small compartment of **pluripotent progenitor stem cells** that resemble small lymphocytes and are capable of forming all myeloid elements
2. Large compartment of committed, proliferating cells of myeloid, erythroid, and megakaryocytic lineage
3. Large compartment of postmitotic maturing cells (Fig. 149.1)

The bone marrow is the major storage organ for mature neutrophils and contains about seven times the intravascular pool of neutrophils. It contains 2.5–5 times as many cells of myeloid lineage as cells of erythroid lineage. Smaller numbers of megakaryocytes, plasma cells, histiocytes, lymphocytes, and stromal cells are also stored in the marrow.

Erythropoiesis (red blood cell [RBC] production) is controlled by erythropoietin (EPO), a glycoprotein that stimulates primitive pluripotential stem cells to differentiate along the erythroid line. It is made by the juxtaglomerular apparatus of the kidney in response to local tissue hypoxia. The normally high hemoglobin level of the fetus is a result of fetal EPO production in the liver in response to low partial pressure of oxygen (PO₂) in utero. EPO leads to production of the **erythroid colony-forming unit**. The earliest recognizable erythroid cell is the erythroblast, which forms eight or more daughter cells. The RBC nucleus becomes gradually pyknotic and eventually is extruded. The cell is then released from the marrow as a **reticulocyte** that maintains residual mitochondrial and protein synthetic capacity. These relatively large, highly specialized RBC precursors are engaged primarily in the production of **globin chains**, **glycolytic enzymes**, and **heme**. Iron is taken up via transferrin receptors and incorporated into the heme ring, which combines with globin chains synthesized within the immature RBC. When the messenger RNA and mitochondria are gone from the RBC, heme or protein synthesis is no

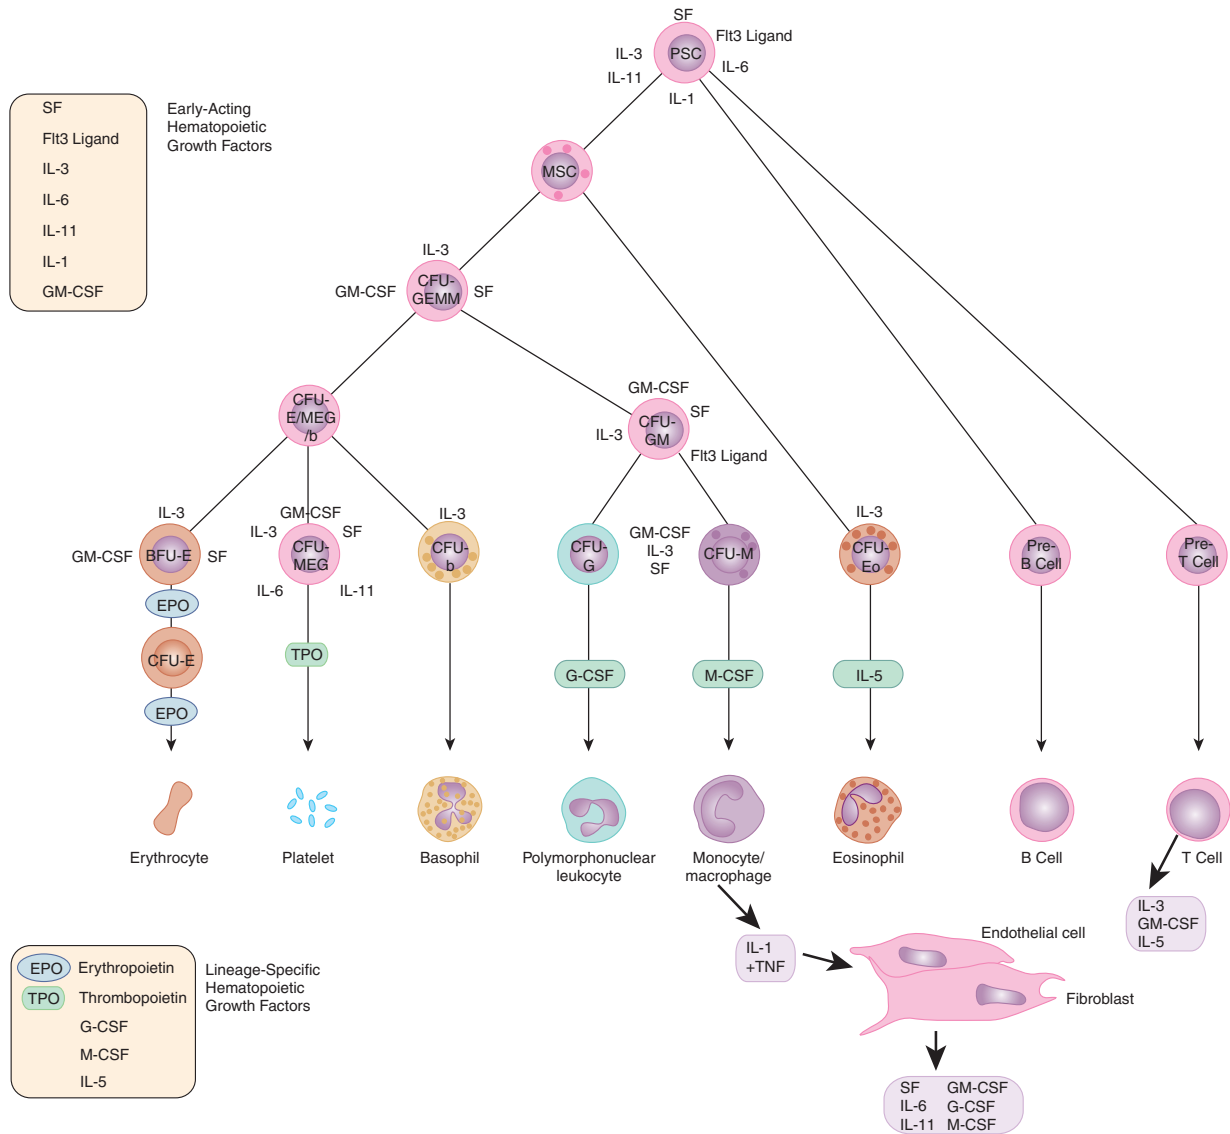

FIGURE 149.1 Major cytokine sources and actions that promote hematopoiesis. Cells of the bone marrow microenvironment, such as macrophages, endothelial cells, and reticular fibroblasts, produce macrophage colony-stimulating factor (*M-CSF*), granulocyte-macrophage colony-stimulating factor (*GM-CSF*), and granulocyte colony-stimulating factor (*G-CSF*) after stimulation. For all lineages, optimal development requires a combination of early and late acting factors. *BFU*, Burst-forming unit; *CFU*, colony-forming unit; *EPO*, erythropoietin; *IL*, interleukin; *MSC*, myeloid stem cell; *PSC*, pluripotent stem cell; *TNF*, tumor necrosis factor; *TPO*, thrombopoietin. WBCs, White blood cells. From Behrman RE, ed. Nelson Textbook of Pediatrics. 14th ed. Philadelphia: WB Saunders; 1992.

longer possible; however, the RBC continues to function for its normal life span of about 120 days.

Embryonic hemoglobins are produced during yolk sac erythropoiesis, then replaced by **fetal hemoglobin** (hemoglobin F, $\alpha_2\gamma_2$) during the hepatic phase. During the third trimester, gamma chain production gradually diminishes, replaced by beta chains, resulting in **hemoglobin A** ($\alpha_2\beta_2$). Some fetal factors (e.g., infant of a diabetic mother) delay onset of beta chain production, but premature birth does not. Just after birth, with rapid increases in oxygen saturation, EPO production stops and thus erythropoiesis ceases. Fetal RBCs have a shorter survival time (60 days).

During the first few months of postnatal life, rapid growth, shortened RBC survival, and cessation of erythropoiesis cause a gradual decline in hemoglobin levels, with a nadir at 8–10 weeks of life. This so-called **physiologic nadir** is accentuated in premature infants with earlier timing and a lower nadir. EPO is produced in response to the decline in hemoglobin and decreased oxygen delivery. Erythropoiesis subsequently resumes with an increase in the reticulocyte count. The hemoglobin level gradually increases, accompanied by synthesis of increasing amounts of hemoglobin A. By 6 months of age in healthy infants, only trace gamma chain synthesis occurs.

Production of **neutrophil precursors** is controlled predominantly by two different colony-stimulating factors (see Fig. 149.1). The most immature neutrophil precursors are controlled by **granulocyte-macrophage colony-stimulating factor** (GM-CSF), produced by monocytes and lymphocytes. GM-CSF increases the entry of primitive precursor cells into the myeloid line of differentiation. **Granulocyte colony-stimulating factor** (G-CSF) augments the production of more mature granulocyte precursors. GM-CSF and G-CSF, working in concert, can augment production of neutrophils, shorten the usual 10- to 14-day production time from stem cell to mature neutrophil, and stimulate functional activity. The rapid increase in neutrophil count that occurs with infection is caused by release of stored neutrophils from the bone marrow, under the control of GM-CSF. During maturation, a mitotic pool of neutrophil precursors exists—myeloblasts, promyelocytes, and myelocytes possessing primary granules. The postmitotic pool consists of metamyelocytes, bands, and mature polymorphonuclear leukocytes containing secondary or specific granules that define the cell type. Only bands and mature neutrophils are fully functional with regard to phagocytosis, chemotaxis, and bacterial killing. Neutrophils migrate from the bone marrow, circulate for 6–7 hours, and enter the tissues, where they become end-stage cells that do not recirculate. Eosinophil production is under the control of a related glycoprotein hormone, interleukin 3. Eosinophils, which play a role in host defense against parasites, also are capable of living in tissues for prolonged periods.

Megakaryocytes are giant, multinucleated cells derived from the primitive stem cell and are polyploid (16–32 times the normal DNA content) because of nuclear, but not cytoplasmic, cell division. Platelets form by invagination of the megakaryocytic cell membrane and fragment off from these megakaryocyte pseudopods into the blood vessel. **Thrombopoietin** is the primary regulator of platelet production. Platelets adhere to damaged endothelium and subendothelial surfaces via specific receptors for the adhesive proteins, von Willebrand factor, and fibrinogen. Platelets also have dense and alpha granules that readily release their contents after stimulation and trigger the

process of platelet aggregation. Platelets circulate for 7–10 days and have no nucleus.

Lymphocytes are particularly abundant in the bone marrow of young children. These are primarily B lymphocytes arising in the spleen and lymph nodes, but T lymphocytes also are present.

PEARLS FOR PRACTITIONERS

See *Hematology: Pearls for Practitioners* at the end of this section.

CHAPTER 150

Anemia

ETIOLOGY

The diagnosis of anemia is determined by comparison of the patient's **hemoglobin level** with age-specific and sex-specific normal values (see Table 149.2). The production of androgens at the onset of puberty in males causes them to maintain a normal hemoglobin value approximately 1.5–2 g/dL higher than females. The easiest quantitative definition of anemia is any hemoglobin or hematocrit value that is 2 standard deviations (SDs; 95% confidence limits) below the mean for age and sex. Anemia is often a manifestation of another primary process and may accentuate other organ dysfunction.

Anemias are classified based on the size and hemoglobin content of the cells (Fig. 150.1). **Hypochromic, microcytic anemia** is caused by an inadequate production of hemoglobin. The most common causes of this type of anemia are iron deficiency and thalassemia. **Normocytic anemia** is often seen in patients with a systemic illness that impairs adequate marrow synthesis of red blood cells (RBCs). **Macrocytic anemia** is seen in deficiencies of vitamin B₁₂ and/or folic acid. **Hemolytic diseases** are mediated either by disorders intrinsic or extrinsic to the RBC that increase RBC destruction. The most common RBC membrane disorders are **hereditary spherocytosis** and **hereditary elliptocytosis**. In both disorders, abnormalities of proteins within the cytoskeleton lead to malformed RBC shape and function. Numerous RBC enzyme deficiencies may lead to hemolysis, including **glucose-6-phosphate dehydrogenase (G6PD) deficiency** (common) and **pyruvate kinase deficiency** (rare). Extravascular hemolysis occurs with immune-mediated hemolysis when RBCs coated with antibodies or complement are phagocytosed by the reticuloendothelial system. Intravascular hemolysis occurs when antibody binding leads to complement fixation and lysis of RBCs, or mechanical cleavage secondary to intravascular fibrin stranding.

CLINICAL MANIFESTATIONS

Acute onset of anemia can result in a poorly compensated state, manifested as tachycardia, systolic flow murmur, dizziness, poor exercise tolerance, headache, excessive sleeping (especially in infants) or fatigue, irritability, poor feeding, and syncope. In contrast, chronic anemia often is exceptionally well tolerated in children because of their cardiovascular

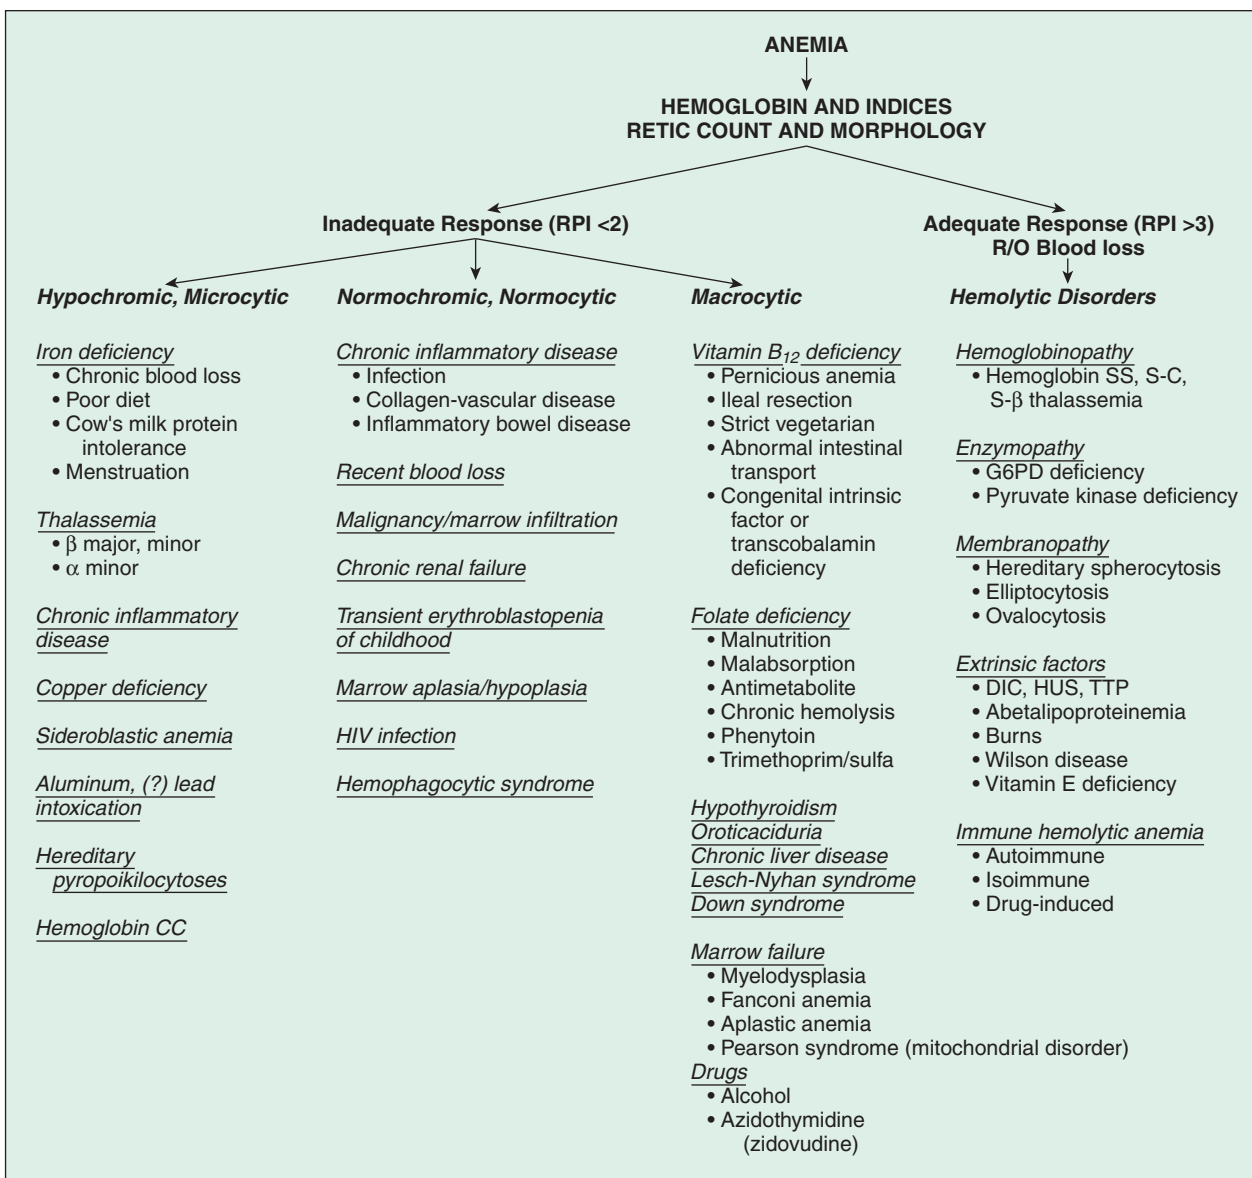

FIGURE 150.1 Use of the complete blood count, reticulocyte count, and blood smear in the diagnosis of anemia. *DIC*, Disseminated intravascular coagulation; *G6PD*, glucose-6-phosphate dehydrogenase; *HUS*, hemolytic uremic syndrome; *R/O*, rule out; *RPI*, reticulocyte production index; *TTP*, thrombotic thrombocytopenic purpura.

reserve. Usually, children with chronic anemia will have minimal tachycardia and a systolic flow murmur on examination. The urgency of diagnostic and therapeutic intervention, especially the use of packed RBC transfusion, should be dictated by the extent of cardiovascular or functional impairment more than the absolute level of hemoglobin.

The causes of anemia often can be suspected from a careful history adjusted for the patient's age (Tables 150.1 and 150.2). Anemia at any age demands a search for **blood loss**. A history of jaundice, pallor, previously affected siblings, drug ingestion by the mother, or excessive blood loss at the time of birth provides important clues to the diagnosis in newborns. A careful **dietary history** is crucial. A history of **jaundice**, **pallor**, and/or **splenomegaly** are often present with hemolytic anemia. Because of increased bilirubin production, **gallstones** (bilirubinate) are a common complication of chronic hemolysis.

Systemic complaints suggest acute or chronic illnesses as probable causes of anemia. In later childhood and adolescence, the presence of constitutional symptoms, unusual diets, drug ingestion, or blood loss, especially from menstrual bleeding, often points to a diagnosis. **Congenital hemolytic disorders** (e.g., enzyme deficiencies, membrane abnormalities) often present in the first 6 months of life and are frequently associated with neonatal jaundice, although these disorders often go undiagnosed when mild. A careful **drug history** is essential for detecting problems that may be drug induced. Pure dietary iron deficiency is rare except in children ages 1–3 years when cow's milk protein intolerance causes gastrointestinal blood loss and further complicates an already inadequate iron intake.

The physical examination may point to the potential cause (see Table 150.2). The **physiologic stability** of the patient may be compromised with both acute blood loss and

TABLE 150.1 Historical Clues in Evaluation of Anemia

VARIABLE	COMMENTS
Age	<p>Iron deficiency rare in the absence of blood loss before 6 mo in term infants or before doubling of birthweight in preterm infants.</p> <p>Neonatal anemia with reticulocytosis suggests hemolysis or blood loss. Neonatal anemia with reticulocytopenia suggests bone marrow failure.</p> <p>Sickle cell anemia and β-thalassemia appear as fetal hemoglobin disappears (4–8 mo of age).</p>
Family history and genetic considerations	<p>X-linked: G6PD deficiency</p> <p>Autosomal dominant: spherocytosis</p> <p>Autosomal recessive: sickle cell anemia, Fanconi anemia</p> <p>Family member with history of cholecystectomy (for bilirubin stones) or splenectomy at an early age: spherocytosis or other inherited hemolytic anemias</p> <p>Ethnicity: thalassemia in persons of Mediterranean origin, African or Asian descent; G6PD deficiency in people of African, Greek, or Middle Eastern descent</p> <p>Race: β-thalassemia in persons of Mediterranean, African, or Asian descent; α-thalassemia in people who are Black or Asian; sickle cell disease in people who are Black</p>
Nutrition	<p>Cow's milk diet: iron deficiency</p> <p>Strict vegetarian: vitamin B₁₂ deficiency</p> <p>Goat's milk diet: folate deficiency</p> <p>Pica: plumbism, iron deficiency</p> <p>Cholestasis, malabsorption: vitamin E deficiency</p>
Drugs	<p>G6PD: oxidants (e.g., nitrofurantoin, antimalarials)</p> <p>Immune-mediated hemolysis (e.g., penicillin)</p> <p>Bone marrow suppression (e.g., chemotherapy)</p> <p>Phenytoin, increasing folate requirements</p>
Diarrhea	<p>Malabsorption of vitamin B₁₂ or E or iron</p> <p>Inflammatory bowel disease and anemia of inflammation with or without blood loss</p> <p>Milk protein intolerance–induced blood loss</p> <p>Intestinal resection: vitamin B₁₂ deficiency</p>
Infection	<p><i>Giardia lamblia</i> infection: iron malabsorption</p> <p>Intestinal bacterial overgrowth (blind loop): vitamin B₁₂ deficiency</p> <p>Fish tapeworm: vitamin B₁₂ deficiency</p> <p>Epstein-Barr virus, cytomegalovirus infection: bone marrow suppression, hemophagocytic syndromes</p> <p><i>Mycoplasma</i> infection: hemolysis</p> <p>Parvovirus infection: bone marrow suppression</p> <p>HIV infection</p> <p>Chronic infection</p> <p>Endocarditis</p> <p>Malaria: hemolysis</p> <p>Hepatitis: aplastic anemia</p>

G6PD, Glucose-6-phosphate dehydrogenase.

acute hemolysis, manifesting as tachycardia, blood pressure changes, and, most ominously, an altered state of consciousness. The presence of **jaundice** suggests hemolysis. **Petechiae** and **purpura** indicate a coagulopathy or systemic illness. **Hepatosplenomegaly** and **adenopathy** suggest infiltrative disorders such as leukemia. **Growth failure** or poor weight gain suggests anemia of inflammation (previously termed anemia of chronic disease). An essential element of the physical examination is the investigation of the stool for the presence of **occult blood**.

LABORATORY STUDIES

A hemoglobin or hematocrit test indicates the severity of the anemia. After anemia has been substantiated based upon age-adjusted normal values, the work-up should include a complete blood count with differential, platelet count, indices, and reticulocyte count. Examination of the peripheral blood smear is vital to assess the morphology of RBCs (Fig. 150.2), white blood cells (WBCs), and platelets. All cell lines should be scrutinized to determine whether anemia is the result of a process limited to the erythroid line or a process that affects other marrow elements. Using data obtained from the indices and reticulocyte count, the work-up can be organized on the basis of whether RBC production is adequate or inadequate and whether the cells are microcytic, normocytic, or macrocytic (see Fig. 150.1).

An appropriate bone marrow response to anemia includes an elevated absolute reticulocyte number, suggesting increased RBC production. This implies either hemolysis or blood loss. Anemia with a normal reticulocyte number suggests decreased or ineffective RBC production for the degree of anemia. Reticulocytopenia signifies either an acute onset of anemia such that the marrow has not had adequate time to respond, that reticulocytes are being destroyed in the marrow (antibody mediated), or that intrinsic bone marrow disease is present. The best indicators of the severity of hemolysis are the hemoglobin level and the elevation of the **reticulocyte count**. Biochemical evidence of hemolysis includes levels of bilirubin and lactate dehydrogenase and a decrease in haptoglobin.

DIFFERENTIAL DIAGNOSIS

Microcytic Anemia

Iron-Deficiency Anemia

Etiology

Infants fed cow's milk when younger than 1 year of age, toddlers fed large volumes of cow's milk, and menstruating adolescent females who are not receiving supplemental iron are at high risk for iron deficiency. **Dietary** iron-deficiency anemia is most common in bottle-fed toddlers who are receiving large volumes of cow's milk and eat minimal amounts of food high in iron content (see Chapters 28 and 31). Gastrointestinal blood loss can lead to iron-deficiency anemia and should be considered, especially in adolescent males. Iron-deficiency anemia also may be found in children with chronic inflammatory diseases, even without **chronic blood loss**.

Epidemiology

The prevalence of iron deficiency, the most common cause of anemia in the world, is approximately 9% in toddlers, 9–11%

TABLE 150.2 Physical Findings in the Evaluation of Anemia

SYSTEM/STRUCTURE	OBSERVATION	SIGNIFICANCE
Skin	Hyperpigmentation	Fanconi anemia, dyskeratosis congenita
	Café-au-lait spots	Fanconi anemia
	Vitiligo	Vitamin B ₁₂ deficiency
	Partial oculocutaneous albinism	Chediak-Higashi syndrome
	Jaundice	Hemolysis
	Petechiae, purpura	Bone marrow infiltration, autoimmune hemolysis with autoimmune thrombocytopenia, hemolytic uremic syndrome, hemophagocytic syndromes
	Erythematous rash	Parvovirus or Epstein-Barr virus infection
	Butterfly rash	SLE antibodies
	Bruising	Bleeding disorder, nonaccidental trauma, scurvy
Head	Frontal bossing	Thalassemia major, severe iron deficiency, chronic subdural hematoma
	Microcephaly	Fanconi anemia
Eyes	Microphthalmia	Fanconi anemia
	Retinopathy	Hemoglobin SS, SC disease (see Table 150.7)
	Optic atrophy	Osteopetrosis
	Blocked lacrimal gland	Dyskeratosis congenita
	Kayser-Fleischer ring	Wilson disease
Blue sclera	Iron deficiency, osteopetrosis	
Ears	Deafness	
Mouth	Glossitis	Vitamin B ₁₂ deficiency, iron deficiency
	Angular stomatitis	Iron deficiency
	Cleft lip	Diamond-Blackfan syndrome
	Pigmentation	Peutz-Jeghers syndrome (intestinal blood loss)
	Telangiectasia	Osler-Weber-Rendu syndrome (blood loss)
	Leukoplakia	Dyskeratosis congenita
Chest	Shield chest or widespread nipples	Diamond-Blackfan syndrome
	Murmur	Endocarditis: prosthetic valve hemolysis; severe anemia
Abdomen	Hepatomegaly	Hemolysis, infiltrative tumor, chronic disease, hemangioma, cholecystitis, extramedullary hematopoiesis
	Splenomegaly	Hemolysis, sickle cell disease, (early) thalassemia, malaria, leukemia/lymphoma, Epstein-Barr virus, portal hypertension
	Nephromegaly	Fanconi anemia
	Absent kidney	Fanconi anemia
Extremities	Absent thumbs	Fanconi anemia
	Triphalangeal thumb	Diamond-Blackfan syndrome
	Spoon nails	Iron deficiency
	Beau line (nails)	Heavy metal intoxication, severe illness
	Mees line (nails)	Heavy metals, severe illness, sickle cell anemia
	Dystrophic nails	Dyskeratosis congenita
Rectal	Hemorrhoids	Portal hypertension
	Heme-positive stool	Gastrointestinal bleeding
Nerves	Irritable, apathy	Iron deficiency
	Peripheral neuropathy	Deficiency of vitamins B ₁ , B ₁₂ , and E; lead poisoning
	Dementia	Deficiency of vitamins B ₁₂ and E
	Ataxia, posterior column signs	Vitamin B ₁₂ deficiency
	Stroke	Hemoglobin SS or S β^0 -thalassemia, paroxysmal nocturnal hemoglobinuria
General	Small stature	Fanconi anemia, HIV infection, malnutrition

TABLE 150.3 Stages in Development of Iron Deficiency Anemia				
HEMOGLOBIN (g/dL)	PERIPHERAL SMEAR	SERUM IRON ($\mu\text{g/dL}$)	BONE MARROW IRON	SERUM FERRITIN (ng/ml)
13+ (normal)	nc/nc	50–150	Fe ²⁺	Male: 40–340 Female: 40–150
10–12	nc/nc	↓	Fe ²⁺ absent, erythroid hyperplasia	<12
8–10	hypo/nc	↓	Fe ²⁺ absent, erythroid hyperplasia	<12
<8	hypo/micro*	↓	Fe ²⁺ absent, erythroid hyperplasia	<12

*Microcytosis, determined by a mean corpuscular volume (in fL) <2 standard deviations (SD) below the mean, must be adjusted for age (e.g., -2SD at 3–6 mo = 74; at 0.5–2 yr = 70; at 2–6 yr = 75; at 6–12 yr = 77; and at 12–18 yr = 78).

Hypo/micro, Hypochromic, microcytic; hypo/nc, hypochromic, normocytic; nc/nc, normochromic, normocytic.

From Andreoli TE, Bennett JC, Carpenter CC, et al. Cecil Essentials of Medicine. 4th ed. Philadelphia: WB Saunders; 1997.

in adolescent females, and less than 1% in adolescent males. Iron-deficiency anemia occurs in approximately one-third of children who are iron deficient (Table 150.3). Children from low socioeconomic status in the United States may be at increased risk for iron deficiency because of poor dietary intake (see Chapter 31). Breast-fed infants are less likely to have iron deficiency than bottle-fed infants because, although there is less iron in breast milk, this iron is more efficiently absorbed. However, infants who continue to be exclusively breast-fed in the second half of the first year of life are at risk for iron deficiency.

Clinical Manifestations

In addition to cardiovascular manifestations of anemia, central nervous system (CNS) abnormalities (**apathy, irritability, poor concentration**) have been linked to iron deficiency,

presumably resulting from alterations of iron-containing enzymes (monoamine oxidase) and cytochromes. Poor muscle endurance, gastrointestinal dysfunction, and impaired WBC and T-cell function have been associated with iron deficiency. Iron deficiency in infancy may be associated with later **cognitive deficits** and poor school performance. The gradually developing nature of anemia associated with iron deficiency allows for physiologic compensation so that some children are minimally symptomatic even with severe anemia.

Treatment

In an otherwise healthy child, a **therapeutic trial of oral iron** is the best diagnostic study for iron deficiency as long as the child is re-examined and a response is documented. The response to oral iron includes rapid subjective improvement, especially in neurologic function (within 24–48 hours)

TABLE 150.4 Differentiating Features of Microcytic Anemias

TEST	IRON-DEFICIENCY ANEMIA	THALASSEMIA MINOR [†]	ANEMIA OF INFLAMMATION [‡]
Serum iron	Low	Normal	Low
Serum iron-binding capacity	High	Normal	Low or normal
Serum ferritin	Low	Normal or high	Normal or high
Marrow iron stores	Low or absent	Normal or high	Normal or high
Marrow sideroblasts	Decreased or absent	Normal or increased	Normal or increased
Free erythrocyte protoporphyrin	High	Normal or slightly increased	High
Hemoglobin A ₂ or F	Normal	High β -thalassemia; normal α -thalassemia	Normal
Red blood cell distribution width [§]	High	Normal	Normal/ \uparrow

^{*}See Table 150.3 for definition of microcytosis.

[†] α -thalassemia minor can be diagnosed by the presence of Bart hemoglobin on newborn screening.

[‡]Usually normochromic; 25% of cases are microcytic.

[§]Red blood cell distribution width quantitates the degree of anisocytosis (different sizes) of red blood cells.

and reticulocytosis (48–72 hours); increase in hemoglobin levels (4–30 days); and repletion of iron stores (1–3 months). The usual therapeutic dose of 3–6 mg/day of elemental iron induces an increase in hemoglobin of 0.25–0.4 g/dL per day (a 1%/day increase in hematocrit). If the hemoglobin level fails to increase within 2 weeks after institution of iron treatment, careful re-evaluation for ongoing blood loss, development of infection, poor compliance, malabsorption, or other causes of microcytic anemia is required (Table 150.4; see Fig. 150.1).

Prevention

Bottle-fed infants should receive an iron-containing formula until 12 months of age. Exclusively breast-fed infants older than 6 months of age should receive an iron supplement. The introduction of iron-enriched solid foods at 6 months of age, followed by a transition to a limited amount of cow's milk and increased solid foods at 1 year, can help prevent iron-deficiency anemia. Adolescent females who are menstruating should have a diet enriched with iron-containing foods. A vitamin with iron may also be used.

Thalassemia Minor

Etiology and Epidemiology

α -thalassemia and β -thalassemia minor are common causes of microcytosis, either with or without a mild hypochromic, microcytic anemia. They are prevalent in certain ethnic groups (e.g., Mediterranean, Southeast Asian, African). Individuals of Asian descent are at risk of having three or four α genes deleted, resulting in hemoglobin H disease (β_4 tetramers) or hydrops fetalis, which is largely Bart (γ_4 tetramers) hemoglobin (Table 150.5 and Fig. 150.3).

Laboratory Testing

The thalassemia minor syndromes (i.e., α -thalassemia trait, β -thalassemia trait) are characterized by a mild hypochromic, microcytic anemia with a low absolute reticulocyte count (see Table 150.5) due at least in part to ineffective erythropoiesis. The RBC count is usually elevated. As a result, if the mean corpuscular volume (MCV) divided by the RBC count is less than 12.5 (Mentzer index), the diagnosis is suggestive of thalassemia trait.

The blood smear reveals only microcytosis with α -thalassemia minor. Outside the neonatal period, when Bart hemoglobin is no longer detectable, the hemoglobin electrophoresis is usually normal in α -thalassemia minor (see Fig. 150.3). Blood smears of patients with β -thalassemia minor also reveal microcytic RBCs. In addition, target cells and basophilic stippled RBCs, caused by precipitation of alpha chain tetramers, may also be present. The diagnosis of β -thalassemia minor is based on an elevation of hemoglobin A₂ and F levels. Molecular testing is indicated for identification of more severe or unusual variants.

Treatment

No treatment is required for children with **thalassemia minor**. However, children with more severe forms of thalassemia, such as β -thalassemia intermedia or major or children with hemoglobin H disease (β_4 tetramers), especially the Constant Spring variant, require chronic transfusion therapy (see Table 150.5).

Lead Poisoning

Lead poisoning may be associated with a hypochromic, microcytic anemia because most patients have concomitant iron deficiency due to competition for uptake between these two divalent cations. The history of living in an older home (built before 1980) with chipped paint or lead dust should raise suspicion of lead poisoning, especially in a child with **pica**. The lead content of water should also be assessed due to the potential for lead-containing pipes. **Basophilic stippling** on the blood smear is common. Lead intoxication rarely causes hemolytic anemia. Detection by routine screening, removal from exposure, chelation therapy, and correction of iron deficiency are crucial to the neurologic development of affected children.

Normocytic Anemia

Etiology and Treatment

Anemia is commonly seen in chronic inflammatory disease. Hepcidin, a protein made in the liver, plays a key role in iron homeostasis. Inflammation causes an increase in the production of hepcidin, interrupting the process of iron release by macrophages and the absorption of iron from the intestines

TABLE 150.5 Thalassemia Syndromes		
DISORDER	GENOTYPIC ABNORMALITY	CLINICAL PHENOTYPE
β-THALASSEMIA		
Thalassemia major (Cooley anemia)	Homozygous β ⁰ -thalassemia	Severe hemolysis, ineffective erythropoiesis, transfusion dependency, hepatosplenomegaly, iron overload
Thalassemia intermedia	Compound heterozygous β ⁰ - and β ⁺ -thalassemia	Moderate hemolysis, splenomegaly, moderately severe anemia, but not transfusion dependent; main life-threatening complication is iron overload
Thalassemia minor	Heterozygous β ⁰ - and β ⁺ -thalassemia	Microcytosis, mild anemia
α-THALASSEMIA		
Silent carrier	α-/αα	Normal complete blood count
α-thalassemia trait	αα/- (α-thalassemia 1, cis deletion) or α-/α- (α-thalassemia 2, trans deletion)	Mild microcytic anemia
Hemoglobin H	α-/-	Microcytic anemia and mild hemolysis; not transfusion dependent*
Hydrops fetalis	-/-	Severe anemia, intrauterine anasarca from congestive heart failure; death in utero or at birth

*The Constant Spring variant may require chronic transfusion.

From Andreoli T, Carpenter C, Griggs R, et al. Cecil Essentials of Medicine. 7th ed. Philadelphia: Saunders; 2007.

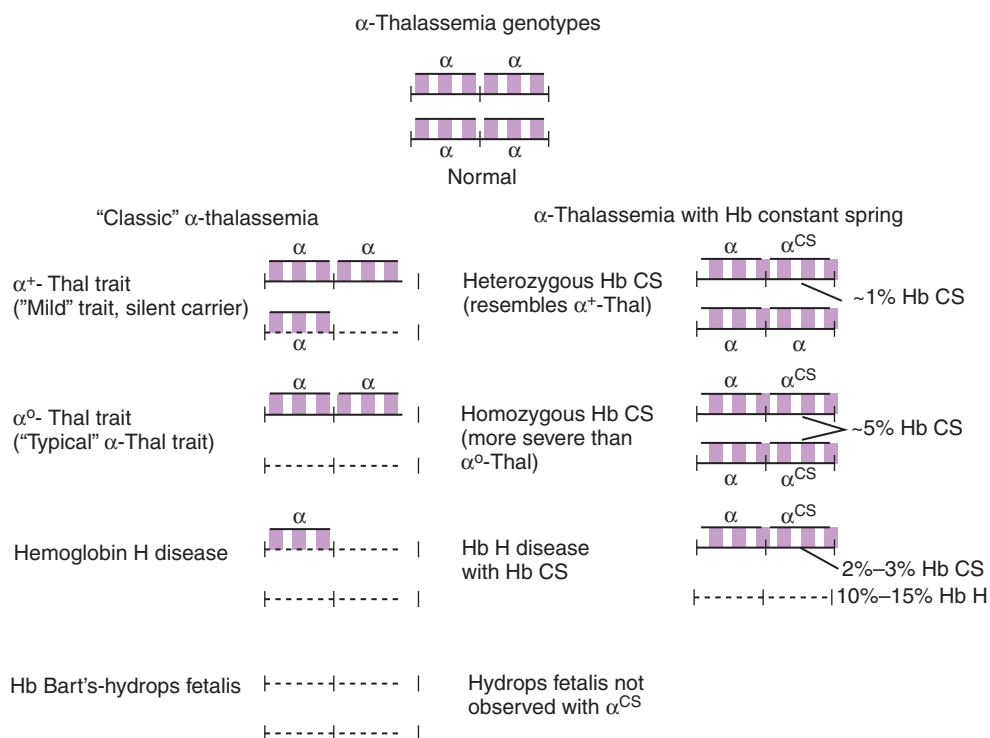

FIGURE 150.3 Genetic origins of the classic α-thalassemia syndromes due to gene deletions in the α-globin gene cluster. Hb Constant Spring (Hb CS) is an α-globin chain variant synthesized in such small amounts (1–2% of normal) that it has the phenotypic impact of a severe nondeletion α-thalassemia allele; however, the α^{CS} allele is always linked to a functioning α-globin gene, so it has never been associated with hydrops fetalis. (From Hoffman R, Benz EJ, Shattil SS, et al, eds. *Hematology: Basic Principles and Practice*. 5th ed. Philadelphia: Churchill Livingstone; 2008.)

leading to anemia. The **anemia of inflammation** may be normocytic or, less often, microcytic. This may pose a clinical challenge, when children with inflammatory disorders associated with blood loss (e.g., inflammatory bowel disease) exhibit a microcytic anemia. In these circumstances, only a bone marrow

aspiration with staining of the sample for iron can differentiate the two entities clearly (see Table 150.4). Low ferritin levels indicate concurrent iron deficiency. A trial of iron therapy is not indicated without a specific diagnosis in children who appear to be systemically ill.

TABLE 150.6 Differentiation of Red Blood Cell Aplasias and Pancytopenia

DISORDER	AGE AT ONSET	CHARACTERISTICS	TREATMENT
CONGENITAL			
Diamond-Blackfan syndrome (congenital hypoplastic anemia)	Newborn–1 mo; 90% of patients are <1 yr of age	Pure red blood cell aplasia, autosomal recessive trait, elevated fetal hemoglobin, fetal i antigen present, macrocytic, short stature, webbed neck, cleft lip, triphalangeal thumb; late-onset leukemia, mutation analysis	Prednisone, transfusion, hematopoietic stem cell transplant
ACQUIRED			
Transient erythroblastopenia of childhood (TEC)	6 mo–5 yr of age; 85% of patients are >1 yr of age	Pure red blood cell defect; no anomalies, fetal hemoglobin, or i antigen; spontaneous recovery, normal MCV	Expectant transfusion for symptomatic anemia
Idiopathic aplastic anemia (status posthepatitis, drugs, unknown)	All ages	All cell lines involved; exposure to felbamate, chloramphenicol, radiation	Hematopoietic stem cell transplantation, antithymocyte globulin, cyclosporine, androgens
FAMILIAL			
Fanconi anemia	Usually before 10 yr of age; mean is 8 yr	All cell lines; microcephaly, absent thumbs, café-au-lait spots, cutaneous hyperpigmentation, short stature; chromosomal breaks, high MCV and hemoglobin F; horseshoe or absent kidney; leukemic transformation; autosomal recessive trait	Androgens, corticosteroids, hematopoietic stem cell transplantation
Paroxysmal nocturnal hemoglobinuria	After 5 yr	Initial hemolysis followed by aplastic anemia; increased complement-mediated hemolysis; thrombosis; iron deficiency; CD59 low	Iron, hematopoietic stem cell transplantation, androgens, steroids, eculizumab
Dyskeratosis congenita	Mean is 10 yr for skin; mean is 17 yr for anemia	Pancytopenia; hyperpigmentation, dystrophic nails, leukoplakia; X-linked recessive; lacrimal duct stenosis; high MCV and fetal hemoglobin	Androgens, splenectomy, hematopoietic stem cell transplantation
Familial hemophagocytic lymphohistiocytosis	Before 2 yr	Pancytopenia; fever, hepatosplenomegaly, hypertriglyceridemia, CSF pleocytosis	Transfusion; often lethal; VP-16, hematopoietic stem cell transplantation, IVIG, cyclosporine
INFECTIOUS			
Parvovirus	Any age	Any chronic hemolytic anemia, typically sickle cell; new-onset reticulocytopenia and severe anemia	Red blood cell transfusion
Epstein-Barr virus (EBV)	Any age; usually <5 yr of age	X-linked immunodeficiency syndrome, pancytopenia	Transfusion, bone marrow transplantation
Virus-associated hemophagocytic syndrome (CMV, HHV-6, EBV)	Any age	Pancytopenia; hemophagocytosis in marrow, fever, hepatosplenomegaly	Transfusion, antiviral therapy, IVIG

CMV, Cytomegalovirus; CSF, cerebrospinal fluid; HHV-6, human herpesvirus 6; IVIG, intravenous immunoglobulin; MCV, mean corpuscular volume; VP-16, etoposide.

Bone marrow **infiltration by malignant cells** commonly leads to a normochromic, normocytic anemia. The mechanism by which neoplastic cells interfere with RBC and other marrow cell synthesis is multifactorial. The reticulocyte count is often low. Immature myeloid elements may be released into the peripheral blood because of the presence of the infiltrating tumor cells. An examination of the peripheral blood may reveal myelo- or lymphoblasts; when solid tumors metastasize to the marrow, these cells are seldom seen in the peripheral blood. Teardrop cells may be seen in the peripheral blood. A bone marrow examination is frequently necessary in the face of normochromic, normocytic anemia.

Congenital hypoplastic anemia (Diamond-Blackfan syndrome), a lifelong disorder, usually presents in the first few months of life or at birth with severe anemia and mild macrocytosis or normocytic anemia. This RBC disorder is due to a deficiency of bone marrow RBC precursors (Table 150.6). More than a third of patients have short stature. Many patients (50–66%) respond to corticosteroid treatment but must receive therapy indefinitely. Patients who do not respond to corticosteroid treatment are transfusion dependent and are at risk of the multiple complications of long-term transfusion therapy, especially iron overload. These patients have a higher rate of developing leukemia or other hematologic malignancies than the general population.

In contrast to the congenital hypoplastic anemias, **transient erythroblastopenia of childhood (TEC)**, a normocytic anemia caused by suppression of RBC synthesis, usually appears between 6 months and 5 years of age in an otherwise well-appearing child (see [Table 150.6](#)). Viral infections are thought to be the trigger, although the mechanism leading to RBC aplasia is poorly understood. The onset is gradual, but anemia may become severe. Transfusion of packed RBCs may be necessary if the anemia becomes symptomatic before recovery. Recovery is usually spontaneous. Mild neutropenia can be seen in patients with TEC; the well-appearing child with an otherwise normal physical exam helps differentiate from an underlying marrow infiltrative process. Differentiation from Diamond-Blackfan syndrome, in which erythroid precursors also are absent or diminished in the bone marrow, may be challenging.

Aplastic crises may complicate any chronic hemolytic anemia. Human parvovirus B19 (the cause of fifth disease) infects erythroid precursors and shuts down erythropoiesis. In children with chronic hemolytic anemia, these periods of severe reticulocytopenia can lead to an acute exacerbation of the anemia that may precipitate cardiovascular decompensation. Transient erythroid aplasia is without consequence in individuals with normal RBC survival. Recovery from parvovirus infection in hemolytic disease is spontaneous, but patients may need transfusion if the anemia is severe.

Macrocytic Anemia

See [Fig. 150.1](#).

Marrow Failure/Pancytopenia

Etiology

Pancytopenia is a simultaneous quantitative decrease in formed elements of the blood—erythrocytes, leukocytes, and platelets. Patients more often exhibit symptoms of infection or bleeding than anemia because of the relatively short life span of WBCs and platelets compared with the life span of RBCs. Causes of pancytopenia include failure of production (implying intrinsic bone marrow disease), sequestration (hypersplenism), and increased peripheral destruction.

Differential Diagnosis

Features that suggest **bone marrow failure** and mandate an examination of the bone marrow include a low reticulocyte count, teardrop forms of RBCs (implying marrow replacement, not just failure), presence of abnormal forms of leukocytes or myeloid elements more immature than band forms, small platelets, and an elevated MCV in the face of a low reticulocyte count. Pancytopenia resulting from bone marrow failure is usually a gradual process, starting with one or two cell lines but later involving all three cell lines. Features suggesting **increased destruction** include reticulocytosis, jaundice, immature erythroid or myeloid elements on the blood smear, large platelets, and increased serum bilirubin and lactic dehydrogenase.

Aplastic Anemia

Etiology and Epidemiology

In a child with aplastic anemia, pancytopenia evolves as the hematopoietic elements of the bone marrow disappear and the marrow is replaced by fat. In developed countries, aplastic

anemia is most often idiopathic. The disorder may be induced by drugs such as chloramphenicol and felbamate or by toxins such as benzene. Aplastic anemia also may follow infections, particularly hepatitis and infectious mononucleosis (see [Table 150.6](#)). Immunosuppression of hematopoiesis is postulated to be an important mechanism in patients with postinfectious and idiopathic aplastic anemia.

Laboratory Studies

A **bone marrow aspirate and biopsy** are crucial to determine cellularity or the extent of depletion of the hematopoietic elements.

Treatment

Survival rate is approximately 20% in severe aplastic anemia with supportive care alone, although the duration of survival may be years when vigorous blood product and antibiotic support is provided. For children with severe aplastic anemia—defined by an absolute reticulocyte count less than 50,000/ μL , absolute neutrophil count less than 500/ mm^3 , platelet count less than 20,000/ mm^3 , and bone marrow cellularity on biopsy specimen less than 25% of normal—the treatment of choice is **hematopoietic stem cell transplantation (HSCT)** from a sibling with identical human leukocyte antigen (HLA) and compatible mixed lymphocytes. When HSCT occurs before the recipient is sensitized to blood products, survival rate is greater than 80%. The treatment of aplastic anemia without an HLA-matched donor for HSCT is evolving, with two major options: potent immunosuppressive therapy or unrelated or partially matched HSCT. Data using immunosuppressive therapy with antithymocyte globulin, cyclosporine or tacrolimus, and corticosteroids in combination with hematopoietic growth factors have been encouraging. Such therapy is often toxic, and relapses often occur when therapy is stopped.

Fanconi Anemia

Etiology and Epidemiology

Fanconi anemia is a constitutional form of aplastic anemia that usually presents in the latter half of the first decade of life and may evolve over years. A group of genetic defects in proteins involved in **DNA repair** have been identified in Fanconi anemia, which is inherited in an autosomal recessive manner. The diagnosis is based on demonstration of increased chromosomal breakage after exposure to agents that damage DNA. The repair mechanism for DNA damage is abnormal in all cells in Fanconi anemia, which may contribute to the increased risk of malignancies. Acute leukemia develops in 10% of cases. Other malignancies that can occur include solid tumors of the head and neck, gastrointestinal tumors, and gynecologic tumors.

Clinical Manifestations

Patients with Fanconi anemia have numerous characteristic clinical findings (see [Table 150.6](#)).

Treatment

HSCT can cure the pancytopenia caused by bone marrow aplasia. Many patients with Fanconi anemia and approximately 20% of children with aplastic anemia seem to respond for a time to **androgenic therapy**, which induces masculinization and may cause liver injury and liver tumors. Androgenic

therapy increases RBC synthesis and may diminish transfusion requirements. The effect on granulocytes, and especially the platelet count, is less impressive.

Other less common etiologies of familial bone marrow failure resulting in pancytopenia are outlined in Table 150.6. These include dyskeratosis congenita and familial hemophagocytic lymphohistiocytosis.

Marrow Replacement

Marrow replacement may occur because of **leukemia**, **solid tumors** (especially neuroblastoma), **storage diseases**, **osteopetrosis** in infants, and **myelofibrosis**, which is rare in childhood. The mechanisms by which malignant cells impair marrow synthesis of normal hematopoietic elements are complex and incompletely understood. Bone marrow aspirate and biopsy are needed for precise diagnosis of the etiology of marrow synthetic failure.

Pancytopenia Resulting from Destruction of Cells

Pancytopenia resulting from destruction of cells may be caused by **intramedullary destruction** of hematopoietic elements (e.g., myeloproliferative disorders, deficiencies of folic acid and vitamin B₁₂) or by the **peripheral destruction** of mature cells. The usual site of peripheral destruction of blood cells is the spleen, although the liver and other parts of the reticuloendothelial system may contribute. **Hypersplenism** may be the result of anatomic causes (portal hypertension or splenic hypertrophy from thalassemia), infections (including malaria or Epstein-Barr virus [EBV]), storage diseases (Gaucher disease), or malignancy (lymphomas, histiocytosis). Splenectomy is indicated only when the pancytopenia is of clinical significance.

Hemolytic Anemias

Major Hemoglobinopathies

Alpha Chain Hemoglobinopathies

Etiology. Because alpha chains are needed for fetal erythropoiesis and production of hemoglobin F ($\alpha_2\gamma_2$), **alpha chain hemoglobinopathies** are present in utero. Four alpha genes are present on the two number 16 chromosomes (see Fig. 150.3 and Table 150.5). Single gene deletions produce no disorder (silent carrier state) but can be detected by measuring the rates of α and β synthesis or by using molecular biologic techniques. Deletion of two genes produces **α -thalassemia minor** with mild or no anemia and microcytosis. In individuals of African origin, the gene deletions occur on different chromosomes (*trans*). Thus infants born to parents that both have α -thalassemia gene deletions in *trans* have a benign disorder. In the Asian population, deletions may occur on the same chromosome (*cis*). Thus infants born to parents who both have α -thalassemia gene deletions in *cis* may inherit two number 16 chromosomes lacking three or even four genes resulting in severe disease. Deletion of three genes produces moderate hemolytic anemia with γ_4 tetramers (**Bart hemoglobin**) in the fetus and β_4 tetramers (hemoglobin H) in older children and adults (see Table 150.5). Deletion of all four α genes leads to hydrops fetalis, severe intrauterine anemia, and death, unless intrauterine transfusions are administered.

Beta Chain Hemoglobinopathies

Beta chain hemoglobinopathies are more prevalent in the United States than alpha chain disorders, possibly because these abnormalities are not symptomatic in utero. The major beta hemoglobinopathies include those that alter hemoglobin function (e.g., **hemoglobin S, C, E, and D**) and those that alter beta chain production (e.g., **β -thalassemias**). Because each RBC has two copies of chromosome 11 and they express both β -globin genes, most disorders of beta chains are not clinically severe, unless both beta chains are abnormal. By convention, when describing β -thalassemia genes, β^0 indicates a thalassaemic gene resulting in absent beta chain synthesis, whereas β^+ indicates a thalassaemic gene that permits reduced but not absent synthesis of normal β chains. Disorders of the beta chain usually manifest themselves clinically between 4 and 12 months of age when fetal hemoglobin nadirs unless they have been detected prenatally or by cord blood screening.

β -Thalassemia Major (Cooley Anemia)

Etiology and Epidemiology

β -thalassemia major is caused by mutations that impair **beta chain synthesis**. Because of unbalanced synthesis of alpha and beta chains, alpha chains precipitate within the cells, resulting in RBC destruction either in the bone marrow or in the spleen. β -thalassemia major is seen most commonly in individuals of Mediterranean or Asian descent. The clinical severity of the illness varies based on the specific molecular defect (see Table 150.5).

Clinical Manifestations

Signs and symptoms of β -thalassemia major result from the combination of chronic hemolytic anemia, decreased or absent production of normal hemoglobin A, and ineffective erythropoiesis. The anemia is severe and leads to growth failure and high-output heart failure. **Ineffective erythropoiesis** causes increased expenditure of energy and expansion of the bone marrow cavities of all bones, leading to osteopenia, pathologic fractures, extramedullary erythropoiesis with resultant hepatosplenomegaly, and an increase in the rate of iron absorption.

Treatment

Treatment of β -thalassemia major is based on a **hypertransfusion program** that corrects the anemia and suppresses the patient's own ineffective erythropoiesis, limiting the stimulus for increased iron absorption. This suppression permits the bones to heal, decreases metabolic expenditures, increases growth, and limits dietary iron absorption. Splenectomy may reduce the transfusion volume, but it adds to the risk of serious infection. Chelation therapy with deferasirox or deferoxamine should start when laboratory evidence of iron overload (**hemochromatosis**) is present and before there are clinical signs of iron overload (nonimmune diabetes mellitus, cirrhosis, heart failure, bronzing of the skin, and multiple endocrine abnormalities). HSCT in childhood, before organ dysfunction is induced by iron overload, has had a high success rate in β -thalassemia major and is the treatment of choice.

Sickle Cell Disease

Etiology and Epidemiology

The common sickle cell syndromes are **hemoglobin SS disease**, **hemoglobin SC disease**, **hemoglobin S- β^0 -thalassemia**, **hemoglobin S- β^+ -thalassemia**, and other rare variants (Table 150.7).

TABLE 150.7 Comparison of Sickle Cell Syndromes

GENOTYPE	CLINICAL CONDITION	PERCENT HEMOGLOBIN					OTHER FINDING(S)
		HB A	HB S	HB A ₂	HB F	HB C	
SA	Sickle cell trait	55–60	40–45	2–3	–	–	Usually asymptomatic
SS	Sickle cell anemia	0	85–95	2–3	5–15	–	Clinically severe anemia; Hb F heterogeneous in distribution
S-β ⁰ thalassemia	Sickle cell β ⁰ -thalassemia	0	70–80	3–5	10–20	–	Moderately severe anemia; splenomegaly in 50%; smear: hypochromic, microcytic anemia
S-β ⁺ thalassemia	Sickle cell β ⁺ -thalassemia	10–20	60–75	3–5	10–20	–	Hb F distributed heterogeneously; mild microcytic anemia
SC	Hb SC disease	0	45–50	–	–	45–50	Moderately severe anemia; splenomegaly; retinopathy; target cells
S-HPFH	Sickle-hereditary persistence of Hb F	0	70–80	1–2	20–30	–	Often asymptomatic; Hb F is uniformly distributed

From Andreoli T, Carpenter C, Griggs R, et al. Cecil Essentials of Medicine. 7th ed. Philadelphia: Saunders; 2007.

The specific hemoglobin genotype must be identified because the clinical complications differ in frequency, type, and severity. As a result of a single **amino acid substitution** (valine for glutamic acid at the β6 position), sickle hemoglobin crystallizes and forms a gel in the deoxygenated state. When reoxygenated, the sickle hemoglobin is normally soluble. The so-called reversible sickle cell can enter the microcirculation. As the oxygen is extracted and saturation declines, sickling may occur, occluding the microvasculature. The surrounding tissue undergoes infarction, inducing pain and chronic organ dysfunction. This sickling phenomenon is exacerbated by hypoxia, acidosis, fever, hypothermia, and dehydration.

Clinical Manifestations and Treatment

A child with sickle cell disease is vulnerable to **life-threatening infection** by 4 months of age due to splenic dysfunction. **Splenic dysfunction** is caused by sickling of the RBCs within the spleen, resulting in an inability to filter microorganisms from the bloodstream. Splenic dysfunction is followed, eventually, by **splenic infarction**, usually by 2–4 years of age. The loss of normal splenic function makes the patient susceptible to overwhelming infection by encapsulated organisms, especially *Streptococcus pneumoniae* and other pathogens (Table 150.8). The hallmark of infection is fever. A febrile child with sickle cell disease (temperature >38.5°C) must be evaluated immediately (see Chapter 96). Current precautions to prevent infections include prophylactic daily oral penicillin begun at diagnosis and vaccinations against pneumococcus, *Haemophilus influenzae* type b, meningococcus, hepatitis B virus, and influenza virus.

The anemia of hemoglobin SS disease is usually a chronic, moderately severe hemolytic anemia that is not routinely transfusion dependent. The severity depends in part on the patient's phenotype. Manifestations of chronic anemia include jaundice, pallor, variable splenomegaly in infancy, a cardiac flow murmur, and delayed growth and sexual maturation. Decisions about transfusion should be made based on the patient's clinical condition, the hemoglobin level, and the reticulocyte count.

Sickle cell disease is complicated by sudden, sometimes severe and life-threatening events caused by the acute intravascular sickling of the RBCs, with resultant pain or organ dysfunction (i.e., **crisis**). In two different clinical situations, an acute, potentially life-threatening decline in the hemoglobin level may be superimposed on the chronic compensated anemia. **Splenic sequestration crisis** is a life-threatening, hyperacute drop in the hemoglobin level (blood volume) secondary to splenic pooling of the patient's RBCs and sickling within the spleen. The spleen is moderately to markedly enlarged, and the reticulocyte count is elevated. In an **aplastic crisis**, parvovirus B19 infects RBC precursors in the bone marrow and induces transient RBC aplasia with reticulocytopenia and a rapid worsening of anemia because of the very short life span of sickle RBCs. Simple transfusion therapy is indicated for sequestration and aplastic crises when the anemia is symptomatic.

Acute vasoocclusive events may occur in any organ of the body and manifest as pain and/or significant dysfunction (see Table 150.8). The **acute chest syndrome** is a vasoocclusive event within the lungs with evidence of a new infiltrate on chest radiograph. It is often associated with infection and infarction. The patient may first complain of chest pain but within a few hours develops cough, increasing respiratory and heart rates, hypoxia, and progressive respiratory distress. Physical examination reveals areas of decreased breath sounds and dullness on chest percussion. Treatment involves early recognition and prevention of arterial hypoxemia. Oxygen, fluids, judicious use of analgesic medications, antibiotics, bronchodilators, and RBC transfusion (rarely exchange transfusion) are indicated as therapy for acute chest syndrome. *Incentive spirometry* may help reduce the incidence of acute chest syndrome in patients presenting with pain in the chest or abdomen.

Acute painful events are the most common type of vasoocclusive events. Pain usually localizes to the long bones of the arms or legs but may occur in smaller bones of the hands or feet in infancy (dactylitis), ribs, or in the abdomen. Painful events usually last 2–7 days. Repeated painful events within the femur may lead to avascular necrosis of the femoral head and chronic hip disease. Treatment of painful events includes

TABLE 150.8 Clinical Manifestations of Sickle Cell Disease

MANIFESTATION	COMMENTS
Anemia	Chronic, onset 3–4 mo of age; hemoglobin usually 6–10 g/dL
Aplastic crisis	Parvovirus infection, reticulocytopenia; acute and reversible; may need transfusion
Sequestration crisis	Massive splenomegaly (may involve liver), shock; treat with transfusion
Hemolytic crisis	May be associated with G6PD deficiency
Dactylitis	Hand-foot swelling in early infancy
Pain	Microvascular painful vasoocclusive infarcts of muscle, bone, bone marrow, lung, intestines; chronic pain (nervous system sensitization)
Cerebrovascular accidents (overt and silent)	Large and small vessel occlusion → thrombosis/bleeding (stroke); requires chronic transfusion; neurocognitive deficits
Acute chest syndrome	Infection, asthma, atelectasis, infarction, fat emboli, severe hypoxemia, infiltrate, dyspnea, absent breath sounds; treated with transfusions, antibiotics, oxygen, bronchodilators
Chronic lung disease	Pulmonary fibrosis, restrictive lung disease, cor pulmonale, pulmonary hypertension
Priapism	Causes eventual impotence; treated with transfusion, oxygen, or corpora cavernosa-to-spongiosa shunt
Ocular	Retinopathy
Gallbladder disease	Bilirubin stones; cholecystitis
Renal	Hematuria, papillary necrosis, renal concentrating defect; nephropathy
Cardiomyopathy	Heart failure
Skeletal	Osteonecrosis (avascular) of femoral or humeral head
Leg ulceration	Seen in older patients
Infections	Functional asplenia, defects in properdin system; pneumococcal bacteremia, meningitis, and arthritis; deafness from meningitis; <i>Salmonella</i> and <i>Staphylococcus aureus</i> osteomyelitis; severe <i>Mycoplasma pneumoniae</i>
Growth failure, delayed puberty	May respond to nutritional supplements
Psychosocial issues	Depression, anxiety, attention deficit hyperactivity disorder (ADHD)

*Clinical manifestations with sickle cell trait are unusual but include renal papillary necrosis (hematuria), sudden death on exertion, intraocular hyphema extension, and sickling in unpressurized airplanes.
G6PD, Glucose-6-phosphate dehydrogenase.

analgesia (usually opioids and nonsteroidal antiinflammatory drugs), and supplemental oxygen if the patient is hypoxic. Appropriate use of analgesics is imperative to control pain. Patients with sickle cell disease often require high doses of opioids due to tolerance to provide adequate pain control. The frequency of acute painful events increases with age. In

addition, chronic daily pain irrespective of an acute vasoocclusive event is associated with increasing age, occurring in 30–40% of adults and children. Chronic nervous system sensitization is likely a key driver of the chronic pain seen in patients with sickle cell disease.

Priapism occurs in males, usually older than 6 years of age. The child experiences a sudden, painful onset of a tumescent penis that will not relax. Therapeutic steps for priapism include the administration of oxygen, fluids, analgesia, and transfusion when appropriate to achieve a hemoglobin S less than 30%. Urgent partial exchange transfusion is often required to lower the hemoglobin S. Consultation with urology is recommended.

Overt **stroke** occurs in approximately 8–10% of patients with hemoglobin SS/hemoglobin S- β^0 -thalassemia disease. These events may present as the sudden onset of an altered state of consciousness, seizures, or focal paralysis. **Silent stroke**, which is defined as evidence of cerebral infarction on imaging studies but a normal neurologic examination, occurs in approximately 20% of patients with hemoglobin SS/hemoglobin S- β^0 -thalassemia disease. Neurocognitive changes such as a significant change in school performance or behavior is associated with silent stroke, and those with silent stroke are at increased risk for development of overt stroke. Children with hemoglobin SS/hemoglobin S- β^0 -thalassemia disease ages 2–16 years should be screened for increased risk of stroke using transcranial Doppler (TCD). Chronic monthly transfusions are indicated in those with overt stroke, silent stroke, and/or abnormal TCDs.

Laboratory Diagnosis

The diagnosis of hemoglobinopathies is made by identifying the precise amount and type of hemoglobin using **hemoglobin electrophoresis, isoelectric focusing, or high-performance liquid chromatography**. Every member of an at-risk population should have a precise hemoglobin phenotype performed at birth (preferably) or during early infancy. All U.S. states perform newborn screening for sickle cell disease.

Treatment

Disease-modifying therapy for sickle cell disease is evolving. Data support the use of chronic RBC transfusions in children who have had an overt or silent stroke or elevated TCD. Chronic RBC transfusions can also be used successfully for short time periods to prevent recurrent vasoocclusive events, including pain, acute chest syndrome, and priapism. **Hydroxyurea**, which increases hemoglobin F, decreases the number and severity of painful events, frequency of acute chest syndrome, and need for transfusions in children as early as 1 year of age. Current published clinical care guidelines from the National Institutes of Health (NIH)/National Heart, Lung, and Blood Institute (NHLBI) for patients with sickle cell disease recommend hydroxyurea should be initiated in asymptomatic children with severe sickle cell disease (HbSS or HbS- β^0 -thalassemia). Three new disease-modifying drugs have been Food and Drug Administration approved for the treatment of sickle cell disease in the past 2 years (i.e., crizanlizumab, voxelotor, L-glutamine). HSCT using a matched sibling donor has cured many children with sickle cell disease. HSCT using alternative donors for children, without a suitable sibling match, is being studied. Multiple approaches for gene therapy to treat sickle cell disease are also under investigation.

Supportive care for the treatment of end-organ complications (e.g., cardiopulmonary, renal) is vital to decrease morbidity.

Enzymopathies

Etiology

G6PD deficiency is an abnormality in the **hexose monophosphate shunt pathway** of glycolysis that results in the depletion of reduced nicotinamide adenine dinucleotide phosphate (NADPH) and the inability to regenerate reduced glutathione. When a patient with G6PD deficiency is exposed to significant oxidant stress, hemoglobin is oxidized, forming precipitates of sulfhemoglobin (**Heinz bodies**), which are visible on specially stained preparations.

The severity of hemolysis depends on the enzyme variant. In many G6PD deficiencies, the enzymes become unstable with aging of the RBC and cannot be replaced because the cell is anucleated. Older cells are most susceptible to oxidant-induced hemolysis. In other variants, the enzyme is kinetically abnormal.

Epidemiology

The most common variants of G6PD deficiency have been found in areas where malaria is endemic. G6PD deficiency protects against parasitism of the erythrocyte. The most common variant with normal activity is termed **type B** and is defined by its electrophoretic mobility. The approximate gene frequencies in Blacks are 70% type B, 20% type A, and 10% type A-. Only the **A- variant**, termed the *African variant*, is unstable. Ten percent of Black males are affected. A group of variants found in Sardinians, Sicilians, Greeks, Sephardic and Oriental Jews, and Arabs is termed the **Mediterranean variant** and is associated with chronic hemolysis and potentially life-threatening hemolytic disease. Because the gene for G6PD deficiency is carried on the X chromosome, clinical hemolysis is most common in males. Heterozygous females who have randomly inactivated a higher percentage of X chromosomes with the normal gene may become symptomatic, as may homozygous females with the A- variant (0.5–1% of females of African descent).

Clinical Manifestations

G6PD deficiency has two common presentations. Individuals with the A- variant have normal hemoglobin values when well but develop an **acute episode of hemolysis** triggered by serious (bacterial) infection or ingestion of an oxidant drug. The RBC morphology during episodes of acute hemolysis is striking, appearing to have “bites” taken out of them (cookie cells). These are areas of absent hemoglobin that are produced by phagocytosis of Heinz bodies by splenic macrophages; as a result, the RBCs appear blistered. Clinically evident jaundice, dark urine resulting from bilirubin pigments, hemoglobinuria when hemolysis is intravascular, and decreased haptoglobin levels are common during hemolytic episodes. Early on, the hemolysis usually exceeds the ability of the bone marrow to compensate, so the reticulocyte count may be low for 3–4 days.

Laboratory Studies

The diagnosis of G6PD deficiency is based on decreased NADPH formation. However, G6PD levels during an acute, severe hemolytic episode may be normal because the most deficient cells have been destroyed and reticulocytes are enriched with G6PD. Repeating the test at a later time when the patient

is in a steady-state condition, testing the mothers of boys with suspected G6PD deficiency, or performing electrophoresis to identify the precise variant present aids in diagnosis.

Treatment and Prevention

The treatment of G6PD deficiency is supportive. Transfusions are indicated when significant anemia associated with cardiovascular compromise is present. Maintaining hydration and urine alkalization protects the kidneys against damage from precipitated free hemoglobin. Hemolysis is prevented by avoidance of known oxidants, particularly long-acting sulfonamides, nitrofurantoin, primaquine, dimercaprol, and moth balls (naphthalene). Fava beans (favism) have triggered hemolysis, particularly in patients with the Mediterranean variant. Serious infection also is a potential precipitant of hemolysis in G6PD-deficient young children.

Pyruvate kinase deficiency is much less common than G6PD deficiency and represents a clinical spectrum of disorders caused by the functional deficiency of pyruvate kinase. Some individuals have a true deficiency state, and others have abnormal enzyme kinetics. The metabolic consequence of pyruvate kinase deficiency is adenosine triphosphate (ATP) depletion, impairing RBC survival. Pyruvate kinase deficiency is usually an autosomal disorder, and most children who are affected are double heterozygotes for two abnormal enzymes. Hemolysis is not aggravated by oxidant stress due to the profound reticulocytosis in this condition. Aplastic crises are potentially life threatening. The spleen is the site for RBC removal in pyruvate kinase deficiency. Most patients have amelioration of the anemia and a reduction of transfusion requirements after splenectomy.

Membrane Disorders

Etiology

The biochemical basis of **hereditary spherocytosis** and **hereditary elliptocytosis** is similar. Both conditions appear to have a defect in the protein lattice (spectrin, ankyrin, protein 4.2, band 3) that underlies the RBC lipid bilayer and provides stability of the membrane shape. In hereditary spherocytosis, pieces of membrane bud off as microvesicles because of abnormal vertical interaction of the cytoskeletal proteins and uncoupling of the lipid bilayer from the cytoskeleton. When the RBC loses membrane, cell shape changes from a biconcave disk to a spherocyte. This shape is less deformable when passing through narrow passages in the spleen. Hereditary elliptocytosis is a disorder of spectrin dimer interactions that occurs primarily in individuals of African descent. The transmission of hereditary spherocytosis can be autosomal dominant, autosomal recessive, or occur by a spontaneous mutation. **Hereditary pyropoikilocytosis** (unusual instability of the erythrocytes when they are exposed to heat at 45°C) is the result of a structural abnormality of spectrin.

Clinical Manifestations

Hereditary spherocytosis varies greatly in clinical severity, ranging from an asymptomatic, well-compensated, mild hemolytic anemia that may be discovered incidentally to a severe hemolytic anemia with growth failure, splenomegaly, and chronic transfusion requirements in infancy necessitating early splenectomy. The most common variant of hereditary elliptocytosis is a clinically insignificant morphologic abnormality

FIGURE 150.4 Coombs or direct antiglobulin test (DAT). In the DAT, so-called Coombs serum that recognizes human immunoglobulin (Ig) or complement (C) is used to detect the presence of antibody or C on the surface of the red blood cells (RBCs) by agglutination. (A) An IgM antibody can bind two RBCs simultaneously because of its multiple antigen-binding sites. The great size of the IgM allows it to bridge the surface repulsive forces (zeta potential) between RBCs and cause agglutination. (B) An IgG antibody is too small to bridge the zeta potential and cause agglutination. (C) On the addition of Coombs serum, the zeta potential is bridged successfully, and RBCs agglutinate. (Modified from Ware RE, Rosse WF. Autoimmune hemolytic anemia. In: Orkin SH, Nathan DG, Look AT, et al., eds. *Hematology of Infancy and Childhood*. 6th ed. Philadelphia: Saunders; 2003:530.)

without shortened RBC survival. The less common variant is associated with spherocytes, ovalocytes, and elliptocytes with a moderate, usually compensated, hemolysis. Far more significant hemolysis occurs in hereditary pyropoikilocytosis. The peripheral blood smear in hereditary pyropoikilocytosis often includes elliptocytes, spherocytes, fragmented RBCs, and striking microcytosis. Such patients may have bizarre blood smears in the newborn period with small, fragmented RBCs.

Laboratory Diagnosis

The clinical diagnosis of hereditary spherocytosis should be suspected in patients with even a few spherocytes found on the blood smear because the spleen preferentially removes spherocytes. An incubated **osmotic fragility test** confirms the presence of spherocytes and increases the likelihood of the diagnosis. The osmotic fragility test result is abnormal in any hemolytic disease in which spherocytes are present (e.g., in antibody-mediated hemolysis). Genetic studies (band 3 gene mutation) can also be done to confirm the diagnosis of hereditary spherocytosis.

Treatment

Splenectomy corrects the anemia and normalizes the RBC survival in patients with hereditary spherocytosis, but the morphologic abnormalities persist. Splenectomy should be reserved for children with severe hereditary spherocytosis and symptoms referable to chronic anemia or growth failure. Splenectomy should be deferred until age 5 years, if possible, to minimize the risk of overwhelming post-splenectomy sepsis and to maximize the antibody response to the polyvalent pneumococcal and meningococcal vaccine. In several reports, partial splenectomy seems to improve the hemolytic anemia and maintain splenic function in host defense.

Hemolytic Anemia Caused by Disorders Extrinsic to the Red Blood Cell

Etiology and Clinical Manifestations

Isoimmune hemolysis is caused by active maternal immunization against fetal antigens that the mother's erythrocytes

do not express (see [Chapter 62](#)). Examples are antibodies to the A, B, and Rh D antigens; other Rh antigens; and the Kell, Duffy, and other blood groups. Anti-A and anti-B hemolysis is caused by the placental transfer of naturally occurring maternal antibodies from mothers who lack A or B antigen (usually blood type O). Positive results of the direct antiglobulin (**Coombs**) test on the infant's RBCs ([Fig. 150.4](#)), the indirect antiglobulin test on the mother's serum, and the presence of spherocytes and immature erythroid precursors (erythroblastosis) on the infant's blood smear confirm this diagnosis. Isoimmune hemolytic disease varies in clinical severity. There may be no clinical manifestations or the infant may exhibit jaundice, severe anemia, and/or hydrops fetalis.

Autoimmune hemolytic anemia is usually an acute, self-limited Coombs-positive process that develops after an infection (e.g., *Mycoplasma*, EBV, or other viral infections) due to the production of autoantibodies that cause red cell destruction. Autoimmune hemolytic anemia may also be the presenting symptom of a chronic autoimmune disease (e.g., systemic lupus erythematosus, lymphoproliferative disorders, or immunodeficiency). Drugs may induce a Coombs-positive hemolytic anemia by forming a hapten on the RBC membrane (penicillin) or by forming immune complexes (quinidine) that attach to the RBC membrane. Antibodies then activate complement-induced intravascular hemolysis. The third type of drug-induced immune hemolysis occurs during treatment with α -methyl dopa and a few other drugs. In this type, prolonged drug exposure alters the RBC membrane, inducing neoantigen formation. Antibodies are produced that bind to the neoantigen; this produces a positive antiglobulin test result far more commonly than it induces hemolysis. In each of these conditions, the erythrocyte is an *innocent bystander*.

A second form of acquired hemolytic disease is caused by mechanical damage to the RBC membrane during circulation. In **thrombotic microangiopathy** the RBCs are trapped by fibrin strands in the circulation and physically broken by shear stress as they pass through these strands. Hemolytic uremic

syndrome, disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura, malignant hypertension, toxemia, and hyperacute renal graft rejection can produce thrombotic microangiopathy. The platelets are usually large, indicating that they are young, but have a decreased survival, even if the numbers are normal. Consumption of clotting factors is more prominent in DIC than in the other forms of thrombotic microangiopathy. The smear shows RBC fragments (schistocytes), microspherocytes, teardrop forms, and polychromasia. Other examples of mechanical injury to RBCs include damage by exposure to nonendothelialized surfaces (as in artificial heart valves) or because of high flow and shear rates in giant hemangiomas (**Kasabach-Merritt syndrome**).

Alterations in plasma lipids, especially cholesterol, may lead to damage to the RBC membrane and shorten RBC survival. Lipids in the plasma are in equilibrium with lipids in the RBC membrane. High cholesterol levels increase the membrane cholesterol and the total membrane surface without affecting the volume of the cell. This condition produces **spur cells** that may be seen in abetalipoproteinemia and liver diseases. Hemolysis occurs in the spleen, where poor RBC deformability results in erythrocyte destruction. **Circulating toxins** (e.g., snake venoms and heavy metals) that bind sulfhydryl groups may damage the RBC membrane and induce hemolysis. Irregularly spiculated RBCs (burr cells) are seen in renal failure. **Vitamin E deficiency** can also cause an acquired hemolytic anemia because of abnormal sensitivity of membrane lipids to oxidant stress. Vitamin E deficiency may occur in premature infants who are not being supplemented with vitamin E or who have insufficient nutrition, in infants with severe malabsorption syndromes (including cystic fibrosis), and in infants with transfusional iron overload, which can lead to severe oxidant exposure.

Laboratory Diagnosis

The peripheral blood smear in autoimmune hemolytic anemia usually reveals spherocytes and occasionally nucleated RBCs. The reticulocyte count varies because some patients have relatively low reticulocyte counts because of autoantibodies that cross react with RBC precursors.

Treatment and Prognosis

Transfusion may be lifesaving in the management of autoimmune hemolytic anemia. Cross matching of RBCs in preparation for transfusion can be difficult since autoantibodies react with virtually all RBCs. In addition to **transfusion**, further management of autoimmune hemolytic anemia depends on antibody type. Acute management may involve administration of **corticosteroids** and, at times, **intravenous immunoglobulin**. Corticosteroids reduce the clearance of sensitized RBCs in the spleen. More than 80% of children with autoimmune hemolytic anemia recover spontaneously. In drug-induced hemolysis, withdrawal of the drug usually leads to resolution of the hemolytic process.

PEARLS FOR PRACTITIONERS

See *Hematology: Pearls for Practitioners* at the end of this section.

CHAPTER 151

Hemostatic Disorders

NORMAL HEMOSTASIS

Hemostasis is the dynamic process of **coagulation** as it occurs in areas of vascular injury, involving the carefully modulated interaction of platelets, vascular wall, and procoagulant and anticoagulant proteins. After an injury to the vascular endothelium, subendothelial collagen induces a conformational change in von Willebrand factor (VWF), an adhesive protein to which platelets bind via their glycoprotein Ib receptor. After adhesion, platelets undergo activation and release various molecular contents, including adenosine diphosphate (ADP), from intracellular granules. These **activated platelets** subsequently induce aggregation of additional platelets. Simultaneously, tissue factor, collagen, and other matrix proteins in tissue activate the coagulation cascade, leading to the formation of the enzyme **thrombin** (Fig. 151.1). Thrombin causes further aggregation of platelets, a positive feedback activation of factors 5 and 8, the conversion of fibrinogen to fibrin, and the activation of factor 11. A **platelet plug** forms and bleeding ceases, usually within 3–7 minutes. This process of platelet plug formation is generally referred to as primary hemostasis. The generation of thrombin leads to formation of a more stable clot by the activation of factor 13, which cross-links fibrin, forming a stable thrombus. Finally, contractile elements within the platelet mediate **clot retraction**. The production and retraction of a thrombin clot is known as secondary hemostasis. Thrombin also contributes to the eventual limitation of clot size by binding to the protein thrombomodulin on intact endothelial cells, converting protein C into activated protein C, which binds to protein S to downregulate the activation of factors 5 and 8. Thrombin also contributes to the eventual lysis of the thrombus by activating plasminogen to plasmin. All the hemostatic processes are closely interwoven and occur on biologic surfaces that mediate coagulation by bringing the critical players—platelets, endothelial cells, and subendothelium—into close proximity with pro- and anticoagulant proteins.

Many view coagulation as having **intrinsic and extrinsic pathways**, but the reality is that these pathways are closely interactive and do not react independently (Fig. 151.2). For ease of use, all coagulation factors are denoted herein using Arabic rather than Roman numerals to prevent misreading factor VII (7) as factor VIII (8), etc. In vivo, factor 7 autocatalyzes to form small amounts of factor 7a. When tissue is injured, **tissue factor** is released and causes a burst of factor 7a generation. Tissue factor, in combination with calcium and factor 7a, activates factor 9 and factor 10. The activation of factor 9 by factor 7a results in eventual generation of thrombin, which positively feeds back on factor 11, generating factor 11a and accelerating thrombin formation. This process explains why deficiency of factor 8 or factor 9 leads to severe bleeding disorders, whereas deficiency of factor 11 is usually mild, and deficiency of factor 12 is asymptomatic.

A series of **inhibitory factors** serve to tightly regulate the activation of coagulation. **Antithrombin** inactivates thrombin and factors 9a, 10a, and 11a. The **protein C and protein S** system inactivates activated factors 5 and 8, which are cofactors

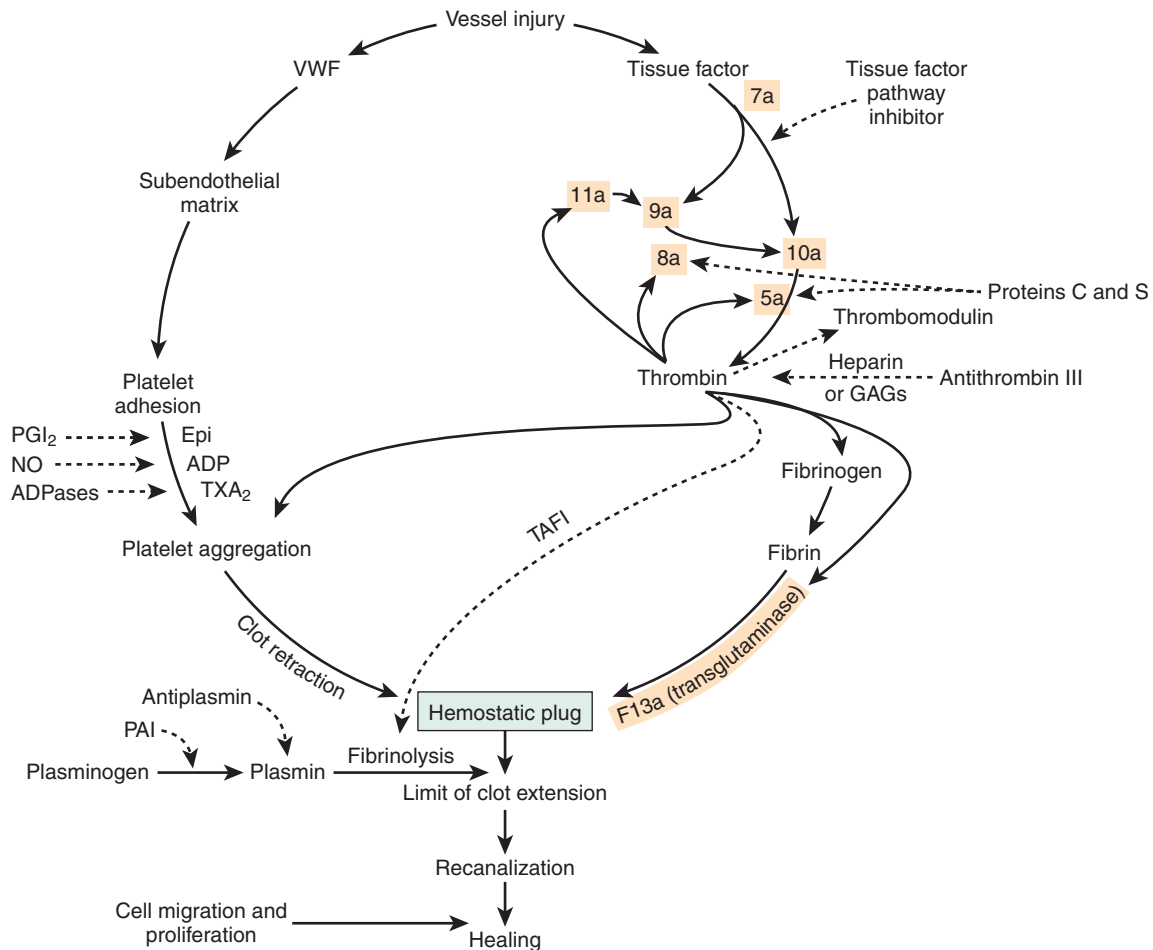

FIGURE 151.1 Diagram of the multiple interactions of the hemostatic mechanism. Solid lines indicate reactions that favor coagulation, and dashed lines indicate reactions that inhibit clotting. *Epi*, Epinephrine; *GAGs*, glycosaminoglycans; *NO*, nitric oxide; *PAI*, plasminogen activator inhibitor; *PGI₂*, prostaglandin I₂ (prostacyclin); *TAFI*, thrombin-activated fibrinolytic inhibitor; *TXA₂*, thromboxane A₂; *VWF*, von Willebrand factor. (Modified from Scott JP, Flood VH, Raffini LJ. Hemostasis. In: Kliegman RM, St. Geme J, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia: Elsevier; 2020 [fig 502.2].)

localized in the “tenase” and “prothrombinase” complexes. The **tissue factor pathway inhibitor**, an anticoagulant protein, limits activation of the coagulation cascade by factor 7a and factor 10a. **Fibrinolysis** is initiated by the action of tissue plasminogen activator on plasminogen, producing plasmin, the active enzyme that degrades fibrin into split products. Fibrinolysis eventually dissolves the clot and allows normal flow to resume. Acquired or inherited deficiencies of anticoagulant proteins may predispose to thrombosis.

DEVELOPMENTAL HEMOSTASIS

In the fetus, procoagulant factors such as fibrinogen, factor 5, factor 8, and platelets approach normal levels during the second trimester. Levels of other clotting factors and anticoagulant proteins increase gradually throughout gestation. The premature infant is simultaneously at increased risk of bleeding or clotting complications that are exacerbated by many of the medical interventions needed for care and monitoring, especially indwelling arterial or venous catheters. Most children attain normal levels of procoagulant and anticoagulant proteins by 1 year of age, although levels of protein C may lag and normalize in adolescence.

HEMOSTATIC DISORDERS

Etiology and Epidemiology

A detailed **family history** is crucial to the diagnosis of bleeding and thrombotic disorders. **Hemophilia** is X linked, and most affected children are male. **von Willebrand disease** (VWD) usually is inherited in an autosomal dominant fashion. The causes of bleeding may be hematologic in origin or due to vascular, nonhematologic causes (Fig. 151.3). In the investigation of thrombotic disorders, a personal or family history of blood clots in the legs or lungs, early-onset stroke, or myocardial infarction suggests a hereditary predisposition to thrombosis. Thrombotic disorders can be congenital or acquired (Table 151.1) and frequently present after an initial event (e.g., central catheter, trauma, malignancy, infection, pregnancy, or treatment with estrogens) provides a nidus for clot formation or a procoagulant stimulus.

Clinical Manifestations

Patients with hemostatic disorders may have complaints of either bleeding or clotting. Age at onset of bleeding can provide clues to whether the problem is congenital or acquired.

FIGURE 151.2 Simplified pathways of blood coagulation. The area inside the solid black line is the intrinsic pathway measured by the activated partial thromboplastin time (APTT). The area inside the green line is the extrinsic pathway, measured by the prothrombin time (PT). The area encompassed by both lines is the common pathway. AT-III, Antithrombin III; F, factor; HMWK, high molecular weight kininogen; P-C/S, protein C/S; PL, phospholipid; TFPI, tissue factor pathway inhibitor. (Modified from Scott JP, Flood VH, Raffini LJ. Hemostasis. In: Kliegman RM, St. Geme J, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia: Elsevier; 2020 [fig 502.1].)

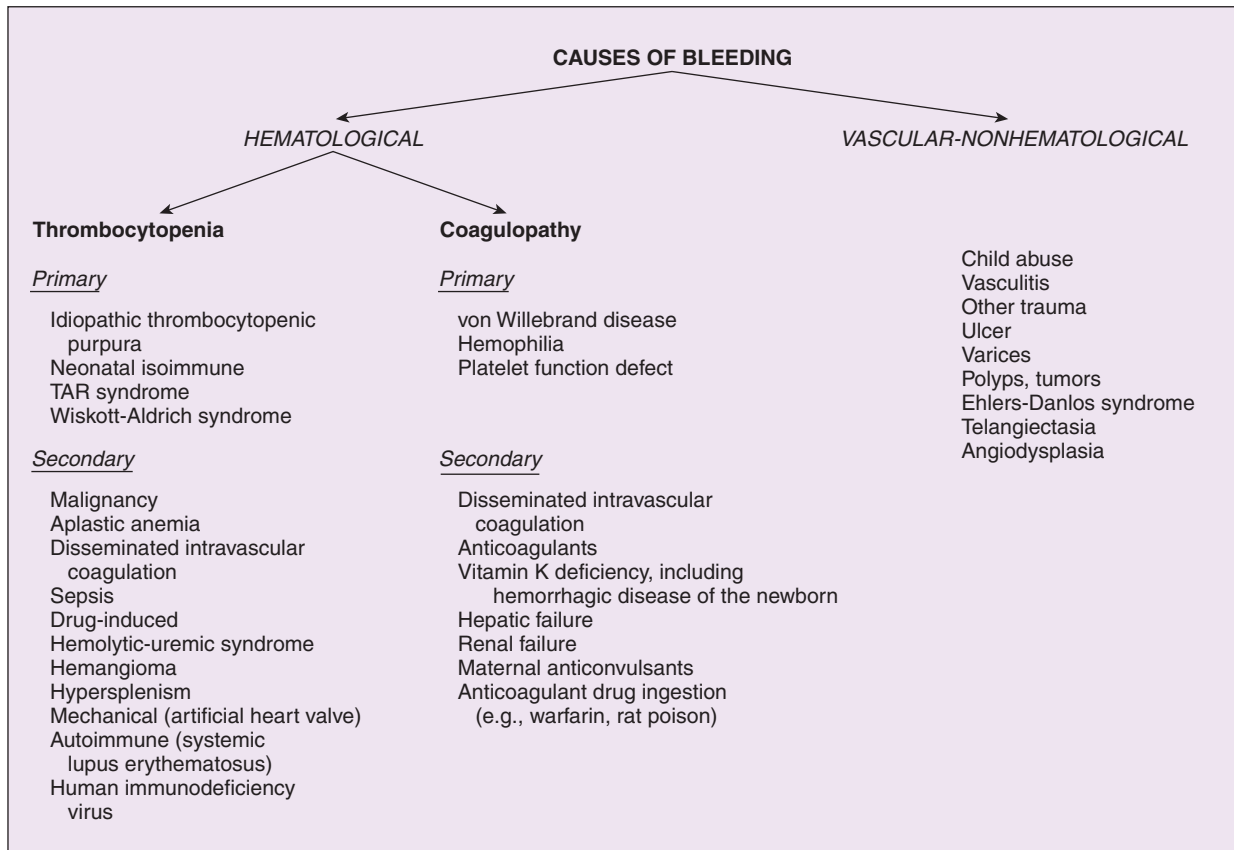

FIGURE 151.3 Common causes of bleeding. TAR, Thrombocytopenia with absence of radius (syndrome).

The **sites of bleeding** (mucocutaneous or muscle/joint) and **degree of trauma** (spontaneous or significant) required to induce injury can suggest the type and severity of the disorder. Certain medications (e.g., aspirin, valproic acid) are known to exacerbate preexisting bleeding disorders by interfering with platelet function.

The **physical examination** should characterize the presence of skin or mucous membrane bleeding and deeper sites of hemorrhage into the muscles and joints or internal bleeding sites. The term **petechia** refers to a nonblanching lesion less than 2 mm in size. **Purpura** is a group of adjoining petechiae, **ecchymoses** (bruises) are isolated lesions larger than petechiae, and **hematomas** are raised, palpable ecchymoses.

The physical examination should also search for manifestations of an underlying disease, lymphadenopathy, hepatosplenomegaly, vasculitic rash, or chronic hepatic or renal disease. **Superficial venous thrombi (thrombophlebitis)** can manifest as erythematous, painful “cord” type swelling along the track of a superficial vein, often following localized trauma such as venipuncture or peripheral intravenous (IV) insertion. **Deep venous thrombi** may cause warm, swollen (distended), painful, purplish discolored extremities or no findings. **Pulmonary emboli** can be asymptomatic or cause symptoms such as chest pain, shortness of breath, hypoxia, respiratory distress, and tachycardia. **Cerebral sinus venous thrombosis** can be associated with headache, seizure, or visual disturbance. **Arterial clots** may cause acutely painful, pale, and poorly perfused extremities. Arterial thrombi of the internal organs present with signs and symptoms of infarction.

Laboratory Testing

Screening laboratory studies for bleeding patients include a **platelet count**, **prothrombin time**, **partial thromboplastin time**, **thrombin time**, **fibrinogen**, and screening test of platelet function. Many laboratories have adopted the platelet function analyzer (PFA) to replace the bleeding time as a screening test for platelet function abnormalities and VWD, especially when blood volume is at a premium, as with infants. The PFA has variable sensitivity and specificity for common bleeding disorders. No single laboratory test can screen for all bleeding disorders. The findings on screening tests for bleeding vary with the specific disorder (Table 151.2).

TABLE 151.2 Screening Tests for Bleeding Disorders			
TEST	MECHANISM TESTED	NORMAL VALUES	DISORDER
Prothrombin time	Extrinsic and common pathway	<12sec beyond neonate; 12–18sec in term neonate	Defect in vitamin K–dependent factors; hemorrhagic disease of newborn, malabsorption, liver disease, DIC, oral anticoagulants, ingestion of rat poison
Activated partial thromboplastin time	Intrinsic and common pathway	70sec in term neonate 25–40sec beyond neonate	Hemophilia; von Willebrand disease, heparin; DIC; deficient factors 12 and 11; lupus anticoagulant
Thrombin time	Fibrinogen to fibrin conversion	12–17sec in term neonate; 10–15sec beyond neonate	Fibrin split products, DIC, hypofibrinogenemia, heparin, uremia
Bleeding time	Hemostasis, capillary and platelet function	3–7min beyond neonate	Platelet dysfunction, thrombocytopenia, von Willebrand disease, aspirin
Platelet count	Platelet number	150,000–450,000/mL	Thrombocytopenia differential diagnosis (see Fig. 151.4)
PFA	Closure time		Platelet function disorders
Blood smear	Platelet number and size; RBC morphology	–	Large platelets suggest peripheral destruction; fragmented, bizarre RBC morphology suggests microangiopathic process (e.g., hemolytic uremic syndrome, hemangioma, DIC)

DIC, Disseminated intravascular coagulation; PFA, platelet function analyzer-100; RBC, red blood cell.

Differential Diagnosis

Disorders of Platelets

Platelet counts less than $150,000/\text{mm}^3$ constitute **thrombocytopenia**. Mucocutaneous bleeding and/or petechiae is the hallmark of platelet disorders, including thrombocytopenia. The risk of bleeding correlates imperfectly with the platelet count. Children with platelet counts greater than $80,000/\text{mm}^3$ can withstand all but the most extreme hemostatic challenges, such as surgery or major trauma. Children with platelet counts less than $20,000/\text{mm}^3$ are at risk for spontaneous bleeding. These generalizations are modified by factors such as the age of the platelets (young, large platelets usually function better than older ones) and the presence of inhibitors of platelet function, such as antibodies, drugs (especially aspirin), fibrin degradation products, and toxins formed in the presence of hepatic or renal disease. The size of platelets is routinely measured as the mean platelet volume (MPV). The etiology of thrombocytopenia (Fig. 151.4) may be organized into three mechanisms:

1. Decreased platelet production
2. Increased destruction
3. Sequestration

Thrombocytopenia Resulting from Decreased Platelet Production

Primary disorders of megakaryopoiesis (platelet production) are rare in childhood, other than as part of an aplastic syndrome. **Thrombocytopenia with absent radii syndrome** in newborns is characterized by severe thrombocytopenia in association with orthopedic abnormalities, especially of the upper extremity. The thrombocytopenia usually improves spontaneously over time. **Congenital amegakaryocytic thrombocytopenia** presents at birth or shortly thereafter with findings of severe thrombocytopenia but no other congenital anomalies. The marrow is devoid of megakaryocytes and usually progresses to aplasia of all hematopoietic cell lines. This disorder results from mutations in *c-mpl*, resulting in abnormal thrombopoietin (TPO) receptors that do not respond to stimulation by TPO.

Acquired thrombocytopenia because of decreased production is rarely an isolated finding. It is seen more often in the context of **pancytopenia resulting from bone marrow failure** caused by infiltrative or aplastic processes. Certain chemotherapeutic agents may affect megakaryocytes selectively more than other marrow elements. **Cyanotic congenital heart disease with polycythemia** often is associated with thrombocytopenia, but this is rarely severe or associated with significant clinical bleeding. Congenital (TORCH [toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex]) and acquired **viral infections** (HIV, Epstein-Barr virus, and measles) and some **drugs** (anticonvulsants, antibiotics, cytotoxic agents, heparin, and quinidine) may induce thrombocytopenia. Postnatal infections and drug reactions usually cause transient thrombocytopenia, whereas congenital infections may produce prolonged suppression of bone marrow function.

Thrombocytopenia Resulting from Peripheral Destruction

Etiology

In a child who appears well, **immune-mediated mechanisms** are the most common cause of thrombocytopenia resulting

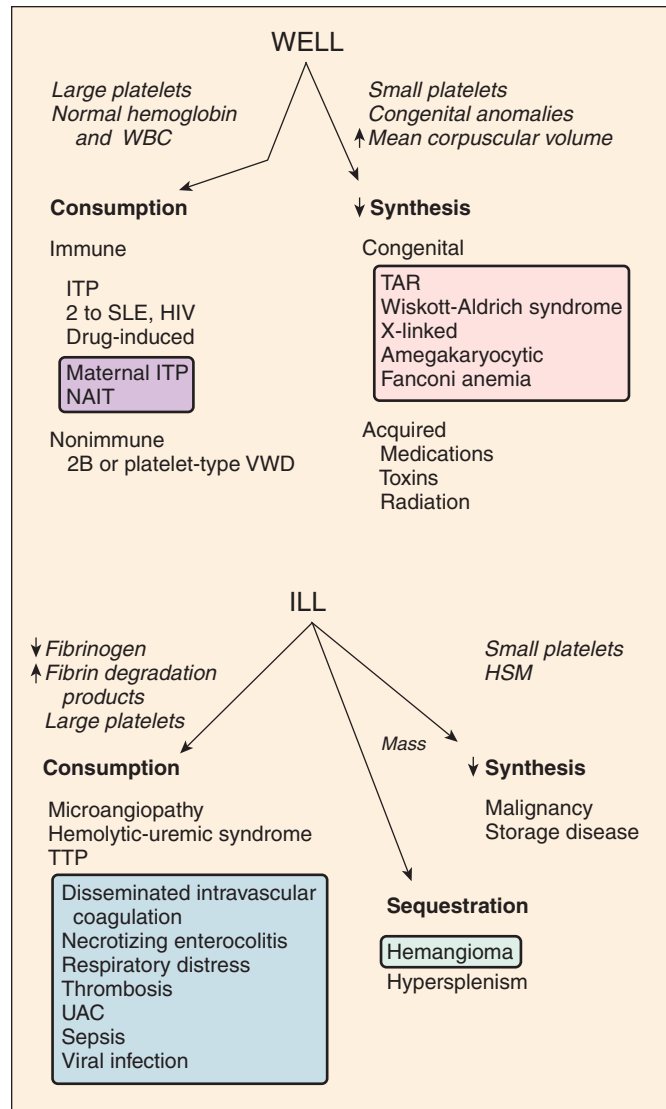

FIGURE 151.4 Differential diagnosis of childhood thrombocytopenic syndromes. The syndromes initially are separated by their clinical appearances. Clues leading to the diagnosis are presented in italics. The mechanisms and common disorders leading to these findings are shown in the lower part of the figure. Disorders that commonly affect neonates are listed in the shaded boxes. *HSM*, Hepatosplenomegaly; *ITP*, idiopathic immune thrombocytopenic purpura; *NAIT*, neonatal alloimmune thrombocytopenia; *SLE*, systemic lupus erythematosus; *TAR*, thrombocytopenia with absence of radius (syndrome); *TTP*, thrombotic thrombocytopenic purpura; *UAC*, umbilical artery catheter; *VWD*, von Willebrand disease; *WBC*, white blood cell. (From Scott JP. Bleeding and thrombosis. In: Kliegman RM, Greenbaum LA, Lye PS, eds. *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia: Saunders; 2004:920.)

from rapid peripheral destruction of antibody-coated platelets by reticuloendothelial cells. **Neonatal alloimmune thrombocytopenia** (NAIT) occurs because of sensitization of the mother to antigens present on fetal platelets (most commonly HPA-1a). Antibodies cross the placenta and attack the fetal platelet (see Chapter 59). Many platelet alloantigens have been identified and sequenced, permitting prenatal diagnosis of the condition in an at-risk fetus. Mothers with idiopathic thrombocytopenic purpura (**maternal ITP**) or with a history of ITP

may have passive transplacental transfer of immunoglobulin G (IgG) antiplatelet antibodies, with resultant neonatal thrombocytopenia (see [Chapter 59](#)). The maternal platelet count is sometimes a useful indicator of the probability that the infant will be affected.

Clinical Manifestations

The infant with NAIT is at risk for **intracranial hemorrhage** in utero and during the immediate delivery process. In ITP, the greatest risk seems to be present during passage through the birth canal, during which molding of the head may induce intracranial hemorrhage. Fetal scalp sampling or percutaneous umbilical blood sampling may be performed to measure the fetal platelet count.

Treatment

Administration of intravenous immunoglobulin (IVIG) before delivery increases fetal platelet counts and may alleviate thrombocytopenia in infants with NAIT and ITP. Delivery by cesarean section is recommended to prevent central nervous system (CNS) bleeding (see [Chapter 59](#)). Neonates with severe thrombocytopenia (platelet counts $<20,000/\text{mm}^3$) may be treated with IVIG or corticosteroids or both until thrombocytopenia remits. If necessary, infants with NAIT may receive washed maternal platelets.

Idiopathic Thrombocytopenic Purpura

Etiology

Autoimmune thrombocytopenic purpura of childhood (childhood ITP) is a common disorder that usually follows an acute viral infection. Childhood ITP is caused by an antibody (IgG or IgM) that binds to the platelet membrane. The condition results in Fc receptor–mediated splenic destruction of antibody-coated platelets. Rarely, ITP may be the presenting symptom of an autoimmune disease, such as systemic lupus erythematosus (SLE).

Clinical Manifestations

Young children typically exhibit ITP 1–4 weeks after viral illness, with abrupt onset of petechiae, purpura, and epistaxis. The thrombocytopenia usually is severe. Significant adenopathy or hepatosplenomegaly is unusual, and the red blood cell (RBC) and white blood cell (WBC) counts are normal.

Diagnosis

The diagnosis of ITP usually is based on clinical presentation and the platelet count and does not often require a bone marrow examination. Peripheral blood smear reveals severe thrombocytopenia with increased platelet size and normal RBC and WBC morphology. If atypical findings are noted, however, marrow examination is indicated to rule out an infiltrative disorder (leukemia) or an aplastic process (aplastic anemia). In ITP, an examination of the bone marrow reveals increased megakaryocytes and normal erythroid and myeloid elements.

Treatment and Prognosis

Therapy is seldom indicated for platelet counts greater than $20,000\text{--}30,000/\text{mm}^3$. Therapy does not affect the long-term outcome of ITP but is intended to increase the platelet count acutely. For moderate and severe clinical bleeding with severe thrombocytopenia (platelet count $<10,000/\text{mm}^3$), therapeutic

options include **prednisone**, starting dose of 2 mg/kg per 24 hours or IVIG, 1 g/kg. These approaches seem to decrease the rate of clearance of sensitized platelets, rather than decreasing production of antibody. Splenectomy is indicated in acute ITP only for life-threatening bleeding. Approximately 80% of children have a spontaneous resolution of ITP within 6 months after diagnosis. Serious bleeding, especially intracranial bleeding, occurs in fewer than 1% of patients with ITP. There is no evidence that early treatment prevents intracranial bleeding.

ITP that persists for 6–12 months is classified as **chronic ITP**. Repeated treatments with IVIG, high-dose pulse steroids, and/or rituximab can be effective in delaying the need for splenectomy. The thrombopoietin receptor agonists, eltrombopag and romiplostim, have undergone studies in children with chronic ITP and should also be considered in the management of children with moderate-severe chronic ITP.

Secondary causes of chronic ITP, especially SLE or immunologic abnormalities, should be ruled out. Splenectomy induces a remission in 70–80% of childhood chronic ITP cases. The risks of splenectomy (surgery, sepsis from encapsulated bacteria, pulmonary hypertension) must be weighed against the risk of severe bleeding.

Other Disorders

Wiskott-Aldrich syndrome is an X-linked disorder characterized by hypogammaglobulinemia, eczema, and microthrombocytopenia caused by a molecular defect in a cytoskeletal protein common to lymphocytes and platelets (see [Chapter 74](#)). Small platelets are seen on a peripheral blood smear. Nevertheless, thrombocytopenia often is improved by splenectomy. Hematopoietic stem cell transplantation cures the immunodeficiency and thrombocytopenia. Familial X-linked thrombocytopenia can be seen as a variant of Wiskott-Aldrich syndrome or a mutation in the *GATA1* gene. Autosomal macrothrombocytopenia is due to deletions in chromosome 22q11 or mutations in 22q12.

Thrombotic microangiopathy causes thrombocytopenia, anemia secondary to intravascular RBC destruction, and, in some cases, depletion of clotting factors. Children with thrombotic microangiopathy usually are quite ill. In a child with disseminated intravascular coagulation (**DIC**), the deposition of fibrin strands within the vasculature and activation of thrombin and plasmin result in a wide-ranging hemostatic disorder with activation and clearance of platelets. **Hemolytic uremic syndrome** occurs because of exposure to a toxin that induces endothelial injury, fibrin deposition, and platelet activation and clearance (see [Chapter 164](#)). In **thrombotic thrombocytopenic purpura**, platelet consumption, precipitated by a congenital or acquired (antibody-mediated) deficiency of a metalloproteinase that cleaves VWF, seems to be the primary process, with a modest deposition of fibrin and RBC destruction.

Disorders of Platelet Function

Etiology

Primary disorders of platelet function may involve receptors on platelet membranes for adhesive proteins. Deficiency of glycoprotein Ib complex (VWF receptor) causes **Bernard-Soulier syndrome**. A deficiency of glycoprotein IIb-IIIa (the fibrinogen receptor) causes **Glanzmann thrombasthenia**. Mild abnormalities of platelet aggregation and granule release,

detectable by platelet aggregometry, are far more common. Secondary disorders caused by toxins and drugs (uremia, valproic acid, aspirin, nonsteroidal antiinflammatory drugs, and infections) may cause a broad spectrum of platelet dysfunction.

Clinical Manifestations

Disorders of platelet function present with mucocutaneous bleeding and a prolonged bleeding time or delayed PFA closure time; they may be primary or secondary. The bleeding time is an insensitive screen for mild and moderate platelet function disorders but is usually prolonged in severe platelet function disorders, such as Bernard-Soulier syndrome or Glanzmann thrombasthenia.

Disorders of Clotting Factors

Etiology

Hereditary deficiencies of most procoagulant proteins lead to bleeding. The genes for factor 8 and factor 9 are on the X chromosome, whereas virtually all the other clotting factors are coded on autosomal chromosomes. **Factor 8 and factor 9 deficiencies** are the most common severe inherited bleeding disorders. **von Willebrand disease** is the most common inherited bleeding disorder. Of the procoagulant proteins, low levels of the so-called contact factors (prekallikrein, high molecular weight kininogen, and Hageman factor [factor 12]) cause a prolonged activated partial thromboplastin time (aPTT) but are not associated with a predisposition to bleeding.

Hemophilia

Etiology

Hemophilia A (factor 8 deficiency) occurs in 1 in 5,000 males. **Hemophilia B** (factor 9 deficiency) occurs in approximately

1 in 25,000 males. Clinically, the two disorders are indistinguishable other than by their therapy (Table 151.3). The lack of factor 8 or factor 9 delays the generation of thrombin, which is crucial to forming a normal, functional fibrin clot and solidifying the platelet plug that has formed in areas of vascular injury. The severity of the disorder is determined by the degree of clotting factor deficiency.

Clinical Manifestations

Patients with less than 1% (severe hemophilia) factor 8 or factor 9 may have **spontaneous bleeding** (often in joints or muscles [**hemarthroses**]) or bleeding with minor trauma. Patients with 1–5% (moderate hemophilia) factor 8 or factor 9 usually require moderate trauma to induce bleeding episodes. In mild hemophilia (5–40% factor 8 or factor 9), significant trauma is necessary to induce bleeding; spontaneous bleeding does not occur. Mild hemophilia may go undiagnosed for many years, whereas severe hemophilia manifests in infancy when the child reaches the toddler stage.

Laboratory Studies

The diagnosis of hemophilia is based on a **prolonged aPTT**. In the aPTT, a surface-active agent activates the intrinsic system of coagulation, of which factors 8 and 9 are crucial components. In factor 8 or factor 9 deficiency, the aPTT is quite prolonged but should correct to normal when the patient's plasma is mixed 1:1 with normal plasma. When an abnormal aPTT is obtained, and corrects upon mixing with normal plasma, **specific factor assays** are needed to make a precise diagnosis (see Table 151.2) to determine the appropriate factor replacement therapy. Prenatal diagnosis and carrier diagnosis are possible using molecular techniques.

TABLE 151.3 Comparison of Hemophilia A, Hemophilia B, and von Willebrand Disease

FEATURE	HEMOPHILIA A	HEMOPHILIA B	VON WILLEBRAND DISEASE
Inheritance	X linked	X linked	Autosomal dominant
Factor deficiency	Factor 8	Factor 9	VWF, factor 8
Bleeding site(s)	Muscle, joint, surgical	Muscle, joint, surgical	Mucous membranes, skin, surgical, menstrual
Prothrombin time	Normal	Normal	Normal
Activated partial thromboplastin time	Prolonged	Prolonged	Prolonged or normal
Bleeding time/PFA-100	Normal	Normal	Prolonged or normal
Factor 8 coagulant activity	Low	Normal	Low or normal
VWF antigen	Normal	Normal	Low
VWF activity	Normal	Normal	Low
Factor 9	Normal	Low	Normal
Ristocetin-induced platelet agglutination	Normal	Normal	Normal, low, or increased at low-dose ristocetin
Platelet aggregation	Normal	Normal	Normal
Treatment	DDAVP* or recombinant factor 8	Recombinant factor 9	DDAVP* or VWF concentrate

*Desmopressin (DDAVP) for mild to moderate hemophilia A or type 1 von Willebrand disease. PFA, Platelet function analyzer-100; VWF, von Willebrand factor.

Treatment

Early, appropriate **replacement therapy** is the hallmark of excellent hemophilia care. Acute bleeding episodes are best treated in the home with IV infusion assuming patient cooperation, caregiver comfort, and available IV access (whether through peripheral venipuncture or central venous catheter). Early institution of factor replacement and continuous prophylaxis beginning in early childhood is likely to reduce the chronic joint disease associated with hemophilia.

Bleeding associated with surgery, trauma, or dental extraction often can be anticipated, and excessive bleeding can be prevented with appropriate replacement and antifibrinolytic therapies. Prophylactic therapy starting in infancy has greatly diminished the likelihood of chronic arthropathy in children with hemophilia. To manage life-threatening bleeding, levels of 80–100% of normal factor 8 or factor 9 are necessary. For mild to moderate bleeding episodes (hemarthroses), a 40% level for factor 8 or a 30–40% level for factor 9 is appropriate. The dose can be calculated using the knowledge that 1 U/kg body weight of factor 8 increases the plasma level 2%, whereas 1.5 U/kg of recombinant factor 9 increases the plasma level 1%:

$$\text{Dose for factor 8} = \text{desired level (\%)} \times \text{weight (kg)} \times 0.5$$

or

$$\begin{aligned} \text{Dose for recombinant factor 9} \\ = \text{desired level (\%)} \times \text{weight (kg)} \times 1.5 \end{aligned}$$

Desmopressin acetate (DDAVP) is a synthetic vasopressin analog with minimal vasopressor effect. Desmopressin triples or quadruples the initial factor 8 level (and VWF levels) of a patient with mild or moderate (not severe) hemophilia A but has no effect on factor 9 levels. When adequate hemostatic levels can be attained, desmopressin is the treatment of choice for individuals with mild and moderate hemophilia A. Aminocaproic acid is an inhibitor of fibrinolysis with systemic (and topical, in the liquid form) activity that may be useful for oral/nasal mucosal bleeding.

Patients treated with older factor 8 or 9 concentrates derived from large pools of plasma donors were at high risk for **hepatitis B, C, and D** and **HIV**. Recombinant factor 8 and factor 9 concentrates are safe from virally transmitted illnesses. Complications of AIDS is the most common cause of death in older hemophilia patients (who received plasma-derived factors). Many older patients also have chronic hepatitis C.

Factor inhibitors are IgG antibodies directed against transfused factor 8 or factor 9 in congenitally deficient patients, whose immune systems recognize the transfused factors as foreign proteins. Inhibitors arise in 15–30% of patients with severe factor 8 deficiency but are less common (1–5%) in patients with severe factor 9 deficiency. They may be high or low titer and show an anamnestic response to treatment. The treatment of bleeding patients with an inhibitor is difficult. For low titer inhibitors, options include high-dose or continuous factor 8 infusions. For high titer inhibitors, it is usually necessary to administer a product that bypasses the inhibitor, typically recombinant factor 7a. Activated prothrombin complex concentrates, used in the past to treat inhibitor patients, paradoxically increased the risks of thrombosis, resulting in fatal complications, such as myocardial infarction. For long-term treatment of inhibitor patients, induction of immune

tolerance by repeated infusion of the deficient factor with or without immunosuppression may be beneficial.

A bispecific antibody that mimics the activity of factor 8 to bridge factors 9a and 10, catalyzing the activation of factor 10 and leading to downstream thrombin production, has created a recent paradigm shift in treatment options. The subcutaneous route of administration and infrequent dosing have made this approach popular among patients with and without inhibitors. Additionally, multiple gene therapy strategies are in clinical trials for both hemophilia A and B.

von Willebrand Disease

Etiology

VWD is a common disorder (1% of the White population) caused by a deficiency of **VWF**, an adhesive protein that serves two functions: acting as a bridge between subendothelial collagen and platelets and binding circulating factor 8 and protecting it from rapid clearance from the circulation. VWD usually is inherited as an autosomal dominant trait and, rarely, as an autosomal recessive trait. VWF may be either quantitatively deficient (partial = type 1 or absolute = type 3) or qualitatively abnormal (type 2 = dysproteinemia). Approximately 80% of patients with VWD have classic (type 1) disease (i.e., a mild to moderate deficiency of VWF). Several other subtypes are clinically important, each requiring different therapy.

Clinical Manifestations

Mucocutaneous bleeding, epistaxis, gingival bleeding, cutaneous bruising, and menorrhagia may occur in patients with VWD. In severe disease, factor 8 deficiency may be profound, and the patient may also have manifestations similar to hemophilia A (hemarthrosis). Findings in classic VWD, however, differ from findings in hemophilia A and B (see [Table 151.3](#)).

Laboratory Testing

VWF testing involves measurement of the amount of protein, usually measured immunologically as the **VWF antigen** (VWF:Ag). VWF activity (VWF:Act) is measured functionally in the **ristocetin cofactor assay** (VWFR:Co), which uses the antibiotic ristocetin to induce VWF to bind to platelets. Alternatively, VWF activity may be evaluated using a gain-of-function variant of GPIb (GPIbM) instead of ristocetin. VWF multimer testing is done to assess the protein structure and assists in the diagnosis of the qualitative disorders (type 2 = dysproteinemia).

Treatment

The treatment of VWD depends on the severity of bleeding. **Desmopressin** is the treatment of choice for most bleeding episodes in patients with type 1 disease and some patients with type 2 disease. When high levels of VWF are needed but cannot be achieved satisfactorily with desmopressin, treatment with a virally attenuated, **VWF-containing plasma-derived concentrate or recombinant VWF concentrate** may be appropriate. Cryoprecipitate should not be used because it is not virally attenuated. Hepatitis B vaccine should be given before the patient is exposed to plasma-derived products. As in all bleeding disorders, aspirin and nonsteroidal antiinflammatory drugs should be avoided.

Vitamin K Deficiency

For discussion of vitamin K deficiency, see [Chapters 27 and 31](#).

Disseminated Intravascular Coagulation

Etiology

DIC is a disorder in which widespread activation of the coagulation mechanism is usually associated with decreased organ perfusion seen in shock. Normal hemostasis is a balance between hemorrhage and thrombosis. In DIC, this balance is altered by the severe illness, so the patient has activation of coagulation (thrombosis) mediated by thrombin and fibrinolysis mediated by plasmin (bleeding). Coagulation factors—especially platelets, fibrinogen, and factors 2, 5, and 8—are consumed, as are the anticoagulant proteins, especially antithrombin, protein C, and plasminogen. Endothelial injury (crush injuries, burns), tissue release of thromboplastic procoagulant factors, or, rarely, exogenous factors (snake venoms, severe infections) directly activate the coagulation mechanism (Table 151.4).

Clinical Manifestations

The diagnosis of DIC usually is suspected clinically and is confirmed by laboratory findings of a **decline in platelets and fibrinogen** associated with elevated PTT, aPTT, and elevated levels of D-dimer, formed when fibrinogen is clotted and then degraded by plasmin (Table 151.5). In some patients, DIC may evolve more slowly, and there may be a degree of compensation. In a severely ill patient, the new onset of bleeding from a venipuncture or incision site, gastrointestinal or pulmonary hemorrhage, petechiae, or ecchymosis or evidence of peripheral gangrene or thrombosis suggests the diagnosis of DIC.

Treatment

The treatment of DIC is challenging. General guidelines include the following: Treat the underlying disorder inducing the DIC first; **support** the patient by correcting hypoxia, acidosis, and poor perfusion; and consider replacing depleted blood-clotting factors, platelets, and anticoagulant proteins by transfusion, especially in the bleeding patient.

Heparin may be used to treat significant arterial or venous thrombotic disease unless sites of life-threatening bleeding coexist.

Thrombosis

Etiology

A hereditary predisposition to **thrombosis** (see Table 151.1) may be caused by a deficiency of an anticoagulant protein (**protein C or S, antithrombin, or plasminogen**) (Fig. 151.5), by an abnormality of a procoagulant protein making it resistant to proteolysis by its respective inhibitor (**factor 5 Leiden**), by a mutation resulting in an increased level of a procoagulant protein (prothrombin 20210), or by damage to endothelial cells (**homocysteinemia**). Neonates with deficiency syndromes may be particularly vulnerable to thrombosis. Neonates with homozygous protein C deficiency present with purpura fulminans or thrombosis of the major arteries and veins or both. Many individuals with an inherited predisposition to thrombosis exhibit symptoms in adolescence or early adulthood. Protein C deficiency presenting in young adulthood usually is inherited as an autosomal dominant trait, whereas the homozygous form usually is autosomal recessive and may present in younger children. Protein S and antithrombin deficiencies are inherited as autosomal dominant traits. Factor 5 Leiden is the most common hereditary cause of a predisposition to thrombosis, appearing

TABLE 151.4 Causes of Disseminated Intravascular Coagulation

INFECTIOUS

Meningococcemia (purpura fulminans)
Other gram-negative bacteria (*Haemophilus*, *Salmonella*, *Escherichia coli*)
Rickettsiae (Rocky Mountain spotted fever)
Virus (cytomegalovirus, herpes, hemorrhagic fevers)
Malaria
Fungus

TISSUE INJURY

Central nervous system trauma (massive head injury)
Multiple fractures with fat emboli
Crush injury
Profound shock or asphyxia
Hypothermia or hyperthermia
Massive burns

MALIGNANCY

Acute promyelocytic leukemia
Acute monoblastic or myelocytic leukemia
Widespread malignancies (neuroblastoma)

VENOM OR TOXIN

Snake bites
Insect bites

MICROANGIOPATHIC DISORDERS

“Severe” thrombotic thrombocytopenic purpura
Hemolytic uremic syndrome
Giant hemangioma (Kasabach-Merritt syndrome)

GASTROINTESTINAL DISORDERS

Fulminant hepatitis
Severe inflammatory bowel disease
Reye syndrome

HEREDITARY THROMBOTIC DISORDERS

Antithrombin deficiency
Homozygous protein C deficiency

NEONATAL PERIOD

Maternal toxemia
Group B streptococcal infections
Abruptio placentae
Severe respiratory distress syndrome
Necrotizing enterocolitis
Congenital viral disease (e.g., cytomegalovirus infection or herpes)
Erythroblastosis fetalis

MISCELLANEOUS CONDITIONS/DISORDERS

Severe acute graft rejection
Acute hemolytic transfusion reaction
Severe collagen vascular disease
Kawasaki disease
Heparin-induced thrombosis
Infusion of “activated” prothrombin complex concentrates
Hyperpyrexia/encephalopathy, hemorrhagic shock syndrome

in 3–5% of Whites. **Acquired antiphospholipid antibodies** (anticardiolipin and anti- β_2 -glycoprotein antibodies and lupus anticoagulant) also predispose to thrombosis.

Clinical Manifestations

Neonates and adolescents are the most likely pediatric patients to present with thromboembolic disease. Indwelling catheters (with unfavorable catheter:vein size ratio), vasculitis, sepsis, immobilization, nephrotic syndrome, coagulopathy, trauma, infection, surgery, inflammatory bowel disease, oral contraceptive agents, and pregnancy all predispose to thrombosis. The manifestations of pulmonary emboli vary from no findings to chest pain, diminished breath sounds, a loud S_2 , cyanosis, tachypnea, and hypoxemia.

Diagnostic and Imaging Studies

Venous thrombosis can be detected noninvasively by ultrasound Doppler flow compression studies. The gold standard

for diagnosis is the venogram. An abnormal (*high probability*) ventilation-perfusion scan or detection of an intravascular thrombus on helical computed tomography is diagnostic of pulmonary emboli in young adults. Cerebral sinus venous thrombosis is often diagnosed by magnetic resonance venography. There are no appropriate screening studies for thrombotic disorders. Diagnosis of a congenital or acquired predisposition to thrombosis requires a battery of specific assays.

Treatment

Therapy of thrombotic disorders depends on the underlying condition and usually initially involves unfractionated or low molecular weight **heparin** followed by longer term anticoagulation with **warfarin**. Large clinical trials of new oral agents, including the direct thrombin inhibitors and antifactor 10 compounds have recently demonstrated noninferior safety and efficacy of these medications in children. Major vessel thrombosis, life-threatening thrombosis, or arterial thrombosis may necessitate treatment with **fibrinolytic agents** (recombinant tissue plasminogen activator). In newborns, inherited deficiency syndromes may present as emergencies and necessitate **replacement** with plasma, antithrombin concentrates, or protein C concentrates.

PEARLS FOR PRACTITIONERS

See *Hematology: Pearls for Practitioners* at the end of this section.

CHAPTER 152

Blood Component Therapy

Transfusion of red blood cells (RBCs), platelets, plasma, cryoprecipitate, and granulocytes can be lifesaving or life sustaining (Table 152.1). **Whole blood** is rarely indicated and is most useful to provide both oxygen-carrying capacity and functional procoagulant and anticoagulant factors. Otherwise, **packed RBCs** are used to treat anemia to increase oxygen-carrying capacity. RBC transfusions should not be used to treat asymptomatic nutritional deficiencies that can be corrected by administering the appropriate deficient nutrient (e.g., iron or folic acid).

COMPONENT	CONTENT	INDICATION	DOSE	EXPECTED OUTCOME
Packed RBCs	250–300 mL/unit	↓ Oxygen-carrying RBCs	10–15 mL/kg	↑ Hb by 2–3 g/dL
Platelet concentrate from whole blood donation	$5\text{--}7 \times 10^{10}$ platelets/unit	Severe thrombocytopenia ± bleeding	1 unit/10 kg	↑ Platelet count by 50,000/ μ L
Platelet concentrate	3×10^{11} platelets/unit	Severe thrombocytopenia ± bleeding	1 unit/70 kg	↑ Platelet count by 30,000–50,000/ μ L
Fresh frozen plasma	1 unit of each clotting factor /mL	Multiple clotting factor deficiency	10–20 mL/kg	Improvement in significantly prolonged prothrombin and partial thromboplastin times
Cryoprecipitate	Fibrinogen, factor 8, VWF, factor 13	Hypofibrinogenemia, factor 13 deficiency	1 unit/5–10 kg	↑ Fibrinogen by 50–100 mg/dL
Recombinant factor concentrates	Units as labeled	Hemophilic bleeding or prophylaxis	F8: 20–50 units/kg F9: 40–120 units/kg	F8: ↑ 2%/unit/kg F9: ↑ 0.7 unit/kg
Recombinant factor VIIa (NovoSeven)	Micrograms (μ g)	Hemophilic bleeding in patient with inhibitor; also used for uncontrolled postoperative hemorrhage	30–90 μ g/kg/dose	Cessation of bleeding

Hgb, Hemoglobin; RBCs, red blood cells; VWF, von Willebrand factor.

TYPE OF REACTION	CLINICAL SIGNS	MANAGEMENT
Acute hemolytic transfusion reaction (incidence of 1:250,000 to 1:1,000,000)	Acute shock, back pain, flushing, early fever, intravascular hemolysis, hemoglobinemia, hemoglobinuria (may be delayed 5–10 days and less severe if anamnestic response is present)	<ol style="list-style-type: none"> 1. Stop transfusion; return blood to bank with fresh sample of patient's blood 2. Hydrate intravenously*; support blood pressure, maintain high urine flow, alkalinize urine 3. Check for and correct electrolyte abnormalities (hyperkalemia)
Delayed hemolytic transfusion reaction (incidence of 1:100,000)	Onset 7–14 days after transfusion: pain, fever, jaundice, hemoglobinuria; fall in hemoglobin; reticulocytopenia	Transfuse only antigen-negative RBCs if needed
Febrile nonhemolytic transfusion reaction (incidence of 1:100)	Fever during or within 4 hr after end of transfusion, chills, usually from passively transfused cytokines or recipient reaction to leukocytes Bacterial contamination can occur in 1:100,000 platelet transfusions	Antipyretics for symptomatic treatment or pretreatment for future transfusions; leukocyte reduction has decreased incidence of febrile reactions Blood culture if high suspicion for bacterial infection
Allergic transfusion reaction (incidence of 1:100)	Urticaria, pruritus, maculopapular rash, edema, respiratory distress, hypotension during or within 4 hr of transfusion; often because recipient has preformed antibodies against donor antigens, occasionally from passive infusion of antibodies from atopic donor	Diphenhydramine ± hydrocortisone for acute management For future transfusions consider: <ol style="list-style-type: none"> 1. Pretreatment with diphenhydramine ± hydrocortisone 2. Volume reduction to reduce donor plasma 3. Washing cellular products to remove all donor plasma (for severe reactions)

*Normal saline is the compatible intravenous fluid.

HLA, Human leukocyte antigen; RBCs, red blood cells; WBC, white blood cells.

Modified from Andreoli TE, Bennett JC, Carpenter CC, et al. Cecil Essentials of Medicine. 4th ed. Philadelphia: WB Saunders; 1997.

Blood component therapy requires proper anticoagulation of the component unit, screening for infectious agents, and blood group compatibility testing before administration. Typical **transfusion reactions** are listed in Table 152.2. Transfusion may also result in circulatory overload, especially in the presence of cardiopulmonary deficiency. Filtering of blood products to remove white blood cells (WBCs) may prevent febrile reactions. Long-term complications of transfusions include **infectious diseases** such as **hepatitis B** (<1:1,000,000 units)

and **C** (1:2,000,000 units), **HIV** (<1:2,000,000 units), malaria, syphilis, babesiosis, brucellosis, and Chagas disease. Patients who are chronically transfused are more prone to iron overload and alloimmunization to RBCs and platelets.

PEARLS FOR PRACTITIONERS

CHAPTER 149

Hematology Assessment

- Normal hematologic values vary according to age.
- The physiologic nadir occurs at 8–10 weeks of life; this nadir is accentuated in premature infants.
- The presence of petechiae, purpura, or deeper sites of bleeding, including generalized hemorrhage, indicates abnormalities of platelets, coagulation factors, or both.
- Organ system involvement or systemic symptoms point to a generalized illness as the cause of hematologic abnormalities.

CHAPTER 150

Anemia

- Anemia is any hemoglobin or hematocrit value that is 2 standard deviations (SDs) below the mean for age and sex.
- Androgens at the onset of puberty result in hemoglobin values in males that are about 1.5–2 g/dL higher than females.
- Anemia is classified based on red blood cell (RBC) size: microcytic, normocytic, or macrocytic.
- Key clinical findings in patients with hemolytic anemias are jaundice, pallor, and splenomegaly.
- An elevated reticulocyte count suggests increased RBC production.
- Anemia with a normal reticulocyte count suggests decreased or ineffective production.

Iron-Deficiency Anemia

- Pure dietary iron deficiency is rare except in children 1–3 years of age; it is most common in bottle-fed toddlers receiving large amounts of cow's milk and lacking food high in iron.

- Menstruating adolescent females who are not receiving supplemental iron are at high risk for iron deficiency.
- Iron deficiency in adolescent males is rare and should prompt evaluation for chronic gastrointestinal blood loss.
- In an otherwise healthy child, a therapeutic trial of oral iron is the best diagnostic study for iron deficiency as long as the child is re-examined and a response is documented, including reticulocytosis (48–72 hours), increase in hemoglobin levels (4–30 days), and repletion of iron stores (in 1–3 months).

Thalassemias

- α -thalassemia minor and β -thalassemia minor are common causes of microcytic anemia in otherwise healthy children of Mediterranean, Southeast Asian, or African descent.

Lead Poisoning

- Lead poisoning may be associated with hypochromic, microcytic anemia since most patients have concomitant iron deficiency.

Normocytic Anemia

- Chronic inflammation can lead to normocytic anemia that is likely mediated through hepcidin.
- Malignancy can result in normocytic anemia; RBC aplasia (congenital and acquired) results in normocytic anemia.

Macrocytic Anemia

- Macrocytic anemia should result in evaluation for vitamin B₁₂ and folate deficiency as well as careful evaluation for bone marrow failure, dysplasia, or infiltrative process.

Pancytopenia

- Pancytopenia is a simultaneous quantitative decrease in all formed elements of the blood.
- A low reticulocyte count, presence of abnormal forms of leukocytes or myeloid elements less mature than band forms, small platelets, and an elevated mean corpuscular volume in the face of a low reticulocyte count suggest bone marrow failure and require bone marrow examination.

- The etiology of aplastic anemia can be idiopathic, drug induced, or postinfectious.
- Fanconi anemia, an autosomal recessive defect in DNA repair, leads to bone marrow failure, presents with multiple congenital anomalies and can evolve into acute leukemia.

Hemoglobinopathies

- α chain hemoglobinopathies present in utero since alpha chains are needed for fetal erythropoiesis.
- Four alpha genes are present on chromosome 16. A single-gene deletion is a silent carrier, two-gene deletions result in α -thalassemia minor (trait), three-gene deletion results in hemoglobin H disease (moderate hemolytic anemia), and four-gene deletion results in hydrops fetalis with severe intrauterine anemia.
- β chain hemoglobinopathies present between 4 and 12 months of age when fetal hemoglobin nadirs.

Sickle Cell Disease

- The common sickle cell syndromes are hemoglobin SS disease, hemoglobin SC disease, hemoglobin S- β^0 -thalassemia, and hemoglobin S- β^+ -thalassemia.
- A child with sickle cell disease is vulnerable to:
 - Life-threatening infection by 4 months of age due to splenic dysfunction. A febrile patient with sickle cell disease must be evaluated immediately and empirically treated with antibiotics.
 - Sudden, severe, and sometimes life-threatening events caused by the acute intravascular sickling of the RBCs, with resultant pain or organ dysfunction, can occur.
 - Acute painful events are usually localized to the long bones of the arms or legs but may occur in smaller bones of the hands or feet in infancy (dactylitis), ribs, or in the abdomen.
 - Overt stroke occurs in approximately 8–10% of patients with hemoglobin SS or hemoglobin S- β^0 -thalassemia and is an indication for chronic transfusion.
- Hydroxyurea should be initiated in asymptomatic children with severe sickle cell disease (HbSS or HbS β^0 -thalassemia).

Enzymopathies

- RBC enzyme disorders include glucose-6-phosphate dehydrogenase (G6PD) deficiency (common) and pyruvate kinase deficiency (rare).
- The gene for G6PD is on the X chromosome.
- Patients with pyruvate kinase deficiency have depletion of adenosine triphosphate, which impairs RBC survival.

Membrane Disorders

- The most common RBC membrane hemolytic disorders are hereditary spherocytosis and hereditary elliptocytosis.
- A positive osmotic fragility test supports the diagnosis of hereditary spherocytosis.

Hemolytic Anemia Caused by Disorders Extrinsic to the Red Blood Cell

- Isoimmune hemolysis is caused by active maternal immunization against fetal antigens (i.e., A, B, and Rh D antigens).
- Autoimmune hemolytic anemia is Coombs positive due to the production of autoantibodies that cause RBC destruction, often following an infection.
- Treatment of autoimmune hemolytic anemia often requires RBC transfusion in addition to corticosteroids for some types.

CHAPTER 151

Hemostatic Disorders

Normal Hemostasis

- All the hemostatic processes are closely interwoven and occur on biologic surfaces that mediate coagulation by bringing platelets, endothelial cells, and subendothelium into close proximity with pro- and anticoagulant proteins.
- Deficiency of factor 8 or factor 9 leads to severe bleeding disorders, deficiency of factor 11 can be associated with mild bleeding, and deficiency of factor 12 is asymptomatic.
- Fibrinolysis is initiated by the action of tissue plasminogen activator on plasminogen, producing plasmin, the active enzyme that degrades fibrin into split products.

Developmental Hemostasis

- Most children attain normal levels of procoagulant and anticoagulant proteins by 1 year of age; levels of protein C lag and normalize in adolescence.

Hemostatic Disorders

- A detailed family history is crucial to the diagnosis of bleeding and thrombotic disorders.
- No single laboratory test can screen for all bleeding disorders.

Platelet Disorders

- Platelet counts less than 150,000/mm³ constitute thrombocytopenia. Mucocutaneous bleeding is the hallmark of platelet disorders. The risk of bleeding correlates imperfectly with the platelet count.
- The etiology of thrombocytopenia is organized into three mechanisms:
 - Decreased platelet production
 - Increased platelet destruction: neonatal autoimmune thrombocytopenia, acute idiopathic thrombocytopenia purpura, and thrombotic microangiopathy
 - Platelet sequestration/consumption
- Disorders of platelet function present with mucocutaneous bleeding, prolonged bleeding time, or long PFA closure time and can be primary or secondary disorders.

Disorders of Clotting Factors

- Hemophilia A (factor 8 deficiency) and hemophilia B (factor 9 deficiency) are X-linked, potentially severe bleeding disorders.
 - Clinical bleeding often occurs in the muscles and joints; the severity of bleeding is proportional to the patient's baseline level of factor 8 or 9.
 - Factor 8 or factor 9 recombinant replacement therapy is used to treat acute bleeds, for hemostasis for surgical procedures, and as prophylaxis in patients with severe hemophilia.
 - New treatment options, including a bispecific antibody that mimics factor 8 activity, and gene therapy are shifting the paradigm in hemophilia management.
- von Willebrand disease is an inherited bleeding disorder that affects about 1% of the White population.
 - It is associated with mucocutaneous bleeding such as epistaxis, gingival bleeding, cutaneous bruising, and menorrhagia.
 - The treatment depends on the type and the severity of bleeding; it commonly includes desmopressin (DDAVP).

Disseminated Intravascular Coagulation

- Disseminated intravascular coagulation (DIC) is a disorder with widespread activation of coagulation (thrombosis) and fibrinolysis (bleeding).
- Diagnosis usually is suspected clinically and is confirmed by laboratory findings.
- General treatment guidelines include:
 - Treat the underlying disorder inducing DIC first.
 - Support the patient by correcting hypoxia, acidosis, and poor perfusion.
 - Replace depleted blood-clotting factors, platelets, and anticoagulant proteins by transfusion, especially in a bleeding patient.

Thrombosis

- Hereditary predisposition to thrombosis:
 - Protein C or S, antithrombin, or plasminogen deficiency
 - Abnormality of a procoagulant protein (factor 5 Leiden)
 - Increased level of a procoagulant protein (prothrombin 20210)
 - Damage to endothelial cells (homocysteinemia)
- Acquired thrombosis may be due to indwelling catheters, vasculitis, sepsis, immobilization, nephrotic syndrome, coagulopathy, trauma, infection, surgery, inflammatory bowel disease, oral contraceptive agents, and pregnancy.
- Venous thromboses cause warm, swollen, tender, or purplish discolored extremities; arterial thromboses cause painful, pale, and poorly perfused extremities.
 - Venous thrombosis can be detected noninvasively by ultrasound Doppler flow compression studies. The gold

standard for diagnosis is venogram. Pulmonary embolism is detected by spiral computed tomography scan of the chest. Cerebral sinus venous thrombosis is often diagnosed by magnetic resonance venography.

- Therapy of thrombotic disorders usually initially involves unfractionated or low molecular weight heparin followed by longer term anticoagulation with warfarin or other oral anticoagulants.

CHAPTER 152

Blood Component Therapy

- Transfusion of RBCs, platelets, plasma, cryoprecipitate, and granulocytes can be lifesaving or life sustaining.
- Packed RBCs are used to treat anemia to increase oxygen-carrying capacity.
- Long-term complications of transfusions include:
 - Graft-versus-host disease
 - Infectious diseases such as hepatitis B (<1:1,000,000 units) and C (1:2,000,000 units), HIV (<1:2,000,000 units), malaria, syphilis, babesiosis, brucellosis, and Chagas disease.
- Patients who are chronically transfused are prone to developing iron overload and alloimmunization to RBCs and platelets.

ONCOLOGY

Thomas B. Russell | Thomas W. McLean

CHAPTER 153

Oncology Assessment

Childhood cancer is rare; only about 1% of new cancer cases in the United States occur among children younger than 19 years of age. However, cancer is the leading cause of disease-related death in children age 1–14 years. Acute leukemia is the most common childhood cancer, followed by central nervous system (CNS) tumors, lymphomas, and sarcomas of soft tissue and bone (Fig. 153.1). There is wide variability in the age-specific incidence of childhood cancers. Embryonal tumors, such as neuroblastoma and retinoblastoma, peak during the first 2 years of life; acute lymphoblastic leukemia peaks during early childhood (ages 2–4 years); osteosarcoma peaks during adolescence; and Hodgkin disease peaks during late adolescence (Fig. 153.2). The overall incidence of cancer among White children is higher than other ethnic groups and is approximately 50% higher than Black children in the United States.

HISTORY

Many signs and symptoms of childhood cancer are nonspecific. Although most children with fever, fatigue, weight loss, or limp do not have cancer, each of these symptoms may be a manifestation of an underlying malignancy. Uncommonly a child with cancer will have no symptoms at all. An abdominal mass may be palpated on routine examination, or a complete blood count (CBC) may be unexpectedly abnormal.

It is important to explore quality, duration, location, severity, and precipitating events of the chief complaint. A prominent lymph node that does not resolve (with or without antibiotics) may warrant imaging and/or a biopsy. A limp that does not improve within weeks should prompt a CBC and a radiograph. Fever, night sweats, or weight loss should raise the concern for lymphoma. In addition, it is important to obtain the birth history, medical and surgical history, growth history, developmental history, family history, and social history.

Cancer-predisposing genes (such as *TP53*) are mutated in approximately 9% of children and adolescents with cancer, even though family history in most patients does not predict an underlying predisposition syndrome. If known to have a

genetic susceptibility to cancer, the child should be screened appropriately (Table 153.1).

PHYSICAL EXAMINATION

Growth parameters and vital signs are important to obtain in all patients. Pulse oximetry should be obtained if respiratory symptoms are present. The general appearance of the patient should be noted, along with signs of pain, cachexia, pallor, and respiratory distress. Palpable masses should be measured, if possible. Lymphadenopathy and organomegaly should be quantified, if present. A thorough examination of the skin may reveal rashes, bruises, and petechiae. A genitourinary exam is important in any patient with unexplained findings. Careful neurologic and ophthalmologic examinations are crucial if headache or vomiting is present because the vast majority of patients with CNS tumors have abnormal neurologic examinations.

COMMON MANIFESTATIONS

The most common manifestations of childhood cancer are fatigue, anorexia, malaise, pain, fever, abnormal lump or mass, pallor, bruising, petechiae, bleeding, headache, vomiting, visual changes, weight loss, and night sweats (Table 153.2). Lymphadenopathy and organomegaly are common in leukemia, particularly with T-cell acute lymphoblastic leukemia (ALL) or lymphoma. Patients with solid tumors usually have a palpable or measurable mass. Children with retinoblastoma may have leukocoria or absence of the red reflex (which may be seen on a photograph). Other signs and symptoms may include limp, cough, dyspnea, cranial nerve palsies, and papilledema. In general, malignant masses are large/growing, firm, fixed, and nontender, whereas masses that are infectious or inflammatory in nature are relatively smaller/stable in size, softer, mobile, and tender to palpation.

DIFFERENTIAL DIAGNOSIS

Distinguishing a malignant process from another disease can be difficult. Ultimately, a tissue diagnosis (from bone marrow or solid tumor biopsy) with pathologic confirmation is required to confirm a diagnosis of cancer. Infection commonly masquerades as a potential malignancy. Epstein-Barr virus, cytomegalovirus, and mycobacterial infections

FIGURE 153.1 Number of childhood cancer diagnoses per year. Total = 15,780; age 0–19 years. (<http://curesearch.org/Number-of-Diagnoses>)

FIGURE 153.2 Incidence of the most common types of cancer in children by age. The cumulative incidence is shown as a dashed line. (Courtesy Archie Bleyer, MD.)

can mimic leukemia or lymphoma by causing fever, night sweats, lymphadenopathy, organomegaly, weight loss, and abnormal blood counts. Trauma may produce swelling that can mimic solid tumors. Idiopathic thrombocytic purpura and iron deficiency can produce thrombocytopenia and anemia, respectively. Immune deficiencies or irregularities (such as autoimmune hemolytic anemia, autoimmune neutropenia, or transient erythroblastopenia of childhood) can also produce cytopenias. Juvenile idiopathic arthritis and other collagen vascular disease can cause musculoskeletal pain, anemia, or thrombocytopenia, mimicking leukemia. Benign tumors are relatively common in children, including reactive adenopathy, mature germ cell tumors/hamartomas,

hemangiomas or other vascular tumors, mesoblastic nephromas, and bone cysts.

INITIAL DIAGNOSTIC EVALUATION

Screening Tests

A CBC with differential and review of the peripheral blood smear is the best screening test for many pediatric malignancies. Leukopenia (with or without neutropenia), anemia, or thrombocytopenia may be present in leukemia or any cancer that invades the bone marrow (e.g., neuroblastoma, rhabdomyosarcoma, and Ewing sarcoma). Leukemia may also produce leukocytosis, usually with blasts present on the peripheral blood smear. An isolated cytopenia (neutropenia, anemia, or thrombocytopenia) widens the differential diagnosis but still could be the only abnormal laboratory finding. Of note, a patient with leukemia may also have a normal CBC. Lactate dehydrogenase and uric acid are often elevated in fast-growing tumors (leukemia or lymphoma) and occasionally in sarcomas or neuroblastoma. In many cases, it is appropriate to assess electrolytes and renal and hepatic function in the screening process. Elevated blood pressure, if confirmed by repeat measurements, should prompt a urinalysis, as should the palpation of an abdominal mass. Serum (and/or cerebrospinal fluid) α -fetoprotein (AFP) and β -human chorionic gonadotropin (β -HCG) are screening tests (and tumor markers) for germ cell tumors. Serum AFP is also a tumor marker for hepatoblastoma. Urine homovanillic acid and vanillylmandelic acid are tumor markers for neuroblastoma.

Diagnostic Imaging

A chest x-ray (CXR) (posteroanterior and lateral) is the best screening radiographic study for a patient with suspicious cervical lymphadenopathy, fever, and weight loss. Mediastinal masses and pleural effusions can be detected on CXR. Abdominal signs or symptoms usually warrant an ultrasound or computed tomography (CT) scan. Persistent headaches or morning vomiting should prompt a CT scan or magnetic resonance imaging (MRI) of the head. For suspected bone tumors, plain radiographs are indicated and will usually reveal the lesion(s), if present, although radiographs may be normal when a bony pelvic lesion is suspected. CT or MRI should be obtained if radiographs are abnormal. Other imaging studies to delineate a mass and to search for suspected metastases are often indicated. Discussion with a radiologist is almost always helpful. Positron emission tomography (PET), usually combined with CT or MRI, is useful for staging and assessing response for lymphomas and sarcomas. Metaiodobenzylguanidine scans are useful for neuroblastoma. Table 153.3 shows the general use of diagnostic imaging following confirmation of a diagnosis of cancer, assessing the primary tumor and for metastases.

PEARLS FOR PRACTITIONERS

See *Oncology: Pearls for Practitioners* at the end of this section.

TABLE 153.1 Known Risk Factors for Selected Childhood Cancers

CANCER TYPE	RISK FACTOR	COMMENTS
Acute lymphoid leukemia	Ionizing radiation	Prenatal diagnostic x-ray exposure and therapeutic irradiation for cancer treatment increases risk.
	Race	White children have a twofold higher rate than Black children in the United States.
	Genetic conditions	Down syndrome is associated with an estimated 10- to 20-fold increased risk. Neurofibromatosis 1, Bloom syndrome, and ataxia-telangiectasia, among others, are associated with an elevated risk.
Acute myeloid leukemia	Chemotherapy and radiation therapy	Alkylating agents and epipodophylotoxins increase risk, as does radiation therapy for other cancers.
	Genetic factors	Down syndrome and neurofibromatosis 1 are strongly associated. Familial monosomy 7 and several other genetic syndromes are also associated with increased risk.
Brain cancer	Ionizing radiation to the head	Radiation therapy for one brain tumor can lead to a secondary brain tumor.
	Genetic factors	Neurofibromatosis 1 is strongly associated with optic gliomas and, to a lesser extent, with other central nervous system tumors. Tuberous sclerosis and several other genetic syndromes are associated with increased risk.
Hodgkin disease	Family history	Monozygotic twins and siblings are at increased risk.
	Infections	Epstein-Barr virus and papillomaviruses are associated with increased risk.
Non-Hodgkin lymphoma	Immunodeficiency	Acquired and congenital immunodeficiency disorders and immunosuppressive therapy increase risk.
	Infections	Epstein-Barr virus is associated with increased risk in African countries.
Osteosarcoma	Ionizing radiation	Cancer radiation therapy and high radium exposure increase risk.
	Chemotherapy	Alkylating agents increase risk.
	Genetic factors	Increased risk is apparent with Li-Fraumeni syndrome and hereditary retinoblastoma.
Ewing sarcoma	Race	Incidence is about nine times higher in White children than in Black children in the United States.
Neuroblastoma	Genetic factors	Chromosome 6p22 variants and mutations in the <i>ALK</i> and <i>PHOX</i> genes are associated with increased risk.
Retinoblastoma	Genetic factors	Mutations in the <i>Rb</i> gene on chromosome 14
Wilms tumor	Congenital anomalies	Aniridia, Beckwith-Wiedemann syndrome, and other congenital and genetic conditions are associated with increased risk.
Renal medullary carcinoma	Sickle cell trait	Etiology is unknown.
Rhabdomyosarcoma	Congenital anomalies and genetic conditions	Li-Fraumeni syndrome and neurofibromatosis 1 are associated with increased risk.
Hepatoblastoma	Prematurity	Etiology is unknown.
	Genetic factors	Beckwith-Wiedemann syndrome, hemihypertrophy, Gardner syndrome, and familial adenomatous polyposis are associated with increased risk.
Hepatocellular carcinoma	Infections	Hepatitis B virus infection increases risk.
Malignant germ cell tumors	Cryptorchidism	Cryptorchidism is a risk factor for testicular germ cell tumors.

Modified from Scheurer ME, Lupo PL, Bondy ML. Epidemiology of childhood cancer. In: Pizzo PA, Poplack DG, eds. Principles and Practice of Pediatric Oncology. 7th ed. Philadelphia: Wolters Kluwer; 216:10.

TABLE 153.2 Common Manifestations of Childhood Malignancies		
SIGN/SYMP TOM	SIGNIFICANCE	EXAMPLE
HEMATOLOGIC		
Pallor, anemia	Bone marrow infiltration	Leukemia, neuroblastoma
Petechiae, thrombocytopenia	Bone marrow infiltration	Leukemia, neuroblastoma
Fever, neutropenia	Bone marrow infiltration	Leukemia, neuroblastoma
SYSTEMIC		
Bone pain, limp, arthralgia	Primary bone tumor, metastasis to bone	Osteosarcoma, Ewing sarcoma, rhabdomyosarcoma, leukemia, neuroblastoma
Fever of unknown origin, weight loss, night sweats	Lymphoreticular malignancy	Hodgkin or non-Hodgkin lymphoma
Painless lymphadenopathy (especially in the cervical region)	Lymphoreticular malignancy, metastatic solid tumor	Leukemia, Hodgkin and non-Hodgkin lymphoma, Burkitt lymphoma, nasopharyngeal carcinoma, thyroid carcinoma
Cutaneous lesion	Primary or metastatic disease	Neuroblastoma, leukemia, Langerhans cell histiocytosis, melanoma
Abdominal mass	Abdominal/pelvic organ	Neuroblastoma, Wilms tumor, Burkitt lymphoma, hepatoblastoma, germ cell tumor
Hypertension	Sympathetic nervous system tumor	Wilms tumor, neuroblastoma, pheochromocytoma
Diarrhea	Vasoactive intestinal polypeptide	Neuroblastoma
Soft tissue mass	Local or metastatic tumor	Ewing sarcoma, osteosarcoma, neuroblastoma, rhabdomyosarcoma, germ cell tumor, thyroid carcinoma
Diabetes insipidus, galactorrhea, poor growth	Neuroendocrine involvement of hypothalamus or pituitary gland	Germ cell tumor, adenoma, craniopharyngioma, prolactinoma, Langerhans cell histiocytosis
Emesis, visual disturbances, ataxia, headache, papilledema, cranial nerve palsies	Increased intrathecal pressure	Primary brain tumor; metastasis
OPHTHALMOLOGIC		
Leukocoria	White pupil	Retinoblastoma
Periorbital ecchymosis	Metastasis	Neuroblastoma
Miosis, ptosis, heterochromia	Horner syndrome: compression of cervical sympathetic nerves	Neuroblastoma
Opsomyoclonus, ataxia	Paraneoplastic/immune	Neuroblastoma
Exophthalmos, proptosis	Orbital tumor	Rhabdomyosarcoma, neuroblastoma, lymphoma
THORACIC		
Anterior mediastinal mass	Cough, stridor, pneumonia, tracheal-bronchial compression	Germ cell tumor, T-cell lymphoma/leukemia, Hodgkin disease, primary mediastinal large B-cell lymphoma
Posterior mediastinal mass	Vertebral or nerve root compression; dysphagia	Neuroblastoma, ganglioneuroblastoma, ganglioneuroma

TABLE 153.3 Minimum Work-Up Required for Common Pediatric Malignancies to Assess Primary Tumor and Potential Metastases*

MALIGNANCY	BMA/BX	CXR	CT SCAN	MRI	BONE SCAN, PET SCAN, OR PET-CT SCAN	CSF ANALYSIS	MARKER(S)	OTHER
Leukemia	Yes	Yes				Yes		
Non-Hodgkin lymphoma	Yes	Yes	Yes		Yes	Yes		
Hodgkin lymphoma	Yes	Yes	Yes		Yes			
CNS tumors				Yes		Yes		
Neuroblastoma	Yes		Yes		Yes		VMA, HVA	mIBG scan
Wilms tumor		Yes	Yes					
Rhabdomyosarcoma	Yes	Yes	Yes		Yes	Yes, for parameningeal tumors only		
Osteosarcoma		Yes	Yes (chest)	Yes (primary)	Yes			
Ewing sarcoma	Yes	Yes	Yes (chest)	Yes (primary)	Yes			
Germ cell tumors		Yes	Yes				AFP, β -hCG	Consider brain MRI
Liver tumors		Yes	Yes				AFP	
Retinoblastoma	\pm		Yes, if MRI not available	Yes (brain)	\pm	Yes		Rb gene analysis

*Individual cases may require additional studies.

AFP, α -fetoprotein; BMA/bx, bone marrow aspirate/biopsy; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; CXR, chest x-ray; β -HCG, β -human chorionic gonadotropin; HVA, homovanillic acid; mIBG, metaiodobenzylguanidine; MRI, magnetic resonance imaging; PET, positron emission tomography; Rb, retinoblastoma; VMA, vanillylmandelic acid.

CHAPTER 154

Principles of Cancer Treatment

The overall goal of pediatric oncology is to cure all patients with minimal toxicity. Treatment for children with cancer is often multimodal and may involve surgery, radiation therapy, chemotherapy, and immunotherapy. Surgery and radiation are generally local treatment modalities (an exception is total body irradiation as part of a bone marrow or stem cell transplant), whereas chemotherapy and immunotherapy have both local and systemic effects.

Primary prevention strategies for most pediatric malignancies are unknown. Two exceptions are the use of hepatitis B vaccine to lower the rates of hepatocellular carcinoma and the use of human papillomavirus vaccine to reduce the risk of genitourinary and oropharyngeal cancers. Childhood malignancies are not associated with tobacco or alcohol use, dietary factors, or sun exposure. Treatment with certain chemotherapy agents and radiation therapy increases the rate of second malignancies. Secondary prevention may be accomplished by screening the at-risk child (e.g., a child with Beckwith-Wiedemann syndrome or twin of a leukemia patient), but these opportunities are rare.

ONCOLOGIC EMERGENCIES

Adverse effects of tumors and treatments may result in oncologic emergencies in children and adolescents (Table 154.1). Mediastinal masses from lymphoma can cause life-threatening airway obstruction. Tumors with a large tumor burden (e.g., lymphoma, leukemia) may affect renal function adversely from tubular deposition of uric acid crystals. Allopurinol or rasburicase can be administered before chemotherapy to minimize this effect.

A common metabolic emergency is **tumor lysis syndrome**, often seen in treatment of leukemia and lymphoma. Large amounts of phosphate, potassium, and uric acid are released into the circulation from lysed cells. Bleeding, infection, and spinal cord compression with neurologic compromise are other oncologic emergencies.

SURGERY

Appropriate imaging (usually with computed tomography [CT] or magnetic resonance imaging [MRI]) for solid tumors presenting as a palpable mass or mass-related symptoms (pain, respiratory distress, intestinal obstruction) should be obtained and followed by resection (when possible) or biopsy (if complete resection is not feasible or indicated). Pediatric

TABLE 154.1 Oncologic Emergencies				
CONDITION	MANIFESTATIONS	ETIOLOGY	MALIGNANCY	TREATMENT
METABOLIC				
Hyperuricemia	Uric acid nephropathy, renal insufficiency or failure	Tumor lysis syndrome	Lymphoma, leukemia	Allopurinol, hydration, rasburicase
Hyperkalemia	Arrhythmias	Tumor lysis syndrome	Lymphoma, leukemia	Kayexalate; sodium bicarbonate, glucose plus insulin
Hyperphosphatemia	Hypocalcemic tetany; metastatic calcification, photophobia, pruritus	Tumor lysis syndrome	Lymphoma, leukemia	Hydration, diuresis; oral aluminum hydroxide to bind phosphate
Hypercalcemia	Anorexia, nausea, polyuria, pancreatitis, gastric ulcers; prolonged PR/shortened QT interval	Bone resorption; ectopic parathormone, vitamin D, or prostaglandins	Metastasis to bone, rhabdomyosarcoma	Hydration and furosemide diuresis; corticosteroids; mithramycin; calcitonin, diphosphonates
HEMATOLOGIC				
Anemia	Pallor, weakness, heart failure	Bone marrow suppression or infiltration; blood loss	Any with chemotherapy	Packed red blood cell transfusion
Thrombocytopenia	Petechiae, hemorrhage	Bone marrow suppression or infiltration	Any with chemotherapy	Platelet transfusion
Disseminated intravascular coagulation	Shock, hemorrhage	Sepsis, hypotension, tumor factors	Promyelocytic leukemia, others	Fresh frozen plasma; platelets, treat infection
Neutropenia	Infection	Bone marrow suppression or infiltration	Any with chemotherapy	If patient is febrile, administer broad-spectrum antibiotics, consider filgrastim (G-CSF)
Hyperleukocytosis (WBC $\geq 100,000/\text{mm}^3$)	Hemorrhage, thrombosis; pulmonary infiltrates, hypoxia; tumor lysis syndrome	Leukostasis; vascular occlusion	Leukemia	Hydration; chemotherapy; leukapheresis?
Graft-versus-host disease	Dermatitis, diarrhea, hepatitis	Immunosuppression and nonirradiated blood products; bone marrow transplantation	Any with immunosuppression	Corticosteroids; cyclosporine; methotrexate; tacrolimus; mycophenolate mofetil; antithymocyte globulin
SPACE-OCCUPYING LESIONS				
Spinal cord compression	Back pain, motor and sensory deficits	Invasion of spinal canal by primary tumor or metastases	Neuroblastoma, medulloblastoma	MRI for diagnosis; corticosteroids; radiation therapy; laminectomy; chemotherapy
Increased intracranial pressure	Headache, confusion, coma, emesis, headache, hypertension, bradycardia, seizures, papilledema, hydrocephalus; cranial nerve III and VI palsies	Primary or metastatic brain tumor	Astrocytoma, medulloblastoma, others; neuroblastoma	CT or MRI for diagnosis; corticosteroids; ventriculoperitoneal shunt; radiation therapy; chemotherapy
Superior vena cava syndrome	Distended neck veins, plethora, edema of head and neck, cyanosis, proptosis; Horner syndrome	Superior mediastinal mass	Lymphoma	Chemotherapy; radiation therapy
Tracheal compression	Respiratory distress	Mediastinal mass compressing trachea	Lymphoma	Radiation therapy, corticosteroids

CNS, Central nervous system; CT, computed tomography; G-CSF, granulocyte colony-stimulating factor; MRI, magnetic resonance imaging.

lymphomas are chemosensitive and rarely require complete surgical resection.

It is crucial to determine the amount of tissue required and the appropriate distribution of the tissue for testing so that all necessary studies are performed. A general oncologic surgery principle is to resect not just the tumor but also, in most cases, a surrounding margin of normal tissue to ensure the entire tumor has been resected. A central line (usually a port-a-cath) is often inserted at the time of tumor biopsy.

CHEMOTHERAPY

Because most pediatric solid tumors have a high risk for micrometastatic disease at the time of diagnosis, chemotherapy is used in almost all cases (Table 154.2). Exceptions include low-stage neuroblastoma and Wilms tumor (particularly in infants) and low-grade central nervous system (CNS) tumors that have been completely excised. For patients with localized

solid tumors, chemotherapy administered after removal of the primary tumor is referred to as **adjuvant therapy** (often called consolidation). Chemotherapy administered while the primary tumor is still present is referred to as **neoadjuvant chemotherapy**, often called induction. Neoadjuvant chemotherapy has a number of potential benefits, including an early attack on presumed micrometastatic disease, shrinkage of the primary tumor to facilitate local control, and additional time to plan for definitive surgery.

Resistance to chemotherapeutic agents can develop relatively quickly. Thus combinations of chemotherapy drugs are used (as opposed to sequential single agents) to treat childhood cancer. The blood-brain barrier prevents the penetration of chemotherapeutic drugs into the CNS. Thus administration of chemotherapy directly into the cerebrospinal fluid (by lumbar puncture) is used for leukemia and lymphoma. Radiation therapy also circumvents the blood-brain barrier and may be used in selected cases.

DRUG	ACTION	INDICATION	ACUTE TOXICITY*
Methotrexate	Folic acid antagonist; inhibits dihydrofolate reductase	ALL, lymphoma, medulloblastoma, osteosarcoma	Myelosuppression (nadir 7–10 days), mucositis, dermatitis, hepatitis, renal and CNS effects with high-dose administration; prevent with hydration and leucovorin, monitor levels
6-Mercaptopurine	Purine analog	ALL	Myelosuppression; hepatitis; mucositis; allopurinol increases toxicity
Cytosine arabinoside (Ara-C)	Pyrimidine analog; inhibits DNA polymerase	ALL, AML, lymphoma	Myelosuppression, conjunctivitis, mucositis, neurotoxicity
Cyclophosphamide	Alkylates guanine; inhibits DNA synthesis	ALL, lymphoma, sarcoma, brain tumors	Myelosuppression; hemorrhagic cystitis
Ifosfamide	Similar to cyclophosphamide	Lymphoma, Wilms tumor, sarcoma, germ cell and testicular tumors	Similar to cyclophosphamide; neurotoxicity, cardiac toxicity
Carmustine (BCNU), lomustine (CCNU)	Carbamylation of DNA; inhibits DNA synthesis	CNS tumors, lymphoma, Hodgkin disease	Delayed myelosuppression (4–6 wk); pulmonary fibrosis, carcinogenic, stomatitis
Cisplatin	Inhibits DNA synthesis	Osteosarcoma, neuroblastoma, CNS tumors, germ cell tumors	Nephrotoxic; myelosuppression, ototoxicity, neurotoxicity, hemolytic uremic syndrome
Carboplatin	Inhibits DNA synthesis	Same as for cisplatin	Myelosuppression
Doxorubicin and daunorubicin	Intercalation, DNA strand breaks	ALL, AML, osteosarcoma, Ewing sarcoma, lymphoma, neuroblastoma	Cardiomyopathy, red urine, tissue necrosis on extravasation, myelosuppression, conjunctivitis, radiation dermatitis, arrhythmia
Dactinomycin	Intercalation, DNA strand breaks	Wilms tumor, rhabdomyosarcoma, Ewing sarcoma	Tissue necrosis on extravasation, myelosuppression, hepatopathy with thrombocytopenia, stomatitis
Etoposide (VP-16)	DNA strand breaks	ALL, AML, lymphoma, germ cell tumor, sarcoma	Myelosuppression, secondary leukemia, allergic reaction
Topotecan	DNA strand breaks	Neuroblastoma, rhabdomyosarcoma	Myelosuppression, diarrhea, mucositis
Vincristine	Inhibits microtubule formation	ALL, lymphoma, Wilms tumor, Hodgkin disease, Ewing sarcoma, neuroblastoma, rhabdomyosarcoma, brain tumors	Local cellulitis, peripheral neuropathy, constipation, ileus, jaw pain, inappropriate ADH secretion, seizures, ptosis, minimal myelosuppression
Vinblastine	Inhibits microtubule formation	Hodgkin disease, Langerhans cell histiocytosis	Local cellulitis, myelosuppression

Continued

DRUG	ACTION	INDICATION	ACUTE TOXICITY*
Asparaginase	Depletion of asparagine	ALL, AML	Allergic reaction; pancreatitis, hyperglycemia, platelet dysfunction and coagulopathy, encephalopathy, stroke, thrombosis
Prednisone, dexamethasone	Direct lymphocyte cytotoxicity	ALL; Hodgkin disease, lymphoma	Cushing syndrome, cataracts, diabetes, hypertension, myopathy, osteoporosis, infection, peptic ulceration, irritability, psychosis, hunger, fluid retention
Rituximab	Anti-CD20	CD20 + B-cell leukemia, lymphoma	Fever, chills, allergy
Brentuximab	Anti-CD30	CD30+ lymphomas	Myelosuppression, peripheral neuropathy, fatigue, fever
Blinatumomab	Anti-CD19 and anti-CD3	CD19+ B-lymphoblastic leukemia	Cytokine release syndrome, neurotoxicity
Dinutuximab	Anti-G _{D2}	High-risk neuroblastoma	Neuropathic pain, hypotension, hypoxia, fever, capillary leak syndrome, hypersensitivity reactions
Imatinib	Inhibits BCR-ABL, VEGF, c-KIT kinases	Ph+ CML, ALL	Nausea, vomiting, fatigue, headache
Dasatinib	Inhibits BCR-ABL, c-KIT, and other kinases	Ph+ CML, ALL	Fluid retention, rash, nausea
Tretinoin (all- <i>trans</i> retinoic acid [ATRA]) and isotretinoin (<i>cis</i> -retinoic acid [CRA])	Promotes differentiation	Acute promyelocytic leukemia (ATRA); neuroblastoma (CRA)	Fever, respiratory distress, leukocytosis (ATRA); dry mouth, hair loss, pseudotumor cerebri (CRA)
Arsenic	Promotes differentiation, apoptosis	Acute promyelocytic leukemia	Transaminitis, nausea, vomiting, abdominal pain, QTc prolongation
Tisagenlecleucel	Anti-CD19 CART therapy	CD19+ refractory B-lymphoblastic leukemia	Cytokine release syndrome, hypogammaglobulinemia

*Many drugs produce nausea and vomiting during administration, and many cause alopecia with repeated doses.

ADH, Antidiuretic hormone; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CNS, central nervous system; CART, chimeric antigen receptor T cell.

RADIATION THERAPY

Radiation therapy delivers ionizing radiation to malignant cells to kill them directly or, more commonly, prevent them from dividing by interfering with DNA replication. Conventional radiation therapy uses photons, but atomic particles such as electrons, protons, and neutrons can also be used. Not all tumors are radiosensitive, and radiation therapy is not necessary in all tumors that are radiosensitive.

OTHER THERAPIES

Certain cancers have been treated with biologic response modifiers, tyrosine kinase inhibitors, or monoclonal antibodies in addition to standard treatments. **Targeted therapies** specifically target tumor cells, sparing normal host cells. Imatinib, the first tyrosine kinase inhibitor (TKI) that was Food and Drug Administration approved, targets the effects of the t(9;22) translocation (*BCR-ABL*) of chronic myeloid leukemia and acute lymphoblastic leukemia. Since then, many TKIs have been developed to treat a variety of malignancies. Rituximab is a monoclonal antibody directed against the cell surface antigen CD20 expressed in some lymphomas and leukemias. Dinutuximab is an anti-G_{D2} monoclonal antibody used for neuroblastoma.

Chimeric antigen receptor T-cell therapy (tisagenlecleucel) and bi-specific T-cell engager therapy (blinatumomab) are immunotherapies that leverage the patient's own T cells to kill cancer cells.

Supportive care also plays an important role in pediatric oncology, including the use of appropriate antiemetics, antimicrobial agents, blood products, nutritional support, intensive care, psychosocial support, and integrative therapies.

ADVERSE EFFECTS

Because chemotherapy agents are cellular toxins, numerous adverse effects are associated with their use. Bone marrow suppression, immunosuppression, nausea, vomiting, and alopecia are general adverse effects of commonly used chemotherapy drugs. Each chemotherapy drug also has specific toxicities. Doxorubicin can cause cardiac damage; cisplatin can cause renal damage and ototoxicity; cyclophosphamide and ifosfamide can cause hemorrhagic cystitis; and vincristine can cause peripheral neuropathy. Radiation therapy produces many adverse effects such as mucositis, growth retardation, organ dysfunction, and the later development of secondary cancers. Significant therapy-related **late effects** may develop in pediatric cancer patients (Table 154.3).

TABLE 154.3 Long-Term Sequelae of Cancer Therapy

PROBLEM	ETIOLOGIC AGENT(S)
Infertility	Alkylating agents; radiation
Second cancers	Genetic predisposition; radiation; alkylating agents, etoposide, topoisomerase II inhibitors
Sepsis	Splenectomy
Hepatotoxicity	Methotrexate, 6-mercaptopurine; radiation
Hepatic venoocclusive disease	High-dose, intensive chemotherapy (busulfan, cyclophosphamide)±bone marrow transplant
Scoliosis	Radiation
Pulmonary (fibrosis)	Radiation; bleomycin, busulfan
Cardiomyopathy	Doxorubicin, daunorubicin; radiation
Leukoencephalopathy	Cranial radiation, methotrexate
Cognition/intelligence	Cranial radiation, methotrexate
Pituitary dysfunction (growth hormone deficiency, panhypopituitarism)	Cranial radiation
Psychosocial	Stress, anxiety, death of peers; conditioned responses to chemotherapy
Thyroid dysfunction	Radiation
Osteonecrosis	Corticosteroids

PEARLS FOR PRACTITIONERS

See *Oncology: Pearls for Practitioners* at the end of this section.

CHAPTER 155

Leukemia

ETIOLOGY

The etiology of childhood leukemia is unknown and is thought to be multifactorial with both genetics and environmental factors contributing to malignant transformation. A variety of genetic syndromes/diseases including Down syndrome (trisomy 21), Fanconi anemia, Bloom syndrome, ataxia-telangiectasia, Wiskott-Aldrich syndrome, neurofibromatosis type 1, and rare familial leukemia syndromes can predispose children to the development of acute leukemia. Siblings of children with leukemia are also at an increased risk of developing leukemia compared to the general pediatric population. Environmental factors that may increase the risk of leukemia include ionizing radiation and some chemotherapy agents (such as etoposide), and, possibly, some childhood infections. Some leukemias are associated with specific somatic mutations. For example, **chronic myeloid leukemia (CML)** and less commonly in **acute lymphoblastic leukemia (ALL)**, a

translocation involving chromosomes 9 and 22 (Philadelphia [Ph] chromosome) results in a fusion gene called *BCR-ABL*, which leads to a constitutively activated tyrosine kinase that drives development of CML and Ph-positive ALL.

EPIDEMIOLOGY

ALL accounts for approximately 75% of leukemia cases in the pediatric population, followed by **acute myeloid leukemia (AML)** at approximately 20%, and CML at less than 5%. Other chronic leukemias, including juvenile myelomonocytic leukemia, chronic myelomonocytic leukemia, and chronic lymphocytic leukemia, are rare in childhood. ALL is the most common childhood cancer overall, comprising 25% of cancer prior to the age of 15 years (40 per 1 million children age <15 years) and approximately 20% of cancer prior to the age of 20 years.

ALL is classified according to lymphoid lineage as either B cell or T cell. The incidence of B-lineage ALL peaks at 2 to 4 years of age and is slightly more common in boys than in girls. T-cell ALL is associated with male predominance as well as an older age of onset. In the United States, ALL is more common in White than in Black children. The incidence of AML is relatively higher in the first year of life, then drops and stabilizes until adolescence when there is a slight increase, which continues into adulthood (especially beyond age 55 years). Males and females are equally affected by AML. Hispanic and Black children have slightly higher incidence of AML than White children.

CLINICAL MANIFESTATIONS

Signs and symptoms of acute leukemia are related to the infiltration of leukemic cells into normal tissues, resulting in bone marrow failure (anemia, neutropenia, thrombocytopenia), leukocytosis, and/or specific tissue infiltration (lymph nodes, liver, spleen, brain, bone, skin, gingiva, testes). Common presenting symptoms are fever, pallor, petechiae and/or ecchymoses, malaise, anorexia, and musculoskeletal pain. Physical examination frequently reveals lymphadenopathy and hepatosplenomegaly. The testes and central nervous system (CNS) are common extramedullary sites for ALL involvement; neurologic symptoms or a painless enlargement of one or both testes may be seen. Patients with T-cell ALL often have high white blood cell (WBC) counts, an anterior mediastinal mass (mediastinal adenopathy and/or thymic infiltration), cervical lymphadenopathy, hepatosplenomegaly, and CNS involvement. In patients with AML, extramedullary soft tissue tumors may be found in various sites.

LABORATORY AND IMAGING STUDIES

The diagnosis of acute leukemia is confirmed by finding immature blast cells on either the peripheral blood smear, bone marrow aspirate, or both. Most patients have abnormal blood counts; anemia and thrombocytopenia are common. The WBC count may be low, normal, or high; 10% to 20% of patients have a WBC count of 100,000/mm³ or higher (hyperleukocytosis) at presentation. Definitive diagnosis requires the evaluation of cell surface markers (immunophenotype) by flow cytometry. Cytogenetic analysis should be undertaken in all cases of acute leukemia because many recurring

cytogenetic abnormalities have prognostic implications and are used in combination with other risk factors to assign therapy to optimize outcome. In B-lineage ALL, the t(12;21) translocation (*ETV6/RUNX1* fusion) is the most common (approximately 20% of all cases) and is associated with a favorable prognosis when combined with other low-risk features. The t(9;22) translocation (Ph chromosome) occurs in 3% of cases and, historically, has a poor prognosis. However, much like in CML, the use of tyrosine kinase inhibitors (TKIs) in Ph-positive ALL has resulted in significant improvements in outcomes. Ph-like ALL exhibits a similar genotype (by gene expression profiling) to Ph+ ALL but lacks the t(9;22). The use of TKIs in Ph-like ALL is under investigation. The t(4;11) translocation (and other translocations involving the *KMT2A* gene on chromosome 11) often occurs in infant ALL and patients with secondary AML (often in patients that have been exposed to etoposide) and is associated with a poor prognosis. Fluorescent in situ hybridization, polymerase chain reaction, and DNA microarray techniques are now used in most cases of leukemia because many chromosomal abnormalities may not be apparent on routine karyotypes. A lumbar puncture should always be performed at the time of diagnosis to evaluate the possibility of CNS involvement. A chest x-ray should be obtained in all patients to assess for an anterior mediastinal mass. Electrolytes (particularly potassium, phosphorus, and calcium), uric acid, and renal function should be monitored in all patients to assess and treat patients at risk for tumor lysis syndrome.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of acute leukemia includes nonmalignant and malignant diseases. Infection is probably the most common mimicker of acute leukemia, particularly Epstein-Barr virus. Other infections (cytomegalovirus, other viruses, mycobacteria) also can produce signs and symptoms common to leukemia. Noninfectious considerations include aplastic anemia, histiocytosis, juvenile idiopathic arthritis, immune thrombocytopenic purpura, and congenital or acquired conditions that result in neutropenia or anemia. Several malignant diagnoses also can mimic leukemia, including neuroblastoma, rhabdomyosarcoma, and Ewing sarcoma. Newborns with trisomy 21 may have a condition known as transient myeloproliferative disorder, which produces elevated WBC counts with peripheral blasts, anemia, and thrombocytopenia. It usually resolves with supportive care only, but these children have a significantly increased risk (30%) of developing acute leukemia (ALL or AML) within the next few months to years of life.

TREATMENT

Patients with B-lineage ALL generally receive three- or four-agent induction chemotherapy based on their age at diagnosis (1–9 years is favorable) and highest pretreatment WBC count (<50,000/mm³ is favorable). All patients with T-cell ALL receive a four-agent induction. Standard-risk patients receive vincristine, corticosteroids, and pegylated asparaginase over 4 weeks; high-risk patients also receive an anthracycline (typically daunorubicin). Intrathecal therapy with cytarabine or methotrexate is given to treat existing or subclinical CNS leukemia. Following induction therapy, patients undergo an end-of-induction bone marrow evaluation to

assess for remission (nearly all patients with ALL achieve a remission). The intensity of postinduction therapy relies on risk adaptation utilizing a variety of prognostic tools including genetic evaluation of the leukemia cells and minimal residual disease assessment. Patients with ALL and CNS involvement detected at diagnosis require more intensive CNS-directed treatment including intrathecal therapy and, in some cases, cranial radiation therapy, although the omission of cranial radiation therapy for all pediatric leukemia patients holds great promise. After a 1-month induction, the typical phases of therapy include consolidation (2–6 months), intensification (2 months), and maintenance (2+ years), for a total duration of therapy of about 2.5 years. The treatment of AML is divided into three general types including (1) acute promyelocytic leukemia with a t(15;17) translocation (*PML-RARA*) that relies heavily on all-trans retinoic acid and arsenic trioxide, (2) myeloid leukemias of Down syndrome in which less intensive therapy is administered, and (3) AML that parallels the risk and biologic features most commonly seen in adult AML resulting in the need for intensive therapy and, in select high-risk patients, the use of stem cell transplantation after receiving upfront intensive chemotherapy. The majority of pediatric patients with AML have the latter form requiring four or five cycles of intensive cytarabine-based chemotherapy. Much like ALL, risk adaptive therapy is based on cytogenetics and response to therapy. Additionally, the availability of an HLA-matched donor (ideally an HLA-matched sibling) may determine the use of stem cell transplantation in first remission. Unlike ALL, there is little evidence that low-dose continuation therapy is helpful in AML (with the exception of acute promyelocytic leukemia).

COMPLICATIONS

Major short-term complications associated with the treatment of leukemia result from bone marrow suppression caused by chemotherapy. Patients may have bleeding and significant anemia that necessitates transfusion of platelets and red blood cells. The development of neutropenia predisposes patients to a significant risk of both bacterial and fungal infections. Cell-mediated immunosuppression increases the risk of *Pneumocystis jirovecii* pneumonia, hence prophylaxis is recommended, most commonly with oral trimethoprim-sulfamethoxazole. Prophylaxis with antibiotics and antifungal agents is becoming more commonplace, particularly in patients with AML who are at high risk for treatment-related mortality, including obese patients and adolescent/young adult patients. Long-term sequelae of therapy are less common than in previous treatment eras but continue to be a priority for prevention, recognition, and treatment. These sequelae include neurocognitive impairment, cardiac dysfunction, osteonecrosis, infertility, second malignant neoplasms, and psychosocial problems (see Table 154.3).

PROGNOSIS

Patients with ALL are classified into prognostic risk groups based on age, initial WBC count, genetic characteristics, extramedullary involvement at diagnosis (testicular and/or CNS involvement), and response to induction therapy using minimal residual disease techniques. Risk stratification factors are evolving (Table 155.1). Currently, the

TABLE 155.1 General Prognostic Factors in Acute Lymphoblastic Leukemia		
FACTOR	FAVORABLE (LOWER RISK)	UNFAVORABLE (HIGHER RISK)
Age	1–9.99yr	<1 or ≥10yr
Race and ethnicity	White, Asian/Pacific Islanders	Black, Hispanic, Native American
Initial WBC count	<50,000/mm ³	≥50,000/mm ³
CNS disease at diagnosis	Absent	Present
Immunophenotype	B lineage	T cell
Ploidy (number of chromosomes)	Hyperdiploidy (>50)	Hypodiploidy (<44)
Genetics	t(12;21), trisomies of chromosomes 4, 10, and 17	t(4;11), t(9;22), Ph-like, iamp21, IKZF1 mutations
Minimal residual disease after induction therapy	Negative	Positive

CNS, Central nervous system; WBC, white blood cell.

general categories are low, average, high, and very high risk. The overall cure rate for childhood B-lineage ALL is approximately 90%. Relapse of ALL occurs most commonly in the bone marrow but can involve other extramedullary sites, such as the CNS or testicles. Relapse therapy relies on treatment options based on the timing and location of relapse as well as response to initial reinduction with chemotherapy. Thereafter, treatment options include chemotherapy only, combination of chemotherapy with immunotherapy, and stem cell transplantation. Chimeric antigen receptor (CAR) T-cell therapy was approved by the Food and Drug Administration in 2017 for the treatment of selected patients up to 25 years of age with refractory ALL (second or greater relapse). The current overall cure rate for childhood AML is approximately 65%. The prognosis for relapsed AML is poor, particularly in patients who have already received a stem cell transplant.

PEARLS FOR PRACTITIONERS

See *Oncology: Pearls for Practitioners* at the end of this section.

(HL) and **non-Hodgkin lymphoma (NHL)**. The etiologies are multifactorial; both congenital and acquired immunodeficiencies are more commonly associated with NHL, whereas the Epstein-Barr virus (EBV) has been associated with both HL and NHL.

Almost all cases of NHL in childhood are diffuse, highly malignant, and show little differentiation. NHL has three main histologic subtypes: small noncleaved cell (Burkitt lymphoma [BL]), lymphoblastic, and large cell. For simplicity, these may be regarded as B cell, T cell, and large cell (which may be of B-cell or T-cell origin) (Table 156.1). Chromosomal translocations can result in unregulated/increased expression of an oncogene that drives malignant transformation. In BL, translocations occurring between chromosome 8 (*c-myc* oncogene) and the immunoglobulin gene locus (found on chromosome 2, 14, or 22) lead to overexpression of *c-myc*, causing malignant transformation.

EPIDEMIOLOGY

The incidence of HL has a bimodal distribution with peaks in the adolescent/young adult years and again after age 50; it is rarely seen in children younger than 5 years of age. In children, males are affected more commonly than females; in adolescents, the gender ratio is approximately equal. The incidence of NHL increases with age. It is twice as common in Whites as in Blacks and has a male predominance. NHL has been described in association with congenital or acquired immunodeficiency states and after organ or stem cell transplantation. BL commonly is divided into two forms: a sporadic form commonly seen in North America and an endemic form commonly seen in Africa, which has a strong association with EBV.

CLINICAL MANIFESTATIONS

The most common clinical presentation of HL is painless, firm lymphadenopathy often confined to one or two contiguous lymph node areas (most commonly the cervical and supraclavicular nodes). Mediastinal lymphadenopathy producing cough or shortness of breath is a frequent presenting symptom. The presence of one of three B symptoms has adverse prognostic value: fever ($>38^{\circ}\text{C}$ for 3 consecutive days), drenching night sweats, and unintentional weight loss of 10% or more within 6 months of diagnosis.

The sporadic (North American) form of BL more commonly has an abdominal presentation (typically with pain), whereas the endemic (African) form frequently presents with tumors of the head and neck. The anterior mediastinum and cervical nodes are the usual primary sites for T-cell lymphomas. These lymphomas may cause airway or superior vena cava obstruction, pleural effusion, or both.

The diagnosis of lymphoma is established by biopsy of an involvement lymph node. Systemic symptoms such as fever and weight loss may be present, particularly in patients with anaplastic large cell lymphoma, which can be insidious in onset. If the bone marrow contains 20% or greater blasts, the disease is classified as acute lymphoblastic leukemia (ALL; either B-lineage ALL, T-cell ALL, or Burkitt leukemia). This distinction makes little prognostic or therapeutic difference because they all require aggressive, systemic therapy in addition to CNS-directed therapy.

CHAPTER 156

Lymphoma

ETIOLOGY

Lymphomas are malignancies of lymphoid tissues and are the third most common malignancy in childhood, behind leukemias and central nervous system (CNS) tumors. There are two major types of lymphoma: **Hodgkin lymphoma**

TABLE 156.1 Subtypes of Non-Hodgkin Lymphoma in Children

HISTOLOGIC CATEGORY	IMMUNOPHENOTYPE	USUAL PRIMARY SITE	MOST COMMON TRANSLOCATION(S)
Small noncleaved (Burkitt lymphoma)	Mature B cell (surface immunoglobulin present)	Abdomen (sporadic form) Head and neck (endemic form)	t(8;14)(q24;q32) t(2;8)(p11;q24) t(8;22)(q24;q11)
Lymphoblastic	T cell (rarely pre-B cell)	Neck and/or anterior mediastinum	Many
Large cell	T cell, B cell, or indeterminate	Lymph nodes, skin, soft tissue, bone	t(2;5)(p23;q35)

FIGURE 156.1 Chest x-ray of a 15-year-old boy demonstrating a large superior anterior mediastinal mass (large arrows) compressing the trachea and deviating it rightward (arrowheads). Biopsy revealed non-Hodgkin lymphoma.

LABORATORY/IMAGING STUDIES

Patients suspected to have lymphoma should have a complete blood count, erythrocyte sedimentation rate, and measurement of serum electrolytes (particularly potassium, phosphorus, and calcium), lactate dehydrogenase, and uric acid as well as a chest x-ray to assess for a mediastinal mass (Fig. 156.1). The diagnosis ultimately requires a pathologic confirmation from tissue or fluid sampling (pleural or peritoneal fluid). For staging purposes, a bone marrow evaluation, lumbar puncture, and positron emission tomography–computed tomography (PET-CT) scan are indicated to assess extent of disease. The pathologic hallmark of classic HL is the identification of Reed-Sternberg cells. Histopathologic subtypes in childhood HL are the same as those reported in adults. Nodular sclerosis (NS) is the most common subtype in adolescents/young adults, whereas mixed cellularity subtypes and nodular lymphocyte predominant are more common in younger children. Staging of HL is according to the Ann Arbor system. About half of pediatric patients will have stage II involvement at presentation (I, 19%; II, 49%; III, 19%; IV, 13%), and about 39% will have B symptoms.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for lymphomas in children includes leukemia, rhabdomyosarcoma, nasopharyngeal carcinoma, germ cell tumors, and thymomas. Nonmalignant diagnoses include infectious mononucleosis (EBV infection), branchial cleft and thyroglossal duct cysts, cat scratch disease (*Bartonella henselae*), bacterial or viral lymphadenitis, mycobacterial infection, toxoplasmosis, and even tinea capitis, all of which can produce significant lymphadenopathy that can mimic lymphoma. Patients with acute abdominal pain from BL may be misdiagnosed as having appendicitis.

TREATMENT

Pediatric HL is highly curable even with advanced disease, with overall survival rates now exceeding 90%. Risk adaptive therapy using stage, the presence of bulky disease, the presence or absence of B symptoms, serum albumin, and response to upfront chemotherapy has been employed to reduce the need for radiation therapy and excess chemotherapy. Multiagent chemotherapy usually consists of drugs such as doxorubicin, vincristine, vinblastine, etoposide, prednisone, cyclophosphamide, and brentuximab. In general, four to six courses of chemotherapy are given. Response to therapy is usually assessed after two courses of chemotherapy relying on a PET-CT scan to determine the need for subsequent chemotherapy (slow response obligates more aggressive chemotherapy) as well as the need for radiation therapy. Of interest, patients with stage I (single node with complete resection) nodular lymphocyte predominant HL will be cured with surgery alone 80% of the time.

Distant, noncontiguous metastases are common in childhood NHL. Systemic chemotherapy should be administered to virtually all children with NHL, although patients with stage I pediatric-type follicular lymphoma can be cured with surgery alone. B-cell and T-cell lymphoblastic lymphoma and anaplastic large cell lymphoma (ALCL) generally are treated with aggressive multidrug regimens similar to the regimens used in ALL. Surgery and radiation therapy are not commonly used because the disease is rarely localized and is highly sensitive to chemotherapy. BL and diffuse large B-cell lymphomas (even high stage) are highly curable with rituximab, cyclophosphamide, vincristine, prednisolone, doxorubicin, and methotrexate.

COMPLICATIONS

The short-term complications from the treatment of lymphoma are similar to other pediatric malignancies and commonly include immunosuppression, related sequelae from

myelosuppression, nausea, vomiting, and alopecia. Late adverse effects include second malignant neoplasms (acute myeloid leukemia or myelodysplasia, thyroid malignancies, and breast cancer), hypothyroidism, impaired soft tissue and bone growth, and cardiac dysfunction.

PROGNOSIS

Children and adolescents with HL are classified as low, intermediate, or high risk according to stage, nodal bulk, the presence of B symptoms, and the serum albumin at presentation. The prognosis is generally excellent with overall survival exceeding 90% for most patients (approaching 100% for low-risk patients). The overall 3-year survival rates for B-cell, T-cell, and large cell NHL are 70% to 90%.

PEARLS FOR PRACTITIONERS

See *Oncology: Pearls for Practitioners* at the end of this section.

CHAPTER 157

Central Nervous System Tumors

ETIOLOGY

Most central nervous system (CNS) tumors in children and adolescents are **primary tumors** that originate in the CNS and include gliomas (especially low-grade gliomas) and embryonic neoplasms (such as medulloblastoma and CNS primitive neuroectodermal tumors). In contrast, CNS tumors in adults are often high-grade astrocytomas or **secondary tumors** that are metastatic from other carcinomas. Radiation previously directed at the CNS can result in secondary malignancy of the CNS. The classification of CNS tumors is complex and evolving, with the World Health Organization classification being the most complete and accurate system.

EPIDEMIOLOGY

CNS tumors are the most common solid tumors in children, second to leukemia in overall cancer incidence during childhood. However, due primarily to improved outcomes for leukemia, CNS tumors are now the leading cause of childhood cancer deaths. About 1,700 new cases occur each year in the United States; the rate is approximately 33 cases per 1 million children under 15 years of age. The incidence peaks before age 10 years and then decreases until a second peak after age 70. For medulloblastoma and ependymoma, males are more affected than females; for other tumor types, no gender differences exist. In the first 2–3 years of life, White children are affected more than non-White children; otherwise incidence rates are essentially equal for White and non-White children.

Children with certain inherited syndromes, such as neurofibromatosis (types 1 and 2), Li-Fraumeni syndrome, tuberous sclerosis, Turcot syndrome, and von Hippel-Lindau syndrome, have an increased risk for developing a CNS tumor. However, most CNS tumors arise in children with no known underlying disorder or risk factor.

CLINICAL MANIFESTATIONS

Brain tumors can cause symptoms by impingement on normal tissue (usually cranial nerves) or by an increase in intracranial pressure caused either by obstruction of cerebrospinal fluid (CSF) flow or by a direct mass effect. Tumors that obstruct the flow of CSF quickly become symptomatic. Symptoms of **increased intracranial pressure** are lethargy, headache, and vomiting (particularly in the morning on awakening). Irritability, anorexia, poor school performance, and loss of developmental milestones all may be signs of slow-growing CNS tumors. In young children with open cranial sutures, an increase in head circumference may occur. Optic pathway tumors may lead to visual defects. Inability to abduct the eye as the result of sixth cranial nerve palsy is a common sign of increased intracranial pressure. Other cranial nerve deficits suggest involvement of the brainstem. Seizures occur in 20–50% of patients with supratentorial tumors; focal weakness or sensory changes also may be seen. Pituitary involvement can produce neuroendocrine effects such as precocious puberty or diabetes insipidus. Cerebellar tumors are associated with ataxia and diminished coordination. A history and physical examination are fundamental for evaluation and should include a careful neurologic assessment, including visual fields and a fundoscopic examination.

LABORATORY/IMAGING STUDIES

If an intracranial lesion is suspected, **magnetic resonance imaging (MRI)** is currently the examination of choice (Fig. 157.1). Examination of CSF by cytocentrifuge histologic testing is indicated to determine the presence of metastatic disease in primitive neuroectodermal tumors, germ cell tumors, and pineal region tumors. A lumbar puncture should not be performed before imaging has been obtained

FIGURE 157.1 Magnetic resonance imaging of a 9-year-old male showing a heterogeneously enhancing fourth ventricular mass (arrow). It was resected, and pathology revealed medulloblastoma.

to evaluate for evidence of increased intracranial pressure. If a tumor is suspected to have metastatic potential (e.g., medulloblastoma), MRI of the entire spine should be obtained before surgery to assess for neuraxial dissemination. A postoperative MRI study of the brain should be obtained within 24–48 hours of surgery to assess the extent of resection. During follow-up, magnetic resonance spectroscopy may help distinguish recurrent tumor from radiation necrosis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a CNS mass lesion includes malignant tumor, benign tumor, arteriovenous malformation, aneurysm, brain abscess, cysticercosis, granulomatous disease (tuberculosis, sarcoid), Langerhans cell histiocytosis, intracranial hemorrhage, pseudotumor cerebri, vasculitis, and, rarely, metastatic tumor.

TREATMENT

The therapy for children with CNS tumors is individualized and depends on the tumor type, location, size, and associated symptoms. High-dose **dexamethasone** is often administered immediately to reduce tumor-associated edema. Surgical objectives are complete excision, if possible, and maximal debulking if a complete excision is not possible. In children, radiation therapy is often combined with chemotherapy; in young children, radiation therapy may be delayed or avoided altogether to limit late side effects. Primitive neuroectodermal tumors (including medulloblastoma) and germ cell tumors are sensitive to chemotherapy; gliomas are less sensitive to chemotherapy. Chemotherapy plays an especially important role in infants in whom radiation therapy may have devastating effects on growth and neurocognitive development. High-dose chemotherapy with autologous stem cell rescue is sometimes used to help avoid radiation therapy.

COMPLICATIONS

Short-term adverse effects of therapy include nausea, vomiting, anorexia, fatigue, immunosuppression, and cushingoid features. Long-term adverse effects include neurocognitive deficits, endocrinologic sequelae, decreased bone growth, ototoxicity, renal insufficiency, cataracts, infertility, and second malignant neoplasms. The neurocognitive deficits can be significant, particularly in infants and young children, and are the primary reason for the continued search for the lowest efficacious radiation therapy dose and the most conformal delivery methods. **Posterior fossa syndrome** (also known as “cerebellar mutism”) occurs in up to 25% of patients after resection of a posterior fossa tumor and is characterized by an acute decrease in speech, behavioral changes (e.g., irritability, apathy, or both), diffuse cerebellar dysfunction, and other neurologic abnormalities. It may begin within hours to days of surgery and is usually self-resolving within weeks to months, although some neurologic complications may persist. **Somnolence syndrome**, which is characterized by excessive fatigue and sleepiness, may occur in the months after completion of radiation therapy and is self-limited.

TABLE 157.1 Location, Incidence, and Prognosis of Central Nervous System Tumors in Children

LOCATION	INCIDENCE (%)	5-YR SURVIVAL (%)
Infratentorial (posterior fossa)	50–60	
Astrocytoma (cerebellum)	15	90
Medulloblastoma	15	50–80
Glioma (brainstem)	15	High grade: 0–5; low grade: 30
Ependymoma	5	50–60
Supratentorial (cerebral hemispheres)	35–45	
Astrocytoma	20	50–75
Glioblastoma multiforme	10	0–5
Ependymoma	5	50–75
Choroid plexus papilloma	2	95
Midline	10–15	
Craniopharyngioma	6	70–90
Germ cell tumors	3	65–95
Pineal	1	65–75
Optic nerve glioma	3	90

PROGNOSIS

Improvements in diagnosis, neurosurgical techniques, chemotherapy regimens, and radiation therapy techniques have improved overall outcome. The 5-year overall survival rate associated with all childhood CNS tumors is approximately 50–60% (Table 157.1). Patients with low-grade gliomas that are completely resected have an excellent prognosis. Patients with diffuse intrinsic pontine gliomas and glioblastoma multiforme have extremely poor prognoses.

PEARLS FOR PRACTITIONERS

See *Oncology: Pearls for Practitioners* at the end of this section.

CHAPTER 158

Neuroblastoma

ETIOLOGY

Neuroblastoma is derived from **neural crest cells** that form the adrenal medulla and the sympathetic nervous system. The cause is unknown. Most cases occur in young children. Neuroblastoma may rarely (1–2% of cases) be hereditary. Mutations in the *ALK*, *PHOX2B*, and *TP53* genes have been associated with familial cases. In sporadic cases, several somatic genetic mutations have been identified, with *MYCN* amplification being the most common.

EPIDEMIOLOGY

Neuroblastoma is the most common extracranial solid tumor of childhood and the most common malignancy in infancy. The median age at diagnosis is 17 months. There are approximately 800 new cases of neuroblastoma in the United States each year. The prevalence is estimated to be 1 in 7,000 live births.

CLINICAL MANIFESTATIONS

Neuroblastoma is remarkable for its broad spectrum of clinical behavior ranging from spontaneous regression to rapid progression with metastases resulting in death. Children with localized disease are often asymptomatic at diagnosis, whereas children with metastases often appear ill and have systemic symptoms such as fever, weight loss, bruising, and pain. The most common presentation is abdominal pain or mass. The mass is often palpated in the abdomen or flank and is hard and nontender. Approximately 45% of tumors arise in the adrenal gland, and 25% arise in the retroperitoneal sympathetic ganglia. Other sites of origin are the paravertebral ganglia of the chest and neck. Paraspinal tumors may invade through the neural foramina and cause spinal cord compression. Horner syndrome is sometimes seen with neck or apical masses. Several **paraneoplastic syndromes**, including secretory diarrhea, profuse sweating, and **opsomyoclonus**, are associated with neuroblastoma.

Neuroblastoma may metastasize to multiple organs, including the liver, bone, bone marrow, and lymph nodes. Periorbital ecchymoses (“racoon eyes”) are a sign of orbital bone metastases in the presence of thrombocytopenia. A unique category of neuroblastoma, **stage MS**, is defined in infants (<18 months old) with metastases limited to skin, liver, or bone marrow. It is generally associated with a favorable outcome. Some cases of stage MS neuroblastoma can regress spontaneously; others may require chemotherapy to achieve a cure.

LABORATORY/IMAGING STUDIES

A complete blood count and plain radiographs may help identify patients with neuroblastoma. Calcification within abdominal neuroblastoma tumors is often observed on plain radiographs of the abdomen. About 90% of neuroblastomas produce **catecholamines (vanillylmandelic acid; homovanillic acid)** that can be detected in the urine. Definitive diagnosis of neuroblastoma requires tissue biopsy for microscopic examination and genetic testing. A computed tomography (CT) scan of the chest, abdomen, and pelvis (Fig. 158.1); an iodine-123-metaiodobenzylguanidine (¹²³I-MIBG) scan; and bilateral bone marrow aspirations/biopsies complete the evaluation.

DIFFERENTIAL DIAGNOSIS

The abdominal presentation of neuroblastoma must be differentiated from Wilms tumor and hepatoblastoma, which can also present as an abdominal or flank mass. Ultrasound or CT examination usually distinguishes the tumors prior to surgery. Periorbital ecchymoses from orbital metastases can be mistaken for child abuse. Because children with bone marrow involvement may have anemia, thrombocytopenia, or neutropenia, leukemia and metastatic sarcomas are often considered in the differential.

FIGURE 158.1 Neuroblastoma. Computed tomography (CT) scan of a 2-year-old who presented with bilateral periorbital ecchymoses, fatigue, pallor, and pancytopenia. CT revealed a large right suprarenal mass (*blue arrow*) and large retroperitoneal abdominal lymph nodes (*black arrows*). An iodine-123-metaiodobenzylguanidine (¹²³I-MIBG) scan and bone marrow biopsies revealed widespread metastatic disease.

TREATMENT

Treatment of neuroblastoma is based on risk classification (Table 158.1). Complete surgical excision is the initial treatment of choice for localized neuroblastoma. Children with very low or low-risk tumors who undergo a gross total resection require no further therapy. Patients with intermediate-risk disease are usually treated with surgery and four to eight cycles of chemotherapy. In patients with high-risk disease, combination chemotherapy is given after confirmation of the diagnosis. The most commonly used agents are vincristine, cyclophosphamide, topotecan, doxorubicin, cisplatin, and etoposide. Resection of the primary tumor is undertaken after several courses of chemotherapy. Patients then undergo two courses of **high-dose chemotherapy with autologous stem cell rescue**. Radiation therapy is administered to the primary tumor bed and major areas of metastatic disease. Finally, **cis-retinoic acid** (isotretinoin) and **dinutuximab** (a monoclonal antibody directed against the G_{D2} antigen) are administered to treat minimal residual disease. *ALK* aberrations (mutations and amplifications) have been identified in approximately 14% of high-risk neuroblastoma tumors, and they are associated with inferior outcomes. This has led to the investigation of crizotinib, a small molecule *ALK* inhibitor. In addition, therapeutic ¹³¹I-MIBG has shown promising results and is currently under investigation in high-risk neuroblastoma.

INRG STAGE	AGE (MONTHS)	HISTOLOGIC CATEGORY	GRADE OF TUMOR DIFFERENTIATION	MYCN	11Q ABERRATION	PLOIDY	PRETREATMENT RISK GROUP

COMPLICATIONS

Spinal cord compression from neuroblastoma may cause an irreversible neurologic deficit and is an oncologic emergency. Children with opsomyoclonus syndrome may suffer from developmental delay. The aggressive chemotherapy and radiation therapies currently used to treat high-risk neuroblastoma may result in complications such as infection, bleeding, ototoxicity, cardiotoxicity, nephrotoxicity, growth problems, and second malignancies.

PROGNOSIS

The prognosis is affected by age at diagnosis, stage (based on presence or absence of metastases and image-defined risk factors), DNA ploidy, *MYCN* status, 11q aberration, *ALK* mutation, and histopathology (grade of tumor differentiation). Similar to leukemias and sarcomas, a favorable response to induction therapy is associated with improved long-term outcomes. Currently, children with neuroblastoma can be divided into four groups: very low, low, intermediate, and high risk. Patients with favorable biology tend to be younger and often have localized disease. Older patients with metastatic disease most commonly have unfavorable biology; approximately 50% will ultimately relapse due to drug-resistant residual disease. However, the continued intensification of high-risk patients with immunotherapy and high-dose chemotherapy

with autologous stem cell rescue has provided promising improvements in event-free survival that will likely translate into improved long-term outcomes. Although neuroblastoma represents only 8% of cases of childhood cancer, it is responsible for 15% of cancer deaths in children.

PEARLS FOR PRACTITIONERS

See *Oncology: Pearls for Practitioners* at the end of this section.

CHAPTER 159

Wilms Tumor

ETIOLOGY AND EPIDEMIOLOGY

Wilms tumor is thought to arise from primitive, metanephric blastema, the precursor of a normal kidney. Nephrogenic rests are foci of embryonal cells that are rarely (<1%) found in normal infant kidneys and commonly (25–40%) found in Wilms tumor-bearing kidneys. Although the cause of Wilms tumor is unknown, approximately 15–20% of sporadic tumors have *WT1* mutations or deletions. Over 70% of Wilms tumors demonstrate loss of imprinting or loss of heterozygosity at

11p15 leading to overexpression of *IGF2*, thought to play a key role in tumorigenesis. Certain syndromes including Beckwith-Wiedemann and WAGR (Wilms tumor, aniridia, genitourinary anomalies, and retardation; mutation involving 11p13 region) are at increased risk of developing the disease.

Wilms tumor is the most common malignant renal tumor of childhood, with approximately 500 new cases per year in the United States. Unilateral tumors have a median age of diagnosis of 44 months of age versus bilateral tumors, which have a median age of diagnosis of 31 months (bilateral presentations are commonly associated with hereditary forms of the disease).

CLINICAL MANIFESTATIONS

Most children with Wilms tumor are brought to medical attention because they have an abdominal mass that is discovered by their parents. Although many children do not have complaints at the time that the mass is first noted, associated symptoms and signs may include abdominal pain (often mistaken for constipation), fever, hypertension, and hematuria.

LABORATORY/IMAGING STUDIES

An abdominal ultrasound or computed tomography (CT) scan can usually distinguish an intrarenal mass from a mass arising from the adrenal gland (most commonly neuroblastoma) or other surrounding structures. Evaluation of the inferior vena cava is crucial because the tumor may extend from the kidney into the vena cava. The diagnostic workup includes a complete blood count, urinalysis, liver and renal function studies, as well as a CT scan of the chest, abdomen, and pelvis to assess for metastatic involvement. Pulmonary involvement is the most common metastatic site, followed by regional lymph nodes. The diagnosis is confirmed by biopsy and histologic examination of the tumor.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of Wilms tumor includes hydro-nephrosis and polycystic disease of the kidney; benign renal tumors, such as mesoblastic nephroma and hamartoma; and other malignant tumors, such as neuroblastoma, renal cell carcinoma, lymphoma, and retroperitoneal rhabdomyosarcoma.

TREATMENT

The timing of nephrectomy for unilateral, resectable Wilms tumor remains divided between the North American approach and the European approach. Both approaches have a similar overall survival. The North American approach recommends an upfront nephrectomy if deemed safe and feasible (confirming tissue diagnosis) followed by adjuvant chemotherapy with or without radiation therapy, whereas the European approach is to make a diagnosis relying predominantly on imaging (sometimes a biopsy), upfront (neoadjuvant) chemotherapy, then nephrectomy of the involved kidney followed by adjuvant chemotherapy with or without radiation therapy. The Children's Oncology Group (North American approach) relies on stage, histology (favorable vs unfavorable/anaplastic), patient age, tumor weight, loss of heterozygosity of 1p and 16q, and imaging response of pulmonary nodules after initial chemotherapy to risk-stratify patients. Most patients will receive a two- to

three-drug chemotherapy regimen (vincristine, actinomycin, with or without doxorubicin); those with high-risk features will also receive radiation therapy. Patients designated with very low-risk unilateral Wilms tumor are often cured with surgery only.

Bilateral Wilms tumor is present in about 5% of children on initial presentation. The treatment goal for patients with bilateral Wilms tumor is to balance the need to achieve a cure while retaining as much normal kidney function as possible.

PROGNOSIS AND COMPLICATIONS

The overall survival rate for Wilms tumor is 90%. Unfortunately, 25% of survivors will experience serious chronic health conditions. Survivors of Wilms tumor are at risk for renal insufficiency (based on single kidney physiology), cardiomyopathy, hypertension and prehypertension, pulmonary dysfunction, hepatic dysfunction, infertility, and second malignancies. Patients with bilateral Wilms tumor are sometimes left with renal insufficiency or failure, requiring dialysis or a kidney transplant.

PEARLS FOR PRACTITIONERS

See *Oncology: Pearls for Practitioners* at the end of this section.

CHAPTER 160

Sarcomas

Sarcomas are generally divided into soft tissue and bone cancers. Soft tissue sarcomas arise primarily from the connective tissues of the body, such as muscle and connective tissue. **Rhabdomyosarcoma (RMS)**, the most common soft tissue sarcoma in children, is derived from mesenchymal cells of muscle lineage. Less common soft tissue sarcomas include fibrosarcoma, synovial sarcoma, and extrasosseous Ewing sarcoma. The most common malignant bone cancers in children are **osteosarcoma** and **Ewing sarcoma**. Osteosarcomas derive from primitive bone-forming mesenchymal stem cells. Ewing sarcomas are thought to be of neural crest cell origin.

ETIOLOGY

The cause is unknown for most children diagnosed with sarcoma, although a few observations have been made regarding risks. Individuals with Li-Fraumeni syndrome (associated with a germline *TP53* mutation) and neurofibromatosis (associated with *NF1* mutations) have an increased risk of soft tissue sarcomas. There is a 500-fold increased risk for osteosarcoma for individuals with hereditary retinoblastoma. Prior treatment for childhood cancer with radiation therapy or chemotherapy (specifically alkylating agents), or both, increases the risk for osteosarcoma as a second malignancy.

EPIDEMIOLOGY

In the United States, 850–900 children and adolescents under 20 years of age are diagnosed with soft tissue sarcomas each year; approximately 350 are RMS. The incidence of RMS peaks in children 2–6 years old and again in adolescents. The early

peak is associated with tumors in the genitourinary region, head, and neck; the later peak is associated with tumors in the extremities, trunk, and male genitourinary tract. Males are affected 1.5 times more often than females. Of the 650–700 U.S. children and adolescents under 20 years of age diagnosed with bone tumors each year, approximately two-thirds have osteosarcoma and one-third have Ewing sarcoma. Osteosarcoma most commonly affects adolescents; the peak incidence occurs during the period of maximum growth velocity. The incidence of Ewing sarcoma peaks between ages 10 and 20 years but may occur at any age. Ewing sarcoma primarily affects Whites; it rarely occurs in Black or Asian children.

CLINICAL MANIFESTATIONS

The clinical presentation of RMS depends on the site of origin, subsequent mass effect, and presence of metastatic disease. Periorbital swelling, proptosis, and limitation of extraocular motion may be seen with an orbital tumor. Oropharyngeal or nasal mass, dysphagia, neck mass, and cranial nerve involvement may be noted with tumors in other head and neck sites. Urethral or vaginal masses, paratesticular swelling, hematuria, and urinary frequency or retention may be noted with tumors in the genitourinary tract. Trunk or extremity lesions tend to present as rapidly growing masses that may or may not be painful. If there is metastatic disease to bone or bone marrow, limb pain and cytopenias may be present.

Osteosarcoma is often located at the epiphysis or metaphysis of long bones that are associated with maximum growth velocity (distal femur, proximal tibia, proximal humerus), but any bone may be involved. It presents with pain and may be associated with a palpable mass. Because the pain and swelling often are initially thought to be related to trauma, radiographs of the affected region are frequently obtained; the radiographs usually reveal a lytic lesion, sometimes associated with calcification in the soft tissue surrounding the lesion. Although 75–80% of patients with osteosarcoma have apparently localized disease at diagnosis, most patients are believed to have micrometastatic disease as well.

Although Ewing sarcoma can occur in almost any bone in the body, the femur and pelvis are the most common sites. In addition to local pain and swelling, clinical manifestations may include constitutional symptoms such as fever, fatigue, and weight loss.

LABORATORY/IMAGING STUDIES

Tissue biopsy is needed for a definitive diagnosis of sarcoma. Selection of the biopsy site is important and has implications for future surgical resection and radiation therapy. Under light microscopy, RMS and Ewing sarcoma appear as small, round, blue cell tumors. Osteosarcomas are distinguishable by the presence of osteoid.

Immunohistochemical staining for muscle-specific proteins, such as actin and myosin, helps confirm the diagnosis of RMS. Two major histologic variants exist for RMS: embryonal and alveolar. The embryonal variant is most common in younger children with head, neck, and genitourinary primary tumors. The alveolar variant occurs in older patients and is seen most commonly in trunk and extremity tumors. Alveolar RMS is usually characterized by the specific translocations t(2;13) or t(1;13), involving the *FOXO1* gene on chromosome

13. The fusion status (*FOXO1* translocation positive or negative) is preferred over the morphologic description (embryonal vs alveolar) to assign risk group and treatment intensity, with fusion positive being unfavorable. Metastatic evaluation for patients with RMS should include positron emission tomography–computed tomography (PET-CT) scan, chest CT, and bilateral bone marrow aspirations/biopsies. A lumbar puncture is required in patients with a parameningeal tumor due to the risk of direct extension into the central nervous system (CNS).

The diagnosis of osteosarcoma is established with immunohistochemical analyses of the biopsy material and the presence of osteoid matrix. The extent of the primary tumor should be delineated carefully with magnetic resonance imaging (MRI) before starting chemotherapy to determine surgical resection options. Osteosarcoma tends to metastasize to the lungs, most commonly, and, rarely, to other bones. Metastatic evaluation includes a chest CT scan and a bone scan or PET-CT scan.

The diagnosis of Ewing sarcoma is established with immunohistochemical analyses along with cytogenetic and molecular diagnostic studies of the biopsy material. Ewing sarcoma is characterized by a specific chromosomal translocation, t(11;22), which is seen in 95% of tumors. MRI of the primary lesion should be performed to delineate extent of the lesion and any associated soft tissue mass. Metastatic evaluation involves a PET-CT scan (when available), chest CT scan, and bilateral bone marrow aspirations/biopsies.

DIFFERENTIAL DIAGNOSIS

Patients with Ewing sarcoma may be misdiagnosed as having osteomyelitis; children with osteogenic sarcoma are often initially believed to have pain and swelling related to trauma. The differential diagnosis for RMS depends on the location of the tumor. Tumors of the trunk and extremities often present as a painless mass and may initially be thought to be benign tumors. Head and neck RMS may be misdiagnosed as reactive adenopathy, orbital cellulitis, or chronic infection of ears or sinuses. The differential diagnosis for intraabdominal RMS includes other abdominal malignancies, such as Wilms tumor and neuroblastoma.

TREATMENT

Treatment of RMS is currently based on a staging system that incorporates a number of diagnostic features including primary site, histologic subtype, *FOXO1* fusion status, stage (local, regional, or metastatic involvement), and surgical grouping (the ability or inability to achieve a gross total resection prior to chemotherapy/radiation). The most common chemotherapy agents used in RMS are vincristine, dactinomycin, and cyclophosphamide. Other active agents include irinotecan, ifosfamide, and etoposide. Radiation is administered to the primary tumor when surgical resection is incomplete or would be morbid. It may also be administered to involved regional nodal sites and sometimes to distant metastatic sites.

The current treatment of osteosarcoma involves neoadjuvant chemotherapy, surgical resection of the primary tumor, followed by adjuvant chemotherapy. The most common chemotherapy agents used for osteosarcoma are high-dose methotrexate, doxorubicin, and cisplatin. Radiation therapy is ineffective for osteosarcoma, although it is sometimes used

for palliative intent to treat pain. The treatment for Ewing sarcoma is similar to osteosarcoma and requires neoadjuvant chemotherapy, local control measures, and adjuvant chemotherapy. The most common chemotherapy agents used for Ewing sarcoma are vincristine, doxorubicin, and cyclophosphamide in combination with ifosfamide and etoposide. In contrast to osteosarcoma, Ewing sarcoma is radiation sensitive, and radiation therapy is administered to patients where the primary tumor cannot be safely resected as well as for metastatic sites.

COMPLICATIONS

In addition to potential late effects from the chemotherapy, children with sarcomas may have complications related to local control of the tumor. If the local disease is controlled with surgery, the long-term sequelae may include loss of limb or limitation of function. If local control is accomplished with radiation therapy, the late effects depend on the dose of radiation given, the extent of the radiated site, and the development of the child at the time of radiation therapy. Irradiating tissues interferes with growth and development, causes organ damage, and increases the risk of second malignant neoplasms. Other long-term side effects can include cardiotoxicity, infertility, and second malignancies.

PROGNOSIS

For all children with sarcoma, presence or absence of metastatic disease at presentation is the most important prognostic factor. The outlook remains poor for patients who have distant metastases from Ewing sarcoma, RMS, or osteosarcoma. Patients with localized RMS in favorable sites have an excellent prognosis when treated with surgery followed by

chemotherapy. In patients with osteosarcoma, the amount of tumor necrosis after preoperative chemotherapy is prognostic. Patients who achieve greater than 90% tumor necrosis after neoadjuvant chemotherapy have an overall survival rate of approximately 80% versus approximately 50% for patients who have less than 90% tumor necrosis. The overall cure rate for patients with localized osteosarcoma and Ewing sarcoma is approximately 70%. Patients who have lung metastasis at diagnosis have a cure rate of approximately 30%. Patients with metastases to other bones have a very poor prognosis (<20%).

PEARLS FOR PRACTITIONERS

CHAPTER 153

Oncology Assessment

- The most common cancers in children and adolescents are leukemia, brain tumors, and lymphoma, followed by sarcomas of soft tissue and bone.
- Neuroblastoma, Wilms tumor, retinoblastoma, and hepatoblastoma are seen almost exclusively in children, as opposed to adolescents and adults.
- Many signs and symptoms of childhood cancer are nonspecific. Pain, fatigue, pallor, bruising/petechiae/bleeding, and a growing mass are all common presenting signs and symptoms.
- A careful history and physical exam are crucial in a child with suspected cancer.
- Laboratory and imaging tests are helpful. However, almost all cancers require a biopsy of some type to make a definitive diagnosis.
- The prognosis for children with cancer has improved dramatically in the past 60 years, with long-term survival improving from about 20% to 80%.
- Many survivors of childhood cancer suffer from long-term side effects from the treatment.
- As the prognosis for childhood cancer improves, clinical trials are shifting focus from improving survival to decreasing long-term side effects.
- Prognostic factors for pediatric cancers still incorporate many clinical aspects such as age, histology, and the presence or absence of metastases. However, genetic factors (of both the cancer and the patient) and response to initial therapy are becoming more powerful determinants of survival.
- Tumor lysis syndrome is a life-threatening complication and may be seen in patients with leukemia and lymphoma. It is best treated with hydration, allopurinol, and/or rasburicase (to treat hyperuricemia) and treating the underlying cancer.
- Airway compression, spinal cord compression, bleeding, and infection are other oncologic emergencies.

CHAPTER 154

Principles of Cancer Treatment

- Treatment for children with cancer is usually multimodal and may involve surgery, radiation therapy, chemotherapy, and immunotherapy. Targeted therapies (such as rituximab, brentuximab, and tyrosine kinase inhibitors) and immunotherapies (such as chimeric antigen receptor [CAR] T-cell therapy) are more commonly being used to treat pediatric cancers.

CHAPTER 155

Leukemia

- Children with cytopenias and/or blasts in the peripheral blood should be considered for bone marrow aspiration to assess for acute leukemia.
- Unlike adults, children with acute lymphoblastic leukemia generally have an excellent prognosis (90%), whereas children with acute myeloid leukemia have a more guarded prognosis (65%).

CHAPTER 156

Lymphoma

- In general, malignant lymph nodes tend to be large, firm, fixed, and nontender; reactive lymph nodes tend to be small, soft, mobile, and tender.
- Serum (and/or cerebrospinal fluid) α -fetoprotein (AFP) and β -human chorionic gonadotropin (β -HCG) are tumor markers for germ cell tumors.
- AFP is a tumor marker for hepatoblastoma.
- Urine homovanillic acid (HVA) and vanillylmandelic acid (VMA) are tumor markers for neuroblastoma.

CHAPTER 157

Central Nervous System Tumors

- Most central nervous system (CNS) tumors in children and adolescents are primary tumors that originate in the CNS and include astrocytomas/gliomas or embryonic neoplasms (such as medulloblastoma and CNS primitive neuroectodermal tumors).

- Lethargy, headache, ataxia, and morning vomiting are common presenting symptoms of brain tumors; these symptoms should prompt consideration for imaging the brain (computed tomography and/or magnetic resonance imaging).

CHAPTER 158

Neuroblastoma

- A child with an abdominal mass should prompt consideration for neuroblastoma, Wilms tumor, and hepatoblastoma.
- In general, toddlers and older children with neuroblastoma are ill, whereas children with Wilms tumor have few associated symptoms.
- Compared with toddlers and older children, infants with neuroblastoma are generally well, have less aggressive disease, and an excellent prognosis.
- Children with high-risk neuroblastoma have a guarded prognosis, even with aggressive treatment including chemotherapy, surgery, radiation therapy, retinoic acid, and immunotherapy.

CHAPTER 159

Wilms Tumor

- Wilms tumor usually presents with an abdominal mass in a relatively well child. It may be unilateral or bilateral.
- Lungs and lymph nodes are the most common sites of metastases for Wilms tumor.
- The prognosis for patients with Wilms tumor is generally very good with multimodal therapy.

CHAPTER 160

Sarcomas

- Sarcomas originating in the bone, such as osteosarcoma and Ewing sarcoma, usually present with a mass and/or pain.
- Prognostic factors for patients with sarcomas include the presence or absence of metastases, the extent of surgical resection, and the response to chemotherapy (usually measured by the amount of tumor necrosis).

NEPHROLOGY AND UROLOGY

Hiren P. Patel | Beth A. Vogt

CHAPTER 161

Nephrology and Urology Assessment

The kidneys preserve homeostasis through (1) maintaining fluid and electrolyte balance, (2) excreting metabolic waste products through glomerular filtration and tubular secretion, and (3) producing important endocrine hormones (e.g., renin, vitamin D metabolites, erythropoietin). There is a wide variety of renal disorders (Table 161.1), which can manifest in different ways.

RENAL PHYSIOLOGY

Normal kidney function depends on intact **glomerular filtration** and **tubular function** (**proximal tubule** [PT], **loop of Henle**, and **distal tubule** [DT]) to produce **urine** (Fig. 161.1). Net glomerular pressure favors movement of fluid out of glomerular capillaries into Bowman's space, which leads to the PT. **Renin** is generated by cells in the juxtaglomerular apparatus, located at the base of each glomerulus near the afferent/efferent arterioles and DT of that nephron. Renin is released in response to decreased renal perfusion pressure, decreased sodium delivery to the DT, and sympathetic nervous system activity and helps maintain intraglomerular pressure.

The PT reabsorbs (see Fig. 161.1) two-thirds of filtered water, sodium, and chloride. Glucose, amino acids, potassium, and phosphate are almost completely reabsorbed in this segment. Approximately 75% of filtered bicarbonate is reabsorbed in the PT. The PT also secretes compounds such as organic acids, penicillins, and other drugs. The most potent vitamin D analog—1,25(OH)₂-cholecalciferol (**calcitriol**)—is produced by PT cells in response to parathyroid hormone and intracellular calcium and phosphorus concentrations.

The loop of Henle is the site of reabsorption of 25% of filtered sodium chloride (see Fig. 161.1). Active chloride transport drives the countercurrent multiplier and constructs the medullary interstitial hypertonic gradient required for urinary concentration.

The DT is composed of the **distal convoluted tubule** (DCT) and **collecting duct** (CD). The DCT is water impermeable and contributes to urine dilution by active sodium chloride absorption. The CD is the primary site of **antidiuretic hormone** (vasopressin) response, which leads to urine concentration. Sodium-potassium and sodium-hydrogen exchange

in the CD is regulated by aldosterone. Active hydrogen ion secretion, responsible for final acidification of the urine, also occurs in the CD. Renal ammonia production and intraluminal generation of ammonium (NH₄⁺) facilitate urine hydrogen ion excretion.

Maximum **urinary concentrating capacity** in a preterm newborn (~400 mOsm/L) is less than that of a full-term newborn (600–800 mOsm/L), which is less than that of older children and adults (1,200 mOsm/L). Neonates can dilute urine similar to adults (75–90 mOsm/L), but because their **glomerular filtration rate** (GFR) is lower, their capacity to excrete a water load is limited. Tubular reabsorption of sodium, potassium, and bicarbonate and excretion of hydrogen are all reduced in infants relative to adults. These functions mature independently and at different ages, so a neonate rapidly develops the ability to reabsorb sodium efficiently, but it takes 2 years for bicarbonate reabsorption to fully mature. **Erythropoietin** is secreted by interstitial cells in the renal medulla in response to low oxygen delivery and helps regulate bone marrow red blood cell production.

CLINICAL MANIFESTATIONS

The clinical presentation of renal and urologic disease will depend on the type of disorder (glomerular, tubulointerstitial, vascular, lower urinary tract) and its severity (Table 161.2). The presentation will also be influenced by whether the disorder is acute or chronic (congenital in some cases) and whether the disorder is a primary intrinsic renal disease or secondary to a systemic process. Renal and urologic conditions may present with obvious signs (e.g., hematuria, edema, abnormal urine stream) or with nonspecific findings such as poor growth, fever, or vomiting. In some cases, the child may be asymptomatic and have evidence of renal or urologic disease discovered by incidental findings on exam or imaging. Presentation of a disorder may also vary by age. For example, neonates and infants with **urinary tract infections** (UTIs) may present with fever, irritability, and vomiting, whereas frequency and dysuria suggest UTI in older children.

HISTORY AND PHYSICAL EXAMINATION

Depending on the clinical suspicion or scenario, attention must be directed to the applicable history and exam elements as listed in Table 161.2. In addition to the present illness, a detailed past medical and family history is important. In some cases, a prenatal history is also valuable. Congenital renal disorders may be associated with reduced (oligohydramnios) or

TABLE 161.1 Causes of Renal and Urinary Tract Disease in Children	
GLOMERULAR DISORDERS	
Nephrotic syndrome	Minimal change disease Focal segmental glomerulosclerosis Membranous nephropathy Congenital nephrotic syndrome
Glomerulonephritis	Postinfectious GN Infectious GN Lupus nephritis Membranoproliferative GN (C3GN, DDD) IgA nephropathy IgA vasculitis nephritis Pauciimmune GN (GPA, MPA) Anti-GBM disease

ATN, Acute tubular necrosis; C3GN, C3 glomerulonephritis; CAKUT, congenital anomalies of the kidneys and urinary tract; DDD, dense deposit disease; GBM, glomerular basement membrane; GN, glomerulonephritis; GPA, granulomatosis with polyangiitis; HUS, hemolytic uremic syndrome; MPA, microscopic polyangiitis; TTP, thrombotic thrombocytopenic purpura.

increased amniotic fluid volume (polyhydramnios) as fetal urine production is the primary source of amniotic fluid volume in the second and third trimesters. Pulmonary hypoplasia and fetal maldevelopment of the face and extremities may result from insufficient amniotic fluid (Potter sequence; see Chapters 58 and 60).

Risk factors for renal and urologic disease (e.g., acute kidney injury, UTI) can often be detected by a careful history. Congenital renal anomalies may be associated with other extrarenal manifestations including ear, eye, and skin findings or other dysmorphic features. Attention should be paid to the blood pressure as many renal disorders are associated with hypertension.

DIAGNOSTIC STUDIES

Laboratory Studies

Blood urea nitrogen is affected by renal function but is also affected by hydration, nutrition, catabolism, and tissue breakdown. **Serum creatinine** is a more specific marker of kidney function and is commonly used to approximate GFR. Creatinine is derived from muscle and increases with age as muscle mass increases. The correlation between serum creatinine and GFR can be used to estimate GFR with the revised bedside Schwartz formula:

$$\text{GFR} = \frac{0.413 \times \text{Ht}}{\text{Cr}_{\text{serum}}}$$

(height in cm; serum creatinine in mg/dL). This formula is most useful when body habitus and muscle mass are reasonably normal and when renal function is relatively stable. This formula is most accurate in a GFR range of 15–75 mL/min/1.73 m². **Serum cystatin C** is another marker of kidney function that is not affected by muscle mass and can be used to estimate GFR. GFR can be measured rather than estimated by a 24-hour creatinine clearance; however, this will overestimate GFR to some degree due to creatinine secretion in the PT. This degree of overestimation is greater when renal function is lower.

By convention, GFR is corrected to body surface area of 1.73 m² to allow comparison between different-sized individuals. In a full-term newborn, an uncorrected GFR of 4–5 mL/min corrects to approximately 40 mL/min/1.73 m². GFR increases rapidly during the first 2 years of life until it achieves adult values (100–120 mL/min/1.73 m²). After that, GFR and body size increase proportionately, so GFR/1.73 m² remains stable.

Urinalysis is a useful screen for renal abnormalities. **Macroscopic urinalysis** uses a **urine dipstick** to assess urine concentration, pH, and the presence of blood, protein, glucose, ketones, and leukocytes (via **leukocyte esterase** reaction). Dilute urine may result in a false-negative result for protein; false-positive results may occur with alkaline or concentrated urine. Urine dipsticks are exquisitely sensitive to presence of hemoglobin (or myoglobin); there are few false-negative test results but many false-positive results. The **nitrite test** may detect bacteriuria if the bacteria can reduce nitrate to nitrite and have sufficient urine contact time. False-negative results occur with frequent voiding, low urine bacterial count, urinary tract obstruction, and infection with bacteria unable to generate nitrite. Gross hematuria or prolonged contact (uncircumcised boys) may result in a false-positive nitrite test. **Microscopic urinalysis** is used to confirm pyuria and hematuria as well as detect casts and crystals.

Proteinuria can be more accurately assessed by a **spot urine protein/creatinine** (U_{Pr}/Cr) ratio in a single urine specimen, preferably from a first-morning void. This value correlates well with 24-hour urine protein excretion. Normal spot U_{Pr}/Cr ratio is less than 0.2 mg/mg; a U_{Pr}/Cr ratio greater than 2 mg/mg is considered nephrotic range in children.

IMAGING STUDIES

Ultrasound is a noninvasive test that reliably assesses kidney size, urinary tract dilation, and most cysts, stones, and masses unless very small. Ultrasound examination of the kidneys should also include visualization of the bladder. **Pulsed Doppler studies** assess arterial and venous blood flow and

TABLE 161.2 Common Manifestations of Renal and Urinary Tract Disease

TYPE OF DISORDER	COMMON MANIFESTATIONS
Glomerular	H&P: Red urine, swelling, oliguria, hypertension, systemic symptoms and signs related to underlying process (e.g., preceding illness, fever, rash, arthralgias, hemoptysis) Labs: Hematuria, proteinuria, elevated serum creatinine, hypoalbuminemia, hypercholesterolemia, decreased C3/C4 complement, labs related to underlying process (e.g., positive ANA, ANCA, infectious serologies) Imaging: Increased echogenicity and decreased corticomedullary differentiation on ultrasound, enlarged kidneys
Tubulointerstitial	H&P: Oliguria, polyuria, dehydration, exposure history to nephrotoxic agents, abdominal/flank mass, fever, poor growth Labs: Hematuria, proteinuria, glucosuria, pyuria, dilute urine, elevated serum creatinine, electrolyte abnormalities Imaging: Increased echogenicity and decreased corticomedullary differentiation on ultrasound, hydronephrosis, renal cysts, renal mass
Vascular	H&P: Hematuria, oliguria, flank pain, malaise, hypertension, petechiae, flank mass Labs: Hematuria, proteinuria, elevated serum creatinine, anemia, thrombocytopenia Imaging: Increased echogenicity and decreased corticomedullary differentiation on ultrasound, renal vein thrombosis on Doppler ultrasound, papillary necrosis on CT scan
Urinary Tract	H&P: Dysuria, urinary urgency, hematuria, fever, enuresis, flank pain, recurrent UTI, vomiting, flank mass, suprapubic mass, urethral anomalies Labs: Pyuria, hematuria, positive urine culture, hypercalciuria Imaging: Hydronephrosis, urinary tract stones, vesicoureteral reflux on VCUG, thickened bladder wall \pm trabeculation, ureterocele, renal scarring, delayed emptying on renal scintigraphy, renal laceration on CT scan

ANA, Antinuclear antibody; ANCA, antineutrophil cytoplasmic antibody; CT, computed tomography; UTI, urinary tract infection; VCUG, voiding cystourethrogram.

can provide evidence of renal artery stenosis and renal vein thrombosis.

A **voiding cystourethrogram** involves filling of the bladder with contrast to detect vesicoureteral reflux and to evaluate the urethra. **Computed tomography (CT)** and **magnetic**

resonance imaging have replaced the **intravenous pyelogram** to evaluate kidney structure. These two studies provide the most detail on renal structure but are more expensive, may require sedation in younger children, and involve radiation exposure in the case of CT. Radionuclide studies can identify

renal scars, differential renal function, and delayed excretion suggestive of obstruction.

PEARLS FOR PRACTITIONERS

See *Nephrology and Urology: Pearls for Practitioners* at the end of this section.

CHAPTER 162

Nephrotic Syndrome and Proteinuria

ETIOLOGY AND EPIDEMIOLOGY

Small amounts of protein are found in urine of healthy children ($<4\text{ mg/m}^2/\text{hour}$ or urine protein/creatinine [U_{Pr}/Cr] $<0.2\text{ mg/mg}$). **Nephrotic proteinuria** in children is defined as protein excretion greater than $40\text{ mg/m}^2/\text{hour}$ or U_{Pr}/Cr greater than 2 mg/mg . Proteinuria between these levels is mildly to moderately elevated but not nephrotic. There are three general patterns of proteinuria: transient, orthostatic (postural), and persistent (fixed). Nephrotic syndrome is a subset of massive persistent proteinuria.

Transient proteinuria can be seen in children with fever, dehydration, or following seizure or vigorous exercise; it resolves within a few days, does not indicate renal disease, and needs no further evaluation or treatment.

Orthostatic (postural) proteinuria is a benign condition defined by normal protein excretion while recumbent but mild proteinuria (U_{Pr}/Cr $0.2\text{--}1\text{ mg/mg}$) when upright. Orthostatic proteinuria is more common in adolescents and tall, thin individuals; it is not associated with progressive kidney disease. Many children with orthostatic proteinuria continue this process into adulthood.

Persistent (fixed) proteinuria indicates intrinsic kidney disease. Most persistent proteinuria is **glomerular** in origin and characterized by a combination of large and small molecular weight proteins, variable levels of proteinuria, and, often, other evidence of glomerular disease (hematuria, red blood cell casts, hypertension, and renal insufficiency). **Tubular** proteinuria is characterized by preponderance of low molecular weight proteins and is seen in conditions of tubulointerstitial injury. Patients with tubular proteinuria may have a negative urine dipstick since this test specifically measures urinary albumin. The combination of tubular proteinuria with tubular electrolyte wasting and glycosuria is termed **Fanconi syndrome**.

Nephrotic syndrome (NS) is defined as persistent heavy proteinuria (mainly albuminuria; $>40\text{ mg/m}^2/\text{hour}$), **hypoalbuminemia** (serum albumin $<3.0\text{ g/dL}$), **hypercholesterolemia** ($>250\text{ mg/dL}$), and **edema**. Urinary protein losses occur due to abnormalities in the glomerular epithelial cell or podocyte and/or basement membrane that usually restricts protein filtration. The resultant massive proteinuria leads to decreased serum albumin and reduction in plasma oncotic pressure, leading to fluid shifts from vascular to interstitial compartments and plasma volume contraction. Edema results from decreased oncotic pressure as well as increase in tubular sodium reabsorption from reduced effective circulating blood

TABLE 162.1 Primary and Secondary Forms of Nephrotic Syndrome (NS)

PRIMARY NS

Minimal change NS
Primary focal segmental glomerulosclerosis
Idiopathic membranous nephropathy
Hereditary NS (congenital NS, infantile NS)

SECONDARY NS

Systemic lupus erythematosus and other glomerulonephritides (e.g., MPGN, PIGN)
IgA vasculitis, granulomatosis with polyangiitis and other vasculitides
Chronic infections (hepatitis B, hepatitis C, malaria, HIV)
Allergic interstitial nephritis
Diabetes
Amyloidosis
Malignancies

IgA, Immunoglobulin A; MPGN, membranoproliferative glomerulonephritis; PIGN, postinfectious glomerulonephritis.

volume. Hypoalbuminemia stimulates hepatic lipoprotein synthesis and diminishes lipoprotein metabolism, leading to elevated serum lipids (cholesterol, triglycerides) and lipoproteins.

There are three main causes of NS in children and a number of less common secondary causes (Table 162.1). **Minimal change nephrotic syndrome (MCNS)** is the most common histologic form of primary NS in children. More than 80% of children less than 7 years of age with NS have MCNS. Children 7–16 years old with NS have a ~50% chance of having MCNS. Males are affected more frequently than females (2:1), and the peak age of presentation is in the preschool years.

Focal segmental glomerulosclerosis (FSGS) accounts for ~10–20% of children with NS. Children with FSGS may present like those with MCNS or with less severe proteinuria. Some experts believe there is a spectrum of disease from MCNS to FSGS. A circulating factor that increases glomerular permeability is found in some patients with FSGS. More than 35% of children with FSGS progress to end-stage kidney disease.

Membranous nephropathy represents less than 5% of children with NS. It is seen most commonly in adolescents and children with systemic infections (hepatitis B, syphilis, malaria, and toxoplasmosis), exposure to specific medications (gold, penicillamine), or with autoimmune disease such as systemic lupus erythematosus.

NS may be a feature of more severe cases of any type of glomerulonephritis including immunoglobulin A (IgA) nephropathy, IgA vasculitis (Henoch-Schönlein purpura nephritis), postinfectious glomerulonephritis, and membranoproliferative glomerulonephritis. NS may also occur due to several secondary causes including amyloidosis, nonsteroidal anti-inflammatory drug exposure, and lymphoma (see Table 162.1).

Congenital NS (CNS) presents during the first 3 months of life. The most common cause is Finnish type CNS, a rare autosomal recessive disorder that is caused by a mutation in nephrin, a component of the podocyte slit diaphragm. A heterogeneous group of other disorders, including diffuse mesangial sclerosis and conditions associated with drugs or congenital infections, may also cause CNS. **Infantile NS** presents between 3 and 12 months of age and is usually caused by mutations in genes encoding other proteins of the glomerular filtration barrier.

CLINICAL MANIFESTATIONS

Children with NS initially present with facial and periorbital edema that progresses to more widespread edema including abdominal swelling, lower extremity edema, and even anasarca. The early stages of disease may be mistaken for an allergic reaction. Initial presentation often follows an immune trigger such as an upper respiratory infection. Anorexia, malaise, abdominal pain, diarrhea (due to intestinal wall edema), and respiratory distress (due to presence of ascites and/or pleural effusion) may be present. MCNS is characterized by *absence* of gross hematuria, renal dysfunction, and hypertension.

DIAGNOSTIC STUDIES

Proteinuria of 1+ or higher on two to three first-morning urine specimens suggests persistent proteinuria that should be further evaluated. A U_{Pr}/C_r less than 0.2 mg/mg on a first-morning specimen suggests orthostatic proteinuria, and no further evaluation is needed. U_{Pr}/C_r greater than 0.2 mg/mg indicates abnormal proteinuria, with values greater than 2 mg/mg indicative of nephrotic range proteinuria.

Children with persistent proteinuria should have kidney function assessed with serum creatinine, electrolyte panel, and albumin level. Routine testing typically includes a serum C3 complement. In children with NS, a low serum C3 implies a lesion other than MCNS. Renal ultrasound is often useful to rule out structural abnormalities of the urinary tract. Renal biopsy is recommended in children with persistent proteinuria including NS when MCNS is not suspected (e.g., kidney dysfunction, age >13 years, presence of hematuria, and hypertension).

TREATMENT

Because greater than 80% of children less than 13 years of age with NS have steroid-responsive forms (chiefly MCNS), empiric steroid therapy may be initiated without a renal biopsy if a child has typical features of MCNS. Typical initial therapy for MCNS is prednisone, 2 mg/kg per day (60 mg/m² per day, maximum 60 mg/day), provided once a day or split into two doses for 6 weeks followed by 1.5 mg/kg (40 mg/m², maximum 40 mg/day) once every other day for an additional 6 weeks. Over 90% of children who respond to steroids do so within 4 weeks. A renal biopsy is indicated for nonresponders as steroid resistance decreases the chance that MCNS is the underlying disease. Relapses of NS are treated with shorter courses of high-dose steroids. Children with frequent relapses or steroid resistance may require additional immunosuppressive therapy.

Treatment responses in FSGS are highly variable. Approximately 35% of children respond to steroid therapy; others may respond to additional immunosuppressive therapy. Membranous nephropathy often improves with immunosuppressive therapy but does not reliably remit with standard NS steroid therapy. Infants with congenital or infantile NS do not respond to immunosuppression and are treated with supportive care, aggressive nutritional support, dialysis, and transplantation.

The cornerstone to edema management is dietary salt restriction. Severe edema may require use of loop diuretics or fluid restriction. When these therapies are not successful,

cautious parenteral administration of 25% albumin (0.5–1 g/kg intravenously over 2–4 hours) followed by an intravenous loop diuretic may achieve diuresis. Supportive strategies include elevation of the legs or other body parts with severe swelling, careful monitoring of daily weights, and if inpatient, tracking of intake and output.

COMPLICATIONS

Side effects of steroids, such as increased appetite and irritability, are most common in steroid-dependent and frequently relapsing patients who have greatest exposure to steroids. Hypovolemia and even acute kidney injury may result from diarrhea or overaggressive diuresis. Serious infections, including **bacteremia** and **peritonitis** (particularly *Streptococcus pneumoniae*, *Escherichia coli*, or *Klebsiella*), may occur due to urinary loss of immunoglobulins and complement. **Thromboembolism** (TE) including deep vein thrombosis, central sinus thrombosis, renal vein thrombosis, and pulmonary embolism may occur due to a hypercoagulable state caused by urinary losses of coagulation factors, antithrombin, and plasminogen. Although routine anticoagulation is not recommended in children with NS, it may be considered in those with a history of prior TE or at particularly high risk. Persistent hyperlipidemia in children with steroid-resistant NS promotes increased risk of atherosclerotic vascular disease.

PROGNOSIS

Nearly 80% of children with steroid-responsive MCNS experience at least one NS relapse, defined as heavy proteinuria that persists for 3 or more consecutive days. Relapse patterns include **infrequently relapsing**, **frequently relapsing** (four or more relapses/year), and **steroid-dependent** (relapse within 2 weeks of steroid discontinuation). Some children do not respond to steroids initially, or despite initial response they become **steroid resistant**. Steroid-responsive patients have little risk of progressive chronic kidney disease. Patients who are steroid resistant, however, are more likely to progress to end-stage kidney disease (see Chapter 165). Recurrence of disease occurs in ~30% of children with steroid-resistant FSGS who undergo renal transplantation.

PEARLS FOR PRACTITIONERS

CHAPTER 163

Glomerulonephritis and Hematuria

ETIOLOGY AND EPIDEMIOLOGY

Hematuria, defined as five or more red blood cells (RBCs) per high-power field on freshly voided and centrifuged urine, is a common clinical issue in pediatrics. Hematuria may originate

TABLE 163.1 Differential Diagnosis of Red Urine/Hematuria

FACTITIOUS HEMATURIA
Nonpathologic (urate crystals in infants, ingested foods, medications, dyes) Pathologic (hemoglobinuria from hemolytic anemia, myoglobinuria from rhabdomyolysis)
GLOMERULAR
Immunologic injury (GN—e.g., PIGN, IgA nephropathy, MPGN, systemic diseases) Structural disorder (Alport syndrome, thin basement membrane disease) Toxin-mediated injury (HUS)
TUBULOINTERSTITIAL/PARENCHYMAL
Inflammation (interstitial nephritis, pyelonephritis) Vascular (sickle cell trait/disease, nutcracker syndrome) Structural (cyst rupture, Wilms tumor, urinary tract obstruction, renal trauma)
LOWER URINARY TRACT
Inflammation (cystitis, hemorrhagic cystitis, urethritis) Injury (trauma, kidney stone) Hypercalciuria

GN, Glomerulonephritis; HUS, hemolytic uremic syndrome; IgA, immunoglobulin A; MPGN, membranoproliferative glomerulonephritis; PIGN, postinfectious glomerulonephritis.

from glomerular, tubulointerstitial, or lower urinary tract disorders (Table 163.1). **Microscopic hematuria** is found in up to 5% of healthy children but in most cases is a transient finding and resolves on repeated testing. Persistent microscopic hematuria may indicate a number of conditions including glomerular disease, crystalluria, or inherited disorders such as sickle cell trait/disease or polycystic kidney disease. **Macroscopic (gross) hematuria** indicates visible blood in the urine and may be seen in conditions such as urolithiasis, urinary tract infection, and **acute glomerulonephritis (GN)**. **Postinfectious glomerulonephritis (PIGN)** is the most common form of acute GN and immunoglobulin A (IgA) nephropathy is the most common form of chronic GN; however, many other types of GN can occur.

CLINICAL MANIFESTATIONS

Children with acute GN commonly present with hematuria (macro- or microscopic) and other cardinal features of glomerular injury (proteinuria, hypertension, edema, oliguria, acute kidney injury). PIGN occurs most frequently in children 2–12 years of age and is more common in boys. Manifestations of PIGN are typical of acute GN and follow infections with bacterial and viral pathogens. PIGN most commonly develops on average 10 days after streptococcal pharyngitis and 4–6 weeks after impetigo. Antibiotic treatment of streptococcal or other infections does not prevent or delay development of GN.

IgA nephropathy has a more variable presentation and may take the form of acute GN, asymptomatic microscopic hematuria, or the classic presentation of recurrent macroscopic hematuria concurrent with an upper respiratory infection. Children with GN secondary to IgA vasculitis (Henoch-Schönlein

purpura), systemic lupus erythematosus, and vasculitis typically present with other systemic features of the respective condition.

Rapidly progressive glomerulonephritis (RPGN) is a more severe form of acute GN with a rapid loss of kidney function over days to weeks. RPGN may be seen in any form of acute GN. A common feature on renal biopsy is glomerular epithelial cell proliferation with crescents. Early recognition and treatment of RPGN is crucial to prevent progression to end-stage kidney disease (ESKD).

Alport syndrome is caused by mutations in genes encoding type IV collagen, which lead to construction of abnormal glomerular basement membrane (GBM) in the kidneys and ears. The most common inheritance pattern is X linked, but autosomal dominant and recessive forms exist. Males with Alport syndrome present with either painless microscopic or macroscopic hematuria, progressive proteinuria, hypertension, loss of kidney function, and sensorineural hearing loss. Females typically have a more benign course with microscopic hematuria but in some cases may develop ESKD. **Thin basement membrane disease** (benign familial hematuria) is caused by autosomal dominant collagen mutations that lead to isolated GBM thinning and persistent hematuria. There is often a family history of benign hematuria in first-degree relatives. As opposed to Alport syndrome, thin basement membrane disease is typically not progressive and usually has an excellent prognosis.

Nonglomerular causes of hematuria have a more variable presentation related to the underlying etiology. **Urinary tract infection (UTI)** is typically associated with dysuria and urinary frequency. **Urolithiasis** may be associated with flank or abdominal pain, although some children with stones are asymptomatic. **Hypercalciuria** can cause either macroscopic or microscopic hematuria with classic symptoms of UTI but without pyuria or a positive urine culture. **Strenuous exercise, sickle cell trait/disease, or Wilms tumor** may cause painless macroscopic hematuria. **Autosomal dominant polycystic kidney disease** or **nutcracker syndrome** (renal vein compression) may be associated with macroscopic hematuria with flank pain. Hematuria following **trauma** may signify more severe renal or lower urinary tract injury.

DIAGNOSTIC STUDIES

All patients with hematuria should have a careful history and physical (including blood pressure) along with urinalysis including microscopic examination to identify RBCs. Glomerular hematuria is suggested by brownish (tea- or cola-colored) urine and presence of RBC casts and/or dysmorphic RBCs on urine microscopy. A urine color that is more bright red without RBC casts or dysmorphic RBCs is more suggestive of a lower urinary tract source.

Children with macroscopic and microscopic hematuria with associated concerning findings should have additional evaluation. A suggested algorithm for the evaluation of hematuria is given in Fig. 163.1. In patients with suspected GN, complement C3 should be measured as hypocomplementemia narrows the differential diagnosis to PIGN, membranoproliferative GN, and lupus nephritis. Renal ultrasound is helpful in ruling out tumor, hydronephrosis, and urolithiasis. Urine calcium and creatinine ($U_{Ca/Cr}$) ratio may screen for hypercalciuria; abnormal findings (>0.2 mg/mg) should be confirmed with a 24-hour urine collection for calcium and creatinine.

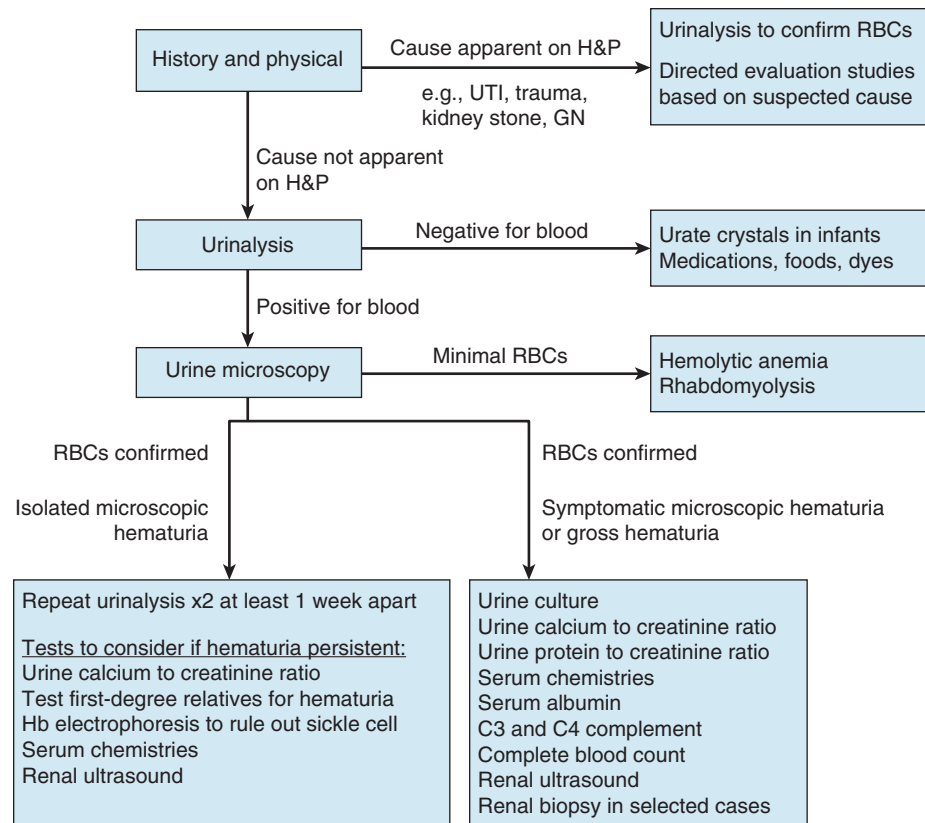

FIGURE 163.1 Suggested algorithm for evaluation of red urine/hematuria. *GN*, Glomerulonephritis; *Hb*, hemoglobin; *H&P*, history and physical; *RBCs*, red blood cells; *UTI*, urinary tract infection.

Children with isolated, asymptomatic microscopic hematuria with negative evaluation may be observed with yearly urinalyses. If hematuria is persistent, or the child develops proteinuria, hypertension, or loss of kidney function, nephrology referral for additional evaluation is appropriate.

TREATMENT

Treatment of PIGN involves supportive care with dietary sodium restriction, diuretics, and antihypertensive agents. Although treating the streptococcal infection does not prevent PIGN, antibiotic treatment is warranted with active streptococcal infection. Treatment of children with other forms of GN depends on underlying cause and severity and may include corticosteroids and/or other immunosuppressive agents. Treatment with angiotensin-converting enzyme inhibitors may reduce proteinuria and glomerular hyperperfusion but should be used with caution in the setting of acute kidney injury.

PROGNOSIS AND PREVENTION

PIGN usually has a favorable outcome. In typical cases, the gross hematuria, proteinuria, and edema decline quickly (5–10 days), while microscopic hematuria may persist for months or even years; greater than 95% of children recover completely with no long-term sequelae.

Children with IgA nephropathy and other forms of chronic GN have greater risk of progression to ESKD, which is variable and related to the underlying disorder and disease severity. The

presence of persistent and heavy proteinuria, hypertension, decreased kidney function, and severe glomerular lesions on renal biopsy are associated with poor outcomes.

Children with idiopathic isolated, asymptomatic microscopic hematuria or suspected thin basement membrane disease typically have an excellent renal prognosis. Long-term follow-up, including yearly urinalysis and blood pressure measurement, is required to exclude progressive forms of kidney disease.

PEARLS FOR PRACTITIONERS

See *Nephrology and Urology: Pearls for Practitioners* at the end of this section.

CHAPTER 164

Hemolytic Uremic Syndrome

ETIOLOGY AND EPIDEMIOLOGY

Hemolytic uremic syndrome (HUS) is characterized by the triad of **microangiopathic hemolytic anemia, thrombocytopenia, and acute kidney injury (AKI)**. The most common form of HUS is associated with **Shiga-toxin producing *Escherichia coli* (STEC)** and is termed **STEC-HUS**. Children with STEC-HUS experience a prodromal diarrheal illness due to hemorrhagic enterocolitis following exposure to a

pathogenic agent (most commonly *E. coli* O157:H7). STEC-HUS outbreaks have been associated with contaminated ground beef, fruit, vegetables, or water. STEC-HUS occurs in ~5–15% of children with STEC infection.

HUS may also occur unrelated to STEC infection (**non-STECHUS**). Infection with *Streptococcus pneumoniae* or HIV has been associated with non-STECHUS. Genetic and acquired defects in complement regulation, medications, malignancy, systemic lupus erythematosus, and pregnancy may also be associated with non-STECHUS. The clinical course of non-STECHUS is usually more severe than STECHUS and more likely to lead to chronic kidney disease.

Less commonly, children may develop a similar microangiopathic syndrome, identified as **thrombotic thrombocytopenic purpura (TTP)**. Children with TTP typically have predominantly central nervous system (CNS) symptoms but may also have significant kidney disease. Because CNS involvement is also seen in HUS, TTP can be difficult to distinguish from HUS. Children with TTP have severe deficiency of ADAMTS13, a von Willebrand factor–cleaving protease.

CLINICAL MANIFESTATIONS

STEC-HUS typically occurs in children less than 5 years of age but can occur in older children. Classic STECHUS begins with enterocolitis, often with bloody stools, followed in 7–10 days by weakness, lethargy, and oliguria/anuria. Physical examination reveals irritability, pallor, and petechiae. Volume depletion is common at presentation; however, some children have volume overload. Hypertension may be present due to volume overload and/or renal injury. CNS involvement, including seizures, occurs in up to 25% of cases. Other potential organ involvement includes pancreatitis, cardiac dysfunction, and colonic perforation. Children with non-STECHUS have similar clinical presentation but usually without a recent history of enterocolitis.

DIAGNOSTIC STUDIES

Common laboratory findings in HUS are listed in Table 164.1. Peripheral blood smear reveals evidence of microangiopathic hemolysis with schistocytes and thrombocytopenia. Coombs test is negative. Serum blood urea nitrogen and creatinine are elevated consistent with AKI, and associated electrolyte abnormalities may be present. Serologic and stool studies may confirm presence of Shiga toxin, although the toxin may no longer be present by the time of diagnosis of HUS. ADAMTS13 level is normal in all forms of HUS but is deficient in TTP.

TREATMENT AND PROGNOSIS

Therapy for STECHUS is supportive and includes volume repletion, treatment of hypertension, and managing complications of AKI, including dialysis when indicated. Early and aggressive intravenous hydration with isotonic saline during the diarrheal phase may lessen the severity of AKI. Red blood cell transfusions are provided as needed. Platelet transfusions should be reserved for active hemorrhage or prior to invasive procedures as they may fuel the thrombotic microangiopathy process. Antibiotics and anti-diarrheal agents should be avoided in children with STEC

TABLE 164.1 Common Laboratory Findings with Hemolytic Uremic Syndrome

EVIDENCE OF MICROANGIOPATHIC HEMOLYTIC ANEMIA

Anemia
Thrombocytopenia
Presence of schistocytes, helmet cells, and burr cells on peripheral blood smear
Increased LDH
Decreased haptoglobin
Increased indirect bilirubin
Increased AST
Elevated reticulocyte count

Positive stool culture for *E. coli* O157:H7
Positive stool test for Shiga toxin
Elevated amylase/lipase

AST, Aspartate aminotransferase; *E. coli*, *Escherichia coli*; LDH, lactate dehydrogenase.

infection as they increase the risk of developing HUS. Most children (>95%) with STECHUS survive the acute phase and recover normal kidney function, although some may have evidence of chronic kidney disease and other morbidity. Treatment of non-STECHUS depends on the underlying etiology.

PEARLS FOR PRACTITIONERS

See *Nephrology and Urology: Pearls for Practitioners at the end of this section.*

CHAPTER 165

Acute Kidney Injury and Chronic Kidney Disease

ACUTE KIDNEY INJURY

Etiology

Acute kidney injury (AKI), formerly termed *acute renal failure*, refers to an abrupt decrease in glomerular filtration rate (GFR) leading to accumulation of waste products (e.g., urea) and disturbance in fluid and electrolyte homeostasis. AKI may be **oliguric** (<1 mL/kg/hr in neonates and infants, <0.5 mL/kg/hr in children) or **nonoliguric**, which may be more difficult to recognize.

Causes of AKI may be divided into prerenal (renal hypoperfusion), intrinsic renal (tubular, glomerular, or vascular injury), and postrenal (urinary tract obstruction) categories (Table 165.1). In many cases, the cause of AKI is multifactorial. **Prerenal AKI** is most commonly due to **volume depletion** but may be secondary to other mechanisms of glomerular

hypoperfusion. **Intrinsic AKI** may be due to **acute tubular necrosis (ATN)**, which can be caused by a hypoxic-ischemic insult and/or exposure to nephrotoxic agents (medications, contrast, myoglobin). Acute glomerulonephritis, acute tubulointerstitial nephritis, and vascular thromboses are other causes of intrinsic renal AKI. **Postrenal AKI** occurs due to conditions that result in either structural or functional **urinary tract obstruction**.

TABLE 165.1 Causes of Acute Kidney Injury

TABLE 165.1 Causes of Acute Kidney Injury

Neurogenic bladder (myelomeningocele, spinal cord injury)	
INTRINSIC	
Acute tubular necrosis	
Nephrotoxins (medications, contrast, myoglobin)	
Infection (sepsis)	
Interstitial nephritis	
Glomerular injury (primary glomerulonephritis, vasculitis, hemolytic uremic syndrome)	
Vascular (renal vein thrombosis, arterial emboli, malignant hypertension)	

Clinical Manifestations

History, physical examination, and basic studies usually allow proper classification of the child with AKI (Table 165.2). Prerenal AKI is characterized by history of precipitating factors leading to volume depletion. Urine output is low. Intrinsic AKI from ATN is associated with precipitating factors such as prolonged hypotension or exposure to nephrotoxic agents. Urine output in ATN may be low, normal, or high, depending on the severity of the injury. Children with glomerulonephritis present with hematuria, edema, hypertension, and oliguria. In postrenal AKI, urine output may be low or normal and may be associated with flank masses or a distended bladder on examination. Depending on the underlying cause and severity of illness, AKI can be associated with signs of dehydration or volume overload.

Diagnostic Studies

Early recognition and management of AKI is crucial. A **urinalysis (UA)** should be obtained in all children with AKI. In children with prerenal AKI, the UA is unremarkable with high specific gravity reflecting appropriate urinary concentration. Neonates, children with preexisting kidney disease, and individuals with sickle cell disease may not be able to concentrate urine well despite volume depletion. In children with AKI from glomerular and vascular injury, hematuria and proteinuria are usually moderate to severe. In children with oliguric AKI, differentiation between prerenal AKI and ATN may be made by determining urine osmolality and fractional excretion of sodium (see Table 165.2). **Renal ultrasound** is helpful in evaluation of obstructive or postrenal AKI (see Table 165.2). Renal biopsy is indicated only in select cases of intrinsic AKI.

Common electrolyte abnormalities seen in AKI include hyperkalemia, metabolic acidosis, hypocalcemia, and hyperphosphatemia. These labs should be trended over time, the frequency of which depends on initial results and the patient's clinical course. A complete blood count should be measured as anemia is frequently observed in children with AKI. Other laboratory studies may be obtained as clinically indicated.

TABLE 165.2 Laboratory and Clinical Evaluation of Acute Kidney Injury

LABORATORY/CLINICAL FEATURE	PRERENAL		RENAL		POSTRENAL
	CHILD	NEONATE	CHILD	NEONATE	
Urine output	Low		Low, normal, or high		Low or normal
Urinalysis	Normal		RBCs, WBCs, protein, casts		Variable
Urine Na ⁺ (mEq/L)	<15	<20–30	>40	>50	Variable, may be >40
FE _{Na} * (%)	<1	<2.5	>2	>2.5	Variable, may be >2
Urine osmolality (mOsm/L)	>500	>350	~300	~300	Variable, may be <300
Renal ultrasound	Normal		Increased echogenicity, decreased corticomedullary differentiation		Hydronephrosis

*FE_{Na} (%) = [(urine sodium/plasma sodium) ÷ (urine creatinine/plasma creatinine)] × 100.
FE_{Na}, Fractional excretion of sodium; RBCs, red blood cells; WBCs, white blood cells.

Treatment

In some cases, treating the underlying disorder will improve AKI. Examples include volume repletion in dehydration, stopping an offending nephrotoxic medication, and relieving urinary tract obstruction. In all cases, efforts should be made to limit additional kidney injury (e.g., ensuring adequate renal perfusion and avoiding nephrotoxic medications). Medication dosages and intervals should be adjusted for decreased GFR as appropriate.

Initial approach to fluid therapy depends on the child's volume status and urine output. If hypovolemia is present, intravascular volume should be expanded using intravenous saline administration. If hypervolemia is present, 1–2 mg/kg of furosemide and fluid restriction is indicated. If euvolemia is present, total fluid input should be adjusted to match insensible losses and urine output, which may be higher or lower than normal. All children with AKI should have careful measurement of intake and output as well as serial body weight measurements and physical examination with attention to volume status.

Treatment of AKI involves prevention and management of potential complications, including electrolyte abnormalities. Potassium intake and medications that increase potassium should be restricted. If hyperkalemia occurs, intravenous calcium will lower the risk of arrhythmia while measures are initiated to shift potassium into cells (bicarbonate, β -agonists, insulin/dextrose) and hasten removal (diuretics, sodium-potassium exchange resins, dialysis). Hyperphosphatemia should be treated with phosphorus restriction and administration of phosphate binders. Hypertension may be treated with diuretics, calcium channel blockers, and vasodilators. Angiotensin-converting enzyme (ACE) inhibitors are usually avoided in the setting of AKI.

Indications for **acute dialysis** (kidney support therapy) are listed in Table 165.3. There is no specific blood urea nitrogen or creatinine level at which dialysis is needed in patients with AKI. Renal replacement options in children include peritoneal dialysis, hemodialysis, and continuous renal replacement therapy. The mode is selected based on individual factors.

Prognosis

Recovery from AKI depends on the etiology and severity of AKI and other patient characteristics. Preterm infants who experience AKI prior to completion of renal development are

at particularly high risk. Even with seemingly good recovery, a history of moderate to severe AKI, especially if dialysis support was required, places the child at increased risk for future chronic kidney disease (CKD).

CHRONIC KIDNEY DISEASE

Etiology and Epidemiology

Congenital anomalies of the kidney and urinary tract (CAKUT), such as renal dysplasia, are the most common causes of CKD in children. Acquired kidney diseases, such as focal segmental glomerulosclerosis and glomerulonephritis (GN), are more common causes of CKD in older children and teens. The risk of progression to end-stage kidney disease (ESKD) is related to the underlying cause and severity of CKD. Kidney function may deteriorate more rapidly during puberty due to increased demands of growth and maturation.

CKD is staged to facilitate appropriate evaluation and monitoring according to estimated GFR (Table 165.4). GFR can be estimated in children using the Schwartz formula (see Chapter 161). Most metabolic complications of CKD do not begin to manifest until at least stage 3 CKD. In stage 4 CKD, complications become more numerous and severe. Children with stage 5 CKD (ESKD) require treatment with either dialysis or kidney transplantation.

Clinical Manifestations

The clinical presentation of a child with CKD is related to both the underlying etiology and stage of CKD at time of diagnosis. A child with CAKUT may have polyuria, polydipsia, and recurrent urinary tract infections. A child with GN may have hematuria, proteinuria, edema, and hypertension. Common complications of CKD in children are listed in Table 165.5. Most of these complications are multifactorial in etiology. For example, **anemia** results primarily from a failure to produce adequate **erythropoietin** as well as iron deficiency. **Growth failure** may result from poor nutrition, metabolic acidosis, hormonal abnormalities, resistance to growth hormone, and **CKD-mineral bone disorder (CKD-MBD)**. CKD-MBD is usually due to **secondary hyperparathyroidism** as a result of hyperphosphatemia, hypocalcemia, and diminished renal 1,25-dihydroxyvitamin D production. If prolonged and/or severe, CKD-MBD may lead

STAGE	GFR (ML/MIN/ 1.73 M ²)*	DESCRIPTION
1	>90	Minimal kidney damage
2	60–89	Kidney damage with mild reduction of GFR
3	30–59	Moderate reduction of GFR
4	15–29	Severe reduction of GFR
5	<15 (or dialysis)	End-stage kidney disease

*GFR ranges apply for children age ≥ 2 yr.

From National Kidney Foundation Kidney Disease Outcomes Quality Initiative. GFR, Glomerular filtration rate.

to rickets and bone deformities. **Hypertension** and **left ventricular hypertrophy** are common cardiovascular complications. Delayed puberty results from altered gonadotropin secretion and regulation. Learning and school performance may also be impaired in children with CKD.

Treatment

The management of children with advanced CKD requires a multidisciplinary team, which ideally includes a pediatric nephrologist, renal dietitian, social worker, and psychologist. Adequate nutrition should be ensured even if it requires dietary supplements and tube feedings. Some infants and young children with CAKUT require supplemental salt due to urinary sodium wasting. Conversely, children with GN require salt restriction to assist in management of hypertension or edema. Common treatment considerations for CKD complications are listed in Table 165.5.

Several measures can be taken to preserve kidney function or slow progression of CKD. ACE inhibitors or angiotensin receptor blockers should be used to reduce proteinuria and control blood pressure. Potentially nephrotoxic medications such as ibuprofen should be avoided when feasible. Medication adjustment for reduced kidney function is important. Protein intake is typically not restricted in pediatric CKD due to growth needs.

Children with stage 5 CKD (ESKD) require either kidney transplantation or dialysis support. The optimal treatment of ESKD is **kidney transplantation**. **Maintenance dialysis** is effective for a child awaiting kidney transplantation or when kidney transplantation is not possible. **Peritoneal dialysis** is done at home by the family. **Hemodialysis** is performed three

times a week at a dialysis facility. Indications for chronic dialysis are listed in Table 165.3.

Prognosis

Children with mild CKD (stages 1 and 2) are usually asymptomatic but need to be monitored for progressive loss of kidney function. Children with stages 3 and 4 CKD have a high likelihood of progressing to ESKD at some point, although the timing can vary. Because children on maintenance dialysis have the highest morbidity and mortality, the goal is to provide a kidney transplant for all children with ESKD. Children with kidney transplants generally do well but must take lifelong immunosuppressive medications associated with a variety of side effects, including infections, nephrotoxicity, cardiovascular complications, and increased risk for certain malignancies. Transplanted kidneys can last for more than 10–20 years, but eventually fail, requiring re-transplantation.

PEARLS FOR PRACTITIONERS

See *Nephrology and Urology: Pearls for Practitioners* at the end of this section.

TABLE 165.5 Common Complications and Treatments of Chronic Kidney Disease

COMPLICATION	TREATMENT
1. Poor growth	Increased caloric intake, treat acidosis, treat CKD-MBD, recombinant GH
2. Anemia	Erythropoietin, iron supplementation
3. CKD–Mineral bone disorder/secondary hyperparathyroidism	1,25-dihydroxyvitamin D supplementation, calcium supplementation, dietary phosphorous restriction, phosphate binders
4. Cardiovascular	
4a. Hypertension	Antihypertensive medications
4b. Left ventricular hypertrophy	Volume control
5. Electrolyte abnormalities	
5a. Hyperkalemia	Low K diet, furosemide, sodium polystyrene sulfonate
5b. Hyponatremia	Sodium supplementation
5c. Metabolic acidosis	Alkali replacement

CKD, Chronic kidney disease; CKD-MBD, chronic kidney disease—mineral bone disorder; GH, growth hormone; K, potassium.

CHAPTER 166

Hypertension

DEFINITION

In children, hypertension (HTN) is defined as blood pressure (BP) greater than 95th percentile for age, gender, and height measured on at least three different occasions. The context of BP measurement (e.g., cuff size, pain, anxiety) is important. Staging of HTN is listed in Table 166.1. Hypertensive emergency is defined as severe BP elevation associated with target organ damage (encephalopathy, heart failure).

ETIOLOGY

Pediatric HTN has many causes (Table 166.2) that are either **primary** (essential) or **secondary**. **Essential HTN** is the most common cause of HTN in children and adolescents, particularly in those who are obese. Secondary HTN should be

TABLE 166.1 Classification of Blood Pressure

BP CATEGORY	AGE 1–<13 YR	AGE ≥13 YR
Normal	<90th BP %	<120/<80
Elevated BP	90th to <95th BP %	120/<80 to 129/<80
Stage 1 hypertension	95th BP % to <95th BP % + 12 mm Hg	130/80 to 139/89
Stage 2 hypertension	≥95th BP % + 12 mm Hg	≥140/90

%, Percentile; BP, blood pressure.

Vasculitis
OTHER CAUSES
Obstructive sleep apnea
Medications, illicit drugs

suspected in younger and/or non-overweight children with more severely elevated BP. **Kidney disease** is the most common cause of secondary HTN in children.

CLINICAL MANIFESTATIONS

Most children with HTN have no symptoms. Severe HTN may be associated with symptoms including encephalopathy (headache, vomiting, seizures), heart failure, stroke, and retinopathy (blurred vision, flame hemorrhage, and cotton wool spots on retinal exam). Neonatal history (low birthweight or use of umbilical artery catheter); family history of HTN, stroke, or heart disease; and dietary history (excessive salt or caffeine, drugs) are important. Additional findings that may suggest specific causes include abdominal bruit (renal artery stenosis); diminished leg pressure and weak femoral pulse (coarctation of aorta); café-au-lait spots (neurofibromatosis-associated renal artery stenosis); flank mass (hydronephrosis, Wilms tumor); tachycardia with flushing and diaphoresis (pheochromocytoma); and truncal

obesity, acne, striae, and buffalo hump (Cushing syndrome). Signs of underlying kidney disease including hematuria, proteinuria, and edema may be present.

DIAGNOSTIC STUDIES

Children with suspected HTN should ideally have a 24-hour ambulatory blood pressure monitoring (ABPM) study to confirm the diagnosis and rule out white coat hypertension (elevated BP in the office setting only). If the ABPM confirms hypertension, the recommended evaluation includes:

1. Baseline assessment—urinalysis, electrolytes, blood urea nitrogen, creatinine, and kidney ultrasound (age <6 years)
2. Focused studies based on clinical suspicion (e.g., plasma metanephrines, renin, aldosterone, thyroid studies, vascular imaging)
3. Assessment of other cardiovascular risk factors (lipids, fasting glucose, hemoglobin A_{1c}, uric acid, sleep study)
4. Assessment for target organ damage (echocardiogram for left ventricular hypertrophy when considering initiation of antihypertensive medication)

TREATMENT

Therapeutic lifestyle changes (diet, exercise) should be initiated for asymptomatic stage 1 HTN. Antihypertensive medication should be started for children with stage 2 or symptomatic HTN and stage 1 HTN that fails to respond to lifestyle changes. Calcium channel blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and thiazide diuretics are recommended first-line antihypertensive agents. More than one agent may be needed. Hypertensive emergency requires prompt hospitalization and may require parenteral antihypertensive treatment with nicardipine, labetalol, esmolol, or sodium nitroprusside.

PROGNOSIS

Prognosis depends on the underlying etiology and adequacy of BP control. Essential HTN is usually not associated with morbidity at presentation. Left untreated, however, even asymptomatic stage 1 HTN may increase risk for cardiovascular, central nervous system, and chronic kidney disease in adulthood.

PEARLS FOR PRACTITIONERS

See *Nephrology and Urology: Pearls for Practitioners at the end of this section.*

CHAPTER 167**Vesicoureteral Reflux**

ETIOLOGY AND EPIDEMIOLOGY

Vesicoureteral reflux (VUR) is retrograde flow of urine from the bladder to the ureter or kidney. Primary VUR is the most common form and results from a congenitally short segment of ureter within the bladder wall, which does not get fully compressed by the contracting bladder muscle during voiding.

VUR is the most common anatomic abnormality found in infants and young children with febrile urinary tract infection (UTI). There is a genetic predisposition to primary VUR with an increased risk in children with affected parents or siblings.

Secondary VUR may be present in children with other urinary tract anomalies. In children with **ureteral duplication**, VUR is commonly seen into the ureter draining the lower pole of the kidney. VUR is seen in up to 50% of children with **neurogenic bladder**. VUR may also be seen in children with increased intravesicular pressure due to **bladder outlet obstruction** (e.g., posterior urethral valves, prune belly syndrome).

CLINICAL MANIFESTATIONS

The most common clinical manifestation of VUR is **febrile UTI** (see Chapter 114). Recurrent febrile UTI is more likely in children with higher grade VUR. **Reflux nephropathy** involves development of renal scarring in a child with VUR and recurrent febrile UTI; this complication is more likely in children with higher grade VUR and more frequent infections. Renal scarring is not always visible on RUS and is best identified by **nuclear renal scanning**.

DIAGNOSTIC STUDIES

Renal ultrasound (RUS) is typically obtained first to evaluate the kidneys and urinary tract. While the findings of renal and urinary tract anomalies make VUR more likely, the absence of these anomalies does not rule out VUR. Therefore a **voiding cystourethrogram** (VCUG) is required to confirm the diagnosis of VUR in a child with recurrent febrile UTI. An international grading system based on VCUG imaging is useful to describe the severity of reflux (Fig. 167.1). For follow-up studies, either VCUG or **radionuclide cystogram** (RNC) may suffice.

The American Academy of Pediatrics recommends obtaining a RUS in children 2–24 months of age following an initial febrile UTI. A VCUG is indicated if the RUS reveals hydronephrosis, scarring, findings suggestive of either high-grade VUR or obstructive uropathy, and in other atypical or

complex clinical circumstances. In children with a normal RUS, a VCUG is recommended after the second febrile UTI.

MANAGEMENT

Grades 1 and 2 primary VUR will likely self-resolve as the intravesicular ureteral segment lengthens with growth. Many cases of grades 3 and 4 primary VUR resolve when VUR is diagnosed before 2 years of age and is unilateral. Severe (grade 5) primary VUR and secondary VUR are less likely to resolve spontaneously. Management options for a child with VUR include surveillance, medical therapy, and surgical intervention, but there is lack of consensus on when these options are indicated.

In children with low-grade VUR, a surveillance approach with early evaluation for febrile UTI may be considered. Antibiotic prophylaxis may benefit children with moderate to high-grade VUR and/or recurrent UTI. While there is evidence that antibiotic prophylaxis reduces UTI frequency, its benefit in preventing renal scarring is less proven. Children with VUR should be monitored for bowel and bladder dysfunction as its medical treatment may facilitate resolution of VUR. Indications for surgical intervention include VUR that does not resolve over time or is complicated by recurrent febrile UTI despite medical therapy. Children with VUR and recurrent UTI should be monitored for evidence of CKD including poor growth, hypertension, and proteinuria.

PEARLS FOR PRACTITIONERS

See *Nephrology and Urology: Pearls for Practitioners* at the end of this section.

FIGURE 167.1 Diagram illustrating classification of vesicoureteral reflux based on voiding cystourethrogram imaging. Grade I: into a nondilated ureter; grade II: into the pelvis and calyces without dilation; grade III: mild to moderate dilation of the ureter, renal pelvis, and calyces with minimal blunting of the fornices; grade IV: moderate ureteral tortuosity and dilation of the pelvis and calyces; grade V: gross dilation of the ureter, pelvis, and calyces; loss of papillary impressions; and ureteral tortuosity. (From Wein A, Kavoussi L, Novick A, et al. *Campbell-Walsh Urology*. 9th ed. Philadelphia: Saunders; 2007.)

CHAPTER 168

Congenital and Developmental Abnormalities of the Urinary Tract

ETIOLOGY AND EPIDEMIOLOGY

Congenital anomalies of the kidneys and urinary tract (CAKUT) are a leading cause of pediatric chronic kidney disease (CKD) and occur in up to 4% of infants. CAKUT may be an isolated condition or may be part of a broader syndrome that includes extrarenal manifestations. Some forms of CAKUT have a male predilection. Both genetic and environmental factors may play a role in development of CAKUT.

Abnormal Kidney Structure

Renal agenesis results from early disruption in embryonal kidney development. In most cases, bilateral renal agenesis is lethal due to severe oligohydramnios and pulmonary hypoplasia since lung development is dependent on fetal urine production. Unilateral renal agenesis can be observed with other CAKUT or extrarenal anomalies such as VACTERL association (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula, renal anomalies, and limb defects). Unilateral renal agenesis is usually characterized by normal or

minimally reduced renal function at birth. However, there may be increased risk for proteinuria, hypertension, and CKD in the future. Children with a solitary kidney should be monitored for these complications and have periodic renal ultrasounds to confirm compensatory hypertrophy of the remaining kidney.

Renal hypoplasia/dysplasia refers to kidneys that are congenitally small, malformed, or both. Renal ultrasonography shows increased echogenicity, decreased corticomedullary differentiation, and in some cases scattered renal cysts. Many affected children will develop progressive CKD due to reduced nephron number, so periodic monitoring of kidney function and surveillance for CKD complications is recommended. Some children have polyuria due to an inability to fully reabsorb sodium and water in which case salt and water supplementation may be indicated.

A **multicystic dysplastic kidney** (MCDK) is a nonfunctioning kidney comprised of many cysts of variable size separated by dysplastic tissue. MCDK may be detected as a flank mass in the neonate if not already identified on prenatal ultrasound. The contralateral kidney is often structurally normal but may be associated with other abnormalities, the most common being vesicoureteral reflux (VUR). In most children, the MCDK spontaneously involutes over time while the contralateral kidney undergoes compensatory hypertrophy. Children with MCDK should be monitored similarly to children with solitary kidney due to renal agenesis.

Polycystic kidney diseases (PKDs) are a group of genetic disorders affecting the kidneys and other tissues. **Autosomal recessive PKD (ARPKD)** is characterized by marked bilateral renal enlargement due to numerous microcysts. In some cases, kidney failure develops in utero resulting in oligohydramnios and pulmonary hypoplasia. Congenital **hepatic fibrosis** is universally present and may lead to bile duct ectasia, biliary dysgenesis, and portal hypertension. Common clinical features include flank masses, hepatosplenomegaly, hypertension, proteinuria, and/or hematuria. End-stage kidney disease often occurs by early childhood.

Autosomal dominant PKD (ADPKD) occurs in 1 in 400–1,000 individuals, making it the most common inherited kidney disease. ADPKD is characterized by progressive development of kidney cysts, typically beginning in childhood or young adulthood, but can manifest in a small subset during infancy. Most children and adolescents are asymptomatic, and complications such as hypertension, flank pain, and progressive CKD usually develop in adulthood. Extrarenal manifestations include cysts in other organs (most commonly the liver) and cerebral aneurysms. Cystic kidney disease can be a feature of other inherited disorders such as tuberous sclerosis complex, Bardet-Biedl syndrome, and von Hippel-Lindau syndrome.

Abnormal Kidney Position

During normal embryologic development, the kidneys migrate from the pelvis to the renal fossae. Disruption of this process can result in ectopic kidney or fusion anomalies. **Pelvic kidney** is the most common form of ectopic kidney and is usually unilateral. Fusion anomalies involve congenital fusion of the kidneys, usually at the lower poles, with at least one kidney being ectopic. **Horseshoe kidney** is the most common fusion anomaly in which the renal pelvis of both kidneys remains on its respective side of the midline. In **crossed fused ectopia**, one kidney crosses the midline to fuse with the contralateral kidney.

Children with renal ectopy or fusion abnormalities have an increased risk of hydronephrosis, VUR, urinary tract infection (UTI), and kidney stones. However, both conditions are asymptomatic with typically excellent prognosis for the majority of patients.

Abnormal Urinary Tract

Anomalies of the urinary tract may occur anywhere from the renal pelvis to the urethra (Table 168.1). **Urinary tract obstruction (UTO)** is one of the most concerning conditions as severe obstruction can lead to irreversible kidney injury. UTO is most commonly identified as urinary tract dilation (**hydronephrosis** ± hydroureter) on prenatal ultrasound or on evaluation following UTI. Severe prenatal obstruction can interfere with normal development resulting in renal dysplasia; obstruction that develops later in childhood can result in kidney scarring. UTO predisposes to UTI due to urinary stasis.

Hydronephrosis in the absence of UTO is one of the most common forms of CAKUT. Hydronephrosis seen on prenatal ultrasound should be confirmed on postnatal ultrasound at least 48 hours after birth when urine output is well established. If clinically indicated due to signs of kidney dysfunction, ultrasound may be obtained sooner than 48 hours. For patients with moderate to severe hydronephrosis, additional imaging with voiding cystourethrogram (to evaluate for VUR and bladder outlet obstruction) and/or diuretic renogram (to evaluate for UTO such as ureteropelvic junction obstruction) may be considered. Diuretic renogram should usually be delayed until 1 month of age when the glomerular filtration rate is higher. Duplicated (or duplex) renal collecting system is also frequently observed and may involve a complete or more commonly partial duplication. Duplicated collecting systems are commonly benign but may have increased risk for UTO of the upper pole and VUR of the lower pole.

Posterior urethral valves (PUV) are the most common cause of **bladder outlet obstruction** in males. Most affected infants are initially identified by the presence of bilateral urinary tract dilation on prenatal ultrasonography. Prenatal obstruction of the bladder leads to abnormal bladder development. Parents may note a poor urinary stream. PUV commonly results in renal dysplasia, hydronephrosis, VUR, and bladder dysfunction, which can persist after valve ablation.

TABLE 168.1 Urinary Tract Anomalies by Site

SITE	URINARY TRACT ANOMALY
Renal pelvis	Duplicated renal collecting system Hydronephrosis Ureteropelvic junction obstruction
Ureter	Duplicated renal collecting system Megaureter Ectopic ureter Ureterocele
Bladder	Vesicoureteral reflux Bladder diverticulum Bladder/cloacal exstrophy
Urethra	Posterior urethral valves Urethral stricture Hypospadias

PEARLS FOR PRACTITIONERS

*We gratefully acknowledge the invaluable contributions of Rama Jayanthi, MD, Pediatric Urology, Nationwide Children's Hospital, Columbus, Ohio.

CHAPTER 169

Other Urinary Tract and Genital Disorders*

URINARY STONE DISEASE

Etiology

An underlying risk factor for **urolithiasis** can be identified in many children with stones. Risk factors for kidney stones include urinary tract structural abnormalities such as hydronephrosis or an underlying metabolic predisposition. Metabolic risk factors include hypercalciuria (most common), hypocitraturia, hyperoxaluria, uric acid disorders, and cystinuria. Risk factors for primary bladder stones include recurrent urinary tract infection (UTI), neurogenic bladder, and intestinal bladder augmentation.

Clinical Manifestations

Acute obstruction of urine flow occurs when a stone becomes lodged in the urinary tract (commonly at the ureteropelvic junction or the ureterovesical junction) and causes renal colic, a severe sharp intermittent pain in the flank or lower abdomen often radiating to the groin and commonly associated with nausea and vomiting. In younger children, fussiness, abdominal pain, and vomiting may be the only symptoms. Hematuria may be gross or microscopic and typically clears rapidly with passage of stone material. Nonobstructing stones in the kidney are typically asymptomatic and may be identified incidentally on imaging done for other purposes.

Diagnostic Studies

Renal ultrasound is usually the initial test of choice for suspected stones in children. Ultrasound can identify hydronephrosis and most stones in the kidney but can miss very small stones and stones distal to the kidney. Noncontrast helical computed tomography (CT) can identify stones of all sizes throughout the entire urinary tract. Plain abdominal radiography is less sensitive for identifying stones than ultrasound and CT. Chemical analysis of stone material can identify the stone composition and inform the underlying stone etiology. After a child has recovered from an acute stone episode and is back to a typical diet, a 24-hour urine collection (or spot studies if not toilet trained) and blood work can help identify underlying metabolic risk factors for stone formation.

*We gratefully acknowledge the invaluable contributions of Rama Jayanthi, MD, Pediatric Urology, Nationwide Children's Hospital, Columbus, Ohio.

Treatment

Acute treatment of urinary calculi consists primarily of hydration and analgesia. Tamsulosin has been increasingly used with success in older children to promote passage of distal ureteral stones. Surgical intervention by a pediatric urologist may be required for children with large, infected, or obstructing stones. Long-term management is directed at stone prevention with the most important component being vigorous fluid intake, ideally at a rate greater than the usual maintenance volume. Specific metabolic conditions require specific treatments. For children with hypercalciuria, dietary interventions include low sodium and oxalate intake with normal calcium intake. Children with hypercalciuria and recurrent stones despite dietary management may benefit from treatment with thiazide diuretics or potassium citrate. Children with hypocitraturia may benefit from potassium citrate supplementation.

VOIDING DYSFUNCTION

Etiology and Epidemiology

Voiding difficulties are frequent in preschool-aged children due to immature bladder and micturition pathways. Normal voiding patterns and continence rely on urinary tract structural integrity, neurologic maturation, and coordination between somatic and autonomic nervous system units. Daytime continence is usually achieved before nighttime continence. Most children are dry during both day and night by 5–7 years of age. Primary nocturnal enuresis is defined as the involuntary loss of urine during sleep in a child 5 years of age and older who has not had a 6-month span of nighttime continence. Up to 15% of 5-year-old children have primary enuresis with a 15% spontaneous resolution per year. Boys are affected more than girls, and there is a familial predisposition (40% prevalence at 6 years of age if one affected parent, 70% if two affected parents). Secondary enuresis involves loss of nighttime control after an extended period of dryness and generally requires further evaluation.

Clinical Manifestations

Dysfunctional voiding (DV) may manifest as incontinence, frequency, urgency, hesitancy, holding maneuvers, dysuria, lower abdominal pain, or recurrent UTI. Concomitant bowel dysfunction is common including constipation and encopresis. DV symptoms may also be affected by recent UTI or life stressors. Most children with DV are anatomically, neurologically, and psychologically normal.

Diagnostic Studies

Evaluation for DV may be performed at any age, but isolated urinary incontinence in an otherwise normal child is usually not evaluated until 5 years of age. Urinalysis and urine culture should be obtained to exclude occult infection and renal disease. Indications for ultrasound imaging include suspicion of neurologic or urinary tract abnormality, UTI, continuous incontinence, and failure to improve with conservative management. Urodynamic evaluation is typically reserved for children with suspected neurogenic bladder, severe bladder dysfunction with hydronephrosis, urinary tract abnormalities, or DV refractory to treatment.

Treatment

Timed voiding and anticholinergic medications are used to treat sensory defects and bladder hyperactivity. More complicated treatment regimens include biofeedback, α -blockers, and intermittent catheterization. For children with isolated primary nocturnal enuresis, bed-wetting alarms provide safe and effective resolution of enuresis for greater than 70% of affected children. Oral desmopressin may also be considered in selected children with anticholinergics and imipramine less commonly used.

DISORDERS OF THE PENIS

Etiology

Hypospadias occurs in ~1 in 500 newborn infants. In this condition, the urethral folds fail to fuse completely over the urethral groove, leaving the urethral meatus ventral and proximal to its normal position. The ventral foreskin is also lacking, and the dorsal portion gives the appearance of a hood. Severe hypospadias with undescended testes is a form of ambiguous genitalia. Both genetic and environmental factors that interfere with androgenic stimulation have been associated with increased risk for hypospadias. Hypospadias often occurs alone, but in severe cases can be associated with a **chordee** (a fixed ventral curvature of the penile shaft). Rarely, when the urethra opens onto the perineum, the chordee is extreme, the scrotum is bifid and sometimes extends to the dorsal base of the penis. Other urinary tract anomalies are uncommonly associated with hypospadias.

In 90% of uncircumcised males, the foreskin should be retractable by adolescence. Before this age, the prepuce may normally be tight and does not need treatment. After this age, the inability to retract the prepuce is termed **phimosis**. The condition may be congenital or the result of inflammation. **Paraphimosis** occurs when the prepuce has been retracted behind the coronal sulcus, cannot resume its normal position, and causes swelling of the glans or pain.

Clinical Manifestations and Treatment

The meatal opening in **hypospadias** may be located anteriorly (on the glans, coronal, or distal third of the shaft), on the middle third of the shaft, or posteriorly (near the scrotum). Testes are undescended in 10% of boys with hypospadias. Inguinal hernias are common. Males with hypospadias should not be circumcised, particularly if the meatus is proximal to the glans, as the foreskin may be necessary for later repair. Most pediatric urologists repair hypospadias before 18 months of age.

Phimosis is rarely symptomatic. Parents should be reassured that loosening of the prepuce usually occurs during puberty. A topical steroid is used for treatment if needed. If the narrowing is severe, gentle stretching may be useful. Circumcision is reserved for the most severe cases. **Paraphimosis** with venous stasis and edema leads to severe pain. When paraphimosis is discovered early, reduction of the foreskin may be possible with lubrication. In some cases, emergent circumcision is needed.

DISORDERS OF THE SCROTUM AND ITS CONTENTS

Epidemiology

Undescended testes (cryptorchidism) are found in ~1% of boys after 1 year of age. It is more common in full-term newborns

(3.4%) than in older children. In neonates, cryptorchidism is more common with shorter gestation (20% in 2,000- to 2,500-g infants and 100% in <900-g infants). Cryptorchidism is bilateral in 30% of cases. Spontaneous testicular descent tends not to occur after 1 year of age, but failure to find one or both testes in the scrotum does not necessarily indicate undescended testicles. **Retractile testes**, **absent testes**, and **ectopic testes** may resemble cryptorchidism in presentation.

Clinical Manifestations

A history of whether the testis was ever noted in the scrotum, maternal drug use (steroids), and family history are important in the evaluation of a child with apparent cryptorchidism. The true undescended testis is found along the normal embryologic path of descent, usually in the presence of a patent processus vaginalis. An undescended testis is often associated with an inguinal hernia; it is also subject to **torsion**. There is a high incidence of infertility in adulthood. When bilateral and untreated, infertility is uniform. There is increased malignancy risk (five times the normal rate) with undescended testis, usually presenting between 20 and 30 years of age. The risk is greater in untreated males and those who had surgical correction during or after puberty.

Retractile testes are normal testes that retract into the inguinal canal from an exaggerated cremasteric reflex. The diagnosis of retractile testes is likely if testes are palpable in the newborn period but not at later examination. Parents frequently describe seeing their son's testes in his scrotum when he is in the bath and seeing one or both "disappear" when he gets cold.

Complications

Testicular torsion is an emergency requiring prompt diagnosis and treatment to save the affected testis. Torsion accounts for 40% of cases of acute scrotal pain and swelling and is the major cause of the acute scrotum in boys less than 6 years of age. It is thought to arise from abnormal fixation of the testis to the scrotum. On examination, the testicle is swollen and tender, and the cremasteric reflex is absent. The absence of blood flow on nuclear scan or Doppler ultrasound is consistent with torsion.

The differential diagnosis of testicular pain includes trauma, incarcerated hernia, and torsion of the testicular epididymal appendix. Torsion of the appendix testis is associated with point tenderness over the lesion and minimal swelling. In adolescents, the differential diagnosis of testicular torsion also must include **epididymitis**, the most common cause of acute scrotal pain and swelling in older adolescents. Diagnosis is aided by an antecedent history of sexual activity or UTI. Testicular torsion must still be considered as the principal diagnosis when acute severe testicular pain is present.

Treatment

The undescended testis is usually histologically normal at birth. Atrophy and dysplasia are found after the first year of life. Some boys have congenital dysplasia in the contralateral descended testis. Surgical correction at an early age results in greater chance of adult fertility. **Orchidopexy** is usually done in the second year of life. Most extraabdominal testes can be brought into the scrotum with correction of the associated hernia. If the testis is not palpable, ultrasound or magnetic resonance imaging may determine its location. The closer the

testis is to the internal inguinal ring, the better the chance of successful orchidopexy.

If surgical correction of testicular torsion is performed within 6 hours of torsion, there is greater than 90% chance of testicular salvage. The contralateral testis usually is fixed to the scrotum to prevent possible torsion. If torsion of the appendix is found, the necrotic tissue is removed.

PEARLS FOR PRACTITIONERS

CHAPTER 161

Nephrology and Urology Assessment

- The kidneys have many important functions including maintaining fluid and electrolyte balance, excreting metabolic waste products, and producing hormones.
- The clinical presentation of renal and urologic disease will be affected by many factors including type of disorder, severity, chronicity, and age with characteristic findings on blood, urine, and imaging studies.
- Fetal urine production contributes to amniotic fluid volume, lung maturation, and somatic development; reduced (oligohydramnios) or increased amniotic fluid volume (polyhydramnios) may be a sign of a congenital renal disorder.
- Glomerular filtration rate (GFR) is normally low in newborns infants (~40 mL/min/1.73 m²), and it takes up to 2 years of age to develop adult levels of GFR (100–120 mL/min/1.73 m²).
- The revised bedside Schwartz formula [$GFR = 0.413 \times Ht \text{ (cm)}/\text{serum Cr (mg/dL)}$] can be used to estimate GFR in children.

CHAPTER 162

Nephrotic Syndrome and Proteinuria

- Urine protein is best quantified by a spot urine protein/creatinine (U_{Pr}/Cr) ratio. U_{Pr}/Cr ratio <0.2 mg/mg is normal, between 0.2 and 2 mg/mg indicates mild to moderate proteinuria, and >2 mg/mg indicates severe (nephrotic range) proteinuria.
- Nephrotic syndrome (NS) is characterized by persistent severe proteinuria (mainly albuminuria; >40 mg/m²/hr), hypoalbuminemia (serum albumin <3 g/dL), edema, and hypercholesterolemia (>250 mg/dL).
- Primary forms of NS include minimal change nephrotic syndrome (MCNS; most common form of childhood NS),

focal segmental glomerulosclerosis, membranous nephropathy, and hereditary NS. In addition, nephrotic syndrome may be secondary to other types of glomerulonephritis.

- For the child with likely MCNS (presentation between 2 and 12 years of age, no signs of systemic disorder, minimal hematuria, normal GFR, and normal C3 complement), a corticosteroid trial is warranted.
- Complications of childhood NS include poor growth, episodes of acute kidney injury, serious bacterial infections, thrombi and thromboembolism, and chronic kidney disease.

CHAPTER 163

Glomerulonephritis and Hematuria

- Hematuria may originate from glomerular, tubulointerstitial, or lower urinary tract disorders.
- Cardinal features of glomerulonephritis (GN) include hematuria, proteinuria, decreased renal function, hypertension, oliguria, and/or edema.
- Postinfectious GN is the most common form of acute GN, while immunoglobulin A (IgA) nephropathy is the most common form of chronic GN in children.
- Hypocomplementemia (low C3) characterizes acute postinfectious GN, membranoproliferative GN, and lupus nephritis; all other causes of GN have normal C3 complement.

CHAPTER 164

Hemolytic Uremic Syndrome

- Hemolytic uremic syndrome (HUS) is characterized by the triad of microangiopathic hemolytic anemia, thrombocytopenia, and acute kidney injury.

- The most common type of HUS is associated with Shiga toxin-producing *Escherichia coli* (STEC-HUS) due to contamination of meat, fruit, vegetables, or water (most commonly with *E. coli* O157:H7) and is most common in children <5 years of age.
- Other causes of HUS include infections, disorders of complement regulation, medications, malignancy, systemic lupus erythematosus, and pregnancy.
- Children with HUS can become critically ill with high risk for needing acute kidney support therapy and red blood cell transfusion.

CHAPTER 165

Acute Kidney Injury and Chronic Kidney Disease

- Acute kidney injury (AKI) may be oliguric or nonoliguric and can be classified as prerenal (renal hypoperfusion), intrinsic renal (tubular, glomerular, or vascular injury), or postrenal (urinary tract obstruction).
- The most common causes of CKD in children are congenital anomalies of the kidney and urinary tract and glomerular disorders.
- Complications of CKD in children include poor growth, anemia, CKD-mineral bone disorder, cardiovascular issues (hypertension, left ventricular hypertrophy), metabolic acidosis, and electrolyte disturbances (Na, K, Ca, P).
- Indications for acute dialysis in children include volume overload, metabolic acidosis, electrolyte abnormalities, severe uremia, certain ingestions, and metabolic disorders (e.g., hyperammonemia); indications for chronic dialysis include all of the above, poor growth due to chronic kidney disease (CKD), and stage 5 CKD due to its significant risks of serious complications.

CHAPTER 166

Hypertension

- Hypertension (HTN) in children is most frequently primary (essential) with secondary forms less common; the most common secondary cause in children is kidney disease.
- Blood pressure (BP) can be classified into categories of normal, elevated BP, stage 1 HTN, and stage 2 HTN.
- Evaluation of children with HTN includes studies to evaluate for underlying secondary causes, co-morbidities (lipids, fasting glucose, uric acid), and evidence of target organ damage (echocardiogram).
- Treatment of HTN includes therapeutic lifestyle changes ± antihypertensive medications.

CHAPTER 167

Vesicoureteral Reflux

- Primary vesicoureteral reflux (VUR) results from congenital incompetence of the ureterovesical (UV) junction and often resolves with growth.
- VUR secondary to urinary tract anomalies is less likely to self-resolve.
- The most common clinical manifestation of VUR is febrile UTI.
- VUR is identified by a voiding cystourethrogram study.
- VUR may be managed with surveillance, medical therapy, and surgical intervention.
- Reflux nephropathy refers to development and progression of renal scarring associated with VUR and febrile UTI; the incidence is higher in children with recurrent UTI.

CHAPTER 168

Congenital and Developmental Abnormalities of the Urinary Tract

- Congenital anomalies of the kidneys and urinary tract (CAKUT) occur in up to 4% of infants.
- The two most common forms of CAKUT are hydronephrosis in the absence of urinary tract obstruction and duplicated renal collecting system.
- CAKUT also includes renal agenesis, renal hypoplasia/dysplasia, multicystic dysplastic kidney, polycystic kidney disease, ectopic kidney, fused kidneys, and urinary tract obstruction. These disorders often result in abnormal kidney function.

CHAPTER 169

Other Urinary Tract and Genital Disorders

- In childhood urinary stone disease, kidney stones result from a urinary tract structural abnormality or an underlying metabolic predisposition.
- The most common metabolic risk factor for urinary stone disease is hypercalciuria.
- Renal ultrasound is the initial test of choice for diagnosing urinary stone disease.
- Most children are dry during both day and night by 5–7 years of age; primary nocturnal enuresis is common.
- Cryptorchidism is associated with increased risk of infertility. Orchidopexy is usually performed during the second year of life.
- Testicular torsion is a urologic emergency and must be identified and treated quickly (ideally within 6 hours) to salvage the testis.

ENDOCRINOLOGY

Paola Palma Sisto | Mary Kathleen Heneghan

CHAPTER 170

Endocrinology Assessment

Endocrinology is the study of unique chemical messengers known as hormones, their impact on normal physiologic processes, and their effect on morbidity from the pathologic effects of their production, action, and hormone signaling in disease states. Classically, hormones are produced in a regulated fashion in one cell, then travel through the bloodstream, often bound to binding factors, to a target cell. Then, hormones either bind to receptors on the plasma membranes of target cells or are transported into cells to bind to intracellular receptors. The target cell has its own

influence on its hormonal regulatory response. Hormones generally are regulated in a feedback loop so that the production of a hormone is linked to its effect or its circulating concentration.

Hormone action also may be **paracrine** (acting on adjacent neighboring cells to the cell of origin of the hormone). The regulation of hormone signaling is tightly controlled and differs between endocrine and paracrine effect and continues to be unraveled with further research (Fig. 170.1). Endocrine disorders generally manifest in one of four ways:

1. By **hormone overproduction**: For example, there is an excess of glucocorticoid present in Cushing syndrome; if the excess is secondary to autonomous glucocorticoid secretion by the adrenal gland, the trophic hormone adrenocorticotrophic hormone (ACTH) is suppressed.

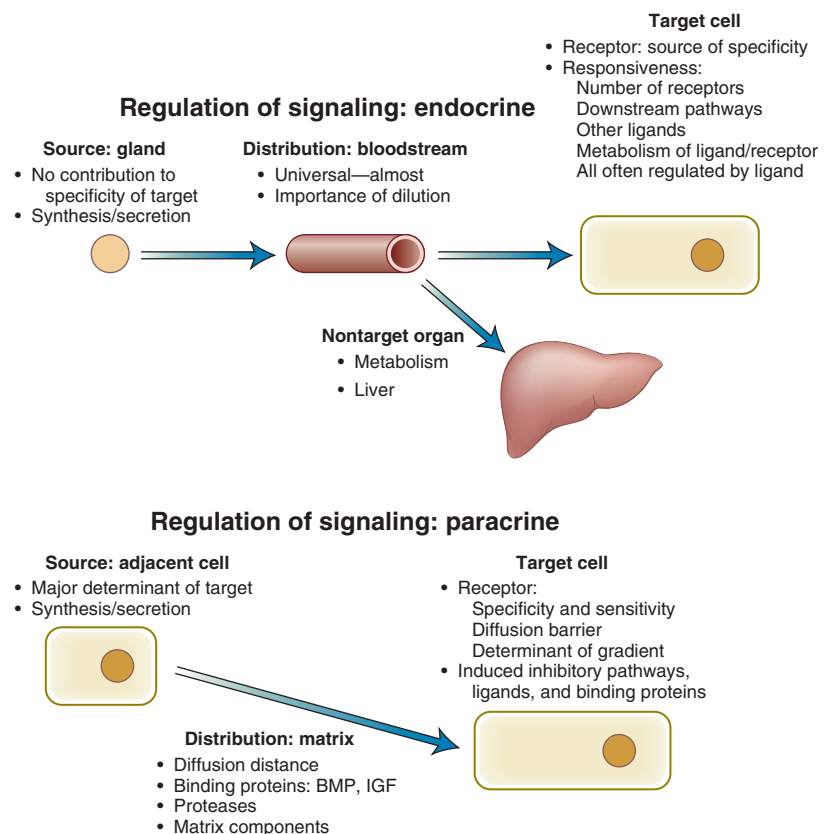

FIGURE 170.1 Comparison of determinants of endocrine and paracrine signaling. *BMP*, Bone morphogenetic protein; *IGF*, insulin-like growth factor. (From Melmed S, Auchus RJ, Goldfine AB, et al. Principles of endocrinology. In: Melmed S, Auchus RJ, Goldfine AB, et al., eds. *Williams Textbook of Endocrinology*. 14th ed. Philadelphia: Elsevier; 2020 [fig. 1.1].)

2. By **hormone underproduction**: For example, there is a reduced production of thyroid hormone caused by autoimmune destruction of thyroid cells in autoimmune hypothyroidism.
3. By an **abnormal response of end-organ** to hormone: For example, defects in the gene (*GNAS1*) encoding the α subunit of the stimulatory G protein (G_s) is manifested by elevated parathyroid hormone (PTH) levels in the face of deficient PTH function (PTH resistance) in pseudohypoparathyroidism.
4. By pathologic **gland enlargement** that may have effects as a result of size rather than function: For example, a large non-functioning pituitary adenoma may compress surrounding tissue, leading to abnormal visual fields and other neurologic signs and symptoms even though the tumor produces no hormone.

Peptide hormones act through specific cell membrane receptors; when the hormone is attached to the receptor, the complex triggers various intracellular second messengers that cause the biologic effects. Peptide hormone receptor number and avidity may be regulated by hormones. **Steroid hormones** exert their effects by attachment to intranuclear receptors. The hormone-receptor complex translocates to the nucleus where it binds with DNA and leads to further gene activation.

The interpretation of serum hormone levels must be related to their regulating factors. For example, a given value of

parathyroid hormone may be normal in a eucalcemic patient but inadequate in a hypocalcemic patient with partial hypoparathyroidism or excessive in a hypercalcemic patient with hyperparathyroidism.

HYPOTHALAMIC-PITUITARY AXIS

The hypothalamus is one of the most critical regions of the mammalian brain. Its essential role in homeostasis comes from its ability to organize coordinated endocrine, autonomic, and behavioral responses. The hypothalamus receives sensory information from both external and internal factors. In turn, the hypothalamus is modulated by a number of factors, including hormones, which can exert both negative and positive feedback. The median eminence is the region that connects the hypothalamus and the anterior pituitary gland. Its location in the center of the tuber cinereum and extensive blood vessels allow direct connections between the hypothalamus and pituitary gland. The pituitary glands, composed of anterior and posterior regions, produce a number of hormones that are released and exert effects on their target glands. The pituitary gland is regulated by the hypothalamus through releasing factors formed in the hypothalamic neurosecretory neurons, through positive and negative feedback of hormones themselves as well as both paracrine and autocrine factors of the pituitary itself (Fig. 170.2).

FIGURE 170.2 Hormonal influences of the hypothalamus and pituitary gland. Solid line represents stimulatory influence; dotted line represents inhibitory influence. ACTH, Adrenocorticotropic hormone; CRH, corticotropin-releasing hormone or CRF; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, GH-releasing hormone or GRF; GnRH, gonadotropin-releasing hormone or luteinizing hormone releasing factor, LRF or LHRH; LH, luteinizing hormone; SRIF, somatotropin release-inhibiting factor, somatostatin or SS; TRH, thyrotropin-releasing hormone or TRF; TSH, thyroid-stimulating hormone; T₃, triiodothyronine; T₄, thyroxine.

TABLE 170.1 Diagnostic Evaluation for Hypopituitarism

MANIFESTATION	CAUSE	TESTS*
Growth failure, hypothyroidism, or both	GH deficiency, TRH/TSH deficiency, or both	Provocative GH tests, free T ₄ , bone age, IGF-1, IGF-BP3
Hypoglycemia	GH deficiency, ACTH insufficiency, or both	Provocative GH tests, test of ACTH secretion, IGF-1, IGF-BP3
Micropenis, pubertal delay or arrest	Hypogonadotropic hypogonadism with or without GH deficiency	Sex steroids (E ₂ , testosterone), basal LH and FSH (analyzed by ultrasensitive assays) or after LHRH administration, provocative GH tests, IGF-1, IGF-BP3
Polyuria, polydipsia	ADH deficiency	Urine analysis (specific gravity), serum electrolytes, urine and serum osmolality, water deprivation test

*Each patient with hypopituitarism should have CNS MRI as part of evaluation to determine the etiology of the condition.

ACTH, Adrenocorticotropic hormone; ADH, Antidiuretic hormone; CNS, central nervous system; E₂, estradiol; FSH, follicle-stimulating hormone; GH, growth hormone; IGF-1, insulin-like growth factor 1; IGF-BP3, insulin-like growth factor-binding protein 3; LH, luteinizing hormone; LHRH, luteinizing hormone releasing hormone; MRI, magnetic resonance imaging; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; T₄, thyroxine.

TABLE 170.2 Anterior Pituitary Hormone Function Testing

RANDOM HORMONE MEASUREMENTS	PROVOCATIVE OR OTHER TESTS	TARGET HORMONE MEASUREMENT
GH (not useful as a random determination except in newborns, and in GH resistance or in pituitary gigantism)	Arginine (a weak stimulus) L-Dopa (useful clinically) Insulin-induced hypoglycemia (a dangerous but accurate test) Clonidine (useful clinically) GHRH 12- to 24-hr integrated GH levels (of questionable utility)	IGF-1, IGF-BP3 (affected by malnutrition as well as GH excess)
ACTH (early-morning sample useful only if in high-normal range)	Cortisol after insulin-induced hypoglycemia (a dangerous but accurate test) ACTH stimulation test (may differentiate ACTH deficiency from primary adrenal insufficiency)	8 A.M. cortisol 24-hr urinary free cortisol
TSH*	TRH (not commonly performed)	FT ₄
LH, FSH*	GnRH (difficult to interpret in prepubertal subjects)	Testosterone/estradiol
Prolactin (elevated in hypothalamic disease and decreased in pituitary disease)	TRH (not commonly performed)	None

*New supersensitive assays allow determination of abnormally low values found in hypopituitarism.

ACTH, Adrenocorticotropic hormone; FSH, follicle-stimulating hormone; FT₄, free thyroxine; GH, growth hormone; GHRH, growth hormone-releasing hormone; LH, luteinizing hormone; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

The assessment of pituitary function is determined by measuring some of the specific pituitary hormone in the basal state; other assessments require the measurement after stimulation. Indirect assessment of pituitary function can be obtained by measuring serum concentrations of the target gland hormones (Table 170.1). Several tests of pituitary function are listed in Table 170.2.

DISORDERS OF THE HYPOTHALAMIC-PITUITARY AXIS

Disorders of pituitary dysfunction arise from a number of causes. Structural defects in hypothalamic and/or pituitary

regions of the brain, whether congenital malformations of the brain (genetic causes such as optic nerve hypoplasia or brain development defects as in holoprosencephaly) or acquired such as through surgical interventions for tumors, are rare causes of hypopituitarism. Acquired conditions that can cause pituitary insufficiency include pituitary tumors such as craniopharyngioma, parasellar masses, hypophysitis, aneurysms, and pituitary apoplexy. Other conditions that can cause pituitary insufficiency include infiltrative processes (Langerhans cell histiocytosis, lymphoma, and sarcoidosis) and CNS radiation therapy, or as a consequence of autoimmunity against the pituitary gland.

Congenital hypopituitarism is more commonly caused by genetic defects at each level of pituitary function, including hormones, receptors, and transcription factors that determine anterior pituitary development. In addition, mutations in specific genes that produce growth hormone, Pro-opiomelanocortin, thyroid stimulating hormone, leuteinizing hormone, and follicle stimulating hormone can lead to single hormone deficiencies.

The magnetic resonance imaging findings of congenital hypopituitarism may include an ectopic posterior pituitary gland *bright spot*, the appearance of a *pituitary stalk transection*, and/or a small pituitary gland.

PEARLS FOR PRACTITIONERS

See *Endocrinology: Pearls for Practitioners* at the end of this section.

CHAPTER 171

Diabetes Mellitus

Diabetes mellitus (DM) is characterized by hyperglycemia and glycosuria and is an end-point of a few disease processes (Table 171.1). The most common type occurring in childhood is type 1 DM (T1D), which is caused by autoimmune destruction of the insulin-producing β cells (islets) of the pancreas, leading to permanent insulin deficiency. Type 2 DM (T2D) results from insulin resistance and relative insulin deficiency, usually in the context of exogenous obesity. The incidence of T1D and T2D in the United States is increasing. Less common types of diabetes result from genetic defects of the insulin receptor or inherited abnormalities in sensing of ambient glucose concentration by pancreatic β cells (see Table 171.1).

DEFINITION

A **diagnosis** of DM is made based on four glucose abnormalities that may need to be confirmed by repeat testing: (1) fasting serum glucose concentration of 126 mg/dL or above, (2) a random venous plasma glucose of 200 mg/dL or above with symptoms of hyperglycemia, (3) an abnormal oral glucose tolerance test (OGTT) with a 2-hour postprandial serum glucose concentration of 200 mg/dL or above, and (4) a hemoglobin A_{1c} (HbA_{1c}) of 6.5% or above.

A patient is considered to have **impaired fasting glucose** if fasting serum glucose concentration is 100–125 mg/dL or **impaired glucose tolerance** if 2-hour plasma glucose following an OGTT is 140–199 mg/dL. Sporadic hyperglycemia can occur in children, usually in the setting of an intercurrent illness. When the hyperglycemic episode is clearly related to an illness or other physiologic stress, the probability of incipient diabetes is small (<5%).

TYPE 1 DIABETES MELLITUS

Etiology

T1D results from the autoimmune destruction of insulin-producing β cells (islets) of the pancreas. In addition to the presence of diabetes susceptibility genes, an unknown

TABLE 171.1 Classification of Diabetes Mellitus in Children and Adolescents

TYPE	COMMENT
TYPE 1 (INSULIN DEPENDENT)	
Transient neonatal	Manifests immediately after birth; lasts 1–3 mo
Permanent neonatal	Other pancreatic defects possible
Classic type 1	Glycosuria, ketonuria, hyperglycemia, islet cell positive; genetic component
TYPE 2 (NON-INSULIN DEPENDENT)	
Secondary	Cystic fibrosis, hemochromatosis, drugs (L-asparaginase, tacrolimus)
Adult type (classic)	Associated with obesity, insulin resistance; genetic component
OTHER	
Gestational diabetes	Abnormal glucose tolerance during pregnancy only, which reverts to normal postpartum; increased risk for later onset of diabetes
Maturity-onset diabetes of youth	Autosomal dominant, onset before age 25 yr; not associated with obesity or autoimmunity
Mitochondrial diabetes	Single-gene mutations include hepatocyte nuclear factors 1 β , 1 α , 4 α ; glucokinase; insulin promoter factor 1 Associated with deafness and other neurologic defects, maternal transmission—mtDNA point mutations

environmental insult presumably triggers the autoimmune process. A variety of studies have produced conflicting data regarding a host of environmental factors. These include cow's milk feeding at an early age, viral infectious agents (coxsackievirus, enterovirus, cytomegalovirus, mumps, rubella), vitamin D deficiency, and perinatal factors. T1D is thought to be primarily a T-cell-mediated disease.

Antibodies to islet cell antigens may be seen months to years before the onset of β dysfunction (Fig. 171.1). These include islet cell antibodies; insulin autoantibodies; and antibodies to insulinoma-associated protein 2 (IA-2), glutamic acid decarboxylase (GAD), Zn Transporter 8 (ZnT8), among others. The risk for diabetes increases with the number of antibodies detected in the serum. In individuals with only one detectable antibody, the risk is only 10–15%, while in individuals with three or more antibodies the risk is 55–90%. When 80–90% of the β -cell mass has been destroyed, the remaining β -cell mass is insufficient to maintain euglycemia, and clinical manifestations of diabetes result (see Fig. 171.1).

Epidemiology

The annual incidence of T1D is increasing steadily with significant geographic differences. In the United States, the annual incidence is approximately 20 in 100,000. The annual incidence in children ranges from a high of 40 in 100,000 among Scandinavian populations to less than 1 in 100,000 in

FIGURE 171.1 Schematic representation of the autoimmune evolution of diabetes in genetically predisposed individuals.

China. The prevalence of T1D in the United States is highest in non-Hispanic Whites followed by Blacks, Hispanics, and American Indians.

No overall gender difference in incidence exists. There is a peak at 4–6 years of age and a second peak at about 10–14 years of age. While genetic determinants play a role in the susceptibility to T1D, the mode of inheritance is complex and multigenic. With no family history of T1D, there is about a 0.4% risk; siblings or offspring of patients with diabetes have a risk of 2–8% for the development of diabetes; an identical twin has a 30–50% risk. The human leukocyte antigen (HLA) region on chromosome 6 provides the strongest determinant of susceptibility, accounting for approximately 40% of familial inheritance of T1D. Specific class II DR and DQ HLA alleles (HLA DR3 and HLA DR4) increase the risk of developing T1D, whereas other specific HLA alleles exert a protective effect. More than 90% of children with T1D possess HLA DR3 alleles, HLA DR4 alleles, or both. The insulin gene region variable number tandem repeat on chromosome 11 is also linked to T1D susceptibility. There is evidence for association, beyond HLA, of more than 100 other loci with T1D. Genetic factors do not fully account for susceptibility to T1D; environmental factors also play a role.

T1D is also associated with celiac disease and other autoimmune or inflammatory polyendocrinopathies such as IPEX (immune dysregulation, polyendocrinopathy, enteropathy X-linked) syndrome.

Clinical Manifestations

Hyperglycemia results when insulin secretory capacity becomes inadequate to enhance peripheral glucose uptake and to suppress hepatic and renal glucose production. Insulin deficiency usually first causes postprandial hyperglycemia and then fasting hyperglycemia. Ketogenesis is a sign of more complete insulin deficiency. Lack of suppression of gluconeogenesis and glycogenolysis further exacerbates hyperglycemia, while fatty acid oxidation generates the

ketone bodies: β -hydroxybutyrate, acetoacetate, and acetone. Protein stores in muscle and fat stores in adipose tissue are metabolized to provide substrates for gluconeogenesis and fatty acid oxidation.

The classic presentation of T1D includes polyuria, polydipsia, polyphagia, and weight loss. Glycosuria occurs when the serum glucose concentration exceeds the renal threshold for glucose reabsorption (from 160–190 mg/dL). Glycosuria causes an osmotic diuresis (including obligate loss of sodium, potassium, and other electrolytes) leading to dehydration. Polydipsia occurs as the patient attempts to compensate for the excess fluid losses. Weight loss results from the persistent catabolic state and the loss of calories through glycosuria and ketonuria.

DIABETIC KETOACIDOSIS

If the clinical features of new-onset T1D are not detected, **diabetic ketoacidosis (DKA)** will occur. DKA may also occur in patients with known T1D if insulin injections are omitted or during an intercurrent illness when greater insulin requirements are unmet in the presence of elevated concentrations of the counter-regulatory and stress hormones (glucagon, growth hormone [GH], cortisol, and catecholamines). DKA can be considered present if (1) the arterial pH is below 7.3, (2) the serum bicarbonate level is below 15 mEq/L, and (3) ketones are elevated in serum or urine.

Pathophysiology

In the absence of adequate insulin secretion, persistent partial hepatic oxidation of fatty acids to ketone bodies occurs. Two of these three ketone bodies are organic acids and lead to metabolic acidosis with an elevated anion gap. Lactic acid may contribute to the acidosis when severe dehydration results in decreased tissue perfusion. Hyperglycemia causes an osmotic diuresis that is initially compensated for by increased fluid intake. As the hyperglycemia and diuresis worsen, most patients are unable to maintain the large fluid

FIGURE 171.2 Pathophysiology of diabetic ketoacidosis.

intake and thus dehydration occurs. Vomiting and increased insensible water losses caused by tachypnea can worsen the dehydration. Electrolyte abnormalities occur through a loss of electrolytes in the urine and transmembrane alterations resulting from acidosis. As hydrogen ions accumulate as a result of ketoacidosis, intracellular potassium is exchanged for hydrogen ions. Serum concentrations of potassium increase initially with acidosis then decrease as serum potassium is cleared by the kidney. Depending on the duration of ketoacidosis, serum potassium concentrations at diagnosis may be increased, normal, or decreased, but intracellular potassium concentrations are depleted. A decreased serum potassium concentration is an ominous sign of total body potassium depletion. Phosphate depletion also can occur as a result of the increased renal phosphate excretion required for elimination of excess hydrogen ions. Sodium depletion is also common in ketoacidosis resulting from renal losses of sodium caused by osmotic diuresis and from gastrointestinal losses from vomiting (Fig. 171.2).

Clinical Presentation

Patients with DKA present initially with polyuria, polydipsia, nausea, and vomiting. Abdominal pain occurs frequently and can mimic an acute abdomen. The abdomen may be tender from vomiting or distended secondary to a paralytic ileus. The presence of polyuria, despite a state of clinical dehydration, indicates osmotic diuresis and differentiates patients with DKA from patients with gastroenteritis or other gastrointestinal disorders. Respiratory compensation for acidosis results in tachypnea with deep (**Küssmaul**) respirations. The *fruity* odor of acetone frequently can be detected on the patient's breath. An altered mental status can occur, ranging from disorientation to coma.

Laboratory studies reveal hyperglycemia (serum glucose concentrations ranging from 200 mg/dL to >1,000 mg/dL).

Arterial pH is below 7.30, and serum bicarbonate concentration is less than 15 mEq/L. Serum sodium concentrations may be elevated, normal, or low, depending on the balance of sodium and free water losses. The measured serum sodium concentration is artificially low, however, because of hyperglycemia. The corrected Na can be calculated using the equation: $\text{Corrected Na} = \text{measured Na} + [1.6(\text{glucose} - 100)/100]$. Hyperlipidemia also contributes to the decrease in measured serum sodium. The level of blood urea nitrogen (BUN) can be elevated with prerenal azotemia secondary to dehydration. The white blood cell count is usually elevated and can be left-shifted without implying the presence of infection. Fever is unusual and should prompt a search for infectious sources that may have triggered the episode of DKA.

Treatment

Therapy for patients with DKA involves careful replacement of fluid deficits, correction of acidosis and hyperglycemia via insulin administration, correction of electrolyte imbalances, and monitoring for complications of treatment. The optimal approach to management of DKA must strike a balance between adequate correction of fluid losses and avoidance of rapid shifts in osmolality and fluid balance. The most serious complication of DKA and its treatment is **cerebral edema** and cerebral herniation.

A patient with severe DKA is assumed to be approximately 10% dehydrated. If a recent weight measurement is available, the precise extent of dehydration can be calculated. An initial intravenous (IV) fluid bolus of a glucose-free isotonic solution (normal saline, lactated Ringer solution) at 10–20 mL/kg should be given to restore intravascular volume and renal perfusion. The remaining fluid deficit after the initial bolus should be added to maintenance fluid requirements; the total should be replaced slowly over 36–48 hours. Ongoing losses resulting

from osmotic diuresis usually do not need to be replaced unless urine output is large or signs of poor perfusion are present. Osmotic diuresis is usually minimal when the serum glucose concentration decreases to less than 300 mg/dL. To avoid rapid shifts in serum osmolality, 0.9% sodium chloride can be used as the replacement fluid for the initial 4–6 hours, followed by 0.45% sodium chloride.

Hyperglycemia

Fast-acting soluble insulin should be administered as a continuous IV infusion (0.1 U/kg/hr). Serum glucose concentrations should decrease at a rate no faster than 100 mg/dL/hr. When serum glucose concentrations decrease to less than 250–300 mg/dL, glucose should be added to the IV fluids. If serum glucose concentrations decrease to less than 200 mg/dL before correction of acidosis, the glucose concentration of the IV fluids should be increased, but the insulin infusion should not be decreased by more than half, and it should never be discontinued before resolution of acidosis.

Acidosis

Insulin therapy decreases the production of free fatty acids and protein catabolism and enhances glucose usage in target tissues. These processes correct acidosis. Bicarbonate therapy should be avoided. Potential adverse effects of bicarbonate administration include paradoxical increases in central nervous system (CNS) acidosis caused by increased diffusion of carbon dioxide across the blood-brain barrier, potential tissue hypoxia caused by shifts in the oxyhemoglobin dissociation curve, abrupt osmotic changes, and increased risk of the development of cerebral edema.

As acidosis is corrected, urine ketone concentrations may appear to rise. β -hydroxybutyrate, which is not detected in urine ketone assays, is converted with treatment to what the assay most detects, acetoacetate. Hence, minute-to-minute urine ketone concentrations are not a required index of the adequacy of therapy.

Electrolyte Imbalances

Regardless of the serum potassium concentration at presentation, total body potassium depletion is likely. Serum potassium concentrations can decrease rapidly as insulin, and then glucose therapy improves acidosis, and potassium is exchanged for intracellular hydrogen ions. When adequate urine output is shown, potassium should be added to the IV fluids. Potassium replacement should be given as 50% potassium chloride and 50% potassium phosphate at a concentration of 20–40 mEq/L. This combination provides phosphate for replacement of deficits, but avoids excess phosphate administration, which may precipitate hypocalcemia. If the serum potassium level is greater than 6 mEq/L, potassium should not be added to IV fluids until the potassium level decreases.

Monitoring

Initial laboratory measurements should include serum glucose, sodium, potassium, chloride, bicarbonate, BUN, creatinine, calcium, phosphate, and magnesium concentrations; arterial or venous pH; and a urinalysis. Serum glucose measurement should be repeated every hour during therapy, and electrolyte concentrations should be repeated every 2–3 hours. Calcium, phosphate, and magnesium concentrations should be measured every 4–6 hours during therapy. Neurologic

and mental status should be assessed at frequent intervals. Any complaints of headache or deterioration of mental status should prompt rapid evaluation for possible **cerebral edema**. Symptoms indicative of possible cerebral edema include a decreased sensorium, sudden severe headache, vomiting, change in vital signs (bradycardia, hypertension, apnea), a dilated pupil, ophthalmoplegia, or seizure.

Complications

Clinically apparent **cerebral edema** occurs in 1–5% of cases of DKA. Cerebral edema is the most serious complication of DKA, with a significant mortality rate. The pathogenesis of cerebral edema likely involves osmolar shift resulting in fluid accumulation in the intracellular compartment and neuronal cell swelling. Subclinical cerebral edema is common in children with DKA, although the factors that exacerbate this process leading to symptomatic brain swelling and possible cerebral herniation are not clearly defined. Cerebral edema typically occurs 6–12 hours after therapy for DKA is begun, often following a period of apparent clinical improvement. Factors that correlate with increased risk for cerebral edema include higher initial BUN concentration, lower initial PCO_2 , failure of the serum sodium concentration to increase as glucose concentration decreases during treatment, and treatment with bicarbonate.

Signs of advanced cerebral edema include obtundation, papilledema, pupillary dilation or inequality, hypertension, bradycardia, and apnea. **Treatment** involves the rapid use of IV mannitol, endotracheal intubation, and ventilation and may require the use of a subdural bolt. Other complications of DKA are intracranial thrombosis or infarction, acute kidney injury with acute renal failure caused by severe dehydration, pancreatitis, arrhythmias caused by electrolyte abnormalities, pulmonary edema, and bowel ischemia. Peripheral edema occurs commonly 24–48 hours after therapy is initiated and may be related to residual elevations in antidiuretic hormone and aldosterone.

Transition to Outpatient Management

When the acidosis has been corrected and the patient tolerates oral feedings, the IV insulin infusion can be discontinued, and a regimen of subcutaneous (SC) insulin injections can be initiated. The first SC insulin dose should be given 30–45 minutes before discontinuation of the IV insulin infusion. Further adjustment of the insulin dose should be made over the following 2–3 days. A patient already diagnosed with T1D may be restarted on the prior doses if they were adequate. For a patient with new-onset T1D, typical starting total daily doses are approximately 0.5–0.7 U/kg per 24 hours for prepubertal patients and approximately 0.7–1 U/kg per 24 hours for adolescents, using any number of the available insulin combinations. The best and most common choice for making the transition to SC insulin is to begin by giving injections of fast-acting (bolus) insulin (lispro, aspart, or glulisine insulin) with each meal and long-acting (basal) insulin (glargine, detemir, or degludec) at bedtime. This regimen of multiple daily injections provides the most flexibility but requires the patient to administer many injections per day and to count carbohydrates in food. An alternative is a fixed mixed split dosing regimen (neutral protamine Hagedorn [NPH] and fast-acting insulin) with two daily injections.

Externally worn pumps that provide a continuous SC infusion of fast-acting insulin are available, although not usually used at the very onset of T1D. Insulin pumps provide fast-acting insulin in small basal amounts continuously every hour and will provide bolus insulin when instructed. Insulin pumps may be used by all age groups who are highly motivated to achieve tight control. The absence of SC depot insulin (glargine or detemir) (if medication runs out or the pump stops) can increase the risk of DKA.

Serum glucose concentrations should be assessed before each meal, at bedtime, and periodically at 2–3 A.M. to provide information for adjustment of the regimen. Patients and their families should begin learning the principles of diabetes care as soon as possible. Demonstration of the ability to administer insulin injections and test glucose concentrations using a glucose meter is necessary before discharge, as is knowledge of hypoglycemia management. Meal planning is crucial to control glucose in T1D. Nutrition services must be part of the care delivered to the families from diagnosis.

Honeymoon Period

In some patients with new onset of T1D, the β -cell mass has not been completely destroyed. The remaining functional β cells seem to recover function with insulin treatment. When this occurs, exogenous insulin requirements decrease. This is a period of stable blood glucose control, often with nearly normal glucose concentrations. This phase of the disease, known as the honeymoon period, usually starts in the first weeks of therapy, often continues for 3–6 months, and can last 2 years.

Outpatient Type 1 Diabetes Mellitus Management

Management of T1D in children requires a comprehensive approach with attention to medical, nutritional, and psychosocial issues. Therapeutic strategies should be flexible with the individual needs of each patient and the family taken into account. Optimal care involves a team of diabetes professionals, including a physician, a diabetes nurse educator, a dietitian, and a social worker or psychologist.

Goals

The Diabetes Control and Complications Trial established that intensive insulin therapy, with the goal of maintaining blood glucose concentrations as close to normal as possible, can delay the onset and slow the progression of complications of diabetes (retinopathy, nephropathy, neuropathy). Attaining this goal using intensive insulin therapy can increase the risk of hypoglycemia. The adverse effects of hypoglycemia in young children may be significant because the immature CNS may be more susceptible to glycopenia. Although the risk for diabetic complications increases with duration of diabetes, there is controversy as to whether the increase of risk is lower in the prepubertal years than in adolescence and adulthood.

Given the benefits of stable, near normal blood glucose concentrations, a goal of HbA_{1c} below 7.5% is set for children of all ages. Preprandial blood glucose target concentrations are 90–130 mg/dL and concentrations before bedtime and overnight of 90–150 mg/dL. Goals of therapy need to take into account other individual characteristics, such as a past history of severe hypoglycemia and the abilities of the patient and family.

Insulin Regimens

Many types of insulin differ in duration of action and time to peak effect (Table 171.2). These insulins can be used in various combinations, depending on the needs and goals of the individual patient. The most commonly used regimen is that of multiple injections of fast-acting insulin given with meals in combination with long-acting basal insulin given at bedtime. This regimen provides flexibility but requires administration of many injections per day and will require assistance for young children. After the total daily dose of insulin is determined, 30–50% is given as long-acting insulin, and the remainder is given as fast-acting insulin, divided according to the need for corrections of high glucose levels and for meals. To correct for hyperglycemia, one can determine the insulin sensitivity using the 1,800/1,500 rule: dividing 1,800 (or 1,500) by the total daily dose of insulin to determine how many milligrams per deciliter of glucose will decrease with one unit of insulin. The insulin:carbohydrate ratio is used to calculate insulin for the

TABLE 171.2 Representative Profiles of Insulin

INSULIN	ONSET	PEAK ACTION	DURATION
VERY SHORT ACTING			
Lispro, aspart, glulisine	5–15 min	30–90 min	3–5 hr
SHORT ACTING			
Regular	30–60 min	2–3 hr	5–8 hr
INTERMEDIATE ACTING			
Neutral protamine Hagedorn (NPH) (isophane)	2–4 hr	4–10 hr	10–16 hr
LONG ACTING			
Glargine	2–4 hr	None	20–24 hr
Detemir	2–4 hr	6–14 hr	16–20 hr
Degludec	2–4 hr	None	24+ hr

Data from Wolfsdorf JL, ed. Intensive Diabetes Management. 4th ed. Alexandria, VA: American Diabetes Associations; 2009.

carbohydrate content of food; 500 divided by the total daily dose determines the number of grams of carbohydrate that requires one unit of insulin.

Lispro, aspart, and glulisine insulin are synthetic human insulin analogs in which amino acid alterations result in fast absorption and onset of action (see Table 171.2). Because of the short duration of action, these are used in combination with long-acting insulin. Glargine and detemir are insulin analogs with increased solubility at acidic pH and decreased solubility at physiologic pH. They have a duration of greater than 24 hours and act as a basal insulin.

Newly diagnosed patients in the honeymoon period may require 0.4–0.6 U/kg per 24 hours. Prepubertal patients with diabetes longer than 1–2 years typically require 0.5–1 U/kg per 24 hours. During middle adolescence when elevated GH concentrations produce relative insulin resistance, insulin requirements increase by 40–50%, and doses of 1–2 U/kg per 24 hours are typical.

Blood Glucose Testing

Blood glucose should be routinely monitored before each meal and at bedtime. Hypoglycemia during the night or excessive variability in the morning glucose concentrations should prompt additional testing at 2 or 3 A.M. to ensure that there is no consistent hypoglycemia or hyperglycemia. During periods of illness or when blood glucose concentrations are higher than 300 mg/dL, urine ketones also should be tested. Continuous glucose monitors (CGM), which provide minute-to-minute blood glucose concentration information, can be useful in following trends of blood glucose concentrations and have been approved to replace fingerstick blood glucose testing.

Insulin Pumps, Continuous Glucose Monitors, and Closed-Loop Systems

Insulin pumps that provide a continuous SC infusion of short-acting insulin also are available and are being used by children and adolescents who are highly motivated to achieve tight control. Sensor augmented insulin pump therapy refers to the use of an insulin pump in conjunction with a CGM. Data from a CGM is used to manually adjust the insulin pump settings. Sensor augmented insulin pump therapy with threshold suspend refers to the use of an insulin pump and CGM system that will either detect or predict low blood glucose (BG) and suspend insulin pump until normoglycemia is achieved. Hybrid closed-loop system refers to the recent advent of an insulin pump and CGM system that automatically increases, decreases, or suspends basal rates in response to glucose levels. One such system will also give additional bolus insulin based on rate of rise of BG value and elevation of BG level. These closed-loop systems are preparing the way for a fully automated closed loop.

Nutrition

Balancing the daily meal plan with the dosages of insulin is crucial for maintaining serum glucose concentrations within the target range and avoiding hypoglycemia or hyperglycemia. The content and schedule of meals vary according to the type of insulin regimen used. It is recommended that carbohydrates contribute 50–65% of the total calories, protein 12–20%, and fat less than 30%. Saturated fat should contribute

less than 10% of the total caloric intake, and cholesterol intake should be less than 300 mg per 24 hours. High-fiber content is recommended.

Patients using multiple daily injections or the insulin pump can maintain a more flexible meal schedule with regard to the timing of meals and the carbohydrate content. These patients give an injection of insulin before or immediately after each meal with the total dose calculated according to the carbohydrate content of the meal. Further adjustments in the dose can be made based on the measured serum glucose concentration and plans for activity during the day. Children using a twice-a-day combination of intermediate-acting and fast-acting insulins need to maintain a relatively consistent meal schedule so that carbohydrate absorption and insulin action peaks correspond. A typical meal schedule for a patient using this type of regimen involves three meals and three snacks daily. The total carbohydrate content of the meals and snacks should be kept constant.

Long-Term Glycemic Control

Measurements of **glycohemoglobin** or **HbA_{1c}** reflect the average blood glucose concentration over the preceding 3 months and provide a means for assessing long-term glycemic control. HbA_{1c} should be measured four times a year, and the results should be used for counseling of patients. The American Diabetes Association has set HbA_{1c} targets for children at less than 7.5%. Measurements of HbA_{1c} are inaccurate in patients with hemoglobinopathies. Glycosylated albumin or fructosamine can be used in these cases.

Complications

Patients with T1D for more than 3–5 years should receive an annual ophthalmologic examination for retinopathy. Urine should be collected annually for assessment of microalbuminuria, which suggests early renal dysfunction and indicates a high risk of progression to nephropathy. Treatment with angiotensin-converting enzyme inhibitors may halt the progression of microalbuminuria. In children with T1D, annual cholesterol measurements and periodic assessment of blood pressure are recommended. Early detection of hypertension and hypercholesterolemia with appropriate intervention can help limit future risk of coronary disease.

Other Disorders

Chronic autoimmune lymphocytic thyroiditis is particularly common and can result in hypothyroidism. Because symptoms can be subtle, thyroid function tests should be performed annually. Other disorders that occur with increased frequency in children with T1D include celiac disease, immunoglobulin A deficiency, Addison disease, and peptic ulcer disease.

Special Problems: Hypoglycemia

Hypoglycemia occurs commonly in patients with T1D. For patients in adequate or better control, it is expected to occur on average once or twice a week. Severe episodes of hypoglycemia, resulting in seizures or coma or requiring assistance from another person, occur in 10–25% of these patients per year.

Hypoglycemia in patients with T1D results from a relative excess of insulin in relation to the serum glucose concentration. This excess can be caused by alterations in the dose, timing, or absorption of insulin; alterations of carbohydrate intake; or changes in insulin sensitivity resulting from activity. Defective counter-regulatory responses also contribute to hypoglycemia. Abnormal glucagon responses to falling serum glucose concentrations develop within the first few years of the disease, and abnormalities in epinephrine release occur after a longer duration.

Lack of awareness of hypoglycemia occurs in approximately 25% of patients with diabetes. Recent episodes of hypoglycemia may play a role in the pathophysiology of *hypoglycemia unawareness*; after an episode of hypoglycemia, autonomic responses to subsequent episodes are reduced. A return of symptoms of hypoglycemia can be exhibited in these patients after 2–3 weeks of strict avoidance of hypoglycemic episodes.

Symptoms of hypoglycemia include those resulting from neuroglycopenia (headache, visual changes, confusion, irritability, or seizures) and those resulting from the catecholamine response (tremors, tachycardia, diaphoresis, or anxiety). Mild episodes can be treated with administration of rapidly absorbed oral glucose (glucose gel or tablets or fruit juices). More severe episodes that result in seizures or loss of consciousness at home should be treated with glucagon, which can be given as an injection or intranasal. IV glucose should be given in hospital settings.

Prognosis

Long-term complications of T1D include retinopathy, nephropathy, neuropathy, and macrovascular disease. Evidence of organ damage caused by hyperglycemia is rare in patients with diabetes of less than 5–10 years duration; clinically apparent disease rarely occurs before 10–15 years duration. Diabetic retinopathy is the leading cause of adult blindness in the United States. Nephropathy eventually occurs in 30–40% and accounts for approximately 30% of all new adult cases of end-stage renal disease. Neuropathy occurs in 30–40% of postpubertal patients with T1D and leads to sensory, motor, or autonomic deficits. Macrovascular disease results in an increased risk of myocardial infarction and stroke among individuals with diabetes.

Intensive control of diabetes, using frequent blood glucose testing, continuous glucose monitoring, and multiple daily injections of insulin or an insulin pump, can reduce the development or progression of diabetic complications, including a 76% reduction of risk for retinopathy, a 39% reduction in microalbuminuria, and a 60% reduction in clinical neuropathy. For pubertal and adult patients, the benefits of intensive therapy likely outweigh the increased risk for hypoglycemia. For younger patients, in whom the risks for hypoglycemia are greater and the benefits of tight glucose control may be lower, a less intensive regimen may be appropriate.

TYPE 2 DIABETES MELLITUS

Pathophysiology

T2D can occur as the result of various pathophysiologic processes; however, the most common form results from

peripheral insulin resistance and compensatory hyperinsulinemia, followed by failure of the pancreas to maintain adequate insulin secretion (see Table 171.1).

Epidemiology

The prevalence of T2D in children is increasing in parallel with childhood obesity and is highest in children of ethnic groups with a high prevalence of T2D in adults, including those of Native, Hispanic, and African descent. Obesity, metabolic syndrome, ethnicity, and a family history of T2D are risk factors. Autoantibodies to the pancreas are present among some clinically assumed to have T2D, compounding the difficulty in differentiating T1D from T2D at the time of diagnosis.

Clinical Manifestations and Differential Diagnosis

Fasting and postprandial glucose levels for diagnosis of T2D are the same as those for T1D. The diagnosis of T2D may be suspected on the basis of polyuria and polydipsia in a background of the metabolic syndrome. Differentiating T2D from T1D in children on clinical grounds alone can be challenging. The possibility of T2D should be considered in patients who are obese, have a strong family history of T2D, have other characteristics of the metabolic syndrome, or have absence of antibodies to β -cell antigens at the time of diagnosis of diabetes. **Acanthosis nigricans**, a dermatologic manifestation of hyperinsulinism and insulin resistance, presents as hyperkeratotic pigmentation in the nape of the neck and in flexural areas and is noted as a sign in the metabolic syndrome (Fig. 171.3). Although ketoacidosis occurs far more commonly in T1D, it also can occur in patients with T2D under conditions of physiologic stress and cannot be used as an absolute differentiating factor. T2D can be confirmed by the evaluation of insulin or C-peptide responses to stimulation with oral carbohydrate and in the absence of islet cell autoreactivity.

Therapy

T2D is the result of a combination of insulin resistance, relative insulin deficiency, and a secretory β -cell defect. Asymptomatic patients with mildly elevated glucose values (slightly >126 mg/dL for fasting or slightly >200 mg/dL for random glucose) may be managed initially with lifestyle modifications, including nutrition therapy (dietary adjustments) and increased exercise, which has been shown to decrease insulin resistance. In most children with new-onset, uncomplicated T2D, oral agents are usually the first line of therapy. Metformin, an insulin secretagogue, and liraglutide, a GLP-1 analog, are approved by the U.S. Food and Drug Administration for use in children. Metformin carries the rare side effect of lactic acidosis, occurring mainly in patients with compromised renal function. The most common side effect of metformin is gastrointestinal upset. Liraglutide is typically added if monotherapy with metformin fails. If ketonuria or ketoacidosis occur, insulin treatment is necessary to first achieve adequate glycemic control but may be discontinued within weeks with continuation of oral medications. Insulin therapy may be added if monotherapy with metformin fails.

FIGURE 171.3 Acanthosis nigricans. Velvety hyperpigmentation involves the axillae in this patient. From Paller AS, Mancini AJ. *Hurwitz Clinical Pediatric Dermatology: A Textbook of Skin Disorders of Childhood and Adolescence*. 5th ed. Elsevier; 2016 [fig. 23–26].

Because T2D may have a long preclinical course, early diagnosis is possible in subjects at risk who have the **metabolic syndrome**. Significant lifestyle modifications, such as improved eating habits and increased exercise, have a role in preventing or decreasing the morbidity of T2D. Finally, it is critical to monitor and manage the other components of metabolic syndrome, such as advanced pubertal development, hypertension, hyperlipidemia, and polycystic ovary syndrome in females.

MATURITY-ONSET DIABETES OF YOUTH (MODY)

MODY comprises a group of monogenetic dominantly inherited forms of relatively mild diabetes with onset before age 25 years. Insulin resistance does not occur in these patients; instead, the primary abnormality is an insufficient insulin secretory response to glycemic stimulation. There are multiple forms, but the most common forms are due to mutations in HNF1 α , HNF4 α , HNF1 β , and glucokinase genes. Treatment depends on the type and can include the use of sulfonylureas.

PEARLS FOR PRACTITIONERS

See *Endocrinology: Pearls for Practitioners* at the end of this section.

CHAPTER 172

Hypoglycemia

Hypoglycemia in infancy and childhood can result from a large variety of hormonal and metabolic defects (Table 172.1). Hypoglycemia occurs most frequently in the early neonatal period, often as a result of transient neonatal hyperinsulinemia in infants of diabetic mothers or as a result of inadequate energy stores to meet the disproportionately large metabolic needs of premature or small for gestational age newborns. Hypoglycemia during the first few days of life in an otherwise normal newborn is less frequent and warrants concern (see Chapter 6). After the initial 2–3 days of life, hypoglycemia is far less common and is more frequently the result of endocrine or metabolic disorders (although sepsis must always be considered).

DEFINITION

Clinical hypoglycemia is defined as a plasma glucose (PG) concentration low enough to cause symptoms (usually <60 mg/dL in children >1 month of life) and/or signs of impaired brain function and improvement of symptoms with glucose administration (Whipple triad). Brain glucose utilization is reduced at a PG concentration of approximately 55–65 mg/dL. **Autonomic system** (neurogenic) symptoms are perceived at a PG concentration less than 55 mg/dL. Cognitive function is impaired (**neuroglycopenia**) at a PG concentration less than 50 mg/dL (Table 172.2).

CLINICAL MANIFESTATIONS

The symptoms and signs of hypoglycemia result from direct depression of the central nervous system owing to lack of energy substrate and the counter-regulatory adrenergic response to low glucose via catecholamine secretion designed to correct hypoglycemia (see Table 172.2). Compared with older children, infants do not usually show adrenergic symptoms. Symptoms of hypoglycemia in newborns and infants may be less obvious and include cyanosis, apnea, bradycardia, hypothermia, hypotonia, poor feeding, lethargy, and seizures, all due to the deprivation of glucose for normal brain function. In older children, signs and symptoms include confusion, irritability, headaches, visual changes, tremors, pallor, sweating, tachycardia, weakness, seizures, and coma.

Sequelae

Failure to recognize and treat severe, prolonged hypoglycemia can result in serious long-term morbidity, including intellectual disability and non-hypoglycemic seizures. Because the greatest development of the brain is in the first year of life, sustained or frequent episodes of hypoglycemia in infants and children can retard brain development and function. Younger infants and patients with more severe or prolonged hypoglycemia are at greatest risk for adverse outcomes. Transient and asymptomatic short-term hypoglycemia has not been found to be associated with these severe sequelae. While the body has a tightly regulated system through use of alternative fuels such as ketone bodies, the ability of a newborn to produce ketone

Pallor	Somnolence
Paresthesia	Dysarthria
Trembling	Personality changes
Anxiety	Inability to concentrate
Weakness	Staring
Nausea	Hunger
Vomiting	Convulsions
	Ataxia
	Coma
	Diplopia
	Stroke

*These features and perceptions of the features may be blunted if the patient is receiving β -blocking agents.

bodies is limited, especially in the presence of hyperinsulinism, which inhibits hepatic glucose output, lipolysis, and ketogenesis. In addition, although the brain may be able to utilize ketones, glucose remains a required form of energy for CNS function.

PATHOPHYSIOLOGY

Table 172.3 lists the classifications of hypoglycemia in infants and children.

Hormonal Signal

Normal regulation of serum glucose concentrations requires appropriate interaction of a number of hormonal signals and metabolic pathways (Fig. 172.1). In a normal individual, a decrease in serum glucose concentrations leads to suppression of insulin secretion (to $<5\mu\text{U}/\text{dL}$) and increased secretion of the counter-regulatory hormones (growth hormone [GH], cortisol, glucagon, and epinephrine (see Fig. 172.1)). These counter-regulatory hormones act together to increase blood glucose concentrations by activating glycogenolytic enzymes (glucagon, epinephrine) and inducing gluconeogenic enzymes (glucagon, cortisol), and by preventing glucose uptake by muscle (epinephrine, growth hormone, cortisol) and aiding in release of amino acids from muscle for gluconeogenesis (cortisol). They all activate lipolysis, providing glycerol for gluconeogenesis and fatty acids for ketogenesis (epinephrine, cortisol, GH, glucagon). Failure of any of the components of this hormonal signal can lead to hypoglycemia.

Hyperinsulinemia

A lack of suppression of insulin secretion in response to low serum glucose concentrations can occur in infants but is uncommon beyond the neonatal period. Hypoglycemia in infants of diabetic mothers is a common cause and primarily

due to hyperinsulinemia and partly due to reduced glucagon secretion. The pancreatic islet hypertrophy results in a brisk, biphasic insulin response to glucose, which is not present in normal infants. The inadequate rise in plasma glucagon immediately after birth and excessive sympathetic activity may cause low epinephrine levels. Therefore the typical plasma hormonal pattern of low insulin, high glucagon, and high catecholamines is reversed to a pattern of high insulin, low glucagon, and low epinephrine, causing a reduction in endogenous glucose production. The hyperinsulinemic state in infants of diabetic mothers is transient, however, usually lasting hours to days.

Hyperinsulinism that persists beyond a few days of age (persistent hyperinsulinemic hypoglycemia of infancy [PHHI]) can result from distinct genetic disorders affecting glucose-regulated insulin release, or **congenital hyperinsulinism**. In these infants, hyperplasia of the pancreatic islet cells develops in the absence of excess stimulation by maternal diabetes. There are several genes associated with monogenic forms of hyperinsulinism (*KCNJ11*, *GCK*, *HADH*, *INSR*, *GLUD1*, *SLC16A1*, *ABCC8*) as well as several syndromic genetic forms of HI (e.g., Beckwith-Wiedemann, Kabuki, and Turner syndromes).

Regardless of the cause, neonates with hyperinsulinism are characteristically large for gestational age (see Chapter 60). Hypoglycemia is severe and frequently occurs within 1–3 hours of a feeding. Glucose requirements are increased, often two to three times the normal basal glucose requirement of 6–8 mg/kg/min. The *diagnosis* of hyperinsulinism in children is determined by evaluating markers of inappropriate insulin effects (e.g., suppressed ketogenesis) because plasma insulin concentrations are frequently not clearly elevated. Diagnosis is most reliably based on a closely monitored provocative fasting test that includes (1) frequent sampling of plasma concentrations of glucose, insulin, β -hydroxybutyrate, and free fatty acids (FFAs) and (2) terminating the test when glucose concentrations decline toward 50 mg/dL with a determination of the glycemic response to glucagon. The absence of serum and urine ketones at the time of hypoglycemia is an important diagnostic feature, distinguishing hyperinsulinism from defects in counter-regulatory hormone secretion.

Treatment initially involves the infusion of intravenous (IV) glucose at high rates. Hyperinsulinism is managed medically initially with diazoxide and then somatostatin analogs. If hypoglycemia does not improve with IV dextrose and maximum doses of diazoxide (up to 15 mg/kg/day) and somatostatin analogs, partial or near-total pancreatectomy should be considered to prevent long-term neurologic sequelae of hypoglycemia. Those patients are generally referred to centers with extensive experience in the procedures.

Factitious Hyperinsulinemia

In rare cases, insulin or a hypoglycemic medication is administered by a parent or caregiver to a child as a form of child abuse, which is a condition referred to as **Munchausen syndrome by proxy**. This *diagnosis* should be suspected if high insulin concentrations are detected ($>100\mu\text{U}/\text{mL}$) and C-peptide concentrations are low or undetectable, which confirms that the insulin is from an exogenous source. Accidental ingestion of oral hypoglycemic agents by a toddler may also produce hyperinsulinemic hypoglycemia.

TABLE 172.3 Classification of Hypoglycemia in Infants and Children

NEONATAL TRANSITIONAL (ADAPTIVE) HYPOGLYCEMIA	Lipolysis Disorders
Associated with Inadequate Substrate or Immature Enzyme	Fatty Acid Oxidation Disorders
Function in Otherwise Normal Neonates	Carnitine transporter deficiency (primary carnitine deficiency)
Prematurity	Carnitine palmitoyltransferase-1 deficiency
Small for gestational age	Carnitine translocase deficiency
Normal newborn	Carnitine palmitoyltransferase-2 deficiency
Transient Neonatal Hyperinsulinism	Secondary carnitine deficiencies
Infant of diabetic mother	Very-long-, long-, medium-, short-chain acyl-CoA dehydrogenase deficiency
Small for gestational age	OTHER ETIOLOGIES
Discordant twin	Substrate-Limited Causes
Birth asphyxia	Ketotic hypoglycemia
Infant of toxemic mother	Poisoning-drugs
NEONATAL, INFANTILE, OR CHILDHOOD PERSISTENT HYPOGLYCEMIA	Salicylates
Hyperinsulinism	Alcohol
Recessive K_{ATP} channel HI	Oral hypoglycemic agents
Recessive HADH (hydroxyl acyl-CoA dehydrogenase) mutation HI	Insulin
Recessive UCP2 (mitochondrial uncoupling protein 2) mutation HI	Propranolol
Focal K_{ATP} channel HI	Pentamidine
Dominant K_{ATP} channel HI	Quinine
Atypical congenital hyperinsulinemia (no mutations in <i>ABCC8</i> or <i>KCN11</i> genes)	Disopyramide
Dominant glucokinase HI	Ackee fruit (unripe)-hypoglycin
Dominant glutamate dehydrogenase HI (hyperinsulinism-hyperammonemia syndrome)	Litchi-associated toxin (toxin hypoglycemic syndrome)
Dominant mutations in HNF-4A and HNF-1A (hepatocyte nuclear factors 4 α and 1 α) HI with monogenic diabetes of youth later in life	Vacor (rat poison)
Dominant mutation in SLC16A1 (the pyruvate transporter)-exercise-induced hypoglycemia	Trimethoprim-sulfamethoxazole (with renal failure)
Activating mutations in the calcium channel CACNA1D (permit calcium influx and thus unregulated insulin secretion)	L-asparaginase and other antileukemic drugs
Acquired or familial islet adenoma associated with mutations in <i>MEN1</i> gene	Liver Disease
Beckwith-Wiedemann syndrome	Reye syndrome
Kabuki syndrome	Hepatitis
Insulin administration (Munchausen syndrome by proxy)	Cirrhosis
Oral sulfonylurea drugs	Hepatoma
Congenital disorders of glycosylation	AMINO ACID AND ORGANIC ACID DISORDERS
Counter-Regulatory Hormone Deficiency	Maple syrup urine disease
Panhypopituitarism	Propionic academia
Isolated growth hormone deficiency	Methylmalonic academia
Adrenocorticotrophic hormone deficiency	Tyrosinosis
Addison disease (including congenital adrenal hypoplasia, adrenal leukodystrophy, triple A syndrome, ACTH receptor deficiency, and autoimmune disease complex)	Glutaric aciduria
Epinephrine deficiency	3-hydroxy-3-methylglutaric aciduria
Glycogenolysis and Gluconeogenesis Disorders	SYSTEMIC DISORDERS
Glucose-6-phosphatase deficiency (GSD Ia)	Sepsis
Glucose-6-phosphate translocase deficiency (GSD Ib)	Carcinoma/sarcoma (secreting-insulin-like growth factor II)
Amylo-1,6-glucosidase (debranching enzyme) deficiency (GSD III)	Heart failure
Liver phosphorylase deficiency (GSD VI)	Malnutrition
Phosphorylase kinase deficiency (GSD IX)	Malabsorption
Glycogen synthetase deficiency (GSD 0)	Antiinsulin receptor antibodies
Fructose-1,6-diphosphatase deficiency	Antiinsulin antibodies
Pyruvate carboxylase deficiency	Neonatal hyperviscosity
Galactosemia	Renal failure
Hereditary fructose intolerance	Diarrhea
	Burns
	Shock
	Chiari malformation
	Postsurgical complication
	Pseudohypoglycemia (leukocytosis, polycythemia)
	Excessive insulin therapy of insulin-dependent diabetes mellitus
	Factitious disorder

FIGURE 172.1 Regulation of serum glucose. ⊖ represents inhibitions. *EPI*, Epinephrine; *FFA*, free fatty acid; *GH*, growth hormone; *TG*, triglyceride.

Defects in Counter-Regulatory Hormones

Abnormalities in the secretion of counter-regulatory hormones that produce hypoglycemia usually involve GH, cortisol, or both. Deficiencies in glucagon and epinephrine secretion are rare. GH and cortisol deficiency occur because of hypopituitarism. Hypopituitarism results from different genetic or structural factors (see Chapter 173). Concern for hypoglycemia should be increased in infants with midline facial or neurologic defects (e.g., cleft lip and palate or absence of the corpus callosum), pendular (roving) nystagmus (indicating visual impairment from possible abnormalities in the development of the optic nerves, which can occur in optic nerve hypoplasia), and the presence of microphallus and cryptorchidism in boys (indicating abnormalities in gonadotropin secretion). Jaundice and hepatomegaly also can occur, simulating neonatal hepatitis. Despite the presence of GH deficiency, these infants are usually of normal length at birth.

Deficient cortisol secretion also can occur in primary adrenal insufficiency, resulting from a variety of causes. In infants it often results from congenital adrenal hyperplasia, most frequently because of 21-hydroxylase deficiency (see Chapters 177 and 178). In older children, primary adrenal insufficiency is seen most frequently in **Addison disease** and other disorders (see Chapter 178).

Confirmation of GH or cortisol deficiency as the cause of hypoglycemia requires the detection of low serum GH and cortisol concentrations during an episode of hypoglycemia or after other stimulatory testing. In contrast to hyperinsulinism, serum and urine ketones are positive at the time of hypoglycemia and FFAs are elevated. Treatment involves supplementation of the deficient hormones in physiologic doses.

ENERGY STORES

Sufficient energy stores in the form of glycogen, adipose tissue, and muscle are necessary to respond appropriately to hypoglycemia. Deficiencies in these stores are a common cause of hypoglycemia in neonates who are small for gestational age or premature (see Chapter 60). Beyond the early neonatal period,

energy stores are usually sufficient to meet the metabolic requirements except in malnourished children.

IDIOPATHIC KETOTIC HYPOGLYCEMIA

A common cause of new-onset hypoglycemia is idiopathic ketotic hypoglycemia, usually seen in children between 18 months and 8 years of age. Patients have symptoms of hypoglycemia after a period of prolonged fasting, often in the setting of an intercurrent illness with decreased feeding. Normal children of similar age can withstand fasting without hypoglycemia developing during the same period, although even normal children may acquire these features by 36 hours of fasting. Children with this disorder are often thin and small, may have a history of being small for gestational age, and often have a history of transient neonatal hypoglycemia. The etiology of ketotic hypoglycemia may be a defect in any of the processes involved in protein catabolism, oxidative deamination of amino acids, transamination, alanine synthesis, or alanine efflux from muscle. There are no specific diagnostic tests for this disorder.

Treatment involves avoidance of fasting and frequent feedings of a high-protein, high-carbohydrate diet. Patients may require hospitalization for IV glucose infusion if they cannot maintain adequate oral intake during a period of illness.

DISRUPTED METABOLIC RESPONSE PATHWAYS

Maintenance of normal serum glucose concentrations in the fasting state requires glucose production via glycogenolysis and gluconeogenesis and the production of alternative energy sources (FFAs and ketones) via lipolysis and fatty acid oxidation.

Glycogenolysis

Some glycogen storage diseases (GSDs) occur in a variety of subtypes that differ in severity (see Chapter 52). Among the subtypes that result in hypoglycemia, the most severe form is glucose-6-phosphatase deficiency, which is characterized by

severe hypoglycemia, massive hepatomegaly, growth retardation, and lactic acidosis. In contrast, deficiencies in the glycogen phosphorylase enzymes may cause isolated hepatomegaly with or without hypoglycemia.

The *diagnosis* of GSD is suggested by a finding of hepatomegaly without splenomegaly (although GSD type 0 is not associated with hepatomegaly). Confirmation of the diagnosis requires specific biochemical studies of leukocytes or liver biopsy specimens. *Treatment* for the most common types involves frequent high-carbohydrate feedings during the day and continuous feedings at night via nasogastric tube. Feedings of uncooked cornstarch overnight are sufficient to maintain serum glucose concentrations in some patients.

Gluconeogenesis

Defects in gluconeogenesis are uncommon and include fructose-1,6-diphosphatase deficiency and phosphoenolpyruvate carboxykinase deficiency. Affected patients exhibit fasting hypoglycemia, hepatomegaly, lactic acidosis, and hyperuricemia. Ketosis occurs and FFA and alanine concentrations are high. *Treatment* involves frequent high-carbohydrate, low-protein feedings (see Chapter 52).

Fatty Acid Oxidation

Fatty acid oxidation disorders of ketogenesis include the fatty acid acyl-coenzyme A (CoA) dehydrogenase deficiencies; long-chain, medium-chain, and short-chain acyl-CoA dehydrogenase deficiencies; and hereditary carnitine deficiency (see Chapter 55). Of these disorders, medium-chain acyl-CoA dehydrogenase deficiency is the most common; it occurs in 1 in 4,000–17,000 live births, depending on the population. Patients often are well in infancy and have the first episode of hypoglycemia at 2 years of age or older. Mild hepatomegaly may be present along with mild hyperammonemia, hyperuricemia, and mild elevations in hepatic transaminases. Episodes of nonketotic hypoglycemia usually occur with prolonged fasting or during episodes of intercurrent illness. *Treatment* involves avoidance of fasting.

OTHER METABOLIC DISORDERS

Many metabolic disorders can lead to hypoglycemia, including galactosemia, hereditary fructose intolerance, and disorders of organic acid metabolism (see Table 172.1). Hypoglycemia in these disorders is usually a reflection of global hepatic dysfunction secondary to the buildup of hepatotoxic intermediates. Many of these disorders present with low concentrations of ketone bodies because ketogenesis also is affected. The finding of non-glucose-reducing substances in the urine after ingestion of offending substances suggests a diagnosis of galactosemia or hereditary fructose intolerance. *Treatment* requires dietary restriction of the specific offending substances.

MEDICATIONS AND INTOXICATION

Hypoglycemia can occur as an adverse effect of numerous medications (see Table 172.1). Ethanol ingestion also can cause hypoglycemia, especially in younger children, because the metabolism of ethanol results in the depletion of co-factors necessary for gluconeogenesis.

DIAGNOSIS

Although the list of causes of hypoglycemia is long and complex, establishing the *etiology* in a particular patient is important. Frequently, it is difficult to make an accurate diagnosis until one can obtain a *critical sample* of blood and urine at the time of the hypoglycemic episode. In a child with unexplained hypoglycemia, a serum sample should be obtained before treatment for the measurement of glucose and insulin, GH, cortisol, FFAs, and β -hydroxybutyrate and acetoacetate. Measurement of serum lactate levels also should be considered. A urine specimen should be obtained for measuring ketones and reducing substances. *Hypoglycemia without ketonuria suggests hyperinsulinism or a defect in fatty acid oxidation.* The results of this initial testing can establish whether endocrine causes are responsible and, if not, provide initial information regarding which types of metabolic disorders are most likely.

EMERGENCY MANAGEMENT

Acute care of a patient with hypoglycemia consists of rapid administration of IV glucose (2 mL/kg of 10% dextrose in water). After the initial bolus, an infusion of IV glucose should provide approximately 1.5 times the normal hepatic glucose production rate (8–12 mg/kg/min in infants, 6–8 mg/kg/min in children). This infusion allows for suppression of the catabolic state and prevents further decompensation in patients with certain metabolic disorders. If adrenal insufficiency is suspected, stress doses of glucocorticoids should be administered.

PEARLS FOR PRACTITIONERS

See *Endocrinology: Pearls for Practitioners* at the end of this section.

CHAPTER 173

Short Stature

GROWTH

Normal growth is the final common pathway of many factors, including endocrine, environmental, nutritional, and genetic influences (see Chapter 5). A normal linear growth pattern is good evidence of overall health and can be considered a *bioassay* for the well-being of the whole child. The effects of certain hormones on growth and ultimate height are listed in Table 173.1. Just as various factors influence stature, stature itself influences psychologic, social, and, potentially, economic well-being. Parental concern about the psychosocial consequences of abnormal stature often causes a family to seek medical attention.

Growth Hormone Physiology

Growth hormone (GH) is a 191–amino acid protein secreted by the pituitary in a pulsatile fashion, stimulated by hypothalamic GH-releasing hormone (GHRH), and inhibited by somatotropin release–inhibiting factor (SRIF) or somatostatin,

TABLE 173.1 Hormonal Effects on Growth

HORMONE	BONE AGE	GROWTH RATE	ADULT HEIGHT*
Androgen excess	Advanced	Increased	Diminished
Androgen deficiency	Normal or delayed	Normal or decreased	Increased slightly or normal
Thyroxine excess	Advanced	Increased	Normal or diminished
Thyroxine deficiency	Retarded	Decreased	Diminished
Growth hormone excess	Normal or advanced	Increased	Excessive
Growth hormone deficiency	Retarded	Decreased	Diminished
Cortisol excess	Retarded	Decreased	Diminished
Cortisol deficiency	Normal	Normal	Normal

*Effect in most patients with treatment.

Modified from Underwood LE, Van Wyk JJ. Normal and aberrant growth. In: Wilson JD, Foster DW, eds. Textbook of Endocrinology. 8th ed. Philadelphia: WB Saunders; 1992.

which interact with their individual receptors on the pituitary somatotrope in a noncompetitive manner. In addition, GH secretion is *enhanced* by α -adrenergic stimulation, hypoglycemia, stress, starvation, exercise, early stages of sleep, GH-releasing peptides (GHRPs), sex steroids, thyroxine, glucocorticoids, ghrelin, and clonidine. It is *suppressed* by β -adrenergic stimulation and hyperglycemia. GH, GHRH, and SRIF are also modulated by multiple neurotransmitters and neuropeptides, including serotonin, histamine, norepinephrine, dopamine, acetylcholine, γ -aminobutyric acid (GABA), thyroid-releasing hormone, vasoactive intestinal peptide, gastrin, neurotensin, substance P, calcitonin, neuropeptide Y, vasopressin, corticotrophin-releasing hormone, and galanin.

GH stimulates insulin-like growth factor 1 (IGF-1) production in the liver along with production of the acid-labile subunit and the IGF-binding protein 3 (IGF-BP3); this forms the complex that delivers IGF-1 to tissue. It is largely accepted that the anabolic actions of GH are mediated through the IGF polypeptides. It appears that GH is also capable of stimulating processes independent of IGF activity, including a variety of metabolic effects, such as lipolysis, amino acid transport in the heart, and production of specific hepatic proteins.

IGF-1 acts primarily as a paracrine and autocrine agent and is most closely associated with postnatal growth. When IGF-1 attaches to its membrane-bound receptor, second messengers are stimulated to change the physiology of the cell and produce growth effects. IGF-1 production is influenced by disease states such as malnutrition, chronic renal and liver disease, hypothyroidism, and obesity.

IGF-BP3 is measurable in clinical assays and is less influenced by nutrition and age than is IGF-1; measuring IGF-1 and IGF-BP3 is useful in evaluating GH adequacy, particularly in infancy and early childhood.

Measurement of Growth

The correct measurement of an infant's length requires one adult to hold the infant's head still and another adult to extend the feet with the soles perpendicular to the lower legs. The use of a recumbent length board, composed of a firm platform, a fixed head plate, and a movable footplate for reading the measurement, requires two people for accurate length

measurement. Marking the position of the head and feet of an infant lying on a sheet of paper on the examining table leads to inaccuracies and may miss true disorders of growth or create false concerns about a disorder of growth in a normal child.

After 2 years of age, the height of a child should be measured in the standing position barefoot against a hard surface. A wall-mounted stadiometer or equivalent device is optimal for the measurement of stature. A decrease of roughly 1.25 cm in height measurement may occur when the child is measured in the standing position rather than in the lying position, leading to the inappropriate referral of many children who appear to be *not growing* to a subspecialist. Accurate measurements of height (standing), or length (lying down), and weight should be plotted on the Centers for Disease Control and Prevention (CDC) growth charts for the timely diagnosis of growth disorders (<http://www.cdc.gov/growthcharts/>).

Measurement of the **arm span** (distance between the tips of the fingers when the patient holds both arms outstretched horizontally while standing against a solid surface) is essential when the diagnoses of Marfan or Klinefelter syndrome, short-limbed dwarfism, or other dysmorphic conditions are considered. The **upper-to-lower segment ratio** is the ratio of the upper segment (determined by subtraction of the measurement from the symphysis pubis to the floor [known as the lower segment] from the total height) to the lower segment. A normal term infant has an upper-to-lower ratio of 1.7:1, a 1-year-old has a ratio of 1.4:1, and a 10-year-old has a ratio of 1:1. Untreated conditions of hypogonadism lead to greatly decreased upper-to-lower ratio in an adult, whereas long-lasting and untreated hypothyroidism leads to a high upper-to-lower ratio in the child.

Endocrine Evaluation of Growth Hormone Secretion

Because concentrations of GH are low throughout the day, except for brief secretory peaks in the middle of the night or early morning, the daytime ascertainment of GH deficiency or sufficiency on the basis of a single determination of a random GH concentration is impossible. Adequacy of GH secretion may be determined by a stimulation test to measure peak GH secretion. A normal response is a vigorous secretory peak after

stimulation, and the lack of such a peak is consistent with GH deficiency. However, there is a high false-positive rate (on any day, about $\geq 10\%$ of normal children may not reach the normal GH peak, even after two stimulatory tests). Indirect measurements of GH secretion, such as serum concentrations of IGF-1 and IGF-BP3, are considered better screens for GH deficiency.

ABNORMALITIES OF GROWTH

Short stature is defined as subnormal height relative to other children of the same gender and age, taking family heights into consideration. It can be caused by numerous conditions (Table 173.2). The CDC growth charts use the 3rd percentile of the growth curve as the demarcation of the lower limit. **Growth failure** denotes a slow growth rate regardless of stature. Ultimately a slow growth rate leads to short stature, but a disease process is detected sooner if the decreased growth rate is noted before the stature becomes short. Plotted on a growth chart, growth failure appears as a curve that crosses percentiles downward and is associated with a height velocity below the 5th percentile of height velocity for age (Fig. 173.1). A corrected midparental, or genetic target, height helps determine whether the child is growing well for the family (see Chapter 6). To determine a range of normal height for the family under consideration, the corrected midparental height is bracketed by 2 standard deviations (SDs), which, for the United States, is approximately 10 cm (4 in.). The presence of a height 3.5 SDs below the mean, a height velocity below the 5th percentile for age, or a height below the target height corrected for midparental height requires a diagnostic evaluation.

Short Stature Caused by Growth Hormone Deficiency

Etiology and Epidemiology

Classic congenital or **idiopathic GH deficiency** occurs in about 1 in 4,000 children. Idiopathic GH deficiency, of unidentified specific etiology, is the most common cause of both congenital and acquired GH deficiency. Less often, GH deficiency is caused by anatomic defects of the pituitary gland, such as pituitary aplasia or other midline defects (such as septo-optic dysplasia), with variable degrees of deficiency of other pituitary functions. Hereditary forms of GH deficiency that affect pituitary differentiation are the result of heterogeneous defects of the gene for GH, GRF, or GH receptor. *Classic GH deficiency* refers to very reduced to absent secretion of GH; numerous short children may have intermediate forms of decreased GH secretion. Acquired GH deficiency causing late-onset growth failure suggests the possibility of a **tumor** of the hypothalamus or pituitary causing compression of the area (Table 173.3; see Table 173.2).

Clinical Manifestations

Infants with congenital GH deficiency achieve a normal or near-normal birth length and weight at term, but the growth rate slows after birth, most noticeably after age 2–3 years. These children become progressively shorter for age and tend to have an elevated weight:height ratio. Careful measurements in the first year of life may suggest the diagnosis, but most patients elude diagnosis until several years of age. A patient with classic GH deficiency often has a high-pitched

voice resulting from an immature larynx. Unless severe hypoglycemia occurs or dysraphism (midline defects) of the head includes a central nervous system (CNS) defect that affects mentation, the patient has normal intellectual growth and age-appropriate speech. Male neonates with GH deficiency with or without gonadotropin deficiency may have a microphallus (a stretched penile length < 2 cm [normal is 3–5 cm]) and fasting hypoglycemia. Patients who lack the adrenocorticotropic hormone (ACTH, stimulates cortisol) in addition to GH may have more profound hypoglycemia because cortisol also stimulates gluconeogenesis.

If chronic disease or familial short stature are ruled out and routine laboratory testing is normal (Table 173.4), two GH stimulatory tests are commonly performed (see Table 170.2). GH testing should be offered to a patient who is short (< 5 th percentile and usually > 3.5 SDs below the mean), growing poorly (< 5 th percentile growth rate for age), or whose height projection, based on bone age, is considerably below the target height when corrected for family height.

Classic GH-deficient patients do not show an increase in serum GH levels after stimulation. Some patients release GH in response to secretagogue testing but cannot release GH spontaneously during the day or night. Tests for GH secretion are insensitive, not very specific, and fairly variable. In equivocal cases, an operational definition of GH deficiency might be that patients grow significantly faster when administered a normal dose of GH than before treatment.

Treatment

GH deficiency is treated with biosynthetic recombinant DNA-derived GH. Dosage is titrated to the growth rate, weight of the patient, and IGF-1 levels. Treatment with GH carries the low risk of an increased incidence of slipped capital femoral epiphysis, especially in rapidly growing adolescents, and of pseudotumor cerebri. Patients who have GH deficiency due to treatment for malignancy may be at higher risk for a secondary malignancy with GH therapy. Risks and benefits must be weighed with the family and treatment team.

Administration of GH to patients with normal GH responsiveness to secretagogues is controversial, but, as noted earlier, diagnostic tests are imperfect; if the patient is growing extremely slowly without alternative explanation, GH therapy is sometimes used. GH is effective in increasing the growth rate and final height in Turner syndrome and in chronic renal failure; GH also is used for treatment of short stature and muscle weakness of Prader-Willi syndrome. Other indications include children born small for gestational age who have not exhibited catch-up growth by 2 years of age and limited use in long-term treatment of idiopathic short stature with height 2.25 SDs or less below the mean. Psychologic support of children with severe short stature is important.

Other Causes of Short Stature

The factors responsible for postnatal growth are not the same as the factors that mediate fetal growth. **Thyroid hormone** is essential for normal postnatal growth although a thyroid hormone-deficient fetus achieves a normal birth length. Similarly, a GH-deficient fetus has a normal birth length, although in IGF-1 deficiency resulting from GH resistance (**Laron dwarfism**), fetuses are shorter than control subjects. A very rare cause of growth failure, GH resistance is inherited in an

TABLE 173.2 Causes of Short Stature

VARIATIONS OF NORMAL	SYNDROMES OF SHORT STATURE
Constitutional (delayed bone age)	Turner syndrome (syndrome of gonadal dysgenesis)
Genetic (short familial height)	Noonan syndrome
ENDOCRINE DISORDERS	Autosomal trisomy 13, 18, 21
GH deficiency	Laurence-Moon-Bardet-Biedl syndrome
<i>Congenital</i>	Prader-Willi syndrome
• Isolated GH deficiency	Autosomal abnormalities
• With other pituitary hormone deficiencies	Dysmorphic syndromes (e.g., Russell-Silver or Cornelia de Lange syndrome)
• With midline defects	Pseudohypoparathyroidism
• Pituitary agenesis	CHRONIC DISEASE
• With gene deficiency	Cardiac disorders
<i>Acquired</i>	Left-to-right shunt
• Hypothalamic/pituitary tumors	Heart failure
• Langerhans cell histiocytosis	Pulmonary disorders
• CNS infections and granulomas	Cystic fibrosis
• Head trauma (birth and later)	Asthma (severe steroid dependent)
• Hypothalamic/pituitary irradiation	Gastrointestinal disorders
• CNS vascular accidents	Malabsorption (e.g., celiac disease, cystic fibrosis)
• Hydrocephalus	Disorders of swallowing
• Autoimmune	Inflammatory bowel disease
• Psychosocial dwarfism (functional GH deficiency)	Hepatic disorders
• Amphetamine treatment for hyperactivity*	Hematologic disorders
Laron dwarfism (increased GH and decreased IGF-1)	Sickle cell anemia
Pygmies (normal GH and IGF-2 but decreased IGF-1)	Thalassemia
Hypothyroidism	Renal disorders
Glucocorticoid excess	Renal tubular acidosis
Endogenous	Chronic uremia
Exogenous	Immunologic disorders
Diabetes mellitus under poor control	Connective tissue disease
Diabetes insipidus (untreated)	Juvenile idiopathic arthritis
Hypophosphatemic vitamin D-resistant rickets	Chronic infection
Virilizing congenital adrenal hyperplasia (tall child, short adult) P-450 _{c21} , P-450 _{c11} deficiencies	AIDS
SKELETAL DYSPLASIAS	Hereditary fructose intolerance
Osteogenesis imperfecta	Malnutrition
Osteochondrodysplasias	Kwashiorkor, marasmus
LYSOSOMAL STORAGE DISEASES	Iron deficiency
Mucopolysaccharidoses	Zinc deficiency
Mucopolipidoses	Anorexia caused by chemotherapy for neoplasms
	Cerebral palsy

*Only if caloric intake is severely diminished.

CNS, Central nervous system; GH, growth hormone; IGF, insulin-like growth factor.

Modified from Styne DM. Growth disorder. In: Fitzgerald PA, ed. Handbook of Clinical Endocrinology. Norwalk, CT: Appleton & Lange; 1986.

FIGURE 173.1 Patterns of linear growth. Normal growth percentiles (5th, 50th, and 95th) are shown along with typical growth curves for (A) constitutional delay of growth and adolescence (short stature with normal growth rate for bone age, delayed pubertal growth spurt, and eventual achievement of normal adult stature); (B) familial short stature (short stature in childhood and as an adult); and (C) acquired pathologic growth failure (e.g., acquired untreated primary hypothyroidism) (see Chapter 5).

autosomal recessive fashion and is caused by abnormal number or function of GH receptors or by a postreceptor defect. Patients have a prominent forehead, hypoplastic nasal bridge, delayed dentition, sparse hair, blue sclerae, delayed bone maturation and osteoporosis, progressive adiposity, hypercholesterolemia, and low blood glucose. They have elevated serum GH concentrations, although serum IGF-1 and IGF-BP3 concentrations are low.

Adequate thyroid hormone is necessary to allow the secretion of GH. Hypothyroid patients may appear to falsely be GH deficient; with thyroid hormone repletion, GH secretion normalizes. Gonadal steroids are important in the pubertal growth spurt. The effects of other hormones on growth are noted in Table 173.1.

Nutrition is the most important factor affecting growth on a worldwide basis (see Chapter 28). Failure to thrive (stunting) may develop in the infant as a result of **maternal deprivation** (nutritional deficiency or aberrant psychosocial interaction) or as a result of organic illness (anorexia, nutrient losses through a form of malabsorption, or hypermetabolism caused by hyperthyroidism or other causes; see Chapter 21). Malnutrition may cause **acquired GH resistance** because serum GH is elevated and IGF-1 is decreased. If the parents were malnourished as children, grew up in a zone of war, or suffered famine, the heights of the parents are less predictive.

Psychologic difficulties also can affect growth, as in **psychosocial or deprivation dwarfism**, in which the child develops

functional temporary GH deficiency and poor growth as a result of psychologic abuse; when placed in a different, healthier psychosocial environment, GH physiology normalizes, and growth occurs.

The common condition known as **constitutional delay** in growth or puberty (or both) is considered a variation of normal growth, caused by a reduced tempo, or cadence, of physiologic development (see Fig. 173.1). Usually a family member had delayed growth or puberty but achieved a final height consistent with mid-parental height predictions. The bone age is delayed, but the growth rate remains mostly within the lower limits of normal. Constitutional delay usually leads to a delay in secondary sexual development. **Genetic or familial short stature** (see Table 173.3) refers to the stature of a child of short parents who is expected to reach a lower than average height and yet normal for these parents.

Phenotypic features suggesting an underlying **chromosomal disorder** can occur in many syndromes. These syndromes can be suspected by assessing arm spans and upper-to-lower segment ratios. Genetic syndromes often combine obesity and decreased height, whereas otherwise normal obese children are usually taller than average and have advanced skeletal development and physical maturation (see Table 173.2). The **Prader-Willi syndrome (PWS)** includes fetal and infantile hypotonia, small hands and feet, postnatal acquired obesity with an insatiable appetite, developmental delay, hypogonadism, and almond-shaped eyes. PWS is caused by a lack of expression of paternally inherited genes in the region of chromosome 15q11.2-q13. The majority of patients (70%) have a deletion of the paternal allele, whereas one-quarter have maternal uniparental disomy [UPD(15q)m].

Laurence-Moon-Bardet-Biedl syndrome is characterized by retinitis pigmentosa, hypogonadism, and developmental delay with an autosomal dominant inheritance pattern. Laurence-Moon syndrome is associated with spastic paraplegia; Bardet-Biedl syndrome is associated with obesity and polydactyly. **Pseudohypoparathyroidism** leads to short stature and developmental delay with short fourth and fifth digits (Albright hereditary osteodystrophy phenotype), resistance to parathyroid hormone and resultant hypocalcemia, and elevated levels of serum phosphorus. **Turner syndrome** is characterized by a karyotype of 45,XO or by a mosaic karyotype and clinically presents with short stature, shield chest, wide-spaced nipples, wide-carrying angle of the upper extremities, high-arched palate, gonadal failure, kidney dysplasias with normal function, and aortic arch abnormalities. **Noonan syndrome (NS)** has an estimated prevalence of 1 in 1000–2,500 live births, equal between sexes. It is inherited in an autosomal dominant pattern (one third of affected children), with two thirds of the diagnoses being de novo mutations, near complete penetrance but marked clinical heterogeneity. NS is characterized by distinctive facial dysmorphic features, congenital heart defects, chest wall abnormalities (pectus carinatum and/or excavatum), and growth delays. Postnatal delay in growth is accompanied by reduced IGF-1 concentrations, but usually normal GH secretion; GH deficiency has been described in some patients.

Diagnosis

If family or other medical history does not provide a likely diagnosis, laboratory screening tests may include a complete

TABLE 173.3 Differential Diagnosis and Therapy of Short Stature

DIAGNOSTIC FEATURE	HYPOGONADISM GH DEFICIENCY*	CONSTITUTIONAL DELAY	FAMILIAL SHORT STATURE	DEPRIVATIONAL DWARFISM	TURNER SYNDROME	HYPOTHYROIDISM	CHRONIC DISEASE
Family history positive	Rare	Frequent	Always	No	No	Variable	Variable
Gender	Both	Males more often affected than females	Both	Both	Female	Both	Both
Facies	Immature or with midline defect (e.g., cleft palate or optic hypoplasias)	Immature	Normal	Normal	Turner facies or normal	Coarse (cretin if congenital)	Normal
Sexual development	Delayed	Delayed	Normal	May be delayed	Female prepubertal	Usually delayed, may be precocious if hypothyroidism is severe	Delayed
Bone age	Delayed	Delayed	Normal	Usually delayed; growth arrest lines present	Delayed	Delayed	Delayed
Dentition	Delayed	Normal; delay usual	Normal	Variable	Normal	Delayed	Normal or delayed
Hypoglycemia	Variable	No	No	No	No	No	No
Karyotype	Normal	Normal	Normal	Normal	45,X or partial deletion of X chromosome or mosaic	Normal	Normal
Free T ₄	Low (with TRH deficiency) or normal	Normal	Normal	Normal or low	Normal: hypothyroidism may be acquired	Low	Normal
Stimulated GH	Low	Normal for bone age	Normal	Possibly low, or high if patient malnourished	Usually normal	Low	Usually normal
Insulin-like growth factor 1	Low	Normal or low for chronologic age	Normal	Low	Normal	Low	Low or normal (depending on nutritional status)
Therapy	Replace deficiencies	Reassurance; sex steroids to initiate secondary sexual development in selected patients	None	Change or improve environment	Sex hormone replacement, GH; oxandrolone may be useful	T ₄	Treat malnutrition, organ failure (e.g., dialysis, transplant, cardiotoxic drugs, insulin)

*Possibly with GnRH, CRH, or TRH deficiency.
CRH, Corticotropin-releasing hormone; GH, growth hormone; GnRH, gonadotropin-releasing hormone; TRH, thyrotropin-releasing hormone; T₄, thyroxine.

TEST	RATIONALE
CBC	<i>Anemia</i> : nutritional, chronic disease, malignancy
	<i>Leukopenia</i> : bone marrow failure syndromes
	<i>Thrombocytopenia</i> : malignancy, infection
ESR, CRP	Inflammation of infection, inflammatory diseases, malignancy
Metabolic panel (electrolytes, liver enzymes, BUN)	Signs of acute or chronic hepatic, renal, adrenal dysfunction; hydration and acid-base status
Carotene, folate, and prothrombin time; celiac antibody panel	Assess malabsorption; detect celiac disease
Urinalysis with pH	Signs of renal dysfunction, hydration, water and salt homeostasis; renal tubular acidosis
Karyotype	Determines Turner (XO) or other syndromes
Cranial imaging (MRI)	Assesses hypothalamic-pituitary tumors (craniopharyngioma, glioma, germinoma) or congenital midline defects
Bone age	Compare with height age and evaluate height potential
IGF-1, IGF-BP3	Reflects growth hormone status or nutrition
Free thyroxine	Detects MPHD or isolated hypothyroidism
Prolactin	Elevated in hypothalamic dysfunction or destruction, suppressed in pituitary disease

BUN, Blood urea nitrogen; *CBC*, complete blood count; *CRP*, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *IGF-1*, insulin-like growth factor 1; *IGF-BP3*, insulin-like growth factor-binding protein 3; *MRI*, magnetic resonance imaging; *MPHD*, multiple pituitary hormone deficiency.

blood count, erythrocyte sedimentation rate, creatinine, glucose, electrolytes, bicarbonate, liver function tests, calcium, phosphate, albumin, celiac screen, FT4, TSH, IGF-1, and IGFBP-3. A urine study should be performed to assess renal function and evaluate for renal tubular acidosis. A karyotype rules out **Turner syndrome** in a girl or in short boys with associated genital abnormalities. A radiograph of the left hand and wrist should be obtained for a bone age evaluation by an expert to estimate the remaining growth potential. Malformations on this radiograph may sometimes point to a skeletal dysplasia.

PEARLS FOR PRACTITIONERS

See *Endocrinology: Pearls for Practitioners* at the end of this section.

CHAPTER 174

Disorders of Puberty

PHYSIOLOGY

The staging of pubertal changes and the sequence of events are discussed in Chapter 67. The onset of puberty is marked by pubarche and gonadarche. **Pubarche** results from adrenal maturation or adrenarche and is marked with the appearance of pubic hair; other features include oiliness of hair and skin, acne, axillary hair, and body odor. **Gonadarche** is characterized by increasing secretion of gonadal sex steroids as a result of the maturation of the hypothalamic-pituitary-gonadal axis. These sex steroids differ by gender, consisting of testosterone from the testes and estradiol and progesterone from the ovaries. In males, physical signs are pubic hair, axillary hair, facial hair, increased muscularity, deeper voice, increased penile size, and increased testicular volume. In females, the physical signs are breast development, development of the female body habitus, increased size of the uterus, and menarche with regular menstrual cycles. The third component is the growth spurt of puberty.

Hypothalamic gonadotropin-releasing hormone (GnRH), produced by cells in the arcuate nucleus, is secreted from the median eminence of the hypothalamus into the pituitary portal system and reaches the membrane receptors on the pituitary gonadotropes to stimulate the production and release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) into the circulation. Numerous genes have been identified that are critical for normal pubertal development and progression. Those include mutations in (1) the pathway that controls the development or function of GnRH-producing neurons (*KAL1*, *FGFR1*, *KISS1R*, *NELF*, *PROK2*, *PROKRR2*), (2) transcription factors critical for ventromedial hypothalamus and pituitary development (*SF1*, *DAX1*, *HESX1*, *LHX3*, *SOX2*, *PROPI*), (3) genes affecting GnRH release and action (*GNRH1*, *GNRHR*), and (4) genes involved in gonadotropin production (*LH β* or *FSH β* , *SF1*, *DAX1*). Kisspeptin and neurokinin B (NKB) are neuropeptides that appear to be “gatekeepers of puberty.”

In females, FSH stimulates the ovarian production of estrogen and, later in puberty, causes the formation and support of corpus luteum. In males, LH stimulates the production of testosterone from the Leydig cells; later in puberty, FSH stimulates the development and support of the seminiferous tubules. The gonads also produce the protein inhibin. Both sex steroids and inhibin suppress the secretion of gonadotropins. The interplay of the products of the gonads and GnRH modulates the serum concentrations of gonadotropins. GnRH is released in episodic pulses that vary during development and during the menstrual period. With the onset of puberty, the amplitude of the pulses of gonadotropins and, in turn, the sex steroids increase first at night and then throughout the day. Adrenarche generally occurs several years earlier than gonadarche and is heralded by increasing circulating dehydroepiandrosterone (DHEA) or androstenedione. Serum DHEA increases years before the appearance of its effects.

The typical developmental sequence in females is **thelarche** (due to gonadarche), followed closely by **pubarche** (due to adrenarche), and finally **menarche** 2–3 years later. In males

the first typical event is scrotal thinning followed by the enlargement of testes and by the appearance of pubic hair (long diameter of the testis >2.5 cm, volume >4 mL). Most of the enlargement of testes during puberty is the result of seminiferous tubule maturation.

DELAYED PUBERTY

Puberty is delayed when there is no sign of pubertal development by age 13 years in females and 14 years in males living in the United States (Tables 174.1 and 174.2).

Constitutional Delay in Growth and Adolescence

Patients with constitutional delay have delayed onset of pubertal development and significant bone age delay (2 standard deviations below the mean, which is equal to a 1.5- to 2-year delay as a teenager). Usually, height gain is below, although fairly parallel to, the normal percentiles on the growth curve. The prepubertal nadir, or deceleration before their pubertal growth spurt, is prolonged or protracted. A family history of delayed puberty in a parent or sibling is reassuring. Spontaneous puberty usually begins in these patients by the time the bone age reaches 12 years in males and 11 years in females. Other causes of delayed puberty must be eliminated before a diagnosis of constitutional delay in puberty is made. Observation and reassurance are appropriate. Adult height normal for the genetic potential is generally attained. In some cases, males may be treated with low-dose testosterone for a few months if the bone age is at least 11–12 years. Treatment is not required for longer than 4–8 months because endogenous hormone production usually ensues. Males who do not initiate endogenous hormone production should be evaluated for other causes of hypogonadism. Estrogen treatment has been used in females with constitutional delay, but there are no clear studies showing the added benefits. Young women with delayed puberty may need to be evaluated for primary amenorrhea.

Hypogonadotropic Hypogonadism

As a cause of delayed or absent puberty, hypogonadotropic hypogonadism may be difficult to distinguish from constitutional delay (see Tables 174.1 and 174.2). Hypogonadotropic hypogonadism precludes spontaneous entry into gonadarche; adrenarche usually occurs to some degree. Throughout childhood and in early puberty, patients with hypogonadotropic hypogonadism have normal proportions and growth. When these patients reach adulthood, they often have an upper-to-lower ratio below the lower limit of normal of 0.9 and an arm span greater than their height due to prolonged time growing.

Isolated Gonadotropin Deficiency

Disorders that can cause hypogonadism include congenital hypopituitarism, tumors, infiltrative disease (hemochromatosis), and many syndromes, including Laurence-Moon-Bardet-Biedl, Prader-Willi, and Kallmann syndromes. If there is an inability to release gonadotropins but no other pituitary abnormality, the patient has isolated gonadotropin deficiency

(almost universally a result of absent GnRH). Patients grow normally until the time of the pubertal growth spurt, when they fail to experience the accelerated growth characteristic of the normal growth spurt. There are at least 31 known mutations

TABLE 174.2 Differential Diagnostic Features of Delayed Puberty and Sexual Infantilism

CAUSATIVE CONDITION/DISORDER	STATURE	PLASMA GONADOTROPINS	GNRH TEST: LH RESPONSE	PLASMA GONADAL STEROIDS	PLASMA DHEAS	KARYOTYPE	OLFACTION
Constitutional delay in growth and puberty	Short for chronologic age, usually appropriate for bone age	Prepubertal, later pubertal	Prepubertal, later pubertal	Prepubertal, later normal	Low for chronologic age, appropriate for bone age	Normal	Normal
HYPOGONADOTROPIC HYPOGONADISM							
Isolated gonadotropin deficiency	Normal, absent pubertal growth spurt	Low	Prepubertal or no response	Low	Appropriate for chronologic age	Normal	Normal
Kallmann syndrome	Normal, absent pubertal growth spurt	Low	Prepubertal or no response	Low	Appropriate for chronologic age	Normal	Anosmia or hyposmia
Idiopathic multiple pituitary hormone deficiencies	Short stature and poor growth since early childhood	Low	Prepubertal or no response	Low	Usually low	Normal	Normal
Hypothalamic-pituitary tumors	Decrease in growth velocity of late onset	Low	Prepubertal or no response	Low	Normal or low for chronologic age	Normal	Normal

From Grumbach MM, Styne DM. Puberty. In: Wilson JD, Foster DW, eds. Williams Textbook of Endocrinology. 9th ed. Philadelphia: WB Saunders; 1997.

that are associated with hypogonadism (e.g., *GNRHR*, *FGFR1*, *FGF8*, *NSMF*, *GNRH1*, *KISS1*, *KISS1R*, *PROK2*, *PROKR2*, *TAC3*, and its receptor *TACR3*).

Kallmann syndrome combines isolated gonadotropin deficiency with disorders of olfaction. There is genetic heterogeneity; some patients have a decreased sense of smell, others have abnormal reproduction, and some have both. Most cases are sporadic, but a number of patients may have mutations in the (*ANOS1*) *KAL1* gene at Xp 22.31 (X chromosome). The mutation causes the GnRH neurons to remain ineffectually located in the primitive nasal area, rather than migrating to the correct location at the medial basal hypothalamus. Olfactory bulbs and olfactory sulci are often absent on magnetic resonance imaging (MRI).

Abnormalities of the Central Nervous System

Central nervous system (CNS) tumors, including pituitary adenoma, glioma, prolactinoma, or craniopharyngioma, are

important causes of gonadotropin deficiency. Craniopharyngiomas have a peak incidence in the teenage years and may cause any type of anterior or posterior hormone deficiency. Craniopharyngiomas usually calcify, eroding the sella turcica when they expand. They may impinge on the optic chiasm, leading to bitemporal hemianopsia and optic atrophy. Other tumors that may affect pubertal development include astrocytomas and gliomas.

Idiopathic hypopituitarism is the congenital absence of various combinations of pituitary hormones. Genes associated with this include *HESX1*, *OTX2*, *TCF7L1*, *SHH*, *GLI2*, *PRO1*, *POU1F1(PIT1)*, *LHX3*, *LHX4*, *TBX19*, *SOX2*, and *SOX3*. Although this disorder may occur in family constellations, in X-linked or autosomal recessive patterns, sporadic types of congenital idiopathic hypopituitarism are more common. Congenital hypopituitarism may manifest in a male with growth hormone (GH) deficiency and associated gonadotropin deficiency with a microphallus or with hypoglycemia with seizures, especially if adrenocorticotrophic hormone and GH deficiency occurs as well.

Acquired Causes of Hypogonadotropic Hypogonadism

Decreased gonadotropin function occurs when voluntary dieting, malnutrition, or chronic disease results in weight loss to less than 80% of ideal weight. **Anorexia nervosa** is characterized by striking weight loss and psychiatric disorders (see Chapter 70). Primary or secondary amenorrhea frequently is found in affected females, and pubertal development is absent or minimal, depending on the level of weight loss and the age at onset. Regaining weight to the ideal level may not immediately reverse the condition. Increased physical activity, even without weight loss, can lead to decreased menstrual frequency and gonadotropin deficiency in **athletic amenorrhea**; when physical activity is interrupted, menstrual function may return. Chronic or systemic illness (e.g., cystic fibrosis, diabetes mellitus, inflammatory bowel disease, or hematologic diseases) can lead to pubertal delay or to amenorrhea from hypothalamic dysfunction. **Hypothyroidism** inhibits the onset of puberty and delays menstrual periods. Conversely, severe primary hypothyroidism may lead to precocious puberty.

Hypergonadotropic Hypogonadism

Hypergonadotropic hypogonadism is characterized by elevated gonadotropins and low sex steroid levels resulting from primary gonadal failure. This permanent condition is almost always diagnosed following the lack of entry into gonadarche and is not suspected throughout childhood. Gonadotropins do not increase to greater than normal until shortly before or around the normal time of puberty.

Ovarian failure is diagnosed by elevated gonadotropins. **Turner syndrome** is a common cause of ovarian failure and short stature. The karyotype is classically 45,XO, but other abnormalities of the X chromosome, or mosaicism, are possible. The incidence of Turner syndrome is 1 in 2,000–3,000 births. The features of a female with Turner syndrome need not be evident on physical examination or by history. The diagnosis must be considered in any female who is short without a contributory history. Patients with other types of gonadal dysgenesis, or galactosemia, as well as patients who have undergone radiation therapy or chemotherapy for malignancy may develop ovarian failure.

Klinefelter syndrome (seminiferous tubular dysgenesis) is the most common cause of **testicular failure**. The karyotype is 47,XXY, but variants with more X chromosomes are possible. The incidence is approximately 1 in 500–1,000 in males. Testosterone levels may be close to normal, at least until mid-puberty, because Leydig cell function may be spared; however, seminiferous tubular function characteristically is lost, causing infertility. Commonly LH levels may be normal to elevated, whereas FSH levels are usually more unequivocally elevated. The age of onset of puberty is usually normal, but secondary sexual changes may not progress because of inadequate Leydig cell function.

Primary Amenorrhea

In addition to other diagnoses mentioned, other conditions need to be considered when evaluating females with lack of menses. The Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome of congenital absence of the uterus occurs in 1 in

4,000–5,000 female births. Anatomic obstruction by imperforate hymen or vaginal septum also presents with normal secondary sexual development without menstruation. The complete syndrome of **androgen insensitivity** includes normal feminization, absence of pubic or axillary hair, and primary amenorrhea. In this syndrome, all müllerian structures, including ovaries, uterus, fallopian tubes, and upper third of the vagina, are lacking; the karyotype is 46,XY, and patients have intraabdominal testes.

Evaluation

When no secondary sexual development is present after the upper age limits of normal pubertal development, serum gonadotropin levels should be obtained to determine whether the patient has a hypogonadotropic or hypergonadotropic hypogonadism (see Table 174.2). Based on gonadotropin measurements only, the differentiation between constitutional delay in growth and hypogonadotropic hypogonadism is difficult; the gonadotropin levels are low in both conditions. Sometimes observation for months or years is necessary before the diagnosis is confirmed. Ultrasound of the pelvic structures in females would be helpful in the work-up of delayed puberty.

Treatment

If a permanent condition is apparent, replacement with sex steroids is indicated. Females are given titrated doses of transdermal estradiol, low-dose oral ethinyl estradiol, or conjugated estrogens until breakthrough bleeding occurs, at which time cycling is started with a dose for 25 days; on days 20–25, a progestational agent, such as medroxyprogesterone acetate (5 mg), is added to mimic the normal increases in gonadal hormones and to induce a normal menstrual period. Alternatively, combined estrogen and progesterone agents (oral contraceptives) may be used after breakthrough bleeding occurs. In males, testosterone enanthate or cypionate (50–100 mg monthly with a progressive increase to 100–200 mg) is given intramuscularly once every 4 weeks. This starting regimen is appropriate for patients with hypogonadotropic or hypergonadotropic hypogonadism, and doses are increased gradually to adult levels, often increasing the frequency of injections as needed. Alternatively, patients are transitioned to daily topical testosterone agents to keep levels more consistent. Oral agents are not used for fear of hepatotoxicity. Patients with apparent constitutional delay in puberty who have, by definition, passed the upper limits of normal onset of puberty may be given a 3- to 6-month course of low-dose, sex-appropriate gonadal steroids to see whether spontaneous puberty occurs. This course of therapy might be repeated once without undue advancement of bone age.

All patients with any form of delayed puberty are at risk for decreased bone density, so adequate calcium intake is essential. Patients with hypogonadotropic hypogonadism may be able to achieve fertility by the administration of gonadotropin therapy or pulsatile hypothalamic-releasing hormone therapy administered by a programmable pump on an appropriate schedule.

In subjects with **Turner syndrome**, the goals of therapy include promoting growth with exogenous human GH supplementation and induction of the secondary sexual characteristics and of menses with low-dose cyclic estrogen/progesterone

replacement therapy. Patients with Turner syndrome have had successful pregnancies after in vitro fertilization with a donor ovum and endocrine support.

SEXUAL PRECOCITY

Classification

Sexual precocity (**precocious puberty**) is classically defined as secondary sexual development occurring before the age of 9 years in males or 8 years in females (Tables 174.3 and 174.4). Studies clearly suggested an earlier age at puberty onset in American females in the 1980s to 1990s compared to the 1930s and 1940s.

A longitudinal study was conducted in females from 2004–2011. Although not nationally representative, they reported the overall distribution of pubertal timing was shifted to earlier ages by approximately 0.75 year for breast development and 0.35 year for menarche than in previous studies. Data showed normal-weight, non-Hispanic Black females achieved pubertal milestones earlier than White females, by about 0.75–1.0 year for thelarche and 0.5–0.75 year for menarche, concluding thelarche normally may occur around 7 years of age in Blacks. Pubertal milestones in Asian females were similar to those in Whites, and in Hispanics to Blacks.

Central precocious puberty, resulting in gonadarche, emanates from premature activation of the hypothalamic-pituitary-gonadal axis (GnRH dependent). **Peripheral precocious puberty**, gonadarche or adrenarche, does not involve the hypothalamic-pituitary-gonadal axis (GnRH independent).

Central Precocious Puberty (GnRH-Dependent Precocious Puberty)

In central precocious puberty, every endocrine and physical aspect of pubertal development is normal but too early; this includes tall stature, advanced bone age consistent with somatic age, increased sex steroid and pulsatile gonadotropin secretion, and increased response of LH to GnRH. The clinical course of central precocious puberty may wax and wane. Benign precocious puberty is the presumptive diagnosis in individuals who begin puberty early on a **constitutional** or **familial** basis. If no cause can be determined, the diagnosis is idiopathic precocious puberty, which occurs much more often in females than in males. Obese females have earlier adrenarche, and sometimes menarche as well, than appropriate-weight females. Compared with females, males with precocious puberty have a higher incidence of CNS disorders, such as tumors and hamartomas, precipitating the precocious puberty.

Almost any condition that affects the CNS, including hydrocephalus, meningitis, encephalitis, suprasellar cysts, head trauma, epilepsy, intellectual disability, and irradiation, can precipitate central precocious puberty and must be considered before central precocious puberty is diagnosed. **Hamartomas** are nonmalignant tumors of the tuber cinereum with a characteristic appearance on computed tomography (CT) or MRI; biopsy is rarely required. The mass of GnRH neurons secrete GnRH and cause precocious puberty. Although hamartomas are not true neoplasms, they may require neurosurgical attention. The resulting precocious puberty is responsive to medical therapy with GnRH agonists, and surgery is rarely indicated.

TABLE 174.3 Classification of Sexual Precocity

TRUE PRECOCIOUS PUBERTY OR COMPLETE ISOSEXUAL PRECOCITY
Idiopathic true precocious puberty
CNS tumors
Hamartomas (ectopic GnRH pulse generator)
Other tumors
Other CNS disorders
True precocious puberty after late treatment of congenital virilizing adrenal hyperplasia
INCOMPLETE ISOSEXUAL PRECOCITY (GNRH-INDEPENDENT SEXUAL PRECOCITY)
Males
Chorionic gonadotropin-secreting tumors (HCG-dependent sexual precocity)
CNS tumors (e.g., germinoma, chorioepithelioma, teratoma)
Tumors in locations outside of the CNS (hepatoblastoma)
LH-secreting pituitary adenoma
Increased androgen secretion by adrenal or testis
Congenital adrenal hyperplasia (21-hydroxylase deficiency, 11-hydroxylase deficiency)
Virilizing adrenal neoplasm
Leydig cell adenoma
Familial male-limited precocious puberty
Females
Estrogen-secreting ovarian or adrenal neoplasms
Ovarian cysts
Males and Females
McCune-Albright syndrome
Primary hypothyroidism
Peutz-Jeghers syndrome
Iatrogenic sexual precocity
VARIATIONS OF PUBERTAL DEVELOPMENT
Premature thelarche
Premature menarche
Premature adrenarche
Adolescent gynecomastia
CONTRASEXUAL PRECOCITY
Males (Feminization)
Adrenal neoplasm
Increased extraglandular conversion of circulating steroids to estrogen
Exogenous estrogens
Females (Virilization)
Congenital adrenal hyperplasia, P-450 _{c21} deficiency, P-450 _{c11} deficiency, 3 β -hydroxysteroid dehydrogenase deficiency
Virilizing adrenal neoplasms
Virilizing ovarian neoplasms (e.g., arrhenoblastomas)
Exogenous androgens

TABLE 174.4 Differential Diagnosis of Sexual Precocity

CAUSATIVE DISORDER	SERUM GONADOTROPIN CONCENTRATION*	LH RESPONSE TO GNRH	SERUM SEX STEROID CONCENTRATIONS	GONADAL SIZE	MISCELLANEOUS
True precocious puberty	Pubertal values	Pubertal	Pubertal values of testosterone or estradiol	Normal pubertal testicular enlargement or ovarian and uterine enlargement (by sonography)	MRI scan of brain to rule out CNS tumor or other abnormality; bone scan for McCune-Albright syndrome
Incomplete sexual precocity (pituitary gonadotropin independent)					
MALES					
Chorionic gonadotropin-secreting tumor in males	High HCG (low LH)	Prepubertal (suppressed)	Pubertal values of testosterone	Slight to moderate uniform enlargement of testes	Hepatomegaly suggests hepatoblastoma; MRI scan of brain if chorionic gonadotropin-secreting CNS tumor suspected
Leydig cell tumor in males	Suppressed	Suppressed	Very high testosterone	Irregular asymmetric enlargement of testes	
Familial male-limited precocious puberty	Suppressed	Suppressed	Pubertal values of testosterone	Testes symmetric and >2.5 cm but smaller than expected for pubertal development; spermatogenesis may occur	Familial; probably sex-linked, autosomal dominant trait
Premature adrenarche	Prepubertal	Prepubertal	Prepubertal testosterone; DHEAS values appropriate for pubic hair stage 2	Testes prepubertal	Onset usually after 6yr of age; more frequent in brain-injured children
FEMALES					
Granulosa cell tumor (presentation may be similar to that with follicular cysts)	Suppressed	Suppressed	Very high estradiol	Ovarian enlargement on physical examination, MRI, CT, or sonography	Tumor often palpable on abdominal examination
Follicular cyst	Suppressed	Suppressed	Prepubertal to very high estradiol values	Ovarian enlargement on physical examination, MRI, CT, or sonography	Single or repetitive episodes; exclude McCune-Albright syndrome (e.g., perform skeletal survey and inspect skin)
Feminizing adrenal tumor	Suppressed	Suppressed	High estradiol and DHEAS values	Ovaries prepubertal	Unilateral adrenal mass
Premature thelarche	Prepubertal	Prepubertal	Prepubertal or early pubertal estradiol	Ovaries prepubertal	Onset usually before 3yr of age
Premature adrenarche	Prepubertal	Prepubertal	Prepubertal estradiol; DHEAS values appropriate for pubic hair Tanner stage 2	Ovaries prepubertal	Onset usually after 6yr of age; more frequent in brain-injured children

*In supersensitive assays.

Modified from Grumbach MM, Styne DM. Puberty. In: Wilson JD, Foster DW, eds. Williams Textbook of Endocrinology. 9th ed. Philadelphia: WB Saunders; 1997.

GnRH-Independent Precocious Puberty

The most common cause of GnRH-independent precocious puberty, **McCune-Albright syndrome**, is more frequent in females than males and includes precocious gonadarche, a bone disorder with polyostotic fibrous dysplasia and hyperpigmented cutaneous macules (café-au-lait spots). The precocious gonadarche results from ovarian hyperfunction and sometimes cyst formation, leading to episodic estrogen secretion. This disorder results from a postconception somatic mutation in the G protein intracellular signaling system (specifically G_{sa}), which leads to unregulated constitutive activation of adenylate cyclase, and of cyclic adenosine monophosphate [cAMP] in the absence of trophic hormone stimulation), in the affected cells in ovary, bone, and skin; other endocrine organs may also autonomously hyperfunction for the same reason. Hyperthyroidism, hyperadrenalism, or acromegaly may occur. **Adrenal carcinomas** usually secrete adrenal androgens, such as DHEA; **adrenal adenomas** may virilize a child as a result of the production of androgen or may feminize a child as a result of the production of estrogen.

Males may have precocious gonadarche on the basis of a rare entity called **familial male-limited precocious puberty**. This condition, with germ cell maturation caused by an X-limited dominant defect, produces constitutive activation of the LH receptor that leads to continuous production and secretion of testosterone without requiring LH or human chorionic gonadotropin (HCG).

HCG-secreting tumors stimulate LH receptors and increase testosterone secretion. These tumors may be found in various places, including the pineal gland (dysgerminomas) or the liver (hepatoblastoma).

Germinomas are noncalcifying hypothalamic or pineal tumors that frequently produce HCG, which may cause sexual precocity in prepubertal boys (HCG cross reacts with the LH receptor because of the similarity of structure between LH and HCG). **Optic or hypothalamic gliomas** (with or without neurofibromatosis), astrocytomas, and ependymomas may cause precocious puberty by disrupting the negative restraint of the areas of the CNS that normally inhibit pubertal development throughout childhood. These tumors may require radiotherapy, which contributes to a significant risk for hypopituitarism.

Ovarian cysts may occur once or may be recurrent. High serum estrogen values may mimic ovarian tumors. **Congenital adrenal hyperplasia (CAH)** is a cause of virilization in females (see Chapter 177).

Evaluation of Sexual Precocity

The first step in evaluating sexual precocity is to determine which characteristics of normal puberty are apparent (see Chapter 67) and whether estrogen effects, androgen effects, or both are present (see Table 174.4). In females the estrogen effect manifests as breast development, uterine increase, and, eventually, menarche. Both males and females manifest the androgen effect as adult body odor, pubic and axillary hair, and facial skin oiliness and acne. In males it is also important to note whether the testes are enlarged more than 2.5 cm in length (4-mL volume), which implies gonadarche. If the testes are not enlarged but virilization is progressing, the source of the androgens may be the adrenal glands or exogenous sources.

Laboratory evaluation includes determination of adrenal androgen and sex steroid levels (testosterone, estradiol, dehydroepiandrosterone sulfate [DHEAS]) and baseline gonadotropin concentrations. The inherent nature of gonadotropin secretion is characterized by low secretory rates throughout childhood and pulsatile secretion in adolescents and adults. If baseline gonadotropin values are elevated into the normal pubertal range, central precocious puberty is likely. If baseline gonadotropins are low, however, no immediate conclusion may be drawn as to GnRH-dependent versus GnRH-independent precocious puberty. This distinction often requires the assessment of gonadotropin responsiveness to GnRH stimulation. A prepubertal GnRH response is FSH predominant, whereas a pubertal response is more LH predominant. Thyroid hormone determination also is useful because severe primary hypothyroidism can cause incomplete precocious puberty. If there is a suggestion of a CNS anomaly or a tumor (CNS, hepatic, adrenal, ovarian, or testicular), MRI of the brain and pituitary with and without contrast is indicated. MRI of the brain is recommended in patients with the diagnosis of central precocious puberty; however, the yield is generally low in females over age 6. Males as well as young females have a higher risk of CNS lesions as a cause of precocious puberty.

Treatment

Long-acting analogs of GnRH (leuprolide depot, histrelin implant, triptorelin) are the treatment of choice for central precocious puberty. They suppress gonadotropin secretion by downregulating GnRH receptors in the pituitary gonadotropes (Table 174.5), causing gonadal secretion to revert to the prepubertal state. Males with GnRH-independent premature Leydig cell and germ cell maturation do not respond to GnRH analogs but require treatment with an inhibitor of testosterone synthesis (e.g., ketoconazole), an antiandrogen (e.g., spironolactone), or an aromatase inhibitor (e.g., testolactone or letrozole). Patients with precocious puberty from a hormone-secreting tumor require surgical removal, if possible. The precocious puberty of the McCune-Albright syndrome is GnRH independent and unresponsive to therapy with GnRH analog. Therapy is provided with antiandrogens or antiestrogen, such as tamoxifen or aromatase inhibitor such as letrozole.

VARIATIONS IN PUBERTAL DEVELOPMENT

Isolated Premature Thelarche (Premature Breast Development)

Benign **premature thelarche** is the isolated appearance of unilateral or bilateral breast tissue in females, usually at ages 6 months to 3 years. The likely cause appears to be an idiopathic subtle over-function of the pituitary-ovarian axis, with FSH levels in those females being sustained around the upper end of the prepubertal normal range. FSH response to GnRH is significantly increased, whereas LH is not. Estradiol levels are generally below the level of detection in most standard assays but are significantly elevated according to ultrasensitive assay. Mild estrogenization of the urogenital mucosa is sometimes found, but without menarche or discharge.

Ingestion or dermal application of estrogen-containing compounds must be excluded. Laboratory investigations are not usually necessary, but a pelvic ultrasound study rarely may be indicated to exclude ovarian disease. Females with this

TABLE 174.5 Pharmacologic Therapy of Sexual Precocity

DISORDER	TREATMENT	ACTION AND RATIONALE
GnRH-dependent true or central precocious puberty	GnRH agonists	Desensitization of gonadotropes; blocks action of endogenous GnRH
GnRH-independent incomplete sexual precocity		
Girls		
Autonomous ovarian cysts	Medroxyprogesterone acetate	Inhibition of ovarian steroidogenesis; regression of cyst (inhibition of FSH release)
McCune-Albright syndrome	Medroxyprogesterone acetate*	Inhibition of ovarian steroidogenesis; regression of cyst (inhibition of FSH release)
Boys		
	Testolactone*	Inhibition of P-450 aromatase; blocks estrogen synthesis
Familial GnRH-independent sexual precocity with premature Leydig cell maturation	Ketoconazole*	Inhibition of P-450 _{c17} (mainly 17,20-lyase activity)
	Spironolactone* or flutamide and testolactone	Antiandrogen inhibition of aromatase; blocks estrogen synthesis
	Medroxyprogesterone acetate*	Inhibition of testicular steroidogenesis

*If true precocious puberty develops, a GnRH agonist can be added.

FSH, Follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone.

Modified from Grumbach MM, Kaplan SL. Recent advances in the diagnosis and management of sexual precocity. *Acta Paediatr Jpn.* 1988;30(Suppl):155.

condition should be re-evaluated at intervals of 6–12 months to ensure that apparent premature thelarche is not the beginning of progression into precocious puberty. The prognosis is excellent; if no progression occurs, no treatment other than reassurance is necessary.

Gynecomastia

In males, breast tissue is termed *gynecomastia*, and it may occur to some degree in 45–75% of normal pubertal males (see Chapter 67). Androgens normally are converted to estrogen by aromatization; in early puberty, only modest amounts of androgens are produced, and the estrogen effect can overwhelm the androgen effects at this stage. Later in pubertal development, the androgen production is so great that there is little effect from the estrogen produced by aromatization. Gynecomastia also can suggest the possibility of **Klinefelter syndrome** as puberty progresses. Prepubertal gynecomastia suggests an unusual source of estrogen either from exogenous sources (oral or dermal estrogen administration is possible from contamination of food or ointments) or from endogenous sources (from abnormal function of adrenal gland or ovary or from increased peripheral aromatization).

Isolated Premature Adrenarche (Pubarche)

The isolated appearance of pubic hair before age 6–7 years in females or before age 9 years in males is termed **premature pubarche**, usually resulting from adrenarche. It is relatively common. If the pubic hair is associated with any other feature of virilization (clitoral or penile enlargement or advanced bone age) or other signs (acne, rapid growth, or voice change), a detailed investigation for a pathologic cause of virilization is indicated. Measurements of serum testosterone, 17-hydroxyprogesterone, and DHEAS are indicated to investigate the possibility of CAH. Ultrasound studies may reveal a hyperplastic adrenal gland or a virilizing adrenal or ovarian tumor. Most patients with isolated pubic hair do not have progressive virilization and simply have

premature adrenarche (*pubarche*) resulting from premature activation of DHEA secretion from the adrenal gland. The skeletal maturation, as assessed by bone age, may be slightly advanced and the height slightly increased, but testosterone concentrations are normal. DHEA levels usually are high for prepubertal age but are consistent with Tanner (sexuality maturity rating) stages II and III. In females, those with premature adrenarche may have a 15–20% increased risk of development of irregular menses or polycystic ovarian syndrome later in adolescence.

See *Endocrinology: Pearls for Practitioners* at the end of this section.

CHAPTER 175

Thyroid Disease

THYROID PHYSIOLOGY AND DEVELOPMENT

Thyrotropin-releasing hormone (TRH), a tripeptide synthesized in the hypothalamus, stimulates the release of pituitary thyroid-stimulating hormone (TSH). Pituitary TSH is a glycoprotein that stimulates the synthesis and release of thyroid hormones by the thyroid gland. Thyroid function develops in three stages. At the end of the first trimester, the gland descends from the floor of the primitive oral cavity to its definitive position in the anterior lower neck. The hypothalamic-pituitary-thyroid axis becomes functional in the second trimester. Peripheral metabolism of thyroid hormones matures in the third trimester.

Thyroxine (T_4), triiodothyronine (T_3), and TSH do not cross the placenta in significant amounts. Concentrations in fetal serum reflect primarily fetal secretion and metabolism.

Maternal thyroid antibodies, iodides (including radioactive iodides), and medications given to mothers to treat hyperthyroidism (methimazole and propylthiouracil) cross the placenta and affect fetal thyroid function. An infant born prematurely or with intrauterine growth restriction may have an interruption of the normal maturational process and appear to have hypothyroidism by standard tests (and newborn screen).

The thyroid gland concentrates iodine and binds it to tyrosine molecules to produce either monoiodotyrosine or diiodotyrosine, with subsequent coupling of two tyrosines, T_4 or T_3 . The major fraction of circulating T_3 (approximately two thirds) is derived from peripheral deiodination of T_4 to T_3 , but some is produced by the gland itself. The conversion of T_4 to

T_3 requires the removal of one iodine from the outer ring of tyrosine; removing an iodine from the inner ring results in reverse T_3 , which has little biologic effect. Preferential conversion of T_4 to reverse T_3 rather than T_3 occurs in utero and in all forms of severe illness, including respiratory distress syndrome, fevers, anorexia, and starvation. Conversion from T_4 to T_3 increases immediately after birth and throughout life. T_4 and T_3 are noncovalently bound to a specific serum carrier protein, thyroxine-binding globulin, and to a lesser extent, albumin. Only small (<0.02%) fractions of T_4 and T_3 are not bound; free T_4 (as it is converted to free T_3) and free T_3 are biologically active. Free T_3 exerts metabolic effects and negative feedback on TSH release (Fig. 175.1).

FIGURE 175.1 Interrelationships of the hypothalamic-pituitary-thyroid axis. Thyroid-stimulating hormone (TSH) from the pituitary gland stimulates the secretion of thyroxine (T_4) and triiodothyronine (T_3) from the thyroid gland. These act at the pituitary gland level to control secretion of TSH by a negative feedback mechanism. In addition, T_4 is metabolized to the potent T_3 within the pituitary gland by a deiodinase. Secretion of TSH is stimulated by thyrotropin-releasing hormone (TRH) from the hypothalamus and inhibited by somatostatin. Thyroid hormone acts at the hypothalamus to stimulate secretion of somatostatin (somatostatin acts as a negative signal to the pituitary secretion of TSH). CRH, Corticotropin-releasing hormone; OB-R, leptin receptor. (From Melmed S, Polonsky K, Kronenberg H, et al., eds. *Williams Textbook of Endocrinology*. 10th ed. Philadelphia: Saunders; 2003:101.)

TABLE 175.1 Laboratory Test Results in Various Types of Thyroid Function Abnormalities in Children*

ABNORMALITY	SERUM			
	TOTAL T ₄	FREE T ₄	SERUM TSH	SERUM TBG
Primary hypothyroidism	↓	↓	↑	N
Hypothalamic (TRH) tertiary hypothyroidism	↓	↓	↓	N
Pituitary (TSH) secondary hypothyroidism	↓	↓	↓	N
TBG deficiency	↓	N	N	↓
TBG excess	↑	N	N	↑

*TSH may be slightly elevated.

↓, Decreased; ↑, increased; N, Normal; T₄, thyroxine; TBG, thyroxine-binding globulin; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

Serum TSH increases just after birth but soon decreases to lower values considered normal for later life. T₄ secretion increases after birth as a result of the peak in TSH and because of maturation of thyroid metabolism. It is important to refer to age-adjusted normative data to interpret thyroid function tests properly, whether relative to making diagnoses of hyperthyroidism or hypothyroidism or when adjusting therapy. Free T₄ is the test of choice because it eliminates the effects of variation in protein binding, which can be substantial.

Table 175.1 summarizes laboratory test results in various types of thyroid abnormalities. In usual circumstances, plasma concentrations of TSH above the normal range indicate primary hypothyroidism, and concentrations below the normal range most often indicate the presence of hyperthyroidism. Thyroid scans with 99m-pertechnetate or 123-I-iodine are occasionally indicated in the evaluation of pediatric thyroid disease. They can be useful in identifying thyroid agenesis or ectopic thyroid tissue.

THYROID DISORDERS

Hypothyroidism

Hypothyroidism is diagnosed by a decreased serum free T₄ and may be the result of diseases of the thyroid gland (primary hypothyroidism), abnormalities of the pituitary gland (secondary), or abnormalities of the hypothalamus (tertiary). Hypothyroidism is congenital or acquired and may or may not be associated with a goiter (Table 175.2).

Congenital Hypothyroidism

Congenital hypothyroidism occurs in approximately 1 in 2,000–4,000 live births and is caused by dysgenesis (agenesis, aplasia, ectopia) or, less often, dyshormonogenesis (e.g., enzyme defects). Thyroid tissue usually is not palpable in these sporadic nongoitrous conditions. Dyshormonogenesis, disorders of intrathyroid metabolism, or goitrous congenital hypothyroidism occurs in about 1 in 30,000 live births. A goiter reflects an inborn error of metabolism in the pathway of iodide incorporation or thyroid hormone biosynthesis or reflects the transplacental passage of antithyroid drugs given to the mother. Routine neonatal screening programs to measure cord blood or heelstick TSH values occur in every state in the United States. An immediate confirmatory serum sample should be obtained from any infant having a positive result on a **screening test**. A low free T₄ and high TSH confirm the finding.

TABLE 175.2 Causes of Hypothyroidism in Infancy and Childhood

AGE GROUP	MANIFESTATION	CAUSE
Newborn	No goiter	Thyroid gland dysgenesis or ectopic location Exposure to iodides TSH deficiency TRH deficiency
	± Goiter	Inborn defect in hormone synthesis* or effect Maternal goitrogen ingestion, including propylthiouracil, methimazole, iodides Severe iodide deficiency (endemic)
Child	No goiter	Thyroid gland dysgenesis Cystinosis Hypothalamic-pituitary insufficiency Surgical after thyrotoxicosis or other thyroid surgery
	Goiter	Hashimoto thyroiditis: chronic lymphocytic thyroiditis Inborn defect in hormone synthesis or effect Goitrogenic drugs, infiltrative (sarcoïd, lymphoma)

*Impaired iodide transport, defective thyroglobulin iodination, defective iodotyrosine dehalogenase, or defective thyroglobulin or its coupling to iodotyrosine.

TRH, Thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

Isolated secondary or tertiary hypothyroidism occurs in 1 in 100,000 live births; the free T₄ is normal to low, as is the TSH. When tertiary or secondary hypothyroidism is detected, assessment of other pituitary hormones and investigation of pituitary-hypothalamic anatomy via magnetic resonance imaging are indicated. Although not a hypothyroid condition, **congenital thyroxine-binding globulin deficiency** occurs in about 1 in 10,000 live births and is associated with low serum total T₄ concentration, normal TSH, and normal serum free T₄.

This is a euthyroid condition and does not require treatment with thyroid hormone because it is merely a binding protein abnormality. It is commonly X-linked dominant.

Clinical manifestations of congenital hypothyroidism in the immediate newborn period usually are subtle but become more evident weeks or months after birth, which is often too late to ensure that there is not a detriment to the infant's cognitive development. Newborn screening is crucial to make an early diagnosis and initiate thyroid replacement therapy by younger than 1 month of age. Findings at various stages after birth include hypothermia, acrocyanosis, respiratory distress, large fontanel, abdominal distention, lethargy and poor feeding, prolonged jaundice, edema, umbilical hernia, mottled skin, constipation, large tongue, dry skin, and hoarse cry. Thyroid hormones are crucial for maturation and differentiation of tissues, such as bone and brain (most thyroid-dependent brain maturation occurs in the first 2–3 years after birth) (Table 175.3).

When **treatment** (with levothyroxine) is initiated within the first month, the prognosis for normal intellectual development is excellent. State screening programs usually allow for therapy within 1–2 weeks of birth. If therapy is instituted after 6 months, when the signs of severe hypothyroidism are present, the likelihood of normal intellectual function is markedly decreased. Growth improves after thyroid replacement even in late diagnosed cases. The dose of levothyroxine changes with age; 10–15 µg/kg of levothyroxine is used for a newborn, but about 3 µg/kg is used later in childhood. In neonatal hypothyroidism, the goal is to bring the serum free T₄ rapidly into the upper half of the range of normal. Suppression of TSH is not seen and not necessary in all cases because such suppression may lead to excessive doses of levothyroxine.

Acquired Hypothyroidism

The **etiology** of acquired hypothyroidism is presented in Table 175.2. The clinical manifestations may be subtle. Hypothyroidism should be suspected in any child who has a decline in growth velocity, especially if **not** associated with weight loss (see Table 175.3). The most common cause of acquired hypothyroidism in older children in the United States is lymphocytic autoimmune thyroiditis (**Hashimoto thyroiditis**). In many areas of the world, iodine deficiency is the etiology of endemic goiter (**endemic cretinism**). The failure of the thyroid gland may be heralded by an increase of TSH before T₄ levels decrease. In contrast to untreated congenital hypothyroidism, acquired hypothyroidism is not a cause of permanent developmental delay.

Hashimoto Thyroiditis

Also known as autoimmune or *lymphocytic thyroiditis*, Hashimoto thyroiditis is a common cause of goiter and acquired thyroid disease in older children and adolescents. A family history of thyroid disease is present in 25–35% of patients. The **etiology** is an autoimmune process targeted against the thyroid gland with lymphocytic infiltration and lymphoid follicle and germinal center formation preceding fibrosis and atrophy.

Clinical manifestations include a firm, nontender euthyroid, hypothyroid, or, rarely, hyperthyroid (hashitoxicosis) diffuse goiter with a pebble-like surface. See Table 175.3 for signs and symptoms, which can be diverse. Onset typically occurs after 6 years of age with a peak incidence in adolescence with

TABLE 175.3 Symptoms and Signs of Hypothyroidism

ECTODERMAL
Poor growth
Dull facies: thick lips, large tongue, depressed nasal bridge, periorbital edema
Dry scaly skin
Sparse brittle hair
Diminished sweating
Carotenemia
Vitiligo
CIRCULATORY
Sinus bradycardia/heart block
Cold extremities
Cold intolerance
Pallor
ECG changes: low-voltage QRS complex
NEUROMUSCULAR
Muscle weakness
Hypotonia: constipation, potbelly
Umbilical hernia
Myxedema coma (carbon dioxide narcosis, hypothermia)
Pseudohypertrophy of muscles
Myalgia
Physical and mental lethargy
Developmental delay
Delayed relaxation of reflexes
Paresthesias (nerve entrapment: carpal tunnel syndrome)
Cerebellar ataxia
SKELETAL
Delayed bone age
Epiphyseal dysgenesis, increased upper-to-lower segment ratio
METABOLIC
Myxedema
Serous effusions (pleural, pericardial, ascites)
Hoarse voice (cry)
Weight gain
Menstrual irregularity
Arthralgia
Elevated CK
Macrocytosis (anemia)
Hypercholesterolemia
Hyperprolactinemia
Precocious puberty in severe cases

CK, Creatine kinase; ECG, electrocardiographic.

a female predominance. Associated autoimmune diseases include celiac disease, type 1 diabetes mellitus, adrenal insufficiency, and hypoparathyroidism. **Autoimmune polyglandular syndrome type I** consists of hypoparathyroidism, Addison disease, mucocutaneous candidiasis, and hypothyroidism. **Autoimmune polyglandular syndrome type II** consists of Addison disease, type 1 diabetes mellitus, and, frequently, hypothyroidism. Trisomy 21 and Turner syndrome are predisposed to the development of autoimmune thyroiditis.

The **diagnosis** may be confirmed by serum antithyroid peroxidase (previously antimicrosomal) and antithyroglobulin antibodies. Neither biopsy nor thyroid scan is indicated in Hashimoto thyroiditis, although a thyroid scan with reduced uptake may differentiate hashitoxicosis from Graves disease.

Treatment with thyroid hormone sufficient to normalize TSH and free T_4 is indicated for hypothyroidism in Hashimoto thyroiditis. Patients without manifestation of hypothyroidism require thyroid function testing (serum TSH and free T_4) every 6–12 months to detect the later development of hypothyroidism. Goiter with a normal TSH usually is not an indication for treatment.

Hyperthyroidism

Graves Disease

Most children with hyperthyroidism have Graves disease, the autonomous functioning of the thyroid caused by autoantibodies (thyroid-stimulating immunoglobulins [TSIs]) stimulating the thyroid. The resulting excessive synthesis, release, and peripheral metabolism of thyroid hormones produce the clinical features. Hashimoto thyroiditis and thyrotoxicosis are on a continuum of autoimmune diseases; there is overlap in their immunologic findings.

Antithyroid peroxidase and antithyroglobulin antibodies may be present in thyrotoxicosis, although the values are usually lower than in Hashimoto thyroiditis. Exceptionally high titers of antibodies may indicate the thyrotoxic phase of Hashimoto thyroiditis with the subsequent evolution toward permanent hypothyroidism. In Graves disease, serum free T_4 , free T_3 , or both levels are elevated, whereas TSH is suppressed. Rare causes of hyperthyroidism include McCune-Albright syndrome, thyroid nodule (often an adenoma), TSH hypersecretion, subacute thyroiditis, and iodine or thyroid hormone ingestion.

Clinical Manifestations

Graves disease presents as hyperthyroidism (Table 175.4) and is about five times more common in females than in males with a peak incidence in adolescence. Personality changes, mood instability, and poor school performance are common initial problems. Tremor, anxiety, inability to concentrate, and weight loss may be insidious and confused with a psychologic disorder until thyroid function tests reveal the elevated serum free T_4 level. In rare cases, serum free T_4 may be near normal, whereas serum T_3 is selectively elevated (T_3 toxicosis). A firm homogeneous goiter is usually present. Many patients complain of neck fullness. Thyroid gland enlargement is best visualized with the neck only slightly extended and with the examiner lateral to the patient. Palpation of the thyroid gland is best performed with the examiner's hands around the neck from the back. The patient swallows so that the examiner can

TABLE 175.4 Clinical Manifestations of Hyperthyroidism

ASSOCIATED CHANGE	SIGN/SYMPTOM

feel and examine the size, consistency, nodularity, and motion of the gland. The examiner should watch the patient swallow to note any discernible enlargement or asymmetry of the thyroid lobes. Auscultation may reveal a bruit over the gland that needs to be differentiated from a carotid bruit.

Treatment

Three treatment choices are available: pharmacologic, radioactive iodine, and surgical.

Drugs

Medical therapy to block thyroid hormone synthesis consists of methimazole (0.4–0.6 mg/kg/day once or twice daily) or

propylthiouracil (5–7 mg/kg/day divided every 8 hours). Both medications are equally effective; however, propylthiouracil is no longer a first-line therapy secondary to concerns of severe liver injury and acute liver failure. A β blocker, such as propranolol or atenolol, is started if symptoms are severe to control cardiac manifestations and is tapered as the methimazole takes effect. Antithyroid medication is usually continued for 1–2 years because the remission rate is approximately 25% per year. In patients complying with the treatment regimen, the 2-year course of treatment can be repeated. Medication should suppress thyroid function to normal without the need to add thyroid hormone replacement to normalize serum free T_4 . Complications of methimazole are muscle pain, rash, granulocytopenia, and jaundice. The granulocytopenia is an idiosyncratic complication of rapid onset, which is observed only in the early months after institution of antithyroid medication and requires monitoring the complete blood count. If a suppressed white blood cell count is observed, antithyroid therapy must be discontinued. This potentially lethal rare complication affects 3 in 10,000 users a year. After resolution, the other of the two antithyroid medications can be started because there is usually less than a 50% chance of a similar reaction from the other medication. Iodine administration, which may suppress thyroid function but becomes ineffective in a few weeks, is sometimes used as a preparation for surgery but never for long-term therapy.

Radioiodine

Radioiodine (^{131}I) is slower in exerting therapeutic effects, may require repeated dosing, and is likely to cause permanent hypothyroidism. Hypothyroidism is the desired outcome because it is easier and safer to treat than continued hyperthyroidism. Although studies reveal no long-term consequences, concern remains about possible sequelae in children. This method of treatment is entering the mainstream for children and adolescents. Radioiodine given to a pregnant teenager renders the fetus hypothyroid and is contraindicated.

Surgery

Surgical treatment consists of partial or complete thyroidectomy. Risks associated with thyroidectomy include the use of anesthesia and the possibility that the thyroid removal will be excessive, causing hypothyroidism, or that it will be inadequate, resulting in persistent hyperthyroidism. In addition, keloid formation, recurrent laryngeal nerve palsy, and hypoparathyroidism (transient postoperative or permanent) may occur. Thyroid storm caused by the release of large amounts of preformed hormone is a serious but rare complication. Even with optimal immediate postoperative results, patients may become hypothyroid within 10 years.

Thyroid Storm

Thyroid storm (see Table 175.4) is a rare medical emergency consisting of tachycardia, disorientation, elevated blood pressure, and hyperthermia. Treatment includes reducing the hyperthermia with a cooling blanket and administering a β blocker to control the tachycardia, hypertension, and autonomic hyperfunction symptoms. Iodine may be given to block thyroid hormone release after an antithyroid medication is started. Hydrocortisone may be indicated for relative adrenal insufficiency, and therapy for heart failure includes diuretics and digoxin.

Congenital Hyperthyroidism

This disorder results from transplacental passage of maternal TSIs and may be masked for several days until the short-lived effects of transplacental maternal antithyroid medication wear off (assuming the mother was receiving such medication), at which time the effects of TSIs are observed. Irritability, tachycardia (often with signs of cardiac failure simulating *cardiomyopathy*), polycythemia, craniosynostosis, bone age advancement, poor feeding, and failure to thrive are the clinical hallmarks. This condition may be anticipated if the mother is known to be thyrotoxic or has an elevated TSI during third trimester of pregnancy. Cure of hyperthyroidism before pregnancy (surgery or radioiodine treatment) limits or curtails T_4 production but not the underlying immune disturbance producing TSIs; thus the infant still may be affected, at least transiently.

Treatment for a severely affected neonate includes methimazole and, as needed, a β blocker to help decrease symptoms. Because the half-life of the immunoglobulin is several weeks, spontaneous resolution of neonatal thyrotoxicosis resulting from transplacental passage of TSIs usually occurs by 2–3 months of age. Observation without treatment is indicated in patients who are minimally affected.

NODULES/TUMORS OF THE THYROID

About 2% of children develop solitary thyroid nodules, most of which are benign. Evaluation of a nodule includes thyroid function tests, neck ultrasound, and, if needed, fine-needle aspiration (FNA). Ultrasound guidance may be needed for aspiration of small nodules or those not palpable. Nodules found to be benign on FNA may be monitored through clinical exam and ultrasound.

Carcinoma of the thyroid is rare in children (1% of all pediatric cancers in the 5- to 9-year-old age group and up to 7% of cancers in the 15- to 19-year-old age group). Papillary and follicular carcinomas represent 90% of childhood thyroid cancers. A history of therapeutic head or neck irradiation or radiation exposure from nuclear accidents predisposes a child to thyroid cancer. Carcinoma usually presents as a firm to hard, painless, nonfunctional solitary nodule and may spread to adjacent lymph nodes. Rapid growth, hoarseness (recurrent laryngeal nerve involvement), and lung metastasis may be present. If the nodule is solid on ultrasound, is *cold* on radioiodine scanning, and feels hard, the likelihood of a carcinoma is high. Excisional biopsy usually is performed, but FNA biopsy also may be diagnostic.

Treatment includes total thyroidectomy, selective regional node dissection, and radioablation with ^{131}I for residual or recurrent disease. Current recommendations have evolved for use of ^{131}I as research has shown noninvasive follicular thyroid neoplasms with papillary-like features have a low recurrence risk without radioablation. The **prognosis** is usually excellent if the disease is diagnosed early.

Medullary carcinoma of the thyroid may be asymptomatic except for a mass. Diagnosis is based on the presence of elevated calcitonin levels, either in the basal state or after pentagastrin stimulation (difficult to obtain) and histologic examination. This tumor most often occurs with multiple endocrine neoplasia 2a or 2b (MEN), possibly in a familial pattern. In some families, the presence of mutations of the

RET protooncogene is predictive of the development of medullary carcinoma of the thyroid. The location of the mutation can help determine when removal of the thyroid is warranted. Genetic screening of other members of the family is indicated after a proband is recognized. Prophylactic thyroidectomy is indicated for the family members with the same allele.

PEARLS FOR PRACTITIONERS

See Endocrinology: Pearls for Practitioners at the end of this section.

CHAPTER 176

Disorders of Parathyroid Bone and Mineral Endocrinology

PARATHYROID HORMONE AND VITAMIN D

Calcium and phosphate are regulated mainly by diet and three hormones: parathyroid hormone (PTH), vitamin D, and calcitonin. PTH is secreted in response to a decrease in serum ionized calcium level. PTH attaches to its membrane receptor then acts via adenylate cyclase to mobilize calcium from bone into the serum and to enhance fractional reabsorption of calcium by the kidney while inducing phosphate excretion; all increase the serum calcium concentration and decrease serum phosphate. Lack of PTH effect is heralded by low serum calcium in the presence of elevated phosphate for age. PTH stimulates vitamin D secretion by increasing renal 1α -hydroxylase activity and acts indirectly to elevate serum calcium concentration by stimulating the production of 1,25-dihydroxyvitamin D from 25-hydroxyvitamin D. Calcitonin increases the deposition of calcium into bone; in normal states the effect is subtle, but calcitonin may be used temporarily to suppress extremely elevated serum calcium values.

1,25-dihydroxyvitamin D enhances calcium absorption from the gastrointestinal tract, increasing serum calcium levels and bone mineralization. Vitamin D is derived from exposure of the skin to ultraviolet rays (usually via the sun) or from oral ingestion. It is modified first to 25-hydroxyvitamin D in the liver and then 1α -hydroxylated to the metabolically active form (1,25-dihydroxyvitamin D) in the kidney. The serum concentration of 25-hydroxyvitamin D is a better reflection of vitamin D sufficiency than the measurement of 1,25-hydroxyvitamin D (see Chapter 31).

HYPOCALCEMIA

The **clinical manifestations** of hypocalcemia result from increased neuromuscular irritability and include muscle cramps, carpopedal spasm (tetany), weakness, paresthesia, laryngospasm, and seizure-like activity. Tetany can be detected by the *Chvostek sign* (facial spasms produced by lightly tapping over the facial nerve just in front of the ear) or by the *Trousseau sign* (carpal spasms exhibited when arterial blood flow to the hand is occluded for 3–5 minutes with a blood pressure cuff inflated to 15 mm Hg above systolic blood pressure). Total

serum calcium concentration is usually measured, although a determination of serum ionized calcium, the biologically active form, is preferable. Albumin is the major reservoir of protein-bound calcium. Disorders that alter plasma pH or serum albumin concentration must be considered when circulating calcium concentrations are being evaluated. The fraction of ionized calcium is inversely related to plasma pH; **alkalosis** can precipitate hypocalcemia by lowering ionized calcium without changing total serum calcium. Alkalosis may result from hyperpnea caused by anxiety or from hyperventilation related to physical exertion. Hypoproteinemia may lead to a false suggestion of hypocalcemia because the serum total calcium level is low even though the ionized Ca^{2+} remains normal. It is best to measure serum ionized calcium if hypocalcemia or hypercalcemia is suspected.

Primary hypoparathyroidism causes hypocalcemia but does not cause rickets. The etiology of primary hypoparathyroidism includes the following:

1. Congenital malformation (e.g., DiGeorge syndrome or other complex syndromes) resulting from developmental abnormalities of the third and fourth branchial arches (see Chapters 143 and 144)
 2. Surgical procedures, such as thyroidectomy or parathyroidectomy, in which parathyroid tissue is removed either deliberately or as a complication of surgery for another goal
 3. Autoimmunity, which may destroy the parathyroid gland
- Pseudohypoparathyroidism** (hypocalcemia and hyperphosphatemia) may occur in one of four forms as follows:
1. *Type Ia*: an abnormality of the G_{sa} protein linking the PTH receptor to adenylate cyclase; biologically active PTH is secreted in great quantities, but does not stimulate its receptor
 2. *Type Ib*: normal phenotype, normal G_{sa} with abnormalities in the production of adenylate cyclase
 3. *Type Ic*: abnormal phenotype, normal production of adenylate cyclase, but a distal defect eliminates the effects of PTH
 4. *Type II*: normal phenotype, normal production of adenylate cyclase, with a postreceptor defect, close to type Ib

Pseudohypoparathyroidism is an autosomal dominant condition that may present at birth or later. Pseudohypoparathyroidism is associated with **Albright hereditary osteodystrophy**, whose clinical manifestations include short stature, stocky body habitus, round facies, short fourth and fifth metacarpals, calcification of the basal ganglia, subcutaneous calcification, and developmental delay. Albright hereditary osteodystrophy may be inherited separately so that a patient may have a normal appearance with hypocalcemia or may have the Albright hereditary osteodystrophy phenotype with normal serum calcium, phosphate, PTH, and response to PTH.

Transient neonatal hypocalcemia. During the first 3 days after birth, serum calcium concentrations normally decline in response to withdrawal of the maternal calcium supply via the placenta. Sluggish PTH response in a neonate may result in a transient hypocalcemia. Hypocalcemia caused by decreased PTH release is found in infants of mothers with hyperparathyroidism and hypercalcemia; the latter suppresses fetal PTH release, causing **transient hypoparathyroidism** in the neonatal period.

Normal serum magnesium concentrations are required for normal parathyroid gland function and action. **Hypomagnesemia**

TABLE 176.1 Important Physiologic Changes in Bone and Mineral Diseases

CONDITION	CALCIUM	PHOSPHATE	PARATHYROID HORMONE	25(OH)D
Primary hypoparathyroidism	↓	↑	↓	NI
Pseudohypoparathyroidism	↓	↑	↑	NI
Vitamin D deficiency	NI(↓)	↓	↑	↓

Hyperparathyroidism	↑	↓	↑	NI
Immobilization	↑	↑	↓	NI

25(OH)D, 25-hydroxyvitamin D; NI, normal; sl, slight; ↑, high; ↓, low.

may cause a secondary hypoparathyroidism, which responds poorly to therapies other than magnesium replacement.

The **etiology** of hypocalcemia usually can be discerned by combining features of the clinical presentation with determinations of serum ionized calcium, phosphate, alkaline phosphatase, PTH (preferably at a time when the calcium is low), magnesium, and albumin. If the PTH concentration is not appropriately elevated in relation to the low serum calcium, hypoparathyroidism (transient, primary, or caused by hypomagnesemia) is present. Vitamin D stores can be estimated by measuring serum 25-hydroxyvitamin D. Renal function is assessed by a serum creatinine measurement or determination of creatinine clearance (Table 176.1).

Treatment of severe tetany or seizures resulting from hypocalcemia consists of intravenous calcium gluconate (1–2 mL/kg of a 10% solution) given slowly over 10 minutes while cardiac status is monitored by electrocardiogram for bradycardia, which can be fatal. Long-term treatment of hypoparathyroidism involves administering vitamin D, preferably as 1,25-dihydroxyvitamin D and calcium. Therapy is adjusted to keep the serum calcium in the lower half of the normal range to avoid episodes of hypercalcemia that might produce nephrocalcinosis and to avoid pancreatitis.

RICKETS

Rickets is defined as decreased or defective bone mineralization in growing children; **osteomalacia** is the same condition in adults. The proportion of osteoid (the organic portion of bone) is excessive. As a result, the bone becomes soft and the metaphyses of the long bones widen. In older infants, poor linear growth, bowing of the legs on weight bearing (which can be painful), thickening at the wrists and knees, and prominence of the costochondral junctions (rachitic rosary) of the rib cage occur. At this stage, x-ray findings are diagnostic.

In **nutritional vitamin D deficiency** calcium is not absorbed adequately from the intestine (see Chapter 31). Poor vitamin D intake or avoidance of sunlight in infants (exacerbated by those exclusively breastfed) may contribute to the development of rickets. Fat malabsorption resulting from hepatobiliary disease (biliary atresia, neonatal hepatitis) or other causes (cystic fibrosis) also may produce vitamin D deficiency because vitamin D is a fat-soluble vitamin. Defects in vitamin D metabolism by the kidney (renal failure, autosomal recessive deficiency of 1 α -hydroxylation, **vitamin**

D-dependent rickets) or liver (defect in 25-hydroxylation) also can cause rickets.

In **familial hypophosphatemic rickets**, the major defect is failure of the kidney to adequately reabsorb filtered phosphate so that serum phosphate decreases and urinary phosphate is high. The *diagnosis* of this X-linked disease usually is made within the first few years of life and is typically more severe in males.

The **etiology** of rickets usually can be determined by an assessment of the mineral and vitamin D status (25-hydroxyvitamin D <8 ng/mL suggests nutritional vitamin D deficiency) (see Table 176.1). Further testing of mineral balance or measurement of other vitamin D metabolites may be required.

Several forms of vitamin D can be used for **treatment** of the different rachitic conditions, but their potencies vary widely. Required dosages depend on the condition being treated (see Chapter 31). Rickets may also be treated with 1,25-hydroxyvitamin D and supplemental calcium. In hypophosphatemic rickets, phosphate supplementation (not calcium) must accompany vitamin D therapy, which is given to suppress secondary hyperparathyroidism. Adequate therapy restores normal skeletal growth and produces resolution of the radiographic signs of rickets. Nutritional rickets is treated with vitamin D given as a single large weekly dose or multiple smaller replacement doses. Surgery may be required to straighten legs in untreated patients with long-standing disease.

PEARLS FOR PRACTITIONERS

See *Endocrinology: Pearls for Practitioners* at the end of this section.

CHAPTER 177

Disorders of Sexual Development

NORMAL SEXUAL DEVELOPMENT

The various actions and interactions of specific genes, epigenetic influences, transcription factors, and hormones are involved in sexual development. Gender identity is reported to not simply be a psychosocial construct but involves a complex interplay of biologic, environmental, and cultural factors. Disturbances in the processes of gene regulation and gene

FIGURE 177.1 Differentiation of male and female external genitalia as proceeding from a common embryonic anlage. Testosterone acts at 9–13 weeks of gestation to virilize the bipotential anlage. In the absence of testosterone action, the female phenotype develops. (From Grumbach MM, Conte FA. Disorders of sexual differentiation. In: Wilson JD, Foster DW, eds. *Textbook of Endocrinology*. 8th ed. Philadelphia: WB Saunders; 1990:873; modified from Spaulding MH. *Contrib Embryol Instit.* 1921;13:69–88.)

expression determining fetal gonadal development result in disorders of sex development (DSD). Approximately 1 in 4,000 infants are estimated to be born with a DSD (see [Chapter 23](#)).

The internal and external genitalia are formed between 6 and 13 weeks of gestation. Fetal gonad and external genitalia are bipotential and have the capacity to support development of a normal male or female phenotype ([Fig. 177.1](#)). In the presence of a gene called *SRY* for sex-determining region on the Y chromosome, the primitive fetal gonad differentiates into a testis (see [Fig. 177.1](#)). The Leydig cells of the testis secrete testosterone, which has direct effects (stimulating development of the wolffian ducts) but also is locally converted to dihydrotestosterone (DHT) by the 5α -reductase enzyme. DHT causes enlargement, rugation, and fusion of the labioscrotal folds into a scrotum; fusion of the ventral surface of the penis to enclose a penile urethra; and enlargement of the phallus with ultimate

development of male external genitalia. Testicular production and secretion of müllerian-inhibitory substance by Sertoli cells cause the regression and disappearance of the müllerian ducts and their derivatives, such as the fallopian tubes and uterus. In the presence of testosterone, the wolffian ducts develop into the vas deferens, seminiferous tubules, and prostate.

The female phenotype develops unless specific *male* influences alter development, although recent studies find there are female determining genes necessary for development as well. In the absence of *SRY*, an ovary spontaneously develops from the bipotential, primitive gonad. In the absence of fetal testicular secretion of müllerian-inhibitory substance, a normal uterus, fallopian tubes, and posterior third of the vagina develop out of the müllerian ducts, and the wolffian ducts degenerate. In the total absence of androgens, the external genitalia appear female.

Classification

The terminology for conditions associated with variations in sexual development is evolving. Sometimes referred to as intersex, disorders of sex differentiation, or differences of sex development, DSDs are categorized under three main subgroups according to karyotype (XX, XY, and sex chromosome for mosaic karyotypes).

ABNORMAL SEXUAL DEVELOPMENT

46,XX Disorders of Sexual Development

Masculinization of the external genitalia of genotypic females (except for isolated enlargement of the clitoris, which can occur from later androgen exposure) is always caused by the presence of excessive androgens during the critical period of development (8–13 weeks of gestation) (Table 177.1). The degree of virilization can range from mild clitoral enlargement to the appearance of a *male* phallus with a penile urethra and fused scrotum with raphe. Congenital virilizing adrenal hyperplasia is the most common cause of female ambiguous genitalia; it is most commonly the result of an enzyme deficiency that impairs synthesis of glucocorticoids but does not affect androgen production. The impaired cortisol secretion leads to adrenocorticotropic hormone (ACTH) hypersecretion, which stimulates hyperplasia of the adrenal cortex and excessive adrenal production of androgens (see Chapter 178).

46,XY Disorders of Sexual Development

Underdevelopment of the male external genitalia occurs because of a relative deficiency of testosterone production or action (see Table 177.1). The penis is small, with various degrees of hypospadias (penile or perineal) and associated chordee or ventral binding of the phallus; unilateral, but more often bilateral, cryptorchidism may be present. The testes should be sought carefully in the inguinal canal or labioscrotal folds by palpation or ultrasound. Rarely, a palpable gonad in the inguinal canal or labioscrotal fold represents a herniated ovary or an ovotestis. The latter patients have ovarian and testicular tissue and usually ambiguous external genitalia. Production of testosterone by a gonad implies that testicular tissue is present and that at least some cells carry the *SRY* gene.

Testosterone production can be reduced by specific deficiencies of the enzymes needed for androgen biosynthesis or by dysplasia of the gonads. In the latter, if müllerian-inhibiting substance production also is reduced, a rudimentary uterus and fallopian tubes are present.

The complete form of **androgen resistance** or **androgen insensitivity syndrome** is the most dramatic example of resistance to hormone action by defects in the androgen receptor. Affected patients have a **46,XY** karyotype, normally formed testes (usually located in the inguinal canal or labia majora), and female external genitalia with a short vagina and no internal müllerian structures. At the time of puberty, testosterone concentrations increase to normal or above normal male range. Because a portion of the testosterone is normally converted to estradiol in peripheral tissues and the estrogen cannot be opposed by the androgen, breast development ensues at the normal age of puberty without growth of pubic, facial, or axillary hair or the occurrence of menstruation.

TABLE 177.1 Associations of Genital Anomalies

ABNORMAL CHARACTERISTICS	EXAMPLES OF ASSOCIATED DISORDERS
MALE-APPEARING GENITALIA	
Micropenis	Growth hormone or luteinizing hormone deficiency
	Testosterone deficiency (in 2nd and 3rd trimesters)
	Partial androgen insensitivity
	Syndrome: idiopathic
Hypospadias (more severe)	Disorders of gonadal development 46,XX DSD
	Ovotesticular DSD
	46,XX or 46,XY DSD
	Syndrome: idiopathic
Impalpable gonads	Anorchia
	Persistent müllerian duct syndrome
	46,XX DSD with 21- or 11 β -hydroxylase deficiency
Small gonads	Cryptorchidism
	47,XXY, 46,XX DSD
	Dysgenetic or rudimentary testes
Inguinal mass (uterus or tube)	Persistent müllerian duct syndrome, dysgenetic testes
FEMALE-APPEARING GENITALIA	
Clitoromegaly	XX with 21- or 11 β -hydroxylase or 3 β -hydroxy dehydrogenase deficiency
	Other 46,XX DSD
	Gonadal dysgenesis, dysgenetic testes, ovotesticular DSD
Posterior labial fusion	46,XY DSD
	Tumor infiltration of clitoris
Palpable gonad(s)	As for clitoromegaly
Inguinal hernia or mass	Gonadal dysgenesis, dysgenetic testes, ovotesticular DSD
	46,XY DSD
	As for palpable gonad(s)

DSD, Disorders of sex development.

From Al Remeithi S, Wherrett DK. Disorders of sex development. In: Martin RJ, Fanaroff AA, Walsh MC, eds. Fanaroff & Martin's Neonatal-Perinatal Medicine. 10th ed. Philadelphia: Elsevier; 2015 (table 98.3).

5 α -reductase deficiency presents at birth with predominantly female phenotype or with ambiguous genitalia, including perineoscrotal hypospadias. The defect is in 5 α reduction of testosterone to its metabolite DHT. At puberty, spontaneous secondary male sexual development occurs.

Sex Chromosome and Ovotesticular Disorders of Sexual Development

Turner syndrome and **Klinefelter syndrome** and their mosaic variants are classified as sex chromosome DSDs. Mixed gonadal dysgenesis (45,X; 46,XY) often may present with genital ambiguity, asymmetric external genitalia, and inguinal hernias. There may be virilization on one side and none on the other. Similar findings may be seen with **ovotesticular DSD**, another classification of DSD.

APPROACH TO THE INFANT WITH GENITAL AMBIGUITY

Ambiguous genitalia in a newborn must be attended to with as little delay as possible and with informed sensitivity to the psychosocial context as required. The laboratory evaluations required might take days or weeks to complete, delaying a sex assignment and naming of the infant, such that choice often precedes diagnosis. Beyond infancy and childhood, and to offset any gender uncertainty in the patient and confusion in the parents, health care providers must help families come to an appropriate closure and gender choice. With that, most centers caring for patients with ambiguous genitalia include a behavioral health specialist with a focus on patients and families encountering these issues.

On physical examination, it is essential to note where the urethral opening lies and whether there is fusion of the anterior portion of the labioscrotal folds. Endogenous excessive production of androgen (as in congenital adrenal hyperplasia [CAH]) in a female fetus between 9 and 13 weeks of gestation leads to ambiguous genitalia. If the vaginal opening is normal, and there is no fusion, but the clitoris is enlarged without ventral fusion of the ventral urethra, the patient likely had later exposure to androgens. In a patient with a fully formed scrotum, even if small, and a normally formed but small penis, termed a *microphallus*, the patient likely had normal exposure to and action of androgen during 9–13 weeks of gestation.

The major goal is a rapid identification of any life-threatening disorders (salt loss and shock caused by the salt-losing form of CAH). Although the classic approach to sex assignment has been based on the feasibility of genital reconstruction and potential fertility rather than on karyotype or gonadal histology, the effects of prenatal androgen must be considered. Experts recommend waiting until the child can be part of the dialogue regarding gender identity and reconstruction when appropriate. Present management of ambiguous genitalia involves extensive open discussion with parents involving the biology of the infant and the likely prognosis. Treatment should be individualized and managed by a team, including an experienced pediatric endocrinologist, urologist or gynecologist, psychologist, geneticist, and the primary care physician.

Diagnosis

The first step toward diagnosis is to determine whether the findings represent virilization of a genetic female (androgen excess) or underdevelopment of a genetic male (androgen

deficiency) (see Fig. 177.1). Inguinal gonads that are evident on palpation usually are testes and indicate that incomplete development of a male phenotype has occurred; this pattern is not consistent, and ovaries and ovotestes may feel similar. Similarly, absence of female internal genitalia (detected by ultrasound) implies that müllerian-inhibiting substance was present and secreted by fetal testes. Karyotype determination is only one of many factors needed to assist the family in the decision of sex of rearing; the *SRY* gene may be found on chromosomes other than the Y chromosome, and, conversely, a Y chromosome may lack an *SRY* gene (it may have been translocated to an X chromosome, leading to the development of a 46,XX male-XX sex reversal, testicular DSD).

Statistically, most virilized females have CAH; 90% of these females have 21-hydroxylase deficiency. The diagnosis is established by measuring the plasma concentration of 17-hydroxyprogesterone and androstenedione (see Chapter 178), which typically is hundreds of times above the normal range. Other enzymatic defects also may be diagnosed by quantifying circulating levels of the adrenal steroid precursor proximal to the defective enzyme block.

Establishing an accurate diagnosis is more difficult in underdeveloped males. When certain types of adrenal hyperplasia coexist with defects in androgen production of the testes, excessive ACTH secretion substantially elevates levels of specific adrenal steroid precursors, allowing a diagnosis. If the defect is restricted to testosterone biosynthesis, the measurement of testosterone and its precursors in the basal state and after stimulation by HCG may be required. Patients with normal levels of testosterone either have persistent androgen resistance or have had an interruption of normal morphogenesis of the genitalia. Abnormalities of the sex chromosomes may be associated with dysgenetic gonads, which may be associated with persistence of müllerian structures.

Treatment

Treatment consists of replacing deficient hormones (cortisol in adrenal hyperplasia or testosterone in a child with androgen biosynthetic defects who will be raised as male), surgical restoration to make the individual look more appropriate for the gender of rearing, and psychologic support of the whole family. Gonads and internal organs discordant for the gender of rearing may be removed. Dysgenetic gonads with Y-genetic material always should be removed because **gonadoblastomas** or **dyssgerminomas** may develop in the organ. Age at which reconstructive surgery is recommended is controversial; some advocate that surgery not be performed in infancy or early childhood so that the child or young adolescent can be involved in the decision. A decision for gender of rearing is recommended from birth; however, the knowledge that the person with a DSD may change gender later on is shared with parents from the outset.

PEARLS FOR PRACTITIONERS

See Endocrinology: Pearls for Practitioners at the end of this section.

CHAPTER 178

Adrenal Gland Dysfunction

PHYSIOLOGY

The adrenal gland consists of an outer cortex, which is responsible for the synthesis of steroids, and an inner medulla derived from neuroectodermal tissue, which synthesizes catecholamines. The *adrenal cortex* consists of three zones: an outer glomerulosa (end product is the mineralocorticoid, aldosterone, which regulates sodium and potassium balance), a middle fasciculata (end product is cortisol), and an inner reticularis (synthesizes sex steroids). The general scheme of these synthetic steps is shown in Fig. 178.1.

Hypothalamic corticotropin-releasing hormone (CRH) stimulates the release of pituitary adrenocorticotropic hormone (ACTH or corticotropin), derived by selective processing from proopiomelanocortin. ACTH governs the synthesis and release of cortisol and adrenal androgens. Primary adrenal insufficiency or cortisol deficiency from any defect in the adrenal gland results in an oversecretion of ACTH; adrenal insufficiency may also occur from ACTH (secondary) or CRH (tertiary) deficiency, resulting in low serum ACTH

concentrations and low cortisol. Endogenous (or exogenous) glucocorticoids feedback to inhibit ACTH and CRH secretion. The renin-angiotensin system and potassium regulate aldosterone secretion; ACTH has little effect on aldosterone production except in excess when it may increase aldosterone secretion.

Steroids that circulate in the free form (not bound to cortisol-binding protein [transcortin]) may cross the placenta from mother to fetus, but ACTH does not. The placenta plays an important role in steroid biosynthesis in utero by acting as a metabolic mediator between mother and child. As the fetal CRH-ACTH-adrenal axis is operational in utero, any deficiencies in cortisol synthesis lead to excessive ACTH secretion. If a virilizing adrenal enzyme defect is present, such as 21-hydroxylase deficiency, the fetal adrenal gland secretes excess androgens, resulting in a virilized fetus. Normal variation of serum cortisol and ACTH levels leads to values that are high early in the morning and lower at night. This normal diurnal variation may take months to years to fully develop in neonates.

ADRENAL INSUFFICIENCY

The **clinical manifestations** of inadequate adrenal function result from inadequate secretion or action of glucocorticoids, mineralocorticoids, or both (Table 178.1). In the case of enzyme

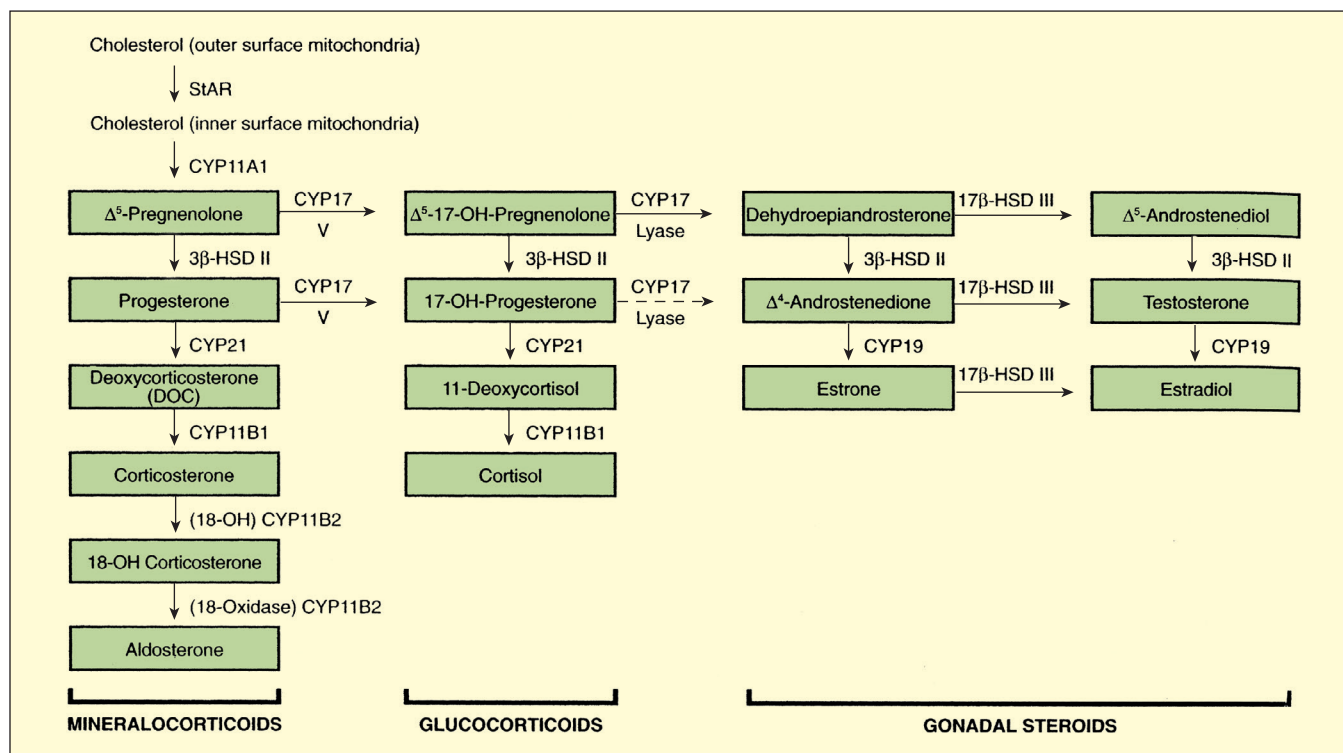

FIGURE 178.1 Diagram of the steroid biosynthetic pathways and the biosynthetic defects that result in congenital hyperplasia. The defect in patients with lipoid adrenal hyperplasia is not (except for one reported case) in the CYP11A1 (cholesterol side-chain cleavage) enzyme, but in StAR, the steroidogenic acute regulatory protein. This protein is involved in the transport of cholesterol from the outer mitochondrial membrane to the inner membrane, where the CYP11A1 enzyme is located. CYP11B1 (11 β -hydroxylase) catalyzes 11 β -hydroxylation of deoxycorticosterone and 11 β -deoxycortisol primarily. CYP17 (17 α -hydroxylase/17,20-lyase) catalyzes 17 α -hydroxylation and splitting of the 17,20 bond, but for the latter it has preferential Δ^5 -17,20-lyase activity. CYP19 (aromatase) catalyzes the conversion of corticosterone to aldosterone. 3 β -HSD I and 3 β -HSD II, 3 β -hydroxysteroid dehydrogenase/ $\Delta^{4,5}$ -isomerase types I and II; CYP21 (P450c21), 21-hydroxylase; 17 β -HSD 3, 17 β -hydroxysteroid dehydrogenase type 3. In the human, deletion of a homozygous null mutation of CYP11A1 (P450_{cc}) is probably lethal in utero, but a heterozygous mutation caused congenital lipoid adrenal hyperplasia. (From Melmed S, Polonsky K, Kronenberg H, et al, eds. *Williams Textbook of Endocrinology*. 10th ed. Philadelphia: Saunders; 2003:917.)

Androgen Excess or Deficiency (Caused by Adrenal Enzyme Defect)
Ambiguous Genitalia in Certain Conditions

defects that affect the gonad and the adrenal gland, overproduction or underproduction of potent androgens can occur depending on the site of enzyme blockade (see Fig. 178.1). Progressive prenatal virilization of the external genitalia may occur in females while incomplete virilization may occur in males. Ambiguity of the external genitalia is a common manifestation of disordered fetal adrenal enzyme function. Precise *diagnosis* is essential for the prescription of appropriate therapy, long-term outlook, and genetic counseling. In patients with enzyme defects, an elevation in the precursor steroid is present proximal to the enzyme block and is metabolized through remaining normal alternate enzyme pathways, whereas a deficiency of steroids is present subsequent to the block.

The dominant clinical features of **congenital adrenal mineralocorticoid deficiency** are hyponatremia and hyperkalemia, usually developing by 5–7 days after birth but not immediately after birth. Vomiting, dehydration, and acidosis soon follow as does hypotensive shock from glucocorticoid deficiency. Death may occur if the disorder remains undiagnosed and untreated. In females, the ambiguity of the external genitalia is an obvious clue that salt-losing congenital adrenal hyperplasia (CAH) or simple virilizing CAH must be ruled out. Because these

forms cannot be distinguished clinically, all presentations of ambiguous genitalia should involve evaluation for mineralocorticoid deficiency. In males, 21-hydroxylase deficiency (the most common form of CAH) does not cause abnormal genitalia; although there may be hyperpigmentation of the scrotal skin, this is a subtle sign and can result in delayed diagnosis. In all infants, the diagnosis of adrenal insufficiency may be overlooked or confused with pyloric stenosis. In pyloric stenosis, vomiting of stomach contents results in hypochloremia, low or normal serum potassium, and alkalosis in contrast to CAH, which has hyponatremia, hyperkalemia, and acidosis. This distinction may be lifesaving in preventing unnecessary investigations or inappropriate therapy.

Not all forms of adrenal hyperplasia present at birth; the spectrum of disorder ranges from severe (classic) to mild (late-onset) or nonclassic. Milder forms may manifest in childhood, adolescence, or even young adulthood (not as glucocorticoid or mineralocorticoid deficiencies, but as androgen excess).

In patients with **congenital adrenal hypoplasia** or **adrenal hemorrhage**, the secretion of all adrenal steroids is low. In contrast, CAH leads to a diagnostic steroid pattern in blood and urine (see Fig. 178.1). Deficiency of 21-hydroxylase is the most common form (95%) and serves as a paradigm for these disorders.

21-HYDROXYLASE DEFICIENCY

The incidence of classic 21-hydroxylase deficiency is about 1 in 15,000 among various White populations. Nonclassic CAH may occur with an incidence of 1 in 50 in certain populations (Ashkenazi Jews). The gene for 21-hydroxylase lies on the short arm of chromosome 6; the genotype may be determined in a proband, permitting prenatal diagnosis in a subsequent pregnancy.

Deficient 21-hydroxylase activity (P-450_{c21} deficiency) impairs the conversion of 17-hydroxyprogesterone (17-OHP) to 11-deoxycortisol and in the salt-losing form, of progesterone to deoxycorticosterone, a mineralocorticoid proximal in the pathway to the production of aldosterone. The decreased production of cortisol causes hypersecretion of ACTH, which stimulates the synthesis of steroids immediately proximal to the block and shunting of these to overproduction of androgens. The primary clinical manifestation is the virilization of the external genitalia of the affected female fetus. The development of the uterus, ovaries, and fallopian tubes is unaffected by the androgens. The degree of virilization varies, ranging from mild clitoromegaly to complete fusion of labioscrotal folds, with severe clitoromegaly simulating a phallus (see Chapter 177). A male infant with this defect appears normal at birth, although penile enlargement may be apparent thereafter. The deficiency in aldosterone, found in about 75% of patients, causes salt wasting with shock and dehydration until the diagnosis is established and appropriate treatment is given.

The treatment of 21-hydroxylase deficiency requires hydrocortisone and fludrocortisone in the case of the salt-losing form. Therapy must be adjusted throughout childhood at regular intervals. Overtreatment will cause growth stunting and weight gain (cushingoid features), whereas undertreatment will cause excessive height gain, skeletal advance, and early appearance puberty, ultimately jeopardizing adult height potential.

Late-onset CAH is typically noted in childhood or adults. Affected subjects have milder manifestations without

ambiguous genitalia, but they may have acne, hirsutism, and, in females, irregular menstrual cycles or amenorrhea. Late-onset CAH in girls may be confused with **polycystic ovarian syndrome**.

Biochemical diagnostic studies show elevated levels of serum 17-OHP, the substrate for the defective 21-hydroxylase enzyme activity. In newborns with CAH, the values are elevated a 100-fold to a 1,000-fold. In late-onset CAH, an ACTH stimulation test may be necessary to show an abnormally high response of 17-OHP. Serum cortisol and aldosterone levels (in salt losers) are low and renin levels are high, whereas the testosterone level is elevated because it is derived from 17-OHP.

The goals of **treatment** are to achieve normal linear growth and bone age advancement. Long-term therapy consists of providing glucocorticoids at a dose of approximately 10–15 mg/m² per 24 hours in three divided doses of oral hydrocortisone or its equivalent. Mineralocorticoid therapy for salt losers consists of fludrocortisone at a dose of 0.1–0.2 mg per 24 hours, often with sodium chloride supplementation in infancy and early childhood. Surgical correction of ambiguous external genitalia may be considered. The adequacy of glucocorticoid replacement therapy is monitored by determining serum concentrations of adrenal precursors, including androstenedione and 17-OHP for 21-hydroxylase deficiency. In addition, the assessment of linear growth and skeletal age, by bone age determination, is required as a reflection of appropriate therapy. To avoid adrenal insufficiency, threefold higher doses of glucocorticoids are given during **stressful states**, such as febrile illnesses and surgery. Intramuscular hydrocortisone is used in severe emergencies or with illnesses involving emesis. Mineralocorticoid therapy is monitored with serum sodium, potassium, and plasma renin activity levels. Prenatal treatment with dexamethasone to suppress fetal ACTH-induced androgen production can reduce or eliminate the ambiguity of the external genitalia in affected female fetuses, if begun at approximately 7 weeks of gestation; however, this remains controversial.

OTHER ENZYME DEFECTS

Other enzyme defects are rare in contrast to 21-hydroxylase deficiency. In **11-hydroxylase deficiency**, the next most common cause of CAH, virilization occurs with salt retention and hypokalemia as a result of the buildup of deoxycorticosterone (see Fig. 178.1), a potent mineralocorticoid. Hypertension develops as a result of excessive mineralocorticoid production. Table 178.2 summarizes the clinical and biochemical features of adrenal insufficiency in infancy.

ADDISON DISEASE

Addison disease is a rare acquired disorder of childhood, usually associated with autoimmune destruction of the adrenal cortex. It is a form of primary adrenal insufficiency with absence of glucocorticoid and mineralocorticoid.

Clinical manifestations are hyperpigmentation, salt craving, postural hypotension, fasting hypoglycemia, anorexia, weakness, and episodes of shock during severe illness. Subnormal baseline and ACTH-stimulated cortisol values confirm the diagnosis. The presence of hyponatremia, hyperkalemia, and

elevated plasma renin activity indicate mineralocorticoid deficiency. Addison disease may occur within the context of autoimmune polyglandular syndromes (APS I and APS II). Other rare causes of adrenal insufficiency include X-linked adrenal leukodystrophy and conditions that affect the hypothalamus-pituitary, whether acquired, such as in craniopharyngioma, or iatrogenic, such as in irradiation for treatment of malignancy.

Replacement **treatment** with 10–15 mg/m² per 24 hours of hydrocortisone is indicated, with supplementation during stress at three times the maintenance dosage or the use of intramuscular hydrocortisone. The dose is titrated to allow a normal growth rate. Mineralocorticoid replacement with fludrocortisone is monitored by plasma renin activity along with serum sodium and potassium determinations.

CUSHING SYNDROME

Classic **clinical manifestations** of Cushing syndrome in children include progressive central or generalized obesity, marked failure of longitudinal growth, hirsutism, weakness, a nuchal fat pad, acne, striae, hypertension, and often hyperpigmentation when ACTH is elevated. The most frequent cause is long-term administration of exogenous glucocorticoids due to chronic medical conditions. Endogenous causes include adrenal adenoma, carcinoma, nodular adrenal hyperplasia, an ACTH-secreting pituitary microadenoma resulting in bilateral adrenal hyperplasia (**Cushing disease**), or an extremely rare ACTH-secreting tumor. **Diagnostic tests** include 24-hour urinary cortisol excretion, low-dose dexamethasone suppression test, high-dose dexamethasone suppression test (helps distinguish Cushing syndrome from Cushing disease), and *late evening* salivary cortisol sampling.

Treatment of Cushing syndrome is directed to the etiology and may include excision of adrenal, pituitary, or ectopic ACTH-secreting tumors. Rarely, adrenalectomy is needed to control the symptoms. Parenteral glucocorticoid therapy is necessary during and immediately after surgical treatment to avoid acute adrenal insufficiency.

PEARLS FOR PRACTITIONERS

CHAPTER 170

Endocrinology Assessment

- Hormones are defined as circulating messengers with action at a distance from the organ (gland) of origin of the hormone.
- Endocrine disorders generally manifest from one of four ways: excess hormone, deficient hormone, abnormal response of end organ, and gland enlargement.
- The assessment of pituitary function is determined by measuring some of the specific pituitary hormone in the basal state; other assessments require measurement after stimulation.

CHAPTER 171

Diabetes Mellitus

- Type 1 diabetes (T1D) is an autoimmune disease and most often presents with hyperglycemia, ketoacidosis, polyuria, and polydipsia.
- T1D is typically treated with multiple daily injections of a short-acting (bolus) insulin and a single dose of long acting (basal) insulin.
- Preprandial blood glucose target concentrations are 90–130 mg/dL and concentrations before bedtime and overnight of 90–150 mg/dL.
- Type 2 diabetes (T2D) is associated with obesity and insulin resistance.
- Treatment of diabetic ketoacidosis (DKA) requires careful management of isotonic fluids, continuous infusions of insulin until acidosis has resolved, and monitoring of blood glucose, electrolytes, and neurologic status.
- Initial management of T2D in children includes lifestyle modifications including nutrition therapy (dietary adjustments) and increased exercise.
- The oral medications, metformin (an insulin secretagogue) and liraglutide (a GLP-1 analog), are first-line drugs for the pharmacologic treatment of T2D and are approved by the U.S. Food and Drug Administration for use in children.
- A goal of $HbA_{1c} < 7.5\%$ is set for children with diabetes (both T1D and T2D) of all ages.
- Diabetes mellitus is a complex chronic illness that requires a team of providers, including endocrinologist, diabetes educator, nutritionist, social worker/psychologist, and close interactions for the family for success.

CHAPTER 172

Hypoglycemia

- Clinical hypoglycemia is defined as a plasma glucose (PG) concentration low enough to cause symptoms and/or signs of impaired brain function.
- After the initial 2–3 days of life, hypoglycemia is far less common and is more frequently the result of endocrine or metabolic disorders (although sepsis must always be ruled out).
- The most common causes for congenital hyperinsulinism involve inactivating K_{ATP} channel mutations and account for approximately 60% of all identifiable mutations.
- The *diagnosis* of hyperinsulinism in children is determined by evaluating markers of inappropriate insulin effects (e.g., suppressed ketogenesis) because plasma insulin concentrations are frequently not clearly elevated.
- Idiopathic ketotic hypoglycemia usually begins at about 18 months of age in thin children and remits by 8 years of age, presenting with symptoms of hypoglycemia after a period of prolonged fasting.
- The *diagnosis* of glycogen storage disease (GSD) is suggested by hypoglycemia in the setting of hepatomegaly without splenomegaly.
- A *critical sample* of blood and urine at the time of the hypoglycemic episode should be obtained before treatment for the measurement of glucose and insulin, growth hormone (GH), cortisol, free fatty acids (FFAs), and β -hydroxybutyrate and acetoacetate.

CHAPTER 173

Short Stature

- A normal linear growth pattern is good evidence of overall health and can be considered a *bioassay* for the well-being of the whole child.
- Insulin-like growth factor 1 (IGF-1) acts primarily as a paracrine and autocrine agent and is most closely associated with postnatal growth, although GH exerts its own metabolic effects.
- Accurate measurements of height (standing) or length (lying down) and weight should be plotted on the Centers for Disease Control and Prevention growth charts for the timely diagnosis of growth disorders.
- Short stature is defined as subnormal height relative to other children of the same gender and age, taking family heights into consideration.

- Nutrition is the most important factor affecting growth on a worldwide basis.
- Adequacy of GH secretion may be determined by a stimulation test to measure peak GH secretion.
- GH deficiency is treated with biosynthetic recombinant DNA-derived GH. Dosage is titrated to the growth rate, weight of the patient, and IGF-1 levels.
- The common condition known as **constitutional delay** in growth or puberty, or both, is considered a variation of normal growth caused by a reduced tempo, or cadence, of physiologic development.

CHAPTER 174

Disorders of Puberty

- Pubarche results from adrenal maturation (adrenarche) and is marked with the appearance of pubic hair, oiliness of hair and skin, acne, axillary hair, and body odor; gonadarche is characterized by increasing secretion of gonadal sex steroids as a result of the maturation of the hypothalamic-pituitary-gonadal axis.
- Puberty is delayed when there is no sign of pubertal development by age 13 years in females and 14 years in males living in the United States.
- Disorders that can cause hypogonadotropic hypogonadism include congenital hypopituitarism, such as midline defects, tumors, infiltrative disease, and many syndromes, including Laurence-Moon-Bardet-Biedl, Prader-Willi, and Kallmann syndromes.
- Decreased gonadotropin function occurs when voluntary dieting, malnutrition, or chronic disease results in weight loss to less than 80% of ideal weight.
- Hypergonadotropic hypogonadism is characterized by elevated gonadotropins and low sex steroid levels resulting from primary gonadal failure.
- Turner syndrome is a common cause of ovarian failure and short stature; Klinefelter syndrome (seminiferous tubular dysgenesis) is the most common cause of testicular failure.
- When no secondary sexual development is present after the upper age limits of normal pubertal development, serum gonadotropin levels should be obtained to determine whether the patient has a hypogonadotropic or hypergonadotropic hypogonadism.
- Central precocious puberty, resulting in gonadarche, emanates from premature activation of the hypothalamic-pituitary-gonadal axis (gonadotropin-releasing hormone [GnRH] dependent); peripheral precocious puberty, gonadarche or adrenarche, does not involve the hypothalamic-pituitary-gonadal axis (GnRH independent).
- Compared with females, males with precocious puberty have a higher incidence of central nervous system disorders, such as tumors and hamartomas, precipitating the precocious puberty.
- The most common cause of GnRH-independent precocious puberty, McCune-Albright syndrome, is more frequent in females than males and includes precocious gonadarche, a bone disorder with polyostotic fibrous dysplasia, and hyperpigmented cutaneous macules (café-au-lait spots).
- The first step in evaluating sexual precocity is to determine which characteristics of normal puberty are apparent and whether estrogen effects, androgen effects, or both are present; laboratory evaluation includes determination of adrenal androgen and sex steroid levels (testosterone, estradiol, dehydroepiandrosterone sulfate [DHEAS]) and baseline gonadotropin concentrations.
- A prepubertal GnRH response is follicle-stimulating hormone (FSH) predominant, whereas a pubertal response is more luteinizing hormone (LH) predominant.
- Long-acting superactive analogs of GnRH (leuprolide depot, histrelin implant, triptorelin) are the treatment of choice for central precocious puberty; antiandrogens, antiestrogens, and aromatase inhibitors are used for peripheral precocious puberty.
- Most patients with isolated pubic hair do not have progressive virilization and simply have premature adrenarche (*pubarche*) resulting from premature activation of DHEA secretion from the adrenal gland; no treatment is needed.

CHAPTER 175

Thyroid Disease

- Hypothyroidism is common in children, and treatment with levothyroxine is typically initiated when a thyroid-stimulating hormone (TSH) is >10 mIU/L.
- Early treatment in congenital hypothyroidism is essential to prevent delayed development.
- Hypothyroidism must be considered in evaluation of short stature, especially if not associated with weight gain.
- Acquired hypothyroidism is an autoimmune disease and may be associated with type 1 diabetes, Addison disease, hypoparathyroidism, and celiac disease.
- Hyperthyroidism is initially treated with pharmacologic therapy, and if remission does not occur, ablation or surgical removal is initiated.
- Most thyroid nodules in children and adolescents are benign.

CHAPTER 176

Disorders of Parathyroid Bone and Mineral Endocrinology

- Calcium and phosphate are regulated mainly by diet and three hormones: parathyroid hormone (PTH), vitamin D, and calcitonin.
- Neonatal hypocalcemia has multiple causes depending on timing of onset and may require treatment with intravenous and/or oral calcium.
- It is essential to make sure both vitamin D and magnesium levels are normal when replacing calcium.
- Hypocalcemia may be associated with multiple nonendocrine disorders and diseases, thus requiring a complete evaluation.

CHAPTER 177

Disorders of Sexual Development

- The various actions and interactions of specific genes, epigenetic influences, transcription factors, and hormones are involved in sexual development. Gender identity is not simply a psychosocial construct but involves a complex interplay of biologic, environmental, and cultural factors.
- Sometimes referred to as intersex, disorders of sexual development (DSD) are categorized under three main subgroups according to karyotype (XX, XY, and sex chromosome for mosaic karyotypes).
- Congenital virilizing adrenal hyperplasia is the most common cause of female ambiguous genitalia.
- Testosterone production can be reduced by specific deficiencies of the enzymes needed for androgen biosynthesis or by dysplasia of the gonads.
- Although the classic approach to sex assignment has been based on the feasibility of genital reconstruction and potential fertility rather than on karyotype or gonadal histology, the effects of prenatal androgen must be considered; experts recommend waiting until the child is able to be part of the dialogue regarding gender identity and reconstruction when appropriate.
- The first step toward diagnosis of ambiguous genitalia is to determine whether the findings represent virilization of a genetic female (androgen excess) or under development of a genetic male (androgen deficiency)

- Treatment of DSD consists of replacing deficient hormones (cortisol in adrenal hyperplasia or testosterone in a child with androgen biosynthetic defects who will be raised as male), surgical restoration to make the individual look more appropriate for the gender of rearing, and psychologic support of the whole family.

CHAPTER 178

Adrenal Gland Dysfunction

- The clinical manifestations of inadequate adrenal function result from inadequate secretion or action of glucocorticoids, mineralocorticoids, or both.
- The dominant clinical features of congenital adrenal mineralocorticoid deficiency are hyponatremia and hyperkalemia, usually developing by 5–7 days after birth but not immediately after birth. Deficiency of 21-hydroxylase is the most common form (95%).
- Early diagnosis and treatment of salt wasting congenital adrenal hyperplasia involves replacement therapy with hydrocortisone, fludrocortisone, and saline solution.
- Adrenal insufficiency (Addison disease) is associated with hyperpigmentation, salt craving, postural hypotension, fasting hypoglycemia, anorexia, weakness, and episodes of shock during severe illness.
- Cushing syndrome is commonly a result of chronic use of high-dose oral steroids.

NEUROLOGY

Rachel J. Gottlieb-Smith | Erin E. Neil | Jocelyn Huang Schiller

CHAPTER 179

Neurology Assessment

A neurologic evaluation, including history, physical examination, and judicious use of ancillary studies, allows the localization and diagnosis of nervous system pathology. The process and interpretation of the neurologic examination varies with age; the newborn is unique, with many transient and primitive reflexes, whereas the examinations of adolescents and adults are similar. Careful evaluations of social, cognitive, language, fine motor, and gross motor skills, and their age appropriateness, are key.

HISTORY

Gathering neurologic history follows the traditional medical model while focusing on the **pace** and **localization** of the problem and the developmental assessment. The symptom evolution provides clues to the underlying process. Symptoms may evolve in a **progressive, static, or episodic** fashion. Progressive symptoms may present acutely over minutes or hours (e.g., epidural hemorrhage), subacutely over days or weeks (e.g., brain tumor), or slowly over years (e.g., hereditary neuropathies). Static neurologic abnormalities are observed early in life and do not change in character over time (e.g., cerebral palsy due to congenital brain abnormalities or prenatal/perinatal brain injury). Intermittent attacks of recurrent, stereotyped episodes suggest epilepsy, migraine, or vascular syndromes. Episodic disorders are characterized by periods of symptoms, followed by partial or complete recovery (e.g., demyelinating diseases).

Careful evaluations of social, cognitive, language, fine motor, and gross motor skills are key to distinguish normal development from isolated or global delays (see [Chapter 7](#)). Loss of skills over time (regression) is particularly worrisome and may suggest an underlying degenerative disease, emerging autism spectrum disorder, or epileptic encephalopathy.

PHYSICAL EXAMINATION

Observation of the child's appearance, movement, and behavior begins at the start of the encounter. For example, the child may display an unusual posture, abnormal gait, or lack of awareness of the environment.

The brain and skin have the same embryonic origin (ectoderm), so abnormalities of hair, skin, teeth, and nails are

associated with congenital brain disorders (neurocutaneous disorders) such as neurofibromatosis (NF type 1), in which **café-au-lait macules** (flat, light brown macules) are characteristic. **Facial angiofibromas** (fibrovascular lesions that look like acne on the nose and malar regions), nail fibromas, ash-leaf spots (hypopigmented macules), and Shagreen patches (flesh-colored soft plaques with prominent follicular openings) are commonly seen in older children and adults with tuberous sclerosis.

The **head circumference** is measured in its largest occipitofrontal circumference and plotted against standard growth curves (see [Chapter 5](#)). **Microcephaly** and **macrocephaly** represent an occipitofrontal circumference 2 or more standard deviations below or above the mean, respectively. Measurements plotted over time may show an accelerating pattern (e.g., hydrocephalus) or decelerating pattern (e.g., brain injury, degenerative neurologic disorder). The anterior fontanel is slightly depressed and pulsatile when a calm infant is upright. A tense or bulging fontanel may indicate increased intracranial pressure (ICP) but may also be seen in a crying or febrile infant. Premature closure of one or more sutures (**craniosynostosis**) results in an unusual shape of the head. Abnormal shape, location, or condition of the face, eyes, nares, philtrum, lips, or ears (dysmorphic features) are found in many genetic syndromes.

A careful **ocular examination** is essential and should include a search for epicanthal folds, coloboma, conjunctival telangiectasias, and cataracts. Direct ophthalmoscopy assesses the optic discs and macula for abnormalities, such as papilledema or a cherry red spot. A complete examination of the retina involves dilating the pupil and indirect ophthalmoscopy.

Examination of the hands and feet may reveal abnormal creases or digits (see [Chapters 50 and 201](#)). The neck and spine should be examined for obvious (e.g., myelomeningocele) or subtle (e.g., cutaneous dimples, sinus tracts, hair tufts, subcutaneous lipomas) midline defects. Nervous system abnormalities may result in kyphosis or scoliosis (see [Chapter 202](#)).

NEUROLOGIC EXAMINATION OF A NEONATE

The neonatal neurologic examination primarily assesses the function of the basal ganglia, brainstem, and more caudal structures due to limited cortical function.

Mental Status

A healthy newborn infant should have periods of quiet, sustained wakefulness interspersed with sleep. Irritability,

TABLE 179.1 Central Nervous System Reflexes of Infancy

REFLEX	DESCRIPTION	AGE AT APPEARANCE	AGE AT DISAPPEARANCE
Moro	Light drop of head produces sudden extension followed by flexion of the arms and legs	Birth	3–6 mo
Grasp	Placing finger in palm results in flexing of infant's fingers	Birth	3–4 mo
Rooting	Tactile stimulus at the side of the mouth causes the mouth to pursue the stimulus	Birth	3–4 mo
Trunk incurvation (Gallant)	Stroking the skin along the edge of vertebrae produces curvature of the spine with concavity on the side of the stimulus	Birth	4 mo
Placing	When dorsum of foot is brought into contact with the edge of a surface, infant places foot on the surface	Birth	4–6 mo
Asymmetric tonic neck	With infant supine, turning of the head results in ipsilateral extension of the arm and leg with flexion of opposite extremities in a "fencing" posture	Birth	3 mo
Parachute	Infant is suspended face down by the chest. When infant is moved toward a table, the arms extend as if to protect self	8–10 mo	Never
Babinski	Stroking lateral aspect of sole from heel up results in dorsiflexion of the great toe and fanning of the remaining toes	Birth	12–18 mo

lethargy, or more severely depressed consciousness are non-specific signs of abnormal brain function.

Reflexes

Examination of the **primitive reflexes** provides assessment of the functional integrity of the brainstem and basal ganglia (Table 179.1). Many of these stereotyped motor responses are present at birth. They are symmetric and typically disappear by 4–6 months of age, indicating the normal maturation of descending inhibitory cerebral influences. Asymmetry or persistence of the primitive reflexes may indicate focal brain or peripheral nerve lesions.

Motor Examination and Tone

Posture is the position that a calm infant naturally assumes when placed supine. An infant at 28 weeks of gestation lies with extended extremities. By 32 weeks, there is an increase in tone and flexion of the lower extremities. At 34 weeks, the lower extremities are flexed; the upper extremities are extended. The term infant flexes both lower and upper extremities. **Recoil**, the readiness with which an arm or leg springs back to its original position after passive stretching and release, is essentially absent in very premature infants but is brisk at term. Because of the asymmetric tonic neck reflex, it is essential to maintain the infant's head in a neutral position (facing forward) during assessment of posture and tone. Spontaneous movements of premature infants are slow and writhing; those of term infants are more rapid.

NEUROLOGIC EXAMINATION OF A CHILD

The purpose of the neurologic examination is to localize or identify the region from which the symptoms arise. The **mental status** and **developmental examinations** assess cerebral cortex function. The **cranial nerve examination** evaluates the

integrity of the brainstem. The **motor examination** evaluates upper and lower motor neuron function. The **sensory examination** assesses the peripheral sensory receptors and their central reflections. **Deep tendon reflexes** assess upper and lower motor connections.

Mental Status and Developmental Evaluation

Alertness is assessed in infants by observing spontaneous activities, feeding behavior, and visual ability to fix and follow objects. Note responses to tactile, visual, and auditory stimuli. If consciousness is altered, note the response to painful stimuli. Observation of toddlers at play allows a nonthreatening assessment of developmentally appropriate skills. In addition to language function, older children can be tested for reading, writing, numeric skills, fund of knowledge, abstract reasoning, judgment, and memory.

The simplest way to assess intellectual abilities is through language skills. **Language function** is receptive (understanding speech or gestures) and expressive (speech and use of gestures). Abnormalities of language resulting from cerebral hemisphere disorders are referred to as **aphasias**. Anterior, expressive aphasia (Broca aphasia) is characterized by sparse, nonfluent language. Posterior, receptive aphasia (Wernicke aphasia) is characterized by an inability to understand language, with speech that is fluent but nonsensical. Global aphasia refers to impaired expressive and receptive language.

CRANIAL NERVE EVALUATION

The cranial nerve evaluation assesses brainstem integrity but depends on the stage of brain maturation and the ability to cooperate. A colorful toy may capture a young child's attention and permit observation of coordination, movement, and cranial nerve function.

Cranial Nerve I

Smell can be assessed in verbal, cooperative children older than 2 years of age. Aromatic substances (perfumes, vanilla) should be used instead of volatile substances (ammonia), which irritate the nasal mucosa and stimulate the trigeminal nerve.

Cranial Nerve II

Term newborns in a quiet, awake state follow human faces, lights in a dark room, or large, optokinetic strips. Visual acuity has been estimated to be 20/200 in newborns and gradually matures throughout childhood. Standard visual charts displaying pictures instead of letters can be used to assess visual acuity in toddlers. Peripheral vision is tested by surreptitiously bringing objects into the visual field from behind. A reduced pupillary reaction to light suggests a lesion to the anterior visual pathway (e.g., retina, optic nerves, chiasm). Unilateral lesions are identified by the swinging flashlight test. With an optic nerve abnormality, both pupils constrict when light is directed into the normal eye. When light is swung over to the abnormal eye, both pupils dilate inappropriately; this is called an afferent pupillary defect (**Marcus Gunn pupil**). Interruption of the sympathetic innervation to the pupil produces **Horner syndrome** (ptosis, miosis, and unilateral facial anhidrosis). In this instance, anisocoria (unequal pupils) is more pronounced in a dark room because the affected pupil is unable to dilate appropriately. Lesions of the posterior visual pathway (e.g., lateral geniculate, optic radiations, occipital cortex) have normal pupillary light reactions but are expressed by loss of visual fields.

Cranial Nerves III, IV, and VI

These three cranial nerves control eye movements and are most easily examined with the use of a colorful toy to capture the child's attention. For infants too young to fix and follow, rotating the infant's head assesses the **oculocephalic reflex** (doll's-eye maneuver). If the brainstem is intact, rotating a newborn or comatose patient's head to the right causes the eyes to move to the left, and vice versa. In awake, older patients, voluntary eye movements mask the reflex.

Abnormalities of these cranial nerves may cause diplopia (double vision). With unilateral third cranial (oculomotor) nerve palsy, the involved eye deviates down and out (infraducted, abducted), with associated ptosis and a dilated (mydriatic) pupil. Injury to cranial nerve IV (trochlear) causes weakness of downward eye movement with consequent vertical diplopia. Cranial nerve VI (abducens) palsy results in the inability to move the eye outward. Cranial nerve VI has a long intracranial route within the subarachnoid space; failure of abduction of one or both eyes is a frequent, but nonspecific, sign of increased intracranial pressure.

Cranial Nerve V

The muscles of mastication can be observed as an infant sucks and swallows. The **corneal reflex** tests cranial nerves V ophthalmic division (sensory arc) and VII (motor arc). Facial sensation of light touch can be determined with cotton gauze. Facial sensation can be functionally assessed in an infant by

gently brushing the cheek, which will produce the **rooting reflex**.

Cranial Nerve VII

Facial muscles are assessed by observing the face during rest, crying, and blinking if a child is not old enough to voluntarily smile or move the face. Weakness of all unilateral muscles of the face, including the forehead, eye, and mouth, indicates a lesion of the ipsilateral peripheral facial nerve (e.g., **Bell palsy**). Since the upper third of the face receives bilateral cortical innervation, if the weakness affects only the lower face and mouth, a contralateral lesion of upper motor neurons in the brain (e.g., tumor, stroke, abscess) must be considered.

Cranial Nerve VIII

Lesions of cranial nerve VIII cause deafness, tinnitus, and vertigo. Normally, alert neonates blink in response to a bell or other abrupt, loud sound. Four-month-old infants turn the head and eyes to localize a sound. Delayed language development or any concerns about hearing should trigger a referral for a formal hearing assessment.

Lesions of the vestibular component of cranial nerve VIII produce symptoms of vertigo, nausea, vomiting, diaphoresis, and nystagmus. Nystagmus is an involuntary beating eye movement with a rapid phase in one direction and a slow phase in the opposite direction. By convention, the direction of the nystagmus is defined by the fast phase and may be horizontal, vertical, or rotatory.

Cranial Nerves IX and X

The gag reflex is brisk at all ages except the very immature neonate. An absent gag reflex suggests a lesion of the brainstem, cranial nerves IX or X, neuromuscular junction, or pharyngeal muscles. Weak, breathy, or nasal speech; a weak suck; drooling; and gagging are additional symptoms of cranial nerve X dysfunction.

Cranial Nerve XI

Observing the infant's posture and spontaneous activity assesses the functions of the trapezius and sternocleidomastoid muscles. Head tilt and drooping of the shoulder suggest lesions involving cranial nerve XI. In later childhood, strength in these muscles can be tested directly.

Cranial Nerve XII

Atrophy and fasciculation (quivering muscle movements that are typically best seen on the lateral aspect of the tongue) usually indicate a lesion of the anterior horn cells (spinal muscular atrophy). Assessment is most reliable when an infant is asleep. The tongue deviates toward the weak side in unilateral lesions.

MOTOR EXAMINATION

Tone

Tone represents the dynamic resistance of muscles to passive stretch. Lower motor neuron and cerebellar lesions produce decreased tone (**hypotonia**). Hypertonia is seen with upper

motor neuron or extrapyramidal (e.g., basal ganglia) lesions; upper motor neuron lesions produce spasticity (velocity-dependent increased tone) while extrapyramidal disease often leads to rigidity (increase in resistance present throughout passive movement of a joint).

Bulk

Muscle bulk may be decreased due to disuse or to lower motor neuron or neuromuscular disease. Excessive muscle bulk is seen in rare conditions, such as myotonia congenita; boys with Duchenne muscular dystrophy have pseudohypertrophy of the calves.

Strength

In infants, strength is assessed by observation of spontaneous movements. Extremity movements should be symmetric and are best seen when the infant is held supine with one hand supporting the buttocks and one supporting the shoulders. As with adults, strength is graded as follows:

- 5 Normal
- 4 Weak but able to provide resistance
- 3 Able to move against gravity but not against resistance
- 2 Movement in the plane of gravity
- 1 Muscle contraction but no movement
- 0 Complete paralysis

Strength in toddlers is assessed by observing functional abilities, such as walking, stooping to pick up an object, and standing up from the floor. An older child should be able to easily reach high above the head, wheelbarrow walk, run, hop, go up and down stairs, and arise from the ground. Cooperative children can undergo individual muscle strength testing. **Gower sign** (child arises from lying on the floor by using arms to climb up legs and body) is a sign of significant proximal weakness. Subtle upper extremity asymmetry can be detected when the child extends arms out in front with the palms upward and eyes closed. The hand on the weaker side cups and begins to pronate slowly (**pronator drift**). **Muscle fasciculations** indicate denervation from disease of the anterior horn cell or peripheral nerve.

Coordination

Ataxia is the lack of coordination of movement, which is typically due to a dysfunction of the cerebellar pathways. Watching the child sit or walk assesses truncal stability. Exchanging toys or objects with the child permits assessment of intention tremor and **dysmetria** (errors in judging distance), signs of cerebellar dysfunction. Cooperative children can do repetitive finger or foot tapping to test rapid alternating movements. Cerebellar and corticospinal tract dysfunctions produce slow and irregular alternating movements.

Gait

Watching a child creep, crawl, cruise, or walk is the best global assessment for the motor and coordination systems (see [Chapter 197](#)). Subtle deficits and asymmetries in strength, tone, or balance may be observed. The toddler gait is normally wide based and unsteady. The base of the gait narrows with age. By 6 years, a typical child can walk on the toes or heels

and tandem walk (heel to toe). Cerebellar dysfunction results in a broad-based, unsteady gait accompanied by difficulty in executing turns. Corticospinal tract dysfunction produces a stiff, scissoring gait (legs adduct past midline) and toe walking; arm swing is decreased, and the affected arm is flexed across the body. Extrapyramidal dysfunction produces a slow, stiff, shuffling gait with dystonic postures. A waddling gait occurs with hip weakness due to lower motor neuron or neuromuscular disorders. A steppage gait results from weakness of ankle dorsiflexors (common peroneal palsy).

Reflexes

Deep tendon reflexes can be elicited at any age and are reported on a five-point scale:

- 0 Absent
- 1+ Trace
- 2+ Normal
- 3+ Exaggerated reflex, sometimes with spread to contiguous areas (e.g., tapping a patellar reflex and observing an ankle jerk as well)
- 4+ With clonus

These reflexes are decreased in lower motor neuron diseases and increased in upper motor neuron disease. **Babinski response** (extensor plantar reflex) is an upward movement of the great toe and flaring of the toes on stimulation of the lateral foot and is a sign of corticospinal tract dysfunction. This reflex is unreliable in neonates, except when asymmetric because the “normal” response at this age varies. By 12–18 months of age, the plantar response should consistently be flexor (toes flexing down).

SENSORY EXAMINATION

The sensory examination of newborns and infants is limited to observing the behavioral response to light touch or pinprick. Stimulation of a limb should produce a facial grimace. A spinal reflex alone may produce withdrawal movement of a limb. In a cooperative child, the senses of pain, touch, temperature, vibration, and joint position can be tested individually. The cortical areas of sensation must be intact to identify an object placed in the hand (**stereognosis**) or a number written in the hand (**graphesthesia**) or to distinguish between two sharp objects applied simultaneously and closely on the skin (**two-point discrimination**).

SPECIAL DIAGNOSTIC PROCEDURES

Cerebrospinal Fluid Analysis

Analysis of cerebrospinal fluid (CSF) is essential when central nervous system infection is suspected and provides important clues to other diagnoses ([Table 179.2](#)). Differentiating hemorrhagic CSF caused by a traumatic lumbar puncture (LP) from a true subarachnoid hemorrhage may be difficult. In most cases of traumatic LP, the fluid clears significantly as the sequence of tubes is collected. If there is clinical evidence of increased ICP (papilledema, depression of consciousness, focal neurologic deficits), caution must be exercised before performing an LP to limit risk of cerebral herniation. Neuroimaging (typically a computed tomography [CT] scan) should be performed and confirmed to be normal before the LP if increased ICP is suspected. If increased ICP is present, it must be treated before an LP is performed.

TABLE 179.2 Analysis of Cerebrospinal Fluid

CSF FINDING	NORMAL CSF VALUES	
	NEWBORN	>1 MO OLD
Cell count*	10–25/mm ³	5/mm ³
Protein	65–150mg/dL	<40mg/Dl
Glucose	>2/3 blood glucose or >40mg/dL	>2/3 blood glucose or >60mg/dL
CSF CHANGE	SIGNIFICANCE	
Increased polymorphonuclear cells and decreased CSF glucose	Bacterial infection Brain or parameningeal abscess Parasitic infection	
Increased lymphocytes and decreased CSF glucose	Mycobacterial infection (tuberculosis) Fungal infection Sarcoidosis	
Increased lymphocytes and normal CSF glucose	Viral meningitis Postinfectious disease (ADEM) Vasculitis Multiple sclerosis Tumor (although CSF glucose could be low)	
Increased CSF protein	Infection Guillain-Barré syndrome Inflammatory disease (ADEM, multiple sclerosis) Leukodystrophy Venous thrombosis Hypertension Spinal block (Froin syndrome)	
Decreased glucose without pleocytosis	GLUT-1 transporter deficiency	
Bloody CSF	Subarachnoid hemorrhage Subdural hemorrhage Intraparenchymal hemorrhage Hemorrhagic meningoencephalitis (group B streptococci, HSV) CNS trauma Vascular malformation Coagulopathy Traumatic lumbar puncture	

*In normal children, cells present should be lymphocytes.
ADEM, Acute disseminated encephalomyelitis; CNS, central nervous system;
CSF, cerebrospinal fluid; HSV, herpes simplex virus.

Electroencephalography

The electroencephalogram (EEG) records electrical activity generated by the cerebral cortex. EEG rhythms mature throughout childhood. There are three key features present: background patterns, behavioral state modulation, and presence or absence of epileptiform patterns. The background

varies with age but in general should be symmetric and synchronous between the two hemispheres. Persistent focal slowing suggests an underlying structural abnormality (e.g., brain tumor, abscess, stroke). Diffuse slow wave activity suggests bilateral cerebral involvement (e.g., increased ICP, metabolic encephalopathy). Spikes, polyspikes, and spike-and-wave abnormalities, either in a localized region (focal) or bihemispherical (generalized), suggest an increased risk for seizures.

Electromyography and Nerve Conduction Studies

Electromyography (EMG) and nerve conduction velocities (NCVs) assess for abnormalities of the neuromuscular apparatus, including anterior horn cells, peripheral nerves, neuromuscular junctions, and muscles. EMG evaluates the electrical activity of muscle, typically via needle electrodes. Normal muscle is electrically silent at rest. Spontaneous discharges of motor fibers (**fibrillations**) or groups of muscle fibers (**fasciculations**) indicate denervation, revealing dysfunction of anterior horn cells or peripheral nerves. Abnormal muscle responses to repetitive nerve stimulation are seen with neuromuscular junction disorders, such as myasthenia gravis and botulism. The amplitude and duration of the muscle compound action potentials are decreased in primary diseases of muscle. NCVs assess the action potential transmission along peripheral nerves. NCVs are slowed in demyelinating neuropathies (e.g., Guillain-Barré syndrome). The amplitude of the signal is diminished in axonal neuropathies.

Neuroimaging

Imaging the brain and spinal cord is accomplished using CT or magnetic resonance imaging (MRI). CT is quick and accessible for emergency purposes. Advantages to MRI include detection of posterior fossa lesions, subtle cerebral abnormalities, vascular anomalies, low-grade tumors, ischemic changes, and greater detail, but at greater expense and time. MRI provides finer detail and, with different sequences, permits detection of posterior fossa lesions, subtle cerebral abnormalities, vascular anomalies, low-grade tumors, and ischemic changes. Fast MRI techniques have been developed to reduce imaging times and are often used in evaluating ventricular size without the need for radiation; it is limited in detection of certain findings such as sinovenous thrombosis and extraaxial hemorrhage. For a child with an acute head injury or sudden headache, cranial CT is the study of choice because it can rapidly reveal intracranial hemorrhage or other large lesions. For a child with new-onset focal seizures who has returned to baseline, MRI is typically the study of choice because an area of focal cortical dysplasia or other subtle lesions might not be apparent on CT. MRI also provides excellent views of the spinal cord. Cranial ultrasonography is a noninvasive bedside procedure used to visualize the brain and ventricles of infants with open fontanelles.

PEARLS FOR PRACTITIONERS

See *Neurology: Pearls for Practitioners* at the end of this section.

CHAPTER 180

Headache and Migraine

ETIOLOGY AND EPIDEMIOLOGY

Headache is a common symptom among children and adolescents. Headaches can be a primary problem such as migraines or tension-type headaches. Secondary headaches are most often associated with minor illnesses such as upper respiratory infections or sinusitis but may be the first symptom of serious conditions (e.g., meningitis, brain tumors), so a systematic approach is necessary.

CLINICAL MANIFESTATIONS

The temporal pattern (acute, recurrent episodic, chronic progressive, chronic nonprogressive) is useful in the differential diagnosis of headache (Table 180.1).

Tension-type headaches are the most common type of recurrent primary headaches in children and adolescents. Because they are generally mild, without associated symptoms, they typically do not disrupt daily activities. The pain is global and squeezing or pressing in character and can last for hours or days. There is no associated nausea, vomiting, phonophobia, or photophobia. Headaches can be related to environmental stresses or symptomatic of underlying anxiety or depression.

Migraine headaches are another common type of recurrent headaches and frequently begin in childhood. Headaches are stereotyped attacks of frontal, bitemporal, or unilateral, moderate to severe, pounding or throbbing pain that are aggravated by activity and last 1–72 hours. Associated symptoms include nausea, vomiting, pallor, photophobia, phonophobia, and an intense desire to seek a quiet, dark room for rest. Toddlers may be unable to verbalize the source of their discomfort and exhibit episodes of irritability, sleepiness, pallor, and/or vomiting. An aura can precede or coincide with the headache and typically persists between 5 and 60 minutes. Visual auras are common and consist of spots, flashes, or lines of light that flicker in one or both visual fields. Complex, atypical auras (e.g., hemiparesis, monocular blindness, vertigo, confusion) that are accompanied by a headache warrant careful diagnostic investigation, such as neuroimaging and electroencephalogram.

Common causes of **secondary headaches** include head trauma, viral illness, and sinusitis. Medication-overuse headaches may complicate primary and secondary headaches. Serious causes of secondary headache include increased intracranial pressure (ICP) caused by a mass (e.g., tumor, vascular malformation) or intrinsic increase in pressure (pseudotumor cerebri). Increased ICP should be suspected if the headache and associated vomiting are worse when lying down or on first awakening, if they awaken the child from sleep, if they remit on arising, or if they are exacerbated by coughing, Valsalva maneuver, or bending over. Papilledema (Fig. 180.1) or focal neurologic deficits should trigger an intensive etiologic investigation.

DIAGNOSTIC STUDIES

For most children, a thorough history and physical examination provide an accurate diagnosis and obviate the need

TABLE 180.1 Four Temporal Patterns of Childhood Headache

Acute: Single episode of pain without a history of such episodes. The “first and worst” headache raises concerns for aneurysmal subarachnoid hemorrhage in adults, but is commonly due to febrile illness related to upper respiratory tract infection in children. Regardless, more ominous causes of acute headache (hemorrhage, meningitis, tumor) must be considered.

Acute recurrent: Pattern of attacks of pain separated by symptom-free intervals. Primary headache syndromes, such as migraine or tension-type headache, usually cause this pattern. Recurrent headaches are occasionally due to specific epilepsy syndromes (benign occipital epilepsy), substance abuse, or recurrent trauma.

Chronic progressive: Implies a gradually increasing frequency and severity of headache. The pathologic correlate is increasing ICP. Causes of this pattern include pseudotumor cerebri, brain tumor, hydrocephalus, chronic meningitis, brain abscess, and subdural collections.

Chronic nonprogressive or chronic daily: Pattern of frequent or constant headache. Chronic daily headache generally is defined as >3-mo history of ≥ 15 headaches/mo. Affected patients have normal neurologic examinations; psychologic factors and anxiety about possible underlying organic causes are common.

ICP, Intracranial pressure.

FIGURE 180.1 Papilledema with dilation of the vessels, obliteration of the optic cup, loss of disc margin, and hemorrhages around disc. From Kliegman RE, Behrman RM, Jenson HB, eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:2107.

for further testing. Neuroimaging is usually not necessary. Imaging is warranted, however, if the patient has an abnormal neurologic examination, symptoms of increased ICP, unusual neurologic features during the headache (atypical aura), or progressive worsening of headaches. In these cases, brain magnetic resonance imaging is the study of choice, providing the highest sensitivity for detecting posterior fossa lesions and other, more subtle abnormalities. When the headache has a

sudden, severe onset, emergent computed tomography (CT) can quickly evaluate for intracranial bleeding. If the CT is negative, a lumbar puncture should be performed to measure opening pressure and evaluate for pleocytosis, elevated red blood cells, and xanthochromia to evaluate for a subarachnoid bleed.

TREATMENT

Treating migraines requires an individually tailored regimen to address the frequency, severity, and disability produced by the headaches. Intermittent symptomatic (abortive) analgesics are the mainstay for treatment of infrequent episodes of migraine. Symptomatic therapy requires early analgesic administration, often accompanied by rest in a quiet, dark room. Acetaminophen or a nonsteroidal antiinflammatory drug such as ibuprofen or naproxen sodium is often effective. Hydration and antiemetics are useful adjunctive therapies. If these first-line medications are insufficient, triptan agents may be considered. Triptans, available in injectable, nasal spray, oral disintegrating, and tablet form, are serotonin receptor agonists that can alleviate migraine symptoms promptly. Based on theoretical concerns regarding increased risk for stroke, it is generally recommended that triptans be avoided for patients with hemiplegic migraine or migraine with brainstem aura.

Many children suffer severe and frequent migraines that disrupt their daily lives. Before initiating daily medications, lifestyle modifications including increasing fluid intake, avoiding skipping meals, engaging in good sleep hygiene, and exercising regularly, as well as identification and elimination of any precipitating or aggravating influences (e.g., caffeine, certain foods, stress, missed meals, dehydration), are beneficial. Other adjunctive treatment options include psychologic support, stress management, and biofeedback. Although there is limited data on the effectiveness of nutraceuticals, riboflavin and magnesium may be helpful for migraine prophylaxis with a low side-effect profile. Children with more than one disabling headache per week may require **daily preventive agents** to reduce both attack frequency and severity. Preventive medications include tricyclic antidepressants (e.g., amitriptyline, nortriptyline), anticonvulsants (e.g., topiramate, valproic acid), antihistamines (e.g., cyproheptadine), β blockers (e.g., propranolol), and calcium channel blockers (e.g., verapamil). The use of calcitonin gene-related peptide receptor antagonists is currently being studied in children.

ETIOLOGY AND EPIDEMIOLOGY

The differential diagnosis of paroxysmal disorders includes **seizures** and **nonepileptic events** (Table 181.1). Nonepileptic paroxysmal events are often normal or benign phenomena, although some are clinically significant and consequential. A thorough medical history from the patient and primary witnesses is the most reliable tool for establishing the correct diagnosis.

Acute symptomatic seizures are secondary to an acute problem affecting brain excitability, such as electrolyte imbalance or infection (Table 181.2). In the classification of seizures, “symptomatic” refers to seizures that are temporally correlated with an acute neurologic or systemic insult. In contrast, **epilepsy** is defined as recurrent, unprovoked seizures. Epileptic seizures are generally classified as focal, arising from one region of the cortex, or generalized, which arise from both hemispheres simultaneously (Table 181.3). Approximately 4–10% of children experience at least one seizure. The incidence of childhood epilepsy is 1–2%.

FOCAL SEIZURES

Clinical symptoms of focal seizures may include motor (tonic, clonic, myoclonic), sensory, psychic, or autonomic abnormalities.

Focal seizures with retained awareness (previously termed *simple partial seizures*) arise from a specific anatomic focus and may or may not spread to surrounding brain regions. The location and extent of spread of the seizure focus determine the clinical symptoms.

CHAPTER 181

Seizures

A seizure is a transient occurrence of signs or symptoms resulting from abnormal excessive or synchronous neuronal activity in the brain.

TABLE 181.3 Classification of Seizures and Epilepsy Syndromes
FOCAL ONSET
With retained awareness (focal aware seizures)
Motor onset (can be tonic, clonic, myoclonic, atonic, or epileptic spasms)
Nonmotor onset (e.g., autonomic, visual, auditory, olfactory, gustatory, vertiginous, sensory)
With impaired awareness (dyscognitive features)
Motor or nonmotor onset (see above)
Focal to bilateral tonic-clonic seizures
GENERALIZED ONSET
Motor (can be tonic, clonic, myoclonic, atonic, or epileptic spasms)
Nonmotor (absence)
UNKNOWN ONSET
Motor (can be tonic-clonic, epileptic spasms)
Nonmotor (behavioral arrest)

Focal seizures with impaired awareness (previously termed *complex partial seizures*) can have similar sensorimotor signs but also have associated alteration of consciousness. Although the child may not be completely unresponsive, subtle slowing or alteration of mental status (dyscognitive features) may occur. Along with altered responsiveness, patients may have automatisms or stare during these seizures. Automatisms are automatic semi-purposeful movements of the mouth (lip smacking, chewing) or extremities (rubbing of fingers, shuffling of feet). Focal seizures that manifest only with psychic or autonomic symptoms, such as a feeling of déjà vu during a temporal lobe seizure, can be difficult to recognize.

When focal seizures spread to involve both cerebral hemispheres, they are said to have evolved to a bilateral tonic-clonic seizure (previously called a *secondarily generalized seizure*). It is often difficult to distinguish primary generalized tonic and clonic seizures from those that evolved from focal seizures on purely clinical grounds. Clarifying any premonitory symptoms suggestive of an aura can be helpful. This distinction is important because evaluation and treatment for focal or generalized epilepsy syndromes are quite different.

GENERALIZED SEIZURES

Tonic, clonic, and biphasic **tonic-clonic** seizures may occur alone or in association with other seizure types. Typically, the seizure begins abruptly but occasionally is preceded by a series of myoclonic jerks. During a tonic-clonic seizure, consciousness and control of posture are lost, followed by tonic stiffening and upward deviation of the eyes. Pooling of secretions, pupillary dilation, diaphoresis, and hypertension are common. Clonic jerks follow the tonic phase. In the postictal phase, the child might be hypotonic. Irritability and headache are common as the child awakens.

TABLE 181.4 Differentiating Absence Seizures and Focal Seizures with Impaired Awareness

FEATURE	ABSENCE SEIZURE	FOCAL SEIZURE WITH IMPAIRED AWARENESS
Duration	Seconds	Minutes
Provoking maneuver	Hyperventilation Photic stimulation	Variable, but often none
Postictal phase	None (return immediately to baseline)	Confusion, sleepiness
Number of seizures	Many per day	Infrequent (rarely >1/day)
EEG features	Interictal: normal except bursts of generalized spike wave and sometimes occipital intermittent rhythmic delta activity Ictal: 3-Hz generalized spike-wave	Interictal: normal or focal slowing, sharp waves, or spikes Ictal: focal discharges (with or without spread to contiguous regions or the contralateral hemisphere)
Neurologic examination	Normal	Normal, or focal deficits
Neuroimaging	Normal*	Normal, or focal abnormalities (mesial temporal sclerosis, focal cortical dysplasia, neoplasm, encephalomalacia)
First-line treatment	Ethosuximide or valproic acid [†]	Often levetiracetam, oxcarbazepine, or lamotrigine are used

*In the proper clinical context, and with an appropriate EEG, a diagnosis of absence epilepsy should be made without neuroimaging.

[†]Oxcarbazepine and carbamazepine are relatively contraindicated for children with typical absence epilepsy, as their seizures can be exacerbated by these medications.

EEG, Electroencephalographic.

Absence Seizures

Seizures in which the primary clinical feature is staring can be either absence (generalized) or focal seizures. The clinical hallmark of absence seizures is a brief (<15 seconds) loss of awareness accompanied by eyelid fluttering or simple automatisms, such as fumbling with the fingers and lip smacking. Absence seizures usually begin between 4 and 6 years of age. Neurologic examination and brain imaging are normal. The characteristic electroencephalographic (EEG) patterns consist of **generalized 3-Hz spike-and-wave activity**. An absence seizure can often be provoked by **hyperventilation**. Differentiating absence from focal seizures with impaired awareness can be difficult but is essential for appropriate evaluation and treatment (Table 181.4).

Atypical Absence, Myoclonic, and Atonic Seizures

Atypical absence seizures manifest as episodes of impaired consciousness with automatisms, autonomic phenomena,

and motor manifestations, such as eye opening, eye deviation, and body stiffening. They are associated with slower EEG discharges (2 Hz) and accompany other seizure types. **Myoclonus** is a sudden jerk of all or part of the body; not all myoclonus is due to epilepsy. Nonepileptic myoclonus may be benign, as in sleep myoclonus, or indicate serious disease. Myoclonic epilepsy usually is associated with multiple seizure types. The underlying disorder producing myoclonic epilepsy may be static (e.g., **juvenile myoclonic epilepsy** [JME]) or progressive and associated with neurologic deterioration (e.g., neuronal ceroid lipofuscinosis). **Myoclonic absence** refers to body jerks that commonly accompany typical or atypical absence seizures. Atonic seizures involve a sudden loss of postural tone that often results in falls and injuries; though typically brief (lasting 1–2 seconds), they are very disabling.

Febrile Seizures

Seizures in the setting of fever may be caused by central nervous system infections (meningitis, encephalitis, brain abscess), first presentation of epilepsy triggered by fever, or **febrile seizures**. The latter represents the most common cause of seizures among children between 6 months and 5 years of age, occurring in about 4% of all children. By definition, a febrile seizure occurs in the presence of fever. **Simple febrile seizures** are generalized at onset, last less than 15 minutes, and occur only once in a 24-hour period. If the seizure has focal features, lasts longer than 15 minutes, or recurs within 24 hours, the seizure is referred to as a **complex febrile seizure**.

The prognosis of children with simple febrile seizures is excellent. Although febrile seizures recur in 30–50% of children, intellectual achievements are normal. The risk of subsequent epilepsy is not substantially greater than that of the general population (~2%). Factors that increase the risk for the development of epilepsy include abnormal neurologic examination or development, family history of epilepsy, and complex febrile seizures.

Since simple febrile seizures are brief and the outcome is benign, most children require no treatment. Rectal diazepam can be administered during a seizure to abort a prolonged convulsion; it is appropriate to provide a rescue medication for children with a history of prolonged febrile seizures. Since antiseizure medications have side effects and children with febrile seizures have an excellent prognosis, daily antiseizure medication to prevent febrile seizures is not recommended. Administration of antipyretics during the same fever episode may reduce the risk of recurrence within that illness, but it does not seem to impact febrile seizure recurrence during subsequent fever episodes.

Psychogenic Nonepileptic Events

Psychogenic nonepileptic events (PNEE) (previously termed *pseudoseizures*) may be the manifestation of functional neurologic symptom disorder (i.e., somatic symptom disorder or conversion disorders). Additionally, children with epilepsy may, consciously or subconsciously, exhibit concurrent PNEE. PNEE semiology typically differs from epileptic seizures. In PNEE, the patient's eyes are often closed and the movements are tremulousness or thrashing. In contrast, during seizures, the eyes are typically open and movements are tonic or clonic.

Verbalization and pelvic thrusting are seen more commonly in PNEE, urinary and fecal continence is usually preserved, and injury does not usually occur. If the tongue is bitten, more often the tip of the tongue is injured (as opposed to the sides of the tongue in epileptic seizures). PNEE can often be initiated or terminated by suggestion. An EEG performed during PNEE does not show epileptiform patterns. The diagnosis is critical because appropriate mental health care, and not anti-convulsant medications, is the crux of treatment. Careful assessment and intervention for physical or sexual abuse, as well as other social stressors, is a key component of the care of children with PNEE.

EPILEPSY SYNDROMES

Epilepsy syndromes have distinctive EEG and clinical features (age of seizure onset, specific seizure types). Recognition of epilepsy syndromes provides useful information regarding the underlying etiologies that must be considered, treatments that may be helpful (or harmful), and long-term prognostic information. Comorbid learning difficulties, especially language-based learning disabilities, and attention-deficit/hyperactivity disorder (ADHD) are common. There is no contraindication to treating these children's ADHD with stimulant medication.

Childhood epilepsy with centrotemporal spikes, also known as **benign Rolandic epilepsy**, is among the most common epilepsy syndromes and usually begins between ages 5 and 10 years. The seizures typically occur only during sleep or on awakening. Affected children usually have focal motor seizures involving the face and arm (abnormal movement or sensation around the face and mouth, drooling, rhythmic guttural sound, impaired speech and swallowing). Seizures sometimes evolve to bilateral convulsions. The interictal EEG classically demonstrates independent bilateral centrotemporal sharp waves but is otherwise normal. With a classic history and EEG and a normal neurologic examination, the diagnosis can be made with confidence and neuroimaging is not required. Seizures usually respond promptly to antiseizure medication. Intellectual outcome is typically normal and the epilepsy resolves after puberty.

Childhood absence epilepsy is another common syndrome. Absence seizures typically begin in the early school years and usually resolve by late childhood or adolescence. If absence does not remit, nearly half will go on to develop JME (see later discussion). Ethosuximide is usually the first-choice medication. A subset of patients also has generalized tonic-clonic seizures. For these children, valproic acid is the first choice as it can prevent both absence and convulsive seizures.

JME is the most common generalized epilepsy among adolescents and young adults. Onset is typically in early adolescence with myoclonic jerks (exacerbated in the morning, often causing the patient to drop objects), generalized tonic-clonic seizures, and absence seizures. Seizures usually resolve promptly with antiseizure medication. JME is classically treated with valproic acid; however, there are concerns about side effects and teratogenicity. Levetiracetam has a much lower risk of teratogenicity and is generally well tolerated. As such, levetiracetam is now favored, particularly for girls and women since treatment of JME is usually lifelong.

Infantile spasms are brief contractions of the neck, trunk, and arm muscles, followed by a phase of sustained muscle contraction lasting less than 2 seconds. Spasms occur most frequently when the child is awakening or going to sleep. Each jerk is followed by a brief period of relaxation with repeated spasms in clusters of variable duration. When flexion of the thighs and crying are prominent, the syndrome may be mistaken for colic or gastroesophageal reflux. **West syndrome** is the triad of infantile spasms, developmental regression, and a dramatically abnormal EEG pattern (**hypsarhythmia**—a pattern of chaotic high-voltage slow waves, spikes, and poly-spikes). The peak age at onset of infantile spasms is 3–8 months. The underlying etiology of the spasms dictates the prognosis. More than 200 different etiologies have been identified, including tuberous sclerosis, malformations of cortical development (e.g., lissencephaly), genetic syndromes (e.g., trisomy 21), acquired brain injury (e.g., stroke, perinatal hypoxic-ischemic encephalopathy), and metabolic disorders (e.g., phenylketonuria). Infants for whom an etiology is determined are classified as having “symptomatic” infantile spasms and are at very high risk for long-term neurodevelopmental difficulties. With advances in genetic testing, few children have infantile spasms of uncertain etiology, but those with uncertain etiology have a somewhat better long-term prognosis.

Infantile spasms are a neurologic emergency since rapid initiation of effective therapy offers the best chance for favorable neurodevelopmental outcomes. First-line treatment options for infantile spasms include adrenocorticotropic hormone, high-dose oral corticosteroids, and vigabatrin. Other antiseizure medications are much less effective. For infants with underlying tuberous sclerosis, vigabatrin is the treatment of choice. For other patients, treatment determinations are made on a case-by-case basis.

Lennox-Gastaut syndrome is a severe epilepsy syndrome with variable age of onset although most children present before age 5 years. Frequent, multiple seizure types including atonic, focal, atypical absence, and generalized tonic, clonic, or tonic-clonic semiologies characterize the disorder. Many children have underlying brain injury, malformations, or genetic etiologies. The seizures are typically difficult to control, and most patients have significant intellectual disability.

Benign (self-limited) neonatal convulsions are an autosomal dominant genetic disorder linked to abnormal neuronal potassium channels. Otherwise well newborns present with focal seizures toward the end of the first week of life, leading to the colloquial term *fifth-day fits*. Response to treatment is generally excellent, and the long-term outcome is typically favorable.

Acquired epileptic aphasia (Landau-Kleffner syndrome) is characterized by the abrupt loss of previously acquired language in young children. The language disability is an acquired cortical auditory deficit (auditory agnosia). The EEG is highly epileptiform in sleep, the peak area of abnormality often being in the dominant perisylvian region (language areas). This diagnosis should be considered for young patients with clear language regression, as it is a potentially treatable entity.

STATUS EPILEPTICUS

Status epilepticus is a neurologic emergency defined as (1) ongoing seizure activity for 5 or more minutes or (2) repetitive

seizures without recovery of consciousness. Status epilepticus carries an approximately 14% risk of new neurologic deficits and 4–5% mortality, both related to the underlying etiology. Etiologies include new-onset epilepsy, drug intoxication, drug withdrawal (especially missed anticonvulsant doses among children with epilepsy), hypoglycemia, electrolyte imbalance, acute head trauma, infection, ischemic stroke, intracranial hemorrhage, metabolic disorders, and hypoxia.

The first priority of treatment is to ensure an adequate airway, breathing, and circulation (see Chapter 38). Vital signs should be obtained and oxygen administered as needed. If respirations are inadequate, positive pressure ventilation may be required. Intravenous (IV) access should be obtained, and laboratory evaluation should be undertaken (see later).

Several pharmacologic options exist for management of status epilepticus (Table 181.5). Initial management is with a benzodiazepine and should be administered if the seizure persists longer than 5 minutes. Lorazepam, diazepam, and midazolam are all effective agents and should be given as an adequate single dose (rather than successive smaller doses), which can be repeated one time. IV administration is preferred. When IV access is not available, benzodiazepines may be administered via rectal, intranasal, buccal, or intramuscular routes.

If the seizure does not resolve after two doses of benzodiazepine, a second-line agent must be administered. There are few data from clinical trials to guide subsequent management. For newborns and infants, phenobarbital is reasonable. For older children, IV fosphenytoin (preferred over phenytoin due to tolerability), valproic acid, or levetiracetam may be considered. If the seizures persist, options include repeating one of the second-line medications or beginning a continuous infusion of midazolam or pentobarbital (with appropriate airway protection, blood pressure support, and strong consideration of video-EEG monitoring to evaluate for ongoing subclinical seizures) (see Table 181.5). If this approach is ineffective, preparations for general anesthesia are undertaken. When status epilepticus stops, maintenance therapy is initiated with the appropriate anticonvulsant.

LABORATORY AND DIAGNOSTIC EVALUATION

Children with simple febrile seizures who have recovered completely require little or no laboratory evaluation other than studies necessary to evaluate the source of the fever. Outside of simple febrile seizures, it is important to consider possible provoking factors for a first lifetime seizure, such as meningitis, sepsis, head trauma, metabolic derangements (including glucose, sodium, and calcium abnormalities), and toxins. Laboratory evaluation may include a complete blood count and measurement of glucose, calcium, sodium, potassium, chloride, bicarbonate, urea nitrogen, creatinine, magnesium, and phosphorus, as well as blood or urine toxicology screening. For an otherwise healthy child with a single self-resolved seizure and a normal examination, in the absence of history to suggest a provoking etiology, laboratory evaluation may not be necessary. Children with clinical signs and symptoms of meningitis (e.g., neck stiffness, Kernig sign, Brudzinski sign), or history or physical examination suggestive of intracranial infection, should undergo a lumbar puncture. Cerebrospinal

fluid (CSF) should be analyzed for cell counts, culture, protein, and glucose levels. In children less than 18 months old, particularly young infants, the clinical symptoms of meningitis may be subtle. Neonates also may require testing for inborn errors of metabolism, blood ammonia, CSF glycine and lactate, and a clinical trial of pyridoxine. Evaluation for infections, such as urine and stool cultures, and polymerase chain reactions for herpes simplex virus, cytomegalovirus, and enterovirus should be considered.

The EEG is the most useful neurodiagnostic test for distinguishing seizures from nonepileptic paroxysmal disorders and for classifying seizures as having focal or generalized onset. The EEG must be interpreted in the context of the clinical history; some normal children have focal or epileptiform EEG patterns. Conversely, children with seizures may have normal interictal EEGs. When the diagnosis is unclear, EEG with prolonged recordings and simultaneous

videomonitoring in an attempt to capture a typical event may be necessary.

Magnetic resonance imaging (MRI) is superior to computed tomography (CT) in showing most brain pathology, but in the emergency department setting, CT can be performed rapidly and often shows acute intracranial hemorrhage more clearly than MRI. MRI is unnecessary in patients with the primary generalized epilepsies, such as typical childhood absence and JME. Lesions (e.g., tumors, arteriovenous malformations, cysts, strokes, gliosis, focal atrophy) may be identified in 25% of patients with other epilepsy types, even when the clinical examination and EEG do not suggest focal features. Identification of some lesions, such as focal cortical dysplasia, hamartoma, and mesial temporal sclerosis, can assist in consideration of surgical treatment of pharmacoresistant epilepsy.

LONG-TERM THERAPY

The decision to institute daily seizure medications for a first unprovoked seizure is based on the likelihood of recurrence balanced against the risk of long-term drug therapy. Determination of the recurrence risk is based on the clinical history and neurodiagnostic testing. Absence seizures, infantile spasms, atypical absence seizures, and atonic seizures are universally recurrent at the time of diagnosis, so treatment should be initiated immediately.

The goal of treatment is to maintain an optimal functional state. Medication toxicity should be weighed against the risk of the seizures. Initial drug selection is based on the seizure type (Fig. 181.1). Using a single agent limits toxicity, contains cost, and improves compliance. Approximately 60% of children obtain satisfactory seizure control and minimal side effects with the initial drug. If seizure control is not achieved, despite good compliance, addition of a second drug is considered.

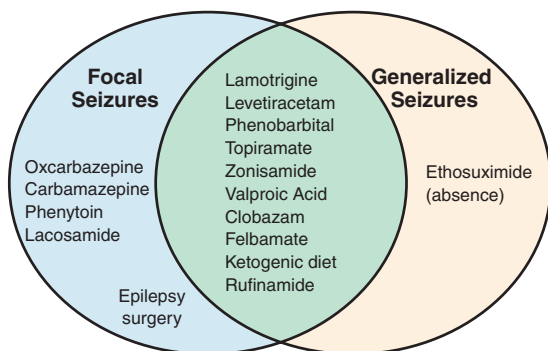

The duration of antiseizure treatment varies according to seizure type and epilepsy syndrome. For most children, medications can be weaned off after 2 years without seizures.

There are some exceptions. For example, children with JME, progressive myoclonic epilepsy, atypical absence seizures, and Lennox-Gastaut syndrome usually require lifelong treatment. Children who have other neurologic comorbidities, seizures that were initially difficult to control, or persistently epileptiform EEGs are at highest risk for recurrence when therapy is discontinued.

There are important safety considerations for people with epilepsy. The risk of drowning is high, so swimming and bathing must only occur under direct adult supervision. Children should use appropriate helmets for sports such as bicycling or ice skating. There is no contraindication to participation in contact sports, but scuba diving, hang gliding, and free climbing are not safe for people with epilepsy. Each country and individual states have specific laws regarding driving for people with epilepsy. Most require a period of seizure freedom before driving.

PEARLS FOR PRACTITIONERS

See *Neurology: Pearls for Practitioners* at the end of this section.

Special circumstances:

1. For absence epilepsy, ethosuximide is the first line treatment.
2. Adrenocorticotrophic hormone, oral corticosteroids, or vigabatrin are used to treat infantile spasms.

FIGURE 181.1 Treatment for epilepsy.

CHAPTER 182

Weakness and Hypotonia

Weakness is a decreased ability to voluntarily move muscles. This may be generalized or localized to one aspect of the body. Hypotonia is a state of low muscle resistance to movement. Hypotonia can be associated with weakness, but in some cases is present with normal motor strength. The differential diagnosis for weakness is extensive ([Table 182.1](#)).

ETIOLOGY

Weakness and hypotonia may be due to disorders of **upper** or **lower motor neurons**. Upper motor neurons originate in the cerebral motor cortex; their axons form the corticospinal tract ending in the spinal cord, controlling voluntary motor activity. The anterior horn cells, their motor roots, peripheral motor nerves, neuromuscular junctions, and muscles represent the lower motor neurons and muscle units. Maintenance of normal strength, tone, and coordination requires integrated communication throughout this complex system, including the cerebral cortex, cerebellum, brainstem, thalamus, basal ganglia, and spinal cord.

CLINICAL MANIFESTATIONS

Weakness caused by upper motor neuron disease differs from weakness produced by lower motor units ([Table 182.2](#)). Dysfunction of the upper motor neuron causes loss of voluntary control, but not total loss of movement because motor nuclei of the basal ganglia, thalamus, and brainstem have tracts that produce simple or complex stereotyped patterns of movement. The corticospinal tract permits fine motor activity and is best tested by fine movements of the distal extremities.

TABLE 182.1 Disorders Causing Weakness in Infants and Children

ANATOMIC REGION	CORRESPONDING DISORDERS
Central nervous system—brain	Brain tumor Trauma (accidental, nonaccidental) Infection (meningitis, encephalitis, abscess, congenital infection) Ischemia (arterial or venous) Hemorrhage Demyelinating disease Metabolic disease (leukodystrophy; inborn error of metabolism; mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes) Degenerative disease Hemiplegic migraine Toxins Electrolyte disorders Functional neurologic symptom disorder (conversion disorder)
Central nervous system—spinal cord	Transverse myelitis Tumor Abscess Trauma Infarction Myelomeningocele Tethered cord
Anterior horn cell	Spinal muscular atrophy Poliomyelitis
Peripheral nerve	Guillain-Barré syndrome Hereditary motor sensory neuropathy Tick paralysis Bell palsy
Neuromuscular junction	Myasthenia gravis (juvenile, transient neonatal, congenital) Botulism
Muscle	Muscular dystrophies (Duchenne, Becker, limb-girdle) Myotonic dystrophies Congenital myopathies Metabolic myopathies Dermatomyositis Polymyositis Myositis/rhabdomyolysis

In the acute phase, upper motor neuron disorders cause hypotonia and decreased deep tendon reflexes. Over time, however, spasticity and hyperreflexia develop. A central lesion usually results in weakness that is more pronounced in the flexors of the lower extremities than in the extensors, so affected patients tend to be spastic with legs extended and adducted. In the upper extremities, the extensors are weaker than flexors, so elbows and wrists are flexed.

TABLE 182.2 Clinical Distinction Between Upper Motor Neuron and Lower Motor Neuron Lesions

CLINICAL SIGN	UPPER MOTOR NEURON (CORTICOSPINAL TRACT)	LOWER MOTOR NEURON (NEUROMUSCULAR)
Tone	Increased (spastic)	Decreased
Reflexes	Increased	Decreased
Babinski reflex	Present	Absent
Atrophy	Possible from disuse	Common and usually more prominent
Fasciculations	Absent	Possible

Damage to the spinal cord leaves residual simple, stereotyped reflex movements coordinated by local spinal reflexes below the level of the lesion.

Destruction of the lower motor neuron, the final common pathway producing muscle activity, leads to hypotonia and absence of movement. Function is best tested by measuring the strength of individual muscle groups or, in a young child, by observing the ability to perform functional tasks requiring particular muscle groups (walk up or down stairs, arise from the ground, walk on toes or heels, raise the hands above the head, squeeze a ball). With lower motor neuron disorders, atrophy and fasciculations are common and deep tendon reflexes are typically decreased or absent.

DISEASE OF THE UPPER MOTOR NEURON

Etiology and Epidemiology

Tumors, trauma, infections, stroke, demyelinating syndromes, metabolic diseases, and neurodegenerative diseases (see Chapters 100, 101, 157, 184 and 185; Section 10) may injure the brain or spinal cord, producing an upper motor neuron pattern of weakness coupled with increased deep tendon reflexes, spasticity, and extensor plantar responses (Babinski sign). In neonates, weakness with upper motor neuron patterns may be caused by congenital infections (see Chapter 66), developmental brain anomalies, hemorrhage, stroke, hypoxia, genetic syndromes, metabolic/electrolyte disturbances, or toxic exposure.

The distribution of weakness depends on the location of the lesion. A tumor in the left frontal region may produce a right hemiparesis. A brainstem glioma may produce a slowly progressive quadriplegia.

Acute disseminated encephalomyelitis (ADEM) is an acute, inflammatory demyelinating disorder that may affect infants and children after a febrile illness. Children may present with a variety of symptoms and signs including monocular vision loss (e.g., acute optic neuritis), hemiparesis, ataxia, seizures, headache, weakness, or dysphagia. The pathophysiology resembles that of multiple sclerosis, except children with ADEM have encephalopathy. Although multiple sclerosis is most commonly diagnosed in adulthood, childhood cases have been increasingly recognized. ADEM and multiple

sclerosis exacerbations are treated with high-dose steroids. Physical and occupational therapies are often helpful.

Acute spinal cord lesions, such as infarction or compression, may produce a **flaccid, areflexic paralysis** that mimics lower motor neuron disease. The hallmarks of spinal cord disease are a sensory level and a motor level of impairment, disturbance of bowel and bladder function, and local spinal pain or tenderness. Patients may be bradycardic and hypotensive due to neurogenic shock. A child who exhibits an acute or subacute flaccid paraparesis is most likely to have an acute cord syndrome or Guillain-Barré syndrome. Acute cord syndrome may be due to a spinal cord injury causing compression, contusion or shear injury to the cord, ischemia, tumors (e.g., neuroblastoma, lymphoma, sarcoma), or space-occupying infections such as epidural abscesses. In addition to neurologic deficits, patients with epidural abscesses often have fever and spinal pain. Compression of the cord may require immediate neurosurgical management to preserve vital function. Another cause of weakness localized to the spine is **transverse myelitis**, an acute postinfectious demyelinating disorder of the spinal cord, which is treated with high-dose steroids.

DISEASES OF THE LOWER MOTOR NEURON

Neuromuscular disease affects component(s) of the lower motor neuron unit. The distribution of muscle weakness can point toward specific diseases (Table 182.3).

Spinal Muscular Atrophy

Etiology

Progressive degeneration of anterior horn cells is the key manifestation of spinal muscular atrophy (SMA), a genetic disease with signs and symptoms that may begin in intrauterine life or any time thereafter. About 55% of patients have a severe infantile form (SMA type 1/**Werdnig-Hoffmann disease**), 30% have a late infantile and more slowly progressive form (SMA type 2/**Kugelberg-Welander syndrome**), and 20% have a more chronic, juvenile form (SMA type 3). SMA is one of the most frequent autosomal recessive diseases, with a carrier frequency of 1 in 50.

Clinical Manifestations

The earlier in life the signs develop, the more severe the progression. Infants with SMA type 1 present in early infancy with severe hypotonia, generalized weakness, and facial involvement. Infants have normal cognitive, social, and language skills and sensation. **Fasciculations** are best identified by inspecting the tongue when the child is asleep. Deep tendon reflexes are absent. With disease progression, breathing patterns change. Weak intercostal muscles and a relatively stronger diaphragm result in a collapsed chest wall (bell-shaped chest) and prominent abdominal movements with rapid, shallow breathing. In an extremely weak child, respiratory compromise leads to atelectasis, pulmonary infection, and death. Without treatment, most infants with SMA type 1 die within the first 2 years. New therapies have altered the natural history of this disease.

TABLE 182.3 Topography of Neuromuscular Diseases

LOCATION	CLINICAL SYNDROMES/DISORDERS
Proximal muscle weakness	Muscular dystrophy (Duchenne/Becker/limb-girdle)
	Spinal muscular atrophy
	Myopathies/dermatomyositis/polymyositis
Distal limb weakness	Polyneuropathy (Guillain-Barré syndrome)
	Hereditary motor sensory neuropathy
	Myotonic dystrophy
	Distal myopathy
Ophthalmoplegia and limb weakness	Myasthenia gravis
	Botulism
	Myotonic dystrophy
	Congenital myotubular myopathy
	Miller Fisher variant of Guillain-Barré syndrome
Facial and bulbar weakness	Myasthenia gravis
	Botulism
	Polio
	Miller Fisher variant of Guillain-Barré syndrome
	Myotonic dystrophy
	Congenital myopathy
	Facioscapulohumeral dystrophy

Laboratory and Diagnostic Studies

The diagnosis of SMA is made by genetic testing. Creatine phosphokinase (CK) may be normal or mildly elevated. Although not currently used to diagnose SMA, muscle biopsy specimens show grouped atrophy, and electromyogram shows fasciculations, fibrillations, and denervation. SMA was added to the Recommended Uniform Screening Panel in 2018 and is now part of newborn screening in many states and being added in others.

Treatment

Recently disease-modifying therapies have become available: nusinersen, an antisense oligonucleotide given by intermittent intrathecal injections; onasemnogene abeparovex, a gene therapy administered as a one-time intravenous infusion; and risdiplam, a small molecule given as a daily oral medication. Clinical trials have shown motor benefits, though the long-term impacts are still under investigation. Preventive care is directed toward minimizing contractures, preventing scoliosis, optimizing nutrition, and avoiding infections. Many patients benefit from early use of noninvasive ventilation to reduce infections. Respiratory infections are managed early and aggressively with preventative pulmonary hygiene and

antibiotics. The use or nonuse of artificial ventilation and tube feedings must be individualized for each patient in each stage of the illness.

Acute Flaccid Myelitis

A more recently described cause of weakness is **acute flaccid myelitis**, a flaccid weakness with gray matter involvement of the spine, sometimes with cranial nerve impairment. Although not definitive, recent cases of acute flaccid myelitis have been temporally related to enteroviral infections. Lesions of the spinal cord are best delineated with magnetic resonance imaging (MRI).

Peripheral Neuropathy

There are many peripheral nerve diseases in childhood, but the most classic presentations are Guillain-Barré syndrome, chronic inflammatory demyelinating polyneuropathy (CIDP), hereditary motor sensory neuropathy (HMSN), and tick paralysis. Peripheral neuropathies due to diabetes mellitus, alcoholism, chronic renal failure, exposure to toxins, vasculitis, and neoplasm are common in adults but rare in children.

Guillain-Barré Syndrome

Guillain-Barré syndrome is an immune-mediated, heterogeneous peripheral neuropathy syndrome with several variants, the most common being **acute inflammatory demyelinating polyradiculoneuropathy (AIDP)**. AIDP classically occurs about 10 days after a respiratory or gastrointestinal infection (e.g., *Mycoplasma pneumoniae* or *Campylobacter jejuni*). It is the most common cause of acute flaccid paralysis in children. A cranial nerve variant of Guillain-Barré syndrome called the **Miller Fisher variant** manifests with ataxia, partial ophthalmoplegia, and areflexia.

The characteristic symptoms of AIDP are areflexia, flaccidity, and symmetric ascending weakness. Progression can occur rapidly, in hours, or more indolently over weeks. Typically, symptoms start with numbness or paresthesia in the hands and feet, then a heavy, weak feeling in the legs. Weakness ascends to involve the arms, trunk, and bulbar muscles (tongue, pharynx, larynx). Deep tendon reflexes are absent even when strength is relatively preserved. Objective signs of sensory loss are usually minor compared with the dramatic weakness, but many patients experience pain. Bulbar and respiratory insufficiency may progress rapidly. Dysfunction of autonomic nerves can lead to blood pressure changes, tachycardia and other arrhythmias, urinary retention or incontinence, or stool retention. This polyneuropathy can be difficult to distinguish from an acute spinal cord syndrome. Loss of arm reflexes, absence of a sensory level, and lack of spinal tenderness point toward Guillain-Barré syndrome.

The cerebrospinal fluid in Guillain-Barré syndrome is sometimes normal early in the illness but classically shows elevated protein levels without significant pleocytosis (albuminocytologic dissociation). MRI with gadolinium may reveal enhancement of the spinal nerve roots. Electromyography (EMG) and nerve conduction velocity are not always required but can provide corroborative diagnostic evidence and prognostic indicators.

Children in early stages of the disease should be admitted to the hospital to monitor pulmonary and cardiac

functions. Those with moderate, severe, or rapidly progressive weakness should be treated in an intensive care unit. Endotracheal intubation is required by patients with impending respiratory failure or an inability to clear secretions. Most patients are treated initially with intravenous immunoglobulin (IVIG). Plasma exchange is an alternative option. Physical, occupational, and speech therapies are mainstays of treatment.

The illness usually resolves spontaneously, albeit slowly; 80% of patients recover normal function within 1–12 months. Twenty percent of patients are left with mild to moderate residual weakness.

Chronic Inflammatory Demyelinating Polyneuropathy

A small minority of patients who initially present with Guillain-Barré syndrome will have a relapsing course and will ultimately be diagnosed with CIDP. CIDP is an immune-mediated peripheral neuropathy typically presenting as both proximal and distal weakness in an episodic, relapsing-remitting pattern. Patients may also experience sensation changes such as numbness, tingling, or pain. The diagnosis is clinical, although EMG or nerve biopsy may confirm the diagnosis. The mainstays of treatment for CIDP are IVIG, glucocorticoids, and plasmapheresis.

Hereditary Motor Sensory Neuropathy

HMSN (also called Charcot-Marie-Tooth disease [CMT]) is a group of inherited, progressive, distal peripheral nerve diseases. Motor components generally dominate the clinical picture, with sensation and autonomic functions affected later. Some subtypes present with severe symptoms starting in infancy, while other forms may have milder symptoms.

Most often, complaints begin in the preschool to early adolescent years, with weakness of the ankles and frequent tripping. Examination shows **pes cavus deformity of the feet** (high-arched feet), bilateral weakness of foot dorsiflexors, and normal sensation despite occasional complaints of paresthesia. Progression of HMSN is slow, extending over years and decades. Eventually, patients may develop weakness and atrophy of the entire lower legs and hands with mild to moderate sensory loss in the hands and feet. There is variability of severity between types of HMSN and even within families affected by the same type. Some patients never have more than a mild foot deformity, loss of ankle reflexes, and electrophysiologic abnormalities. Others in the same family may be confined to a wheelchair and have difficulties performing everyday tasks with the hands.

HMSN can be characterized by demyelination (e.g., CMT1) or axonal (e.g., CMT2) damage. Specific genetic testing is available for many subtypes of HMSN. Specific treatment for HMSN is not available, but braces that maintain the feet in dorsiflexion can maintain function and reduce the risk of injury.

Tick Paralysis

Tick paralysis produces an acute lower motor neuron pattern of weakness, clinically similar to Guillain-Barré syndrome. An attached female tick releases a toxin, similar to botulism, blocking neuromuscular transmission. Affected patients present with a severe generalized flaccid weakness, including ocular, papillary, and bulbar paralysis. A methodic search for an

affixed tick, particularly in hairy areas, must be made in any child with acute weakness. Removal of the tick results in a prompt return of motor function.

Myasthenia Gravis

There are different conditions called myasthenia. Each has a different mechanism and will be discussed here. These include juvenile myasthenia gravis seen in late infancy and childhood, transient neonatal myasthenia seen after birth, and congenital myasthenic syndrome seen in infancy through childhood.

Juvenile Myasthenia

Juvenile myasthenia gravis is an autoimmune condition. Most commonly, antibodies block the acetylcholine receptors (AChR) at the neuromuscular junction, decreasing the number of effective receptors, which results in rapid fatigability of striated muscle; other types of autoantibodies exist. The cardinal feature of myasthenia gravis is fluctuating skeletal muscle weakness. Rapid fatigue of muscles distinguishes myasthenia from other neuromuscular disorders, with progressive worsening over the day or with repetitive activity and improvement after rest. Although myasthenia can produce weakness in any muscle group, variable ptosis, diplopia, ophthalmoplegia, and facial weakness are typical presenting symptoms. There can be any degree of involvement. In some children, the disease never advances beyond ophthalmoplegia and ptosis (ocular myasthenia). Others may have a progressive and potentially life-threatening illness that involves all musculature, including that of respiration and swallowing. Treatment includes pyridostigmine (an acetylcholinesterase inhibitor) and, depending on severity, various forms of immunosuppression.

Transient Neonatal Myasthenia Gravis

A transient myasthenic syndrome develops in the first hours to days after birth in neonates born to mothers with myasthenia gravis related to maternal anti-AChR antibodies. Almost all infants born to mothers with myasthenia have maternal anti-AChR antibodies, but only 10–20% will develop signs. Signs include weak facial movements, poor feeding, hypotonia, respiratory difficulty, and variable extremity weakness; ptosis and ophthalmoplegia can also occur but are less common. Neonates with transient myasthenia gravis require cholinesterase inhibitors and supportive care for a few days to weeks until the weakness remits.

Congenital Myasthenic Syndromes

A variety of rare disorders of the neuromuscular junction have been reported that are not autoimmune mediated. The congenital myasthenic syndromes (CMS) are due to gene mutations in the components of the neuromuscular junction. They typically present in infancy with ptosis, facial diplegia, hypotonia, extremity weakness, and sometimes ophthalmoplegia, although symptoms can present throughout childhood. Respiratory function and feeding may be compromised. Children with CMS usually have lifelong disability. Treatment of CMS depends on the type; some types can respond to pyridostigmine or other drugs that improve neuromuscular junction function, other types can be exacerbated by pyridostigmine.

Diagnostic Studies

Autoimmune myasthenia is most commonly diagnosed through the combination of clinical symptoms and antibody testing. The majority of individuals have antibodies to the AChR, although some have antibodies to other components of the neuromuscular junction. Nerve conduction studies classically reveal an electrodecrement with 3-Hz repetitive stimulation. An ice pack test (applying an ice pack to a closed eyelid) may lead to transient improvement in ptosis, but this can be difficult to interpret. Historically, a Tensilon test (administration of edrophonium chloride) was used to evaluate for transient improvement in strength and ptosis and clarify the diagnosis. Currently, it is not frequently used due to concern for safety.

Infant Botulism

Infant botulism results from intestinal infection by *Clostridium botulinum*, which produces a neurotoxin that blocks presynaptic cholinergic transmission. Young age and the absence of competitive bowel flora predispose infants to this disease. Infants may ingest dust, soil, or food (e.g., honey, poorly canned foods) contaminated with spores. The progressive neuromuscular blockade ranges from mild to severe. Infants typically present with constipation and poor feeding. Hypotonia and weakness develop progressively, along with cranial nerve dysfunction manifested by decreased gag reflex, diminished eye movements, decreased pupillary contraction, and ptosis. Autonomic dysfunction can result in fluctuations in heart rate and blood pressure. Severely affected infants may develop respiratory failure. The diagnosis is made by detecting *C. botulinum* spores and toxin in stool samples. Therapy with botulism immune globulin should be administered as soon as the diagnosis is suspected. With prompt treatment and respiratory and supportive care, the prognosis is good.

Muscular Dystrophy

Muscular dystrophies are a group of genetic muscle diseases characterized by progressive myofiber degeneration and the gradual replacement of muscle by fibrotic tissue.

Etiology

Duchenne muscular dystrophy (DMD) is an X-linked disorder (Xp21) that arises from a mutation in the dystrophin gene. It is the most common muscular dystrophy; approximately 1 in 3,500 boys is affected. **Becker muscular dystrophy** also involves the dystrophin gene but is associated with more mild symptoms due to a semifunctional dystrophin protein.

Clinical Manifestations

Typically, at about 2–3 years of age, boys with DMD develop an awkward gait and an inability to run properly. Some have an antecedent history of mild delay in attaining motor milestones or poor head control during infancy. Examination shows firm pseudohypertrophy of the calves and mild to moderate proximal leg weakness with a hyperlordotic, waddling gait. The child typically arises from a lying position on the floor by using the arms to climb up the legs and body (**Gower sign**). By 12 years of age, most boys are not walking and use a wheelchair full time. Other manifestations include

cardiomyopathy, scoliosis, respiratory decline, and variable cognitive and behavioral dysfunction. In the past, most with DMD died in their 20s or early 30s, usually as a result of progressive respiratory decline or cardiac dysfunction; life expectancy may increase with newer therapies.

Laboratory and Diagnostic Studies

Serum CK levels are always markedly elevated. Diagnosis is established by genetic testing for the dystrophin gene mutation. Approximately one-third of cases represent sporadic mutations. Prenatal genetic testing is possible, and newborn screening for elevated CK is available in some states.

Treatment

Studies have shown that chronic oral steroid therapy delays the motor disability and improves longevity by preventing cardiac and pulmonary decline, even after a boy stops ambulating. Supportive care includes physical therapy, bracing, proper wheelchairs, and treatment of cardiac dysfunction or pulmonary infections. Several exon-skipping medications are Food and Drug Administration approved. They are indicated for use with specific dystrophin mutations.

Myotonic Dystrophy

Etiology and Epidemiology

Myotonic dystrophy (DM) is the second most common muscular dystrophy and the most common form to present in adulthood. An autosomal dominant disease, DM is caused by progressive expansion of a triplet repeat, CTG, in the DM protein kinase gene. Presentation is roughly correlated with the number of CTG repeats, and the disease is characterized by genetic anticipation in which each generation presents with earlier and more severe symptoms.

Clinical Manifestations

Although DM most typically presents in adulthood, it can present at any age. Clinical features of childhood-onset “classic” DM include slowly progressive facial and distal extremity weakness as well as **myotonia**. Myotonia is delayed muscle relaxation after contraction. When patients grasp onto an object, they have difficulty releasing their grasp and may appear to peel their fingers away slowly. The facial appearance is characteristic, with hollowing of muscles around temples, jaw, and neck; ptosis; facial weakness; and drooping of the lower lip. Not only is the striated muscle affected, but smooth muscle of the alimentary tract and cardiac muscle are involved. Patients have variable arrhythmias, endocrinopathies, immunologic deficiencies, and cataracts. Most patients with DM have intellectual disability, and those with congenital DM are more severely impacted.

A severe congenital form of DM can appear in infants of mothers with DM because of rapid expansion of the CTG repeat length. Infants are immobile and hypotonic, with ptosis, absence of sucking and Moro reflexes, poor feeding, and respiratory difficulties. Often, weakness and atony of uterine smooth muscle during labor lead to associated hypoxic ischemic encephalopathy and its sequelae, which make the clinical diagnosis more difficult. The presence of congenital contractures, clubfoot, or a history of poor fetal movements indicates intrauterine neuromuscular disease. Individuals with congenital DM often make significant gains in terms

of motor skills, and nearly all children eventually ambulate independently.

Other Forms of Childhood Muscle Disease

Congenital muscular dystrophies (CMDs) refer to a group of genetically determined conditions that present in infancy or early childhood. The most common subtypes include merosin-deficient CMD, Ullrich CMD, and the dystroglycanopathies. The characteristic clinical features include hypotonia, extremity weakness, delayed motor development, and congenital contractures. Contractures and scoliosis are often progressive and severely worsen; respiratory status diminishes with age. An elevated CK is typical. Diagnosis is established through genetic testing and, less commonly, through muscle biopsy if the genetic testing is unrevealing.

Emery-Dreifuss muscular dystrophy (EDMD), also known as humeroperoneal muscular dystrophy, typically begins in childhood. Patients may experience early contractures, slowly progressive humeroperoneal muscle weakness or wasting, and cardiac disease with conduction defects and arrhythmias. EDMD is associated with mild elevations of serum CK levels and abnormal electrocardiograms (ECG). There are no disease-specific modifying therapies for EDMD, although early placement of defibrillators in patients with abnormal ECGs reduces the incidence of sudden death.

Several forms of **limb-girdle muscular dystrophy** (LGMD) have been described. The majority are inherited in an autosomal recessive pattern, but autosomal dominant forms exist as well. Depending on the subtype of LGMD, presentation can be throughout childhood. LGMD primarily affects muscles of the hip and shoulder girdles. Distal muscles may later become weak and atrophic; some forms are more likely to have progressive cardiac and respiratory failure.

Facioscapulohumeral dystrophy is an autosomal dominant myopathy. Weakness first appears in the facial and shoulder girdle muscles. Shoulder weakness results in the characteristic observation of scapular winging, which can often be asymmetric. Patients have mild ptosis, a decrease in facial expression, inability to pucker the lips or close eyes during sleep, neck weakness, difficulty in fully elevating the arms, and thinness of upper arm musculature (i.e., deltoid muscles).

Congenital myopathies (CM) are a group of nondystrophic muscle disorders that, like CMDs, most typically present in infancy with hypotonia and weakness. Additional signs and symptoms include congenital contractures, hip subluxation/dislocation, small/atrophic muscles, thin body habitus, and characteristic facial appearance (the “myopathic facies”). Symptoms are often nonprogressive or only slowly progressive, although children often have severe lifelong disabilities including use of wheelchairs, severe scoliosis, and respiratory failure. Histopathologic subtypes are distinguished by characteristic features on muscle biopsy, the most common being nemaline myopathy, centronuclear myopathy, and core myopathy. Although no specific therapies currently exist for any CM subtype, several promising therapies have shown efficacy in preclinical models of disease.

Metabolic Myopathies

Glycogen storage disease type II (Pompe disease) and muscle carnitine deficiency are discussed in [Chapters 52 and 55](#).

Several **mitochondrial myopathies** may present with hypotonia, ophthalmoplegia, and progressive weakness, but the phenotype of these disorders is broad (see [Chapter 57](#)). **Endocrine myopathies**, including hyperthyroidism, hypothyroidism, hyperparathyroidism, and Cushing syndrome, are associated with proximal muscle weakness (see [Chapters 175, 176, and 178](#)). **Periodic paralysis** due to familial forms of hypokalemia or hyperkalemia produces episodic weakness.

Laboratory and Diagnostic Studies

For most muscular dystrophies and myopathies, the diagnosis is usually established based on laboratory and genetic testing. If the diagnosis is unclear, muscle biopsy may be needed.

Malignant Hyperthermia

Malignant hyperthermia is a life-threatening syndrome precipitated by exposure to anesthetic agents in patients with a genetic predisposition. Calcium accumulation within skeletal muscles leads to sustained muscle contraction, cellular hypermetabolism, and anaerobic metabolism. These effects can lead to rhabdomyolysis with resulting hyperkalemia, myoglobinuria, and arrhythmia. Hypermetabolism leads to hypercarbia, tachycardia, and hyperthermia. Patients with Duchenne muscular dystrophy, central core myopathy, and other myopathies are susceptible. Some patients may report a family history of unexplained death during anesthesia. Widespread organ dysfunction and disseminated intravascular coagulation may occur. Treatment consists of discontinuation of anesthetic agents, dantrolene, and cooling. In patients without a known predisposing neuromuscular condition, genetic testing is recommended.

NEONATAL AND INFANTILE HYPOTONIA

The clinical distinction between upper and lower motor neuron disorders in infants is blurred because incomplete myelination of the developing nervous system limits expression of many cardinal signs, such as spasticity. The two critical clinical points are whether the child is weak and the presence or absence of deep tendon reflexes. Hypotonia and weakness coupled with depressed or absent deep tendon reflexes suggest a neuromuscular disorder. A stronger child with brisk reflexes suggests an upper motor neuron source for the hypotonia. Causes of neonatal weakness are outlined earlier.

Hypotonia Without Significant Weakness (Central Hypotonia)

Some infants who appear to move well when supine in their cribs are floppy when handled or moved. When lifted, their heads flop, they slip through at the shoulders, do not support weight on their legs, and form an inverted U in prone suspension (**Landau posture**). When placed prone as neonates, they may lie flat with extended arms and legs. Passive tone is decreased, but reflexes are normal. Hypotonia may be associated with significant cerebral disease or may be a benign phenomenon that is outgrown. The most common cause of hypotonia is hypoxic-ischemic encephalopathy (see [Chapter 64](#)).

Prader-Willi syndrome (PWS) presents with severe neonatal hypotonia, profound feeding problems leading to failure to thrive, and small hands and feet; boys, too, present with a small penis, small testicles, and cryptorchidism. Severe hyperphagia and obesity develop in early childhood. Approximately 60–70% of affected individuals have an interstitial deletion of paternal chromosome 15q11q13. PWS and trisomy 21 are the most common genetic causes of neonatal hypotonia.

Infants who have a connective tissue disorder, such as **Ehlers-Danlos syndrome**, **Marfan syndrome**, or familial laxity of the ligaments, may exhibit marked passive hypotonia, ligamentous laxity, and increased skin elasticity. They have normal strength and cognition and achieve motor and mental milestones normally. They may have peculiar postures of the feet or unusual gaits.

STROKE IN CHILDHOOD

Etiology

The incidence of pediatric stroke is 2.5–10 per 100,000 children and is higher among neonates, approaching the incidence in elderly patients. A wide spectrum of conditions can produce stroke in childhood ([Table 182.4](#)). Pediatric strokes may be **arterial ischemic stroke** [AIS], **cerebral sinovenous thrombosis** [CSVT], or hemorrhage. AIS is focal brain infarction that results from occlusion of the arteries in the brain. The most common causes are vasculopathies (including inflammatory and noninflammatory arteriopathies) and cardioembolic infarcts due to congenital heart disease, sickle cell anemia, or coagulation disorders. Coagulation disorders also increase the risk of CSVT (the occlusion of venous structures in the brain), which can result in ischemia and, sometimes, hemorrhage as the cerebral venous pressure rises. CSVT can also be caused by infections or dehydration. **Hemorrhagic strokes** (HS) may be intraparenchymal (primary or secondary bleeding after AIS) or due to subarachnoid hemorrhage. The most common causes of HS are vascular malformations, head trauma, and vasculitis.

Clinical Manifestations

The acute onset of focal neurologic deficits in a child is stroke until proven otherwise. Symptoms may be subtle and nonspecific, which can lead to a delay in diagnosis. AIS typically presents with acute, focal neurologic deficits. Hemiparesis is most common, but visual, speech, sensory, or balance deficits may be present. Focal seizures and headaches are more common in children with AIS than in adults. Neonatal AIS most often presents with acute symptomatic focal seizures (typically in the first day of life) or encephalopathy.

Symptoms of CSVT may progress more gradually and be more variable and nonspecific than AIS. In CSVT, acute focal deficits may occur or the child may have progressive signs of elevated intracranial pressure, including headache, papilledema, diplopia (most often from cranial nerve VI palsy), seizures, lethargy, or confusion.

HS tends to present acutely, with a sudden “thunderclap” headache. HS may also present with loss of consciousness, nuchal rigidity, focal deficits, or seizures and can be rapidly fatal.

Moyamoya disease	

Some early-life strokes are not recognized until later in life, when an infant or child presents with hemiplegia. Such congenital hemiplegia becomes increasingly apparent as infants develop; they may use one side of the body less, have early handedness, or ignore one side of the body or aspects of the environment. Neuroimaging reveals an area of

encephalomalacia in the contralateral cerebral hemisphere that is the residual effect of a prior stroke. The area of encephalomalacia may predispose the child to epilepsy. The details of the child's intrauterine, labor, delivery, and postnatal history are often unremarkable, so the timing of the stroke typically remains uncertain.

Differential Diagnosis

There are many conditions that mimic pediatric stroke, most of which are more common than AIS, HS, or CSVT. Some of these mimics are benign (e.g., migraine, functional neurologic disorder, musculoskeletal abnormalities), but others require specific, prompt diagnosis and treatment (e.g., transient post-ictal weakness, intracranial infection, inflammatory disease of the central nervous system, tumor, posterior reversible leukoencephalopathy syndrome).

Diagnostic Tests and Imaging

On initial presentation, acute neuroimaging is necessary. A noncontrast head computed tomography (CT) scan is highly sensitive to acute HS and can reveal larger, mature AIS, but acute, nonhemorrhagic stroke may not be seen on routine CT. Therefore MRI with diffusion-weighted imaging is required for most presentations. Angiography by magnetic resonance angiography (MRA) or CT angiography is used to confirm arterial occlusion in AIS and can identify underlying arteriopathy, vascular malformations, and aneurysms. Perfusion imaging has recently been used in adults to identify a penumbra (tissue at risk but not yet infarcted), but its role is not yet clear in children. Diagnosis of CSVT requires a high clinical suspicion and purposeful imaging of the cerebral venous system by magnetic resonance venography or CT. If clinical assessment does not reveal the cause of the stroke, a complete laboratory investigation should be undertaken promptly based on suspected etiologies (see Table 182.4). Many children with AIS have more than one predisposing factor, so identifying one risk factor does not obviate the need for a complete evaluation.

Treatment

Treatment must focus on limiting secondary neuronal injury and prevention of future strokes. Neuroprotection by maintaining control of temperature, blood pressure, glucose, and seizures is essential. Emergency thrombolysis with medications or mechanical thrombectomy is not yet established for children but it is an area of active clinical research. Anticoagulants (IV heparin, subcutaneous low molecular weight heparin, oral warfarin) and platelet antiaggregants (aspirin) are used for secondary stroke prevention in some instances. For those with acute, progressive CSVT, anticoagulation is the mainstay of therapy. Long-term rehabilitation programs are required for most survivors.

PEARLS FOR PRACTITIONERS

See *Neurology: Pearls for Practitioners* at the end of this section.

CHAPTER 183

Ataxia and Movement Disorders

ATAXIA

Ataxia is the inability to make accurate, smooth, and coordinated movements. **Truncal ataxia** reflects disturbances of the midline cerebellar vermis (e.g., medulloblastoma, acute postinfectious cerebellar ataxia, ethanol intoxication). **Appendicular ataxia** reflects disturbances of the ipsilateral cerebellar hemisphere (e.g., pilocytic astrocytoma). Ataxias may be acute or chronic. The most common causes of acute ataxia in childhood are postinfectious acute cerebellar ataxia and drug intoxications. Discrete lesions within the posterior

fossa, tumors (e.g., medulloblastoma, ependymoma, cerebellar astrocytoma), cerebellar abscess, demyelinating diseases, acute labyrinthitis, strokes, and hemorrhages may cause ataxia. Other causes include benign paroxysmal vertigo, head trauma, seizures, postictal states, migraine, paraneoplastic opsoclonus-myoclonus syndrome associated with neuroblastoma, and inborn errors of metabolism. Congenital disorders also may produce chronic, nonprogressive ataxia. There are several inherited ataxia syndromes (Table 183.1).

Clinical Manifestations

Signs of ataxia include a broad-based, unsteady gait, difficulty sitting (truncal ataxia), and **dysmetria** (over- or undershoot- ing of the target due to abnormal distance perception). An

TABLE 183.1 Causes of Ataxia

BRAIN TUMORS	VASCULAR DISORDERS
Medulloblastoma*	Cerebellar hemorrhage or infarction
Pilocytic astrocytoma*	Vertebral artery dissection
Ependymoma	DEMYELINATING DISORDERS
Brainstem glioma	Acute disseminated encephalomyelitis

Antihistamines	Vitamin E deficiency
Benzodiazepines	Leigh disease
Carbon monoxide	Wilson disease
Inhalants	Abetalipoproteinemia
Drugs of abuse	

*Common.

intention tremor worsens as the arm/hand approaches the target. Some children may be perceived as clumsy. Classically, these signs stem from disorders of the cerebellar pathways, but peripheral nerve lesions causing loss of proprioceptive inputs to the cerebellum (e.g., Guillain-Barré syndrome) may present with similar findings. In addition, weakness may intensify or mimic ataxia, so strength must be assessed, along with coordination.

Etiologies

Drug intoxication is the most common cause of acute ataxia among children. Overdosage of any sedative-hypnotic agent can produce acute ataxia and lethargy, but ataxia without lethargy usually results from intoxication with ethanol or anticonvulsant drugs. Over-the-counter cough syrups (e.g., dextromethorphan), essential oils (e.g., tea tree), and other toxins (e.g., pesticides) may also cause ataxia. It is important to ask about any medications, drugs of abuse, or other toxins to which the child may have access. Treatment is supportive.

Postinfectious acute cerebellar ataxia may occur 1–3 weeks following varicella, infectious mononucleosis, mild respiratory or gastrointestinal viral illnesses, or other infections. The pathogenesis is uncertain and may represent a direct viral infection of the cerebellum or, more likely, an autoimmune response precipitated by the viral infection and directed at the cerebellar white matter. Symptoms begin abruptly, causing truncal ataxia, unsteady gait, and frequent falls. Dysmetria of the arms, dysarthria, nystagmus, vomiting, irritability, and lethargy may be prominent. Symptoms, which may be severe enough to prevent standing or sitting, usually peak within 2 days, then stabilize and resolve over several weeks. Cerebrospinal fluid (CSF) examination sometimes shows a mild lymphocytic pleocytosis or mild elevation of protein content. Brain magnetic resonance imaging may reveal cerebellar enhancement. Treatment is generally supportive. If children do not improve within several weeks, evaluation for an alternative etiology of ataxia (e.g., tumor, opsoclonus myoclonus syndrome) should be considered.

Difficulty walking with a severe staggering gait is one manifestation of **acute labyrinthitis**, but the diagnosis is usually clarified by the associated symptoms of a severe sense of spinning dizziness (vertigo), nausea and vomiting, and associated signs of pallor, sweating, and nystagmus.

Brain tumors are the second most common neoplasm in children (see Chapter 157). About 50% arise from within the posterior fossa. Tumors that arise in the posterior fossa or brainstem produce progressive ataxia with headache that may be acute or gradual in onset. There is a progressive worsening over days to months, typically with associated signs and symptoms of elevated intracranial pressure. The ataxia and dysmetria may result from primary cerebellar invasion or from obstruction of the CSF pathways (e.g., cerebral aqueduct) with resultant hydrocephalus. The most common tumors in this region include medulloblastoma, ependymoma, pilocytic astrocytoma, and brainstem glioma.

Rarely, a **neuroblastoma**, located in the adrenal medulla or anywhere along the paraspinal sympathetic chain in the thorax or abdomen, is associated with degeneration of Purkinje cells and the development of severe ataxia,

dysmetria, irritability, myoclonus, and opsoclonus (see Chapter 158). An immunologic reaction directed toward the tumor may be misdirected to attack Purkinje cells and other neuronal elements. The myoclonic movements are irregular, lightning-like movements of a limb or the head. Opsoclonus is a rapid, multidirectional, conjugate movement of the eyes, which suddenly dart in random directions. The presence of **opsoclonus-myoclonus** in a child should prompt a vigorous search for an occult neuroblastoma.

Ataxia-telangiectasia, an autosomal recessive genetic disorder of the ATM gene, causes a degenerative ataxia (see Chapter 73). Affected patients present with ataxia around age 2 years, progressing to loss of ambulation by adolescence. In mid-childhood, telangiectasias are evident over the sclerae, nose, ears, and extremities. Abnormalities in immune function and greatly increased risk of lymphoreticular tumors result in early death.

Friedreich ataxia is a relentlessly progressive, autosomal recessive disorder. Children present in the late elementary school years with ataxia, dysmetria, dysarthria, diminished proprioception and vibration sense, absent deep tendon reflexes, and nystagmus. Many develop hypertrophic cardiomyopathy and skeletal abnormalities (e.g., high-arched feet, hammer toes, kyphoscoliosis).

Several rare **inborn errors of metabolism** can present with intermittent episodes of ataxia and somnolence. These include Hartnup disorder, maple syrup urine disease, mitochondrial disorders, abetalipoproteinemia, and vitamin E deficiency (see Chapters 31 and 53).

MOVEMENT DISORDERS

Movement disorders or **dyskinesias** are a diverse group of entities associated with abnormal excessive, exaggerated, chaotic, or explosive movements of voluntary muscles. They are generally the result of abnormalities of the extrapyramidal system including the basal ganglia. Movement disorders in children are typically **hyperkinetic** (increased movement). The abnormal movements are activated by stress and fatigue and often, but not always, disappear in sleep. They are typically diffuse and migratory (e.g., chorea) but may be isolated to specific muscle groups (e.g., segmental myoclonus, palatal myoclonus).

Chorea is a hyperkinetic, rapid, unsustained, irregular, purposeless movement that seems to flow from one body part to another. Affected patients may demonstrate difficulty keeping the tongue protruded or maintaining grip (milkmaid grip). Patients often attempt to incorporate the involuntary movements into more purposeful movements, which make them appear fidgety. Choreiform movement disorders may be autoimmune/parainfectious, infectious, genetic, structural, metabolic, or toxic in origin (Table 183.2). The movements may occur alone or as part of a more extensive disorder (e.g., Sydenham chorea, Huntington chorea, systemic lupus erythematosus, encephalitis).

Athetosis is a hyperkinetic, slow, coarse, writhing movement that is most pronounced in the distal muscle groups. Athetosis is seen frequently in combination with chorea (choreoathetosis). It may be seen in virtually all the disorders mentioned as causes of chorea. Many children with mixed forms of cerebral palsy have spasticity and choreoathetosis.

TABLE 183.2 Causes of Movement Disorders

CHOREA
Autoimmune/parainfectious (e.g., acute rheumatic fever,* systemic lupus erythematosus)
Infectious (e.g., HIV, neurosyphilis, encephalitis)
Genetic (e.g., Huntington disease, ataxia-telangiectasia)
Structural (e.g., stroke, neoplasm)

Benign*
Epilepsy
Infection
Toxin
Metabolic encephalopathies
TICS*
Provisional (transient) tic disorder
Chronic motor tic disorder
Tourette syndrome

*Common.

Dystonia is characterized by abnormally sustained muscle contraction, causing twisting motions (torsion spasm) and repetitive movements or abnormal postures, usually associated with basal ganglia or thalamic lesions. Cerebral palsy is the most common cause of dystonia among children, but many genetic mutations have been implicated in primary dystonias. Antipsychotics and antiemetics can produce **acute dystonic reactions**, typically involving the face

and neck with torticollis, retrocollis, tongue protrusions, and oculogyric crises (eye rotation). Treatment is with anticholinergics and/or antihistamines. **Tardive dyskinesia** is usually associated with chronic antipsychotic drug use and presents with characteristic facial involvement (tongue thrusting, chewing).

Tremor is a hyperkinetic, rhythmic, oscillatory movement caused by simultaneous contractions of antagonist muscles. The amplitude and frequency are regular. In children, tremor is usually due to a physiologic tremor or essential tremor. Essential tremor is the most common movement disorder in adults, and half report onset in childhood. Other causes of tremor include thyrotoxicosis, hypoglycemia, or drugs (e.g., caffeine, bronchodilators, amphetamines, tricyclic antidepressants).

Myoclonus is a hyperkinetic, brief contraction of a muscle group, resulting in a sudden jerk. Myoclonus may be caused by seizures or by other etiologies (see [Chapter 181](#)). Myoclonus is distinguished from tremor in that it is a simple contraction of an agonist muscle, whereas tremor is a simultaneous contraction of agonist and antagonist muscles. Myoclonus is seen as a manifestation of various epilepsies and infectious, toxic, and metabolic encephalopathies. Benign myoclonus is commonly observed during sleep and may be particularly pronounced in neonates.

Tics are rapid, purposeless, involuntary, stereotyped movements and typically involve the face, eyes, shoulder, and arm. Examples of simple motor tics include blinking, nose twitching, and extremity jerking. Complex motor tics are more orchestrated movements, including head shaking, gesturing, or jumping. Phonic tics may be simple (e.g., grunting, throat clearing) or complex (e.g., uttering words, phrases). Approximately 25% of children have transient tics. Most tic disorders in children are transient and not intrusive into the child's life but may be a source of parental anxiety. Although it was previously thought that tics could be unmasked by stimulant agents, a recent meta-analysis did not show an association. Persistent motor tics (lasting >12 months) combined with vocal tics are characteristic of **Tourette syndrome**, a chronic tic disorder that usually begins before age 12 years. The pathophysiology underlying tics is unknown, but a family history of tics is elicited in more than 50% of cases. Comorbid features, such as obsessive-compulsive disorder and attention-deficit/hyperactivity disorder, are present in half of children with Tourette disorder (see [Chapters 13 and 19](#)). Tic disorders are clinical diagnoses, and neurodiagnostic studies have limited value. Many children with tic disorders or Tourette syndrome are unperturbed by their tics and require no therapy. Others may benefit from psychologic support, including Comprehensive Behavioral Intervention for Tics and pharmacologic therapy, typically with α -adrenergic receptor agonists (e.g., clonidine, guanfacine) or neuroleptics (e.g., pimozide, aripiprazole, risperidone). Chronic tic disorders wax and wane regardless of intervention and most often improve substantially or resolve entirely by late adolescence.

PEARLS FOR PRACTITIONERS

See *Neurology: Pearls for Practitioners* at the end of this section.

CHAPTER 184

Altered Mental Status

DISORDERS OF CONSCIOUSNESS

Consciousness is a cortical function that allows for awareness of self and environment (place, time). **Arousal** represents the system that initiates and maintains consciousness and is mediated by the reticular activating system (RAS), which extends from the pons through the midbrain to the hypothalamus and thalamus. Acute changes in consciousness vary in degree from mild lethargy and confusion to deep coma. **Lethargic** patients have difficulty maintaining an aroused state. Patients who are **obtunded** have decreased arousal but are responsive to stimuli. **Stupor** is a state of responsiveness to pain but not to other stimuli. **Coma** is a state of unresponsive unconsciousness and is caused by dysfunction of the cerebral hemispheres bilaterally, the bilateral thalami, and/or the brainstem.

Acute Disorders of Consciousness

In childhood, the most common causes of altered mental status are toxins, infections, head trauma, hypoxia-ischemia (e.g., cardiac arrest, near-drowning), and seizures (e.g., postictal state, subclinical status epilepticus) (Table 184.1).

Assessment

The most common cause of long-term morbidity in a patient with depressed consciousness is hypoxia; therefore airway, breathing, and circulation are addressed first. Vital signs, including pulse oximetry, must be assessed. Breathing patterns may provide important clues to the neurologic localization and etiology of the depressed consciousness. A low respiratory rate may be associated with central nervous system (CNS) depressants or increased intracranial pressure (ICP). Tachypnea may be due to hypoxia, metabolic acidosis, or fever, but in more ominous situations may be due to brainstem herniation. Systemic diseases such as sepsis, ingestions, or cardiac failure may lead to shock. Hypotension may also result from severe traumatic brain injury (TBI) or spinal cord injury. Hypertension may be due to increased ICP. The glucose level should also be checked immediately because hypoglycemia is a rapidly treatable cause of altered mental status. Physical examination searches for clues as to the cause of altered consciousness, such as unusual odors, needle tracts, trauma, dehydration, or organ system failure.

The **Glasgow Coma Scale** (see Table 42.1) can be used to assess unresponsive patients regarding their best verbal and motor responses and eye opening to stimulation with scores ranging from 3–15 points.

Testing the structures immediately adjacent to the reticular system is essential. Changes in pupillary response generally suggest midbrain lesions, though pontine lesions can cause pinpoint pupils. In comatose patients, eye movements are observed or elicited with the **oculocephalic vestibular reflexes** (doll's-eye maneuver) (see Chapter 179). If the oculocephalic responses are not elicited or are unclear, the **oculovestibular response** (cold caloric stimulation) is elicited by flushing cold water into the external ear canal. In a comatose patient, cold

water irrigation into the ear canal elicits a tonic eye deviation toward the irrigated ear if the brainstem is functioning.

Body posture at rest and after noxious stimulation can indicate the anatomic level responsible for the alteration of consciousness. Posturing in response to noxious stimulation indicates more serious neurologic conditions. **Decorticate posturing** consists of rigid extension of the lower extremities, flexion and supination of the arms, and fisting of the hands. It indicates bilateral cortical or subcortical abnormalities or herniation, with preserved brainstem function. **Decerebrate posturing** (rigid extension and internal rotation of the upper and lower extremities) is associated with herniation with midbrain compression or toxic-metabolic abnormalities. These postures may be symmetric or asymmetric. A structural cause is most likely when posturing is asymmetric, whereas symmetric posturing may suggest an underlying toxic-metabolic etiology.

Etiology

The evolution of change in consciousness is an important clue to the etiology. A detailed history and physical examination usually provide sufficient clues to differentiate among the three major diagnostic categories producing coma: **metabolic/toxic**, **infectious**, and **structural**. In most clinical situations, the cause of coma is readily identified.

Care must be taken to investigate background medical conditions that may produce a decline in consciousness (e.g., diabetes mellitus, leukemia, kidney failure, liver disease). Metabolic derangements are common causes of altered mental status and are suggested by spontaneous fluctuations in the level of consciousness, tremors, myoclonus, asterixis, visual and tactile hallucinations, and deep coma with preservation of pupillary light reflexes. Disturbances of blood chemistries (e.g., glucose, sodium, calcium, bicarbonate, blood urea nitrogen, ammonia) may produce depressed mental status, as can hypoxemia and cerebral ischemia (inadequate cerebral perfusion). Acute metabolic or toxic disorders usually produce a hypotonic, limp state, but hypertonia, rigidity, or posturing can be seen in some causes of coma (e.g., hypoglycemia, hepatic encephalopathy, short-acting barbiturates).

Intoxication and ingestion are common causes of acute alteration of consciousness. A thorough history must be taken to search for the offending agent (see Chapter 45). A history of social stressors, depression, substance disorder, or other mental health issues raises concern for self-inflicted injury or toxic ingestion. A subacute course of somnolence progressing to difficulty arousing from a deep sleep (stupor) over hours suggests drug intoxication or organ system failure (e.g., kidney, liver) producing a metabolic encephalopathy. CNS infection usually causes abrupt alteration of mental status, although viral meningoencephalitis (particularly herpes simplex virus) can present with subacute alterations in mental status. The presence of fever, petechiae, chills, and sweats suggests infection. Prodromal photophobia and pain on movement of the head or eyes are symptoms of meningeal irritation. Preceding symptoms, such as abdominal pain, diarrhea, sore throat, conjunctivitis, cough, or rash, point toward viral encephalitis or postinfectious syndrome as the cause of the altered consciousness.

Structural processes, such as hemorrhage, acute hydrocephalus, or stroke, can cause sudden depressed consciousness

TABLE 184.1 Causes of Altered Mental Status and Diagnostic Approach

TABLE 184.1 Causes of Altered Mental Status and Diagnostic Approach	
CAUSES	Increased Intracranial Pressure
Infection	Brain tumor
Meningitis	Cerebral edema
Encephalitis (e.g., herpes simplex virus, arboviruses)	Hydrocephalus
Brain abscess or subdural empyema	Migraine
HIV	Systemic Disorders
Tuberculosis meningitis	Gastrointestinal (e.g., intussusception)
Toxic shock syndrome	Vasculitis (e.g., systemic lupus erythematosus)
Postinfectious (e.g., acute disseminated encephalomyelitis)	Hepatic failure
Trauma	Hypertensive encephalopathy
Abusive head trauma	Reye syndrome
Hemorrhage (e.g., epidural, subdural, subarachnoid)	Endocrine disorders (e.g., adrenal insufficiency, thyroid disorders)
Brain contusion	Renal disorders (e.g., uremia)
Concussion	Demyelinating disorders (e.g., multiple sclerosis, ADEM)
Diffuse axonal injury	Metabolic Derangements
Toxins (Intoxication or Withdrawal)	Hypoglycemia
Ethanol	Hyponatremia or rapid correction
Narcotics	Hypernatremia or rapid correction
Barbiturates	Hyperosmolality or rapid correction
Antihistamines	Hypercapnia
Anticonvulsants	Hyperammonemia
Iron	Inborn errors of metabolism
Acetaminophen	Diabetes mellitus—ketoacidosis or hypoglycemia
Aspirin (Reye syndrome)	DIAGNOSTIC APPROACH
Illicit drugs	Routine laboratory testing
Lead poisoning	Glucose
Thiamine deficiency (Wernicke encephalopathy)	Sodium, potassium, calcium, magnesium, chloride, bicarbonate, BUN, creatinine, AST, ALT, blood gases, ammonia, TSH
Hypoxia-Ischemia	Blood, urine analyses for toxic substances
Near-drowning	Blood, urine cultures if infection suspected
Post-cardiopulmonary arrest (e.g., cardiac arrhythmia, obstructive cardiomyopathy)	Skeletal survey, ophthalmologic examination if child abuse suspected
Carbon monoxide intoxication	Neuroimaging
Perinatal asphyxia	Head CT
Strangulation	Brain MRI, MRA, MRV
Epilepsy	CSF analysis (if no evidence for increased intracranial pressure on neuroimaging)
Subclinical (or nonconvulsive) status epilepticus	Opening pressure
Postictal states	White and red blood cell counts, protein, glucose
Stroke	Culture (±viral PCR testing)
Arterial ischemic stroke	Electrodiagnostic studies
Cerebral sinovenous thrombosis	EEG
Hemorrhage	Secondary laboratory testing (if cause remains unknown)
	Lead level, pyruvate, lactate, serum amino acids, urine organic acids, acylcarnitine profile

ADEM, Acute disseminated encephalomyelitis; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; MRI/MRA/MRV, magnetic resonance imaging/angiography/venography; PCR, polymerase chain reaction; TSH, thyroid-stimulating hormone.

in children. An evolution of headache and morning vomiting suggests increased ICP. A gradual fading of alertness or declining school performance over preceding weeks suggests an expanding intracranial mass, subdural hematoma, or chronic infection.

Clinical Manifestations

Papilledema or paralysis of cranial nerves III (dilated “blown” pupil, eye deviated down and laterally) or VI (unable to move eye laterally) in a patient with depressed consciousness is strong evidence of elevated ICP, a medical and neurosurgical

TABLE 184.2 | Herniation Syndromes

LOCATION	ETIOLOGY	DESCRIPTION	CLINICAL FINDING(S)
Transtentorial Unilateral (uncal) or bilateral	Supratentorial mass lesions, diffuse brain swelling, focal edema, or acute hydrocephalus	Downward displacement of supratentorial brain tissue into infratentorial compartment (below tentorium), compressing the cerebral peduncles, midbrain, third cranial nerve, and posterior circulation	Headache Altered consciousness Dilated ipsilateral pupil Cranial nerve III palsy Hemiparesis Decerebrate posturing Cushing triad Respiratory arrest
Subfalxian	Increased pressure in one hemisphere (mass, focal edema)	Brain tissue displaced under the falx cerebri, compressing the anterior cerebral artery	Weakness, bladder incontinence, coma
Foremen magnum	Cerebellar mass or edema	Downward displacement of cerebellar tonsils, compressing the medulla and upper spinal cord	Bradycardia, bradypnea, hypertension, death

emergency. **Herniations** can occur under the falx, through the tentorial notch, or into the foramen magnum (Table 184.2). Recognition of the signs associated with the major herniation syndromes can be lifesaving if emergent neuroimaging and treatment are initiated. **Uncal herniation** implies displacement of one mesial temporal lobe over the tentorial edge, producing a unilateral third nerve palsy and hemiparesis (which can be ipsilateral due to compression of the contralateral cerebral peduncle or contralateral if the uncus compresses the ipsilateral peduncle). Another type of transtentorial herniation, **central herniation**, occurs when both temporal lobes and the diencephalon (thalamus and hypothalamus) herniate through the tentorium. A progressive loss of consciousness accompanied by miosis, decorticate posturing, and Cheyne-Stokes respirations (rhythmic waxing and waning of respiratory amplitude) suggests incipient transtentorial herniation. Late findings include decerebrate posturing and Cushing triad (bradycardia, irregular respirations, hypertension).

Laboratory and Diagnostic Imaging

Evaluation is guided by the history and physical examination. Clinicians should rapidly consider causes of unresponsiveness that could easily and quickly be reversed (see Table 184.1). If trauma or immersion injuries are suspected, neck manipulation should be avoided until cervical spine imaging excludes vertebral fracture or subluxation.

Computed tomography (CT) remains the preferred imaging technique in emergency situations because it can be performed rapidly, and it accurately identifies intracranial acute hemorrhages, large space-occupying lesions, edema, and shifts of the midline. The initial head CT scan is done without contrast to identify blood and calcifications. Contrast can be administered to identify inflammatory and neoplastic lesions but is not usually required for identification of major lesions.

Examination of the cerebrospinal fluid (CSF) may establish the cause of the alteration of consciousness. Lumbar puncture (LP) in a patient with elevated ICP can result in transtentorial herniation, so neuroimaging must be performed before LP if elevated ICP is suspected. The presence of red blood cells in the CSF may suggest primary subarachnoid hemorrhage,

parenchymal hemorrhage, or hemorrhagic infection (e.g., herpes simplex virus), or trauma from the procedure causing bleeding into the subarachnoid space. White blood cells in the CSF usually denote infectious meningitis or meningoencephalitis but may also be associated with autoimmune disorders or parainfectious syndromes. Elevated CSF protein is seen in patients with meningeal inflammation, tumors, or white matter diseases, whereas abnormal CSF glucose levels are also markers of infection and inflammation (e.g., neurosarcoidosis).

Treatment

Beyond supportive measures, the etiology of altered mental status determines the treatment. Ingestions may necessitate charcoal administration, forced diuresis, dialysis, or specific antidotes (see Chapter 45). Infections are treated with appropriate antibiotics or antiviral agents (see Chapters 100 and 101). If mental status changes are due to increased ICP, acute medical interventions (e.g., osmotic agents, a trial of hyperventilation, and elevating the head of the bed to 30 degrees) must be instituted, emergent neuroimaging performed, and urgent neurosurgical consultation obtained. Structural brain lesions may necessitate medical treatment of increased ICP or surgical excision.

Prognosis

The outcome of altered mental status relates to many variables, including etiology. Intoxication typically carries a good prognosis, whereas herniation carries a poor prognosis. Other prognostic factors include the duration of coma and the age of the patient; children have better outcomes than adults. Complete recovery from traumatic coma of several days' duration is possible in children; however, many survivors of prolonged coma are left in a persistent vegetative state or with severe neuropsychiatric disability.

Transient, Recurrent Depression of Consciousness

Episodic alteration or depression of consciousness with full recovery is usually due to seizure, migraine, syncope, or

metabolic abnormality (e.g., hypoglycemia). Consciousness can be impaired during seizures or in the postictal state. Nonconvulsive (subclinical) status epilepticus (generalized or focal) can directly impair consciousness and is a common complicating factor for infants and children with acute neurologic disorders (e.g., head trauma, meningitis, stroke, following convulsive status epilepticus). **Confusional migraines** can last hours and be accompanied by agitation, ataxia, cortical blindness, vertigo, or cranial nerve palsies; headache may precede or follow the neurologic signs.

Syncope is one of the most common causes of abrupt, episodic loss of consciousness. Neurocardiogenic syncope, cardiac arrhythmia, or obstructive cardiomyopathy can cause recurrent episodes of loss of consciousness. Two-thirds of children with syncope have irregular, myoclonic movements as they lose consciousness (anoxic seizures), which must be distinguished from epilepsy (unprovoked seizures). Children with unexplained syncope require a complete cardiac evaluation (see [Chapter 140](#)).

Metabolic derangements, particularly **hypoglycemia**, can give rise to episodes of lethargy, confusion, seizures, or coma. Several other metabolic disorders cause recurrent bouts of **hyperammonemia** (see [Chapter 53](#)). Symptoms include nausea, vomiting, lethargy, confusion, ataxia, hyperventilation, and coma.

INCREASED INTRACRANIAL PRESSURE

Etiology

When the cranial sutures are fused, the skull becomes a rigid container enclosing a fixed volume, including the brain (80–85%), CSF (10–15%), and blood (5–10%). The exponential relationship between the volume within a closed container and pressure results in a massive increase in ICP as intracranial volume increases. The brain accommodates increased ICP initially by expelling CSF and blood from the intracranial compartment into the spinal subarachnoid space. When the limits of this accommodation are reached, the brain itself begins to shift in response to the continuing elevation of ICP. Brain shifts may cause herniations across the dural extensions or skull barriers (see [Table 184.2](#)).

The most common causes of increased ICP include mass lesions, hydrocephalus, cerebral edema due to trauma or infection, and idiopathic intracranial hypertension (pseudotumor cerebri) ([Tables 184.3 and 184.4](#)).

Mass lesions (e.g., brain tumor, abscess, hemorrhage) may produce increased ICP not only by virtue of large size, but by blockage of CSF pathways, blockage of venous outflow, or creation of vasogenic cerebral edema. Brain abscesses usually present as mass lesions producing focal neurologic signs and increased ICP. Symptoms of infection, such as fever, malaise, anorexia, and stiff neck, may be subtle or absent. Children with chronic cardiac or pulmonary disease may embolize infected material to the brain, predisposing them to brain abscesses. Brain tumors in children are most often located in the posterior fossa and can result in elevated ICP due to obstruction of CSF flow through the cerebral aqueduct and fourth ventricle. Brain tumors and abscesses can both result in vasogenic edema, which further increases ICP.

Hydrocephalus from congenital abnormalities or due to an intracranial mass is typically characterized by a slowly evolving syndrome of increased ICP extending over weeks or months.

TABLE 184.3 Causes of Increased Intracranial Pressure

MASS EFFECT

Endocrinologic disturbance
Obesity

CSF is continuously produced by the choroid plexus within the lateral, third, and fourth ventricles. CSF circulates through the ventricular systems and is then absorbed, predominantly by the arachnoid villi into the large dural sinuses. Hydrocephalus is due to the obstruction of CSF flow anywhere along its course (see [Table 184.4](#)). **Obstructive hydrocephalus** is caused by a block before the CSF flows to the subarachnoid space, usually within the fourth ventricle or at the level of the aqueduct. Congenital hydrocephalus can result from CNS malformations, intrauterine infection, intraventricular hemorrhage, genetic defects, trauma, and teratogens. Acquired hydrocephalus may be caused by CNS infections, brain tumors, or hemorrhage. Impairment of CSF flow within the subarachnoid space or impairment of absorption is known by the misnomer “communicating hydrocephalus,” where there is actually extraventricular obstruction of CSF flow. Hydrocephalus caused by overproduction of CSF without true obstruction is seen in choroid plexus papillomas, which account for 2–4% of childhood intracranial tumors.

Bacterial meningitis may produce increased ICP by blockage of CSF pathways, cytotoxic cerebral edema, increase in cerebral blood flow, or multifocal cerebral infarctions (see [Chapter 100](#)). Most children with bacterial meningitis can undergo LP safely because the brain swelling is diffuse and distributed evenly throughout the brain and spinal CSF compartments. A few

CSF, Cerebrospinal fluid.

patients with meningitis, however, develop transtentorial herniation within a few hours of LP. Focal neurologic signs, poorly reactive pupils, and a tense fontanel are contraindications to LP in a patient with suspected bacterial meningitis.

Idiopathic intracranial hypertension (pseudotumor cerebri) is a cause of increased ICP with normal brain imaging. Patients exhibit a daily debilitating headache associated with diplopia, abducens palsy, transient visual obscurations, and papilledema. If untreated, permanent visual field loss may develop. The syndrome has been associated with ingestion of medications (e.g., tetracycline, vitamin A, oral contraceptive agents) and endocrine disturbances (e.g., thyroid disease, Addison disease). Most commonly, this condition is idiopathic and affects children who are otherwise well except for being overweight, with rapid weight gain being a predisposing factor. Weight loss and cessation of triggering medications are mainstays of treatment. Additional treatment with acetazolamide, another diuretic, or topiramate may be necessary. Infrequently, chronic papilledema from persistent idiopathic intracranial hypertension produces visual impairment, and more aggressive management is required (optic nerve fenestration) to preserve visual function.

Clinical Manifestations

The symptoms and signs of increased ICP include headache, vomiting, lethargy, irritability, altered consciousness, sixth nerve palsy, strabismus, diplopia, and papilledema. Classically,

headaches related to increased ICP worsen with time and with maneuvers that increase ICP such as lying down (nocturnal headaches or upon awakening), bending over, coughing, or Valsalva maneuvers. Specific signs of increased ICP in the infratentorial compartment (posterior fossa) include stiff neck and head tilt. Focal neurologic deficits reflect the site of the lesion that is producing the increased ICP and may include hemiparesis from supratentorial lesions, or ataxia and cranial nerve palsies from infratentorial lesions. Critically increased ICP may result in herniation syndromes, as discussed earlier. In addition, the **Cushing triad** of elevated blood pressure, bradycardia, and irregular respirations is a late sign of critically elevated ICP. Infants who have an open fontanel may present with less specific symptoms such as irritability, lethargy, and poor feeding. Specific signs of increased ICP in infants consist of a bulging fontanel, suture diastasis, distended scalp veins, a persistent downward deviation of the eyes (“sunsetting”), and rapid growth of head circumference. Manifestations of increased ICP may evolve slowly when there is slow growth of a mass or incomplete obstruction allowing for transependymal absorption of CSF into the veins. On the other hand, symptoms may develop rapidly in the setting of acute intracranial hemorrhage or abrupt CSF obstruction.

Laboratory and Diagnostic Studies

The cause of increased ICP is determined by brain imaging with either CT or magnetic resonance imaging (MRI). CT is rapid, readily available, and provides clear visualization of an acute hemorrhage, dilated ventricles, or mass lesions. Diffuse brain swelling produced by hypoxic-ischemic injury, meningitis, encephalitis, metabolic abnormalities, or toxins may be better delineated by MRI. MRI is also superior to CT for visualizing the posterior fossa and cortical contusions. To avoid radiation from head CT, many centers now use limited sequences to allow for a rapid MRI without sedation as an initial screen for acute causes of elevated ICP. LP is the diagnostic test for infection and for documentation of elevated ICP (essential for patients with idiopathic intracranial hypertension). However, LP is contraindicated in the setting of an intracranial mass lesion or clear hydrocephalus because withdrawal of CSF can change pressures between the intracranial compartments and promote brainstem shifts and herniation. Idiopathic intracranial hypertension is diagnosed when direct measurement of ICP with a manometer during LP reveals elevated ICP in the absence of other CSF or imaging abnormalities.

Treatment of Elevated Intracranial Pressure

The treatment of acute increased ICP should be carried out in an intensive care setting with continuous monitoring and vigilant attention to vital signs. The first goal is stabilization of the cardiopulmonary status. Once the child is stabilized, the head is placed at midline, and the head of the bed is elevated to 30 degrees. Indications for endotracheal intubation include refractory hypoxia, hypoventilation, Glasgow Coma Score of 8 or less, loss of airway protective reflexes, and acute herniation requiring controlled hyperventilation. Slight hyperventilation to a P_{aCO_2} not lower than 35 mm Hg produces rapid, but transient, reduction in ICP by cerebral vasoconstriction, leading to decreased cerebral blood volume. More aggressive hyperventilation may cause cerebral ischemia and is only indicated

if there are clinical signs of acute herniation. Mannitol or 3% saline may be used acutely to produce an osmotic shift of fluid from the brain to the plasma. A ventricular catheter may be used to monitor the ICP continuously and to remove CSF. In refractory cases, a pentobarbital-induced coma reduces pressure by severely suppressing cerebral metabolism. The anti-inflammatory effects of corticosteroids may be helpful in the management of vasogenic edema associated with tumors and abscesses. Because acute interventions such as hyperventilation, osmotic therapies, and barbiturates can have negative impacts on systemic and cerebral perfusion and have only transient effects on ICP, they must be used judiciously.

Vasopressor drugs may be necessary to maintain adequate arterial blood pressure and cerebral perfusion pressure. Serum electrolytes and osmolarity should be monitored because of risk of the syndrome of inappropriate antidiuretic hormone or cerebral salt wasting (see [Chapter 35](#)). Maintaining normoglycemia may have a positive impact on outcomes. Other supportive measures include controlling agitation, fever, and seizures.

All treatments for increased ICP are temporary measures intended to prevent herniation until the underlying disease process either is treated or resolves spontaneously. Timely intervention can prevent or reverse cerebral herniation. Complete neurologic recovery is possible, but rare, after signs of transtentorial or foramen magnum herniation have begun. When these signs are complete, however, with bilaterally dilated, unreactive pupils, absent eye movements, and flaccid quadriplegia, recovery is no longer possible.

The **treatment of hydrocephalus** may be medical or surgical, depending on the etiology. After subarachnoid hemorrhage or meningitis, the flow or absorption of CSF may be transiently impaired. In this circumstance, the use of medication that decreases CSF production, such as acetazolamide, may be beneficial. Surgical management consists of removing the obstructive lesion, placing a shunt, or both. A shunt consists of polyethylene tubing extending usually from a lateral ventricle to the peritoneal cavity (**ventriculoperitoneal shunt**). Shunts carry the hazards of infection or sudden occlusion with signs and symptoms of acute hydrocephalus.

TRAUMATIC BRAIN INJURY

Following head injury, children may have immediate depression of consciousness and neurologic deficits or may be completely alert without any immediate signs of neurologic injury. Most serious trauma results from motor vehicle crashes, sports, recreation-related injuries, and violence. Head trauma may result in concussion, posttraumatic intracranial hemorrhage, skull fractures, or cranial nerve or cervical spine injuries. Head injury, or other injuries, with associated retinal hemorrhages in infants and young children should raise the suspicion of abusive head trauma (see [Chapter 22](#)).

Concussion

Concussion is the process in which traumatic forces on the brain result in the rapid onset of short-lived neurologic impairment that typically resolves spontaneously. In some cases, however, symptoms and signs may evolve over minutes to hours, so patients should not be left alone following the injury. Patients may have signs or symptoms in one or more

TABLE 184.5 Protocol for Return to Sport After Concussion

Return to play protocol follows a stepwise progress with each step taking ≥ 24 hr. The athlete should continue to the next level if asymptomatic at the current level.

1. Back to regular activities such as school.
2. Light aerobic exercise such as walking or stationary cycling; no weight lifting.
3. Moderate activity such as jogging, brief running, moderate-intensity stationary biking, moderate-intensity weightlifting (less than their prior weightlifting routine).
4. Heavy, noncontact physical activity such as sprinting/running, regular weightlifting routine, noncontact sport specific drills.
5. Practice and full contact.
6. Competition.

Centers for Disease Control and Prevention. Managing return to activities; 2018. https://www.cdc.gov/headsup/providers/return_to_activities.html. Accessed August 21, 2020.

domain: somatic (headache), cognitive (slowed reaction times, poor attention), emotional (lability, irritability), sleep disturbance (drowsiness), or physical signs (loss of consciousness, amnesia). A player with any features of a concussion should be evaluated by a licensed health care provider onsite or be referred to a physician. Acute symptoms usually reflect a functional disturbance rather than structural injury, and no abnormalities are seen on standard imaging. If the child appears well after several hours and is discharged home, parents should be instructed to call their physician for any change in alertness, orientation, or neurologic functioning. An increase in somnolence, headache, or vomiting is cause for concern and emergent neuroimaging. The majority of concussions resolve within 10 days, although the recovery may be slower in children, and in a small percentage of cases the symptoms are prolonged. Physical and cognitive rest are the cornerstones of initial concussion management, with subsequent gradual return to school and physical activities ([Table 184.5](#)). Repeated concussions, especially within a short time frame (days or weeks), carry a significant risk of permanent brain injury (**second impact syndrome**).

Traumatic Intracranial Hemorrhage

Head trauma can result in epidural, subdural, parenchymal, and subarachnoid intracranial hemorrhages, as well as brain contusions ([Table 184.6](#)). Symptoms include headache, vomiting, lethargy, decreased consciousness, and seizures. The classic presentation of **epidural hemorrhages** involves a lucid interval: Following the primary brain injury, a child has a decreased level of consciousness, then returns to normal for several hours before developing rapidly progressive neurologic symptoms. When associated with neurologic decompensation, prompt evacuation of the epidural hematoma is the primary therapy. **Subdural hemorrhages** may result from direct trauma or rotational forces from vigorous shaking (abusive head trauma). In neonates and infants with open fontanels, signs and symptoms may be absent or nonspecific. **Subarachnoid hemorrhages** classically present as a sudden,

TABLE 184.6 Syndromes of Posttraumatic Intracranial Hemorrhage

SYNDROME	CLINICAL AND RADIOLOGIC CHARACTERISTICS	TREATMENT
Epidural	Onset over minutes to hours Lucid interval followed by progressive neurologic deficits Lens-shaped extracerebral hemorrhage compressing brain	Surgical evacuation or observation Prognosis good with prompt treatment, otherwise poor
Acute subdural	Onset over hours Focal neurologic deficits Crescentic extracranial hemorrhage compressing brain	Surgical evacuation Prognosis guarded
Chronic subdural	Onset over weeks to months Anemia, macrocephaly Seizures, vomiting Crescentic, low-density mass on CT	Subdural taps or subdural shunt as necessary Prognosis can be good
Intraparenchymal	Depressed consciousness Focal neurologic deficits ± Additional multiple contusions	Supportive care Prognosis guarded
Subarachnoid	Stiff neck Worst headache of life Late hydrocephalus	Supportive care Prognosis variable
Contusion	Focal neurologic deficits Brain swelling with transtentorial herniation CT findings: multifocal low-density areas with punctate hemorrhages	Medical treatment of elevated intracranial pressure Prognosis guarded

CT, Computed tomography.

severe headache due to rupture of an intracranial aneurysm. Brain **contusions** are areas of bruising with associated localized ischemia, edema, and mass effect.

Skull Fractures

Skull fractures may present with localized swelling and pain, subcutaneous bleeding over the mastoid process (**Battle sign**) or around the orbit (**raccoon eyes**), blood behind the tympanic membrane (**hemotympanum**), or CSF leak from the nose (rhinorrhea) or ear (otorrhea). Skull fractures may be linear, diastatic (spreading the suture), depressed (an edge displaced inferiorly), or compound (bone fragments breaking the skin surface). Linear, diastatic, and minimally depressed

fractures necessitate no specific treatment, but imaging is indicated to evaluate for associated intracranial hemorrhages. If the depression is more than 0.5–1 cm, surgical elevation of bone fragments and repair of associated dural tears are generally recommended. Compound fractures or penetrating injuries necessitate emergent surgical debridement and tetanus prophylaxis. The risk of associated brain contusion and early seizures is high in compound fractures.

CSF leak occurs when a skull fracture tears adjacent dura, creating communications between the subarachnoid space and the nose, paranasal sinuses, mastoid air cells, or ear. Clear fluid that leaks from the nose or ear after head trauma is presumed to be CSF until proved otherwise. The presence of air within the subdural, subarachnoid, or ventricular space also indicates a dural tear and open communication between the nose or paranasal sinuses and brain. In most cases, the dura heals spontaneously when the patient's head is kept elevated. Patients with CSF leaks are at risk for the development of meningitis or extradural abscesses. If the leak persists or recurs or if meningitis develops, the dura is surgically repaired. **Cranial nerve palsies**, secondary to a laceration or contusion of the cranial nerves, may result from a skull fracture and may be transitory or permanent.

Other Complications of Head Trauma

Cervical spine injuries must be suspected in any unconscious child, especially if bruises are present on the head, neck, or back. In conscious children, findings of neck or back pain, burning or stabbing pains radiating to the arms, paraplegia, quadriplegia, or asymmetric motor or sensory responses of arms or legs suggest spinal cord injury. Cervical spine injury (displaced or fractured vertebra) may result in complete transection of the cord with spinal shock, loss of sensation, and flaccid paralysis. A contused cord (without vertebral abnormality) may present in a similar manner. Any patient with a clinical or radiologic abnormality of the spine requires immediate spine immobilization, cardiopulmonary stabilization, and neurosurgical consultation.

Posttraumatic seizures are divided into one of three patterns: impact seizures, early posttraumatic seizures, and late posttraumatic seizures. Impact seizures occur within seconds of the injury and are presumed to reflect a direct mechanical stimulation to the cortex. The prognosis is excellent, and likelihood of later epilepsy is negligible. Early posttraumatic seizures occurring within the first week of the head injury are likely the result of a localized area of cerebral contusion or edema. The long-term prognosis for these seizures is quite favorable. Late posttraumatic seizures arise more than a week after the trauma and most likely indicate an area of cortical gliosis or scarring that will be a source for long-term epilepsy. These patients often require long-term antiepileptic drug therapy.

Transient neurologic disturbances may develop a few minutes after head trauma and last for minutes to hours before clearing. The most common symptoms are cortical blindness and confusional states, but hemiparesis, ataxia, or any other neurologic deficit may appear. These symptoms may represent a trauma-triggered migraine in susceptible children. Care must be exercised to exclude intracranial pathology.

Evaluation and Treatment

Children who have loss of consciousness or amnesia following a head injury should be evaluated in an emergency

department. High-risk patients include those with persistent depressed or decreasing level of consciousness, focal neurologic signs, penetrating skull injury, depressed skull fractures, or worsening symptoms. Because patients with intracranial hemorrhage may progressively deteriorate and require immediate neurosurgical care, these patients warrant care in a skilled trauma center. The **Glasgow Coma Scale** is a valuable tool for monitoring the course of patients after trauma for signs of deterioration (see [Chapter 42](#)). The observation period varies with the severity of the injury and may include hospitalization.

Immediate management of severe injuries includes ensuring an appropriate airway, breathing, and circulation. Neuroimaging with CT or MRI and cervical spine radiographs are obtained emergently. Patients with intracranial hemorrhage may require emergent surgical intervention for decompression and drainage of the blood collection. Increased ICP may require monitoring, placement of a ventricular drain, and aggressive medical management, including intubation and ventilation, osmotic therapy, and sedation.

Neuroimaging is not necessary for uncomplicated concussions but should be employed whenever suspicion of structural intracranial lesion exists. Drowsiness, headache, and vomiting are common after head trauma. They are not, by themselves, of concern if consciousness is preserved, the clinical trend is one of improvement, and results of the neurologic examination are normal. Children are especially susceptible to somnolence after head trauma but should be easily arousable. If symptoms worsen or persist for more than 1–2 days, neuroimaging may be indicated to evaluate for intracranial hemorrhage or cerebral edema.

Prognosis

Children with mild TBI (without subsequent neurologic deficits) have a favorable long-term prognosis, and late sequelae are rare. Children with moderate TBI usually make good recoveries even when neurologic signs persist for weeks. Long-term sequelae may include headaches, poor memory, slowing of motor skills, decline in cognitive skills, behavioral alterations, or attention deficits. Language function, especially in a young child, frequently makes a good recovery. Rehabilitation programs with physical therapy, behavioral management, and appropriate education may be necessary.

Coma lasting for weeks after head trauma may be compatible with a good outcome, although the risk of late sequelae is significant. Mortality rates for children with severe TBI range from 10–30%. Poor prognostic signs include a Glasgow Coma Scale score below 4 on admission without improvement in 24 hours, absent pupillary light reflexes, and persistent extensor plantar reflexes. Extracranial trauma also contributes to the morbidity of these patients (e.g., aspiration pneumonia, acute respiratory distress syndrome, sepsis, emboli). Children with TBI who experience acute cerebral swelling may improve gradually or may remain in a vegetative state. Maximal recovery may take weeks or months. Patients who remain in a vegetative state for months after head injury are unlikely to improve.

PEARLS FOR PRACTITIONERS

See *Neurology: Pearls for Practitioners* at the end of this section.

CHAPTER 185

Neurodegenerative Disorders

Children typically acquire developmental milestones in a variable but predictable sequence (see Chapter 7). Rarely, children present with stagnation of development or frank loss of previously acquired skills. The **neurodegenerative disorders** encompass a large heterogeneous group of diseases that result from specific genetic and biochemical defects and varied unknown causes. Neurodegenerative disorders can present at any age. Clinical phenotypes vary, but neurologic deterioration may be demonstrated as loss of speech, vision, hearing, and intellectual or motor abilities—sometimes in concert with seizures, feeding difficulties, and intellectual disability. Progression may be slow over many years or may lead to death in early childhood.

HEREDITARY AND METABOLIC DEGENERATIVE DISEASES

Degenerative diseases may affect gray matter (**neuronal degenerative disorders**), white matter (**leukodystrophies**), both gray and white matter, or specific focal regions of the brain. Early seizures and intellectual impairment mark gray matter disorders, whereas upper motor neuron signs and progressive spasticity are the hallmarks of white matter disorders. Neuroimaging, usually with brain magnetic resonance imaging (MRI), is recommended, with specific genetic or metabolic testing considered depending on the result. Many neurodegenerative illnesses result from enzymatic disorders within subcellular organelles, including lysosomes, mitochondria, and peroxisomes. Therefore, for any patient with a degenerative neurologic condition of unknown cause, leukocytes or skin fibroblasts may be harvested for measurement of a standard battery of lysosomal, peroxisomal, and mitochondrial enzymes (see Chapters 56 and 57). An overnight electroencephalogram (EEG) may be considered for patients with unexplained cognitive, language, or motoric regression to evaluate for significant epileptiform activity meeting criteria for electrical status epilepticus of sleep, an EEG finding that can be associated with regression.

Sphingolipidoses

The sphingolipidoses are characterized by intracellular storage of lipid substrates resulting from defective catabolism of the cell membrane sphingolipids. Nearly all are inherited in an autosomal recessive pattern. In most cases, there are several forms of these diseases, and the tempo of disease progression reflects the amount of residual enzyme activity. The infantile forms are generally the most severe, usually presenting in the first or second year of life with rapid disease progression; affected individuals have virtually no normal enzyme activity. Juvenile and chronic forms are manifest somewhat later in childhood or even adulthood and have a less fulminant disease course as there is some residual enzyme activity.

Classic **Niemann-Pick disease** (type A) is caused by a deficiency of sphingomyelinase and should be suspected in infants who exhibit the combination of hepatosplenomegaly, developmental delay, interstitial lung disease, and **retinal**

cherry red spots. The ganglion cells of the retina and macula are distended and appear as a large area of white surrounding a small red fovea that is not covered by ganglion cells. Cognitive regression, myoclonic seizures, hypotonia, and jaundice are also noted within the first year of life.

Although the most common form of **Gaucher disease** is an indolent illness of adults, there is a rapidly fatal infantile form featuring severe neurologic involvement caused by deficiency of the enzyme glucocerebrosidase. Glucosylceramide accumulates in the liver, spleen, and bone marrow leading to hepatosplenomegaly and cytopenias. The characteristic neurologic signs are opisthotonos (arching of the trunk), spasticity, trismus (difficulty opening mouth), eye movement abnormalities, and bulbar signs including difficulty swallowing.

Tay-Sachs disease (GM₂ gangliosidosis) is caused by deficiency of hexosaminidase A and results in the accumulation of GM₂ ganglioside in cerebral gray matter and cerebellum. Infants are typically normal, except for a marked startle response, until 6 months of age, when they develop listlessness, irritability, hyperacusis, cognitive regression, and retinal cherry red spots. Within months, blindness, convulsions, spasticity, and opisthotonos develop.

Metachromatic leukodystrophy (MLD) is a lipidosis caused by deficiency of arylsulfatase that results in demyelination of the central nervous system (CNS) and peripheral nervous system. Children with the late-infantile form present between 1 and 2 years of age. After a period of normal development, progressive gait ataxia, spasticity, optic atrophy, intellectual deterioration, and absent reflexes occur. Diagnostic testing reveals increased cerebral spinal fluid protein (a sign of CNS demyelination) and slowing of motor nerve conduction velocity (a sign of peripheral demyelination). Older school-age children with the juvenile form of MLD may present with gradual onset of behavior difficulties and declining academic abilities, followed by gait difficulties, clumsiness, slurred speech, and, sometimes, seizures. Bone marrow transplant is a treatment option, particularly if a sibling is diagnosed with MLD before symptom onset.

Krabbe disease (globoid cell leukodystrophy) is caused by a deficiency of galactocerebrosidase. Demyelination of the CNS and peripheral nervous system results in upper and lower motor neuron signs. Individuals with the infantile form (85–90% of cases) appear to be normal during the first months of life. Symptoms begin by 6 months of age and include extreme irritability, hyperpyrexia, vomiting, seizures, hypertonia, and blindness. Bone marrow transplant during infancy may be a treatment option.

Neuronal Ceroid Lipofuscinoses

The neuronal ceroid lipofuscinoses are a group of inherited, neurodegenerative lysosomal storage disorders characterized by progressive vision loss, seizures, declining cognitive abilities, motor deterioration, and early death. Ten different types have been characterized, including infantile, late-infantile, and juvenile types.

Adrenoleukodystrophy

The adrenoleukodystrophies (ALDs) are a group of X-linked neurodegenerative disorders that are often associated with adrenocortical insufficiency. ALD is caused by accumulation

of very long chain fatty acids in neuronal and adrenal tissue (see [Chapter 178](#)) and is diagnosed by abnormal very long-chain fatty acid testing. The most common leukodystrophy is **classic X-linked adrenoleukodystrophy**, caused by a mutation in the *ABCD1* gene. X-linked ALD was added to the Recommended Uniform Screening Panel in 2016, and many states are now screening for it as part of the newborn screening process. Boys present between ages 5 and 15 years with academic difficulties, behavioral disturbances, and gait abnormalities, progressing to seizures, spasticity, ataxia, and swallowing difficulties. Brain MRI demonstrates a classic pattern of symmetric abnormal white matter signal in the parietal-occipital regions, with contrast enhancement at the margins. Symptomatic adrenocortical insufficiency with fatigue, vomiting, and hypotension develops in 20–40% of patients with X-linked ALD. ALD should be considered in any male with primary adrenocortical insufficiency, even in the absence of clear-cut neurologic abnormalities. Patients with early stages of cerebral disease can be treated with allogeneic hematopoietic cell transplantation; if that is not an option, gene therapy may be considered.

Mucopolysaccharidoses

Mucopolysaccharidoses (MPS) are caused by defective lysosomal hydrolases resulting in the accumulation of glycosaminoglycans (formerly known as mucopolysaccharides) within lysosomes (see [Chapter 56](#)). There are several types of MPS, the most common being type I (Hurler syndrome), type II (Hunter syndrome), and type III (Sanfilippo syndrome). Signs and symptoms are usually not present at birth with the exception of the more severe forms of MPS type VII. Most types present within the first few years of life, but some of the more attenuated forms can present as late as adolescence to early adulthood. The clinical manifestations are variable and include coarse facies, short stature, kyphoscoliosis, hepatosplenomegaly, cardiovascular abnormalities, corneal clouding, and neurologic involvement. Children with the severe form of Hurler syndrome appear normal during the first 6 months of life, then develop the characteristic skeletal and neurologic features. Intellectual disability, spasticity, deafness, and optic atrophy are progressive. Hydrocephalus frequently occurs because of obstruction to cerebrospinal fluid (CSF) flow by thickened leptomeninges.

Mitochondrial Disorders

Mitochondrial diseases represent a clinically heterogeneous group of disorders that fundamentally share a disturbance in oxidative phosphorylation (adenosine triphosphate synthesis; see [Chapter 57](#)). Symptoms may include short stature, developmental delay, seizures, hearing loss, optic nerve atrophy, ophthalmoplegia, and/or myopathy, including cardiomyopathy. Abrupt symptoms are often manifest concurrent with periods of physiologic stress such as febrile illness or fasting. Specific genetic diagnoses are often difficult to identify because several different gene mutations can cause the same disease, single mutations can have multiple phenotypes, and analysis of mitochondrial protein function is technically demanding.

Specific syndromes include **MELAS** (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes); **MERRF** (myoclonus, epilepsy, and ragged red fibers), which

can also manifest as combinations of dementia, sensorineural hearing loss, optic nerve atrophy, peripheral neuropathy, and occasionally cardiomyopathy with Wolff-Parkinson-White syndrome; and **NARP** (neuropathy, ataxia, and retinitis pigmentosa).

Subacute necrotizing encephalomyelopathy, or Leigh disease, is a neuropathologically defined, degenerative, inherited CNS disease primarily involving the periaqueductal region of the brainstem, caudate, and putamen. Symptoms usually begin before 2 years of age and consist of hypotonia, feeding difficulties, respiratory irregularity, weakness of extraocular movements, and ataxia. Blood and CSF lactate and pyruvate levels are elevated. Several alterations of mitochondrial function produce this clinical syndrome.

Rett Syndrome

Rett syndrome is a neurodevelopmental disorder that classically affects girls. Typically, development appears normal during the first 6–18 months of life, but this is followed by developmental regression, loss of purposeful hand movements, loss of verbal communication skills, gait apraxia, and stereotypic repetitive hand movements that resemble washing, wringing, or clapping of the hands. Girls also develop acquired microcephaly. Episodic apnea and/or hyperpnea, peripheral vasomotor disturbances, growth retardation, abnormal muscle tone, and prolonged QTc interval often occur. The developmental regression plateaus and stabilizes, but seizures, spasticity, and kyphoscoliosis develop. The etiology is a mutation on an X chromosome gene coding for methyl-CpG-binding protein 2 (*MECP2*) transcription factor. Boys with *MECP2* mutations usually do not survive to delivery but can present with severe neonatal encephalopathy, seizures, microcephaly, abnormal tone, and respiratory insufficiency.

Degenerative Diseases with Focal Manifestations

Some neurodegenerative disorders have predilections to target specific regions or systems within the neuraxis and produce symptoms referable to the affected region.

Wilson disease is an autosomal recessive inborn error of copper metabolism resulting in copper deposition in several organs. Abnormal copper deposition produces cirrhosis in the liver, a characteristic green-brown (Kayser-Fleischer) ring in the peripheral cornea, and neuronal degeneration, predominantly in the cerebellum and basal ganglia in the CNS. Neurologic symptoms characteristically begin in the early teenage years with dysarthria, dysphasia, drooling, fixed smile, tremor, and dystonia. Psychiatric manifestations such as depression, personality change, or declining school performance may precede hepatic or neurologic symptoms. Serum ceruloplasmin levels are low. MRI shows abnormalities of the basal ganglia. Treatment is with a copper-chelating agent, such as oral penicillamine.

ACQUIRED ILLNESSES MIMICKING DEGENERATIVE DISEASES

Children with poorly controlled epilepsy may be continuously in either an ictal or a postictal state and may appear stuporous

because of their epileptic encephalopathy. Antiepileptic drugs that are sedating or affect mood, memory, motivation, or attention may contribute to the lack or loss of developmental abilities and school failure.

Chronic drug use or overuse (e.g., sedatives, tranquilizers, anticholinergics) can cause progressive confusion, lethargy, and ataxia. Intoxications with heavy metals, such as lead, may cause chronic learning difficulties or may present acutely with irritability, listlessness, anorexia, and pallor, progressing to fulminant encephalopathy. Vitamin deficiency of thiamine, niacin, vitamin B₁₂, and vitamin E can produce encephalopathy, peripheral neuropathy, and ataxia.

Congenital and acquired hypothyroidism impairs cognition and slows developmental progress. Unrecognized congenital hypothyroidism produces irreversible damage if it is not treated immediately after birth (see [Chapter 175](#)).

Structural brain diseases, such as hydrocephalus and slow-growing tumors, may cause slowly progressive cognitive decline and other focal deficits. Certain indolent brain infections, such as rubeola (measles, causing subacute sclerosing panencephalitis), rubella (German measles), syphilis, and some fungal infections, cause neurologic deterioration over months and years. Congenital HIV infection causes failure of normal development and regression of acquired skills.

Psychiatric disorders, such as depression and severe psychosocial deprivation in infancy, can give rise to apathy and failure to attain developmental milestones (see [Chapter 21](#)). Children with autism spectrum disorder may go through a phase of developmental stagnation or disintegration at about 12–18 months of age after a period of early normal milestones. Depression in older children can lead to blunting of affect, social withdrawal, and poor school performance, which raise the question of encephalopathy or dementia.

PEARLS FOR PRACTITIONERS

See *Neurology: Pearls for Practitioners* at the end of this section.

CHAPTER 186

Neurocutaneous Disorders

The skin, teeth, hair, nails, and brain are derived embryologically from ectoderm. Abnormalities of these surface structures may indicate abnormal brain development. Neurofibromatosis (types 1 and 2), tuberous sclerosis, Sturge-Weber syndrome, von Hippel-Lindau disease, and ataxia-telangiectasia are the most common of the more than 40 neurocutaneous disorders.

NEUROFIBROMATOSIS TYPE 1

Etiology

Neurofibromatosis type 1 (NF1), also known as von Recklinghausen disease, is an autosomal dominant disorder with an incidence of approximately 1 in 3,000. It is caused by mutations of the *NF1* gene, which codes for a tumor suppressor gene, neurofibromin. Neurofibromin is a major negative

regulator of a key signal transduction pathway, the Ras pathway. Mutations result in increased downstream mitogenic signaling. Somatic mosaicism, in which an abnormality in one copy of the *NF1* gene is present in some cells but not others, indicates a postzygotic mutation and is called **segmental neurofibromatosis**.

Clinical Manifestations

The cardinal features of neurofibromatosis are café-au-lait spots, axillary or inguinal freckling, cutaneous neurofibromas, and iris hamartomas (Lisch nodules). **Café-au-lait spots** are present in more than 90% of patients who have NF1 (Fig. 186.1). They typically appear in the first few years of life and increase in number and size over time. The presence of six or more café-au-lait spots larger than 5 mm in a prepubescent child suggests the diagnosis.

Neurofibromas are composed of various combinations of Schwann cells, fibroblasts, mast cells, and vascular elements. Dermal neurofibromas are nearly universal and consist of discrete, small, soft lesions that lie within the dermis and epidermis. They rarely cause any symptoms but can cause significant cosmetic concerns. Neurofibromas may also be situated within viscera or along blood vessels and peripheral nerves. Plexiform neurofibromas are large, occasionally nodular, subcutaneous lesions that lie along the major peripheral nerve trunks. They often cause symptoms including pain, weakness, and invasion of adjacent viscera, bone, or spinal cord. Surgical treatment may be attempted, but results are often unsatisfactory.

FIGURE 186.1 Café-au-lait macules. (From Eichenfield LF, Frieden IJ, Esterly NB. *Textbook of Neonatal Dermatology*. Philadelphia: Saunders; 2001:372.)

Common complications are learning disability, scoliosis, seizures, and cerebral vasculature abnormalities (e.g., moyamoya). Other tumors that occur in NF1 are optic nerve gliomas, astrocytomas of brain and spinal cord, and malignant peripheral nerve tumors. T2-weighted magnetic resonance images (MRIs) reveal hyperintense lesions (hamartomas) in the optic tracts, internal capsule, thalamus, cerebellum, and brainstem that are common and distinctive for the disease. They are benign and disappear in adulthood.

The average life expectancy of patients with NF1 may be reduced by 10–15 years. Malignancy is the most common cause of death. Genetic and psychologic counseling are important components of care for this chronic disorder. Although it is an autosomal dominant disorder, spontaneous mutations account for 30–50% of cases.

Neurofibromatosis Type 2

Neurofibromatosis type 2 (NF2) is an autosomal dominant disorder with an incidence of 1 in 25,000. Half the cases have no family history. The *NF2* gene is a tumor suppressor gene, and disease results in neurologic, eye, and skin lesions. NF2 predisposes patients to multiple intracranial and spinal tumors, including bilateral acoustic schwannomas, schwannomas of other cranial and spinal nerves, meningiomas, and gliomas. Posterior capsular or cortical cataracts are common, and skin lesions include plaque-like lesions, subcutaneous nodules, and cutaneous schwannomas. Lisch nodules, café-au-lait spots, and axillary freckling (seen in NF1) are not features of NF2.

TUBEROUS SCLEROSIS COMPLEX

Etiology

Tuberous sclerosis complex (TSC), an autosomal dominant disorder, is characterized by hamartomas in many organs, especially the brain, eyes, skin, kidneys, and heart. The incidence is 1 in 10,000 births. Two-thirds of cases are sporadic and thought to represent new mutations. Mutations affecting either of the presumed tumor suppressor genes, *TSC1* or *TSC2*, cause tuberous sclerosis. The *TSC1* and *TSC2* genes encode distinct proteins, hamartin and tuberin, which are widely expressed in the brain and result in constitutive activation of the protein kinase mTOR (mammalian target of rapamycin), leading to the formation of numerous benign tumors (hamartomas).

Clinical Manifestations

TSC is an extremely heterogeneous disease with variable expression and a wide clinical spectrum varying from normal intelligence without seizures to severe intellectual disability with refractory seizures and autism, often within the same family. People with TSC may have retinal lesions (retinal hamartomas, white depigmented patches) and brain lesions (cortical tubers, subependymal nodules, hydrocephalus). **Tubers** in the cerebral cortex are areas of dysplasia that, in combination with other microscopic areas of abnormal development, are responsible for the symptoms of intellectual disability and epilepsy. TSC is one of the most common causes of infantile spasms; in this context, the infantile spasms often

respond to treatment with vigabatrin. **Subependymal nodules** are hamartomas that may mutate into a growth phase and become **subependymal giant cell astrocytomas** (SEGAs), causing obstruction of cerebrospinal fluid outflow and resultant hydrocephalus. SEGAs can be treated with everolimus, an mTOR inhibitor, which also can be used for patients with TSC with refractory seizures.

Extracerebral manifestations include typical skin findings of hypomelanotic macules (**ash leaf spots**), which are easiest to visualize under a Wood ultraviolet lamp and are apparent in infancy. Facial angiofibromas (formerly referred to as adenoma sebaceum) appear as small red nodules over the nose and cheeks that are sometimes confused with acne. **Shagreen patches** are elevated, rough plaques of skin with a predilection for the lumbar and gluteal regions that develop in late childhood or early adolescence. Cardiac rhabdomyomas are largest during prenatal life and infancy and are rarely symptomatic. Occasionally, they may cause arrhythmias or cardiac outflow obstruction. Renal angiomyolipomas may undergo malignant transformation and are the most common cause of death in adults with TSC. Interstitial pulmonary disease (pulmonary lymphangioleiomyomatosis) also affects adults with TSC.

STURGE-WEBER SYNDROME

Sturge-Weber syndrome is sporadic (not inherited) and is caused by a somatic mosaic mutation of the *GNAQ* gene. It is characterized by abnormal blood vessels (**angiomas**) of the leptomeninges overlying the cerebral cortex in association with an ipsilateral facial **port-wine stain** involving the ophthalmic division of the trigeminal nerve (forehead and upper eyelid) and, often, glaucoma. The port-wine stain, also known as nevus flammeus, is due to an ectasia of superficial venules and may have a much more extensive and even bilateral distribution. Not all children with a facial port-wine stain have Sturge-Weber syndrome.

MRI with contrast demonstrates leptomeningeal angioma and white matter abnormalities thought to be due to chronic hypoxia and atrophy. Seizures are the most common associated neurologic abnormality, occurring in 75% of patients. Many children with Sturge-Weber syndrome are intellectually normal, and seizures are well controlled with standard anticonvulsants. However, progressive ischemia of the underlying brain develops in some children with Sturge-Weber syndrome, resulting in hemiparesis, hemianopia, intractable focal seizures, cognitive impairment, or strokelike events. Hemispherectomy has been proposed for individuals with unilateral disease whose seizures are difficult to control, both to control the epilepsy and to preserve cognitive and motor development. Low-dose aspirin may result in improved perfusion and thereby reduce strokelike events and seizures. Pulse dye laser surgery is a therapeutic option for cosmetic management of the facial nevus flammeus. Expert ophthalmologic management of glaucoma is required. Endocrinology evaluations are also necessary, as these patients often have growth hormone deficiency and/or hypothyroidism.

PEARLS FOR PRACTITIONERS

See *Neurology: Pearls for Practitioners* at the end of this section.

CHAPTER 187

Congenital Malformations of the Central Nervous System

Central nervous system malformations include disorders of spinal cord and neural tube formation, structure specification (e.g., neuronal migration, gray matter), brain growth and size, and skull growth and shape.

The precursor of the nervous system is the neural plate of the embryonic ectoderm, which develops at 18 days of gestation. The neural plate gives rise to the neural tube, which forms the brain and spinal cord, and neural crest cells, which form the peripheral nervous system, meninges, melanocytes, and adrenal medulla. The neural tube begins to form on day 22 of gestation. The rostral end forms the brain, and the caudal region forms the spinal cord. The lumen of the neural tube forms the ventricles of the brain and the central canal of the spinal cord. Most brain malformations are produced by a variety of injuries occurring during a vulnerable period of gestation. Precipitating factors include chromosomal, genetic, and metabolic abnormalities; congenital infections; and exposure to irradiation, certain drugs, and maternal illness during pregnancy.

CONGENITAL ANOMALIES OF THE SPINAL CORD

Etiology and Clinical Manifestations

Defective closure of the caudal neural tube at the end of week 4 of gestation results in anomalies of the lumbar and sacral vertebrae or spinal cord called **spina bifida**. These anomalies range in severity from clinically insignificant defects of the L5 or S1 vertebral arches to major malformations, leaving the spinal cord uncovered by skin or bone on the infant's back. The latter severe defect, called a **myelomeningocele**, results in flaccid paralysis and loss of sensation in the legs and incontinence of bowel and bladder, with the extent and degree of neurologic deficit dependent on the location of the myelomeningocele. In addition, affected children usually have an associated **Chiari type II malformation** (downward displacement of the cerebellar tonsils and medulla), resulting in hydrocephalus and weakness of face and swallowing. In a **meningocele**, the spinal canal and cystic meninges are exposed on the back, but the underlying spinal cord is anatomically and functionally intact. In **spina bifida occulta**, the skin of the back is apparently intact, but defects of the underlying bone or spinal canal are present. Meningoceles and spina bifida occulta may be associated with a lipoma, dermoid cyst, or tethering of the cord to a thick filum terminale. A dimple or tuft of hair may be present over the affected area. Patients may also have an associated dermoid sinus, an epithelial tract extending from the skin surface to the meninges; this increases the risk of meningitis. Patients with spina bifida occulta or meningocele may have weakness and numbness in the feet that can result in recurrent ulcerations, or difficulties controlling bowel or bladder function that may result in recurrent urinary tract infections, reflux nephropathy, and renal insufficiency.

Diagnostic Studies

Myelomeningocele in the fetus is suggested by an elevated **α -fetoprotein** (AFP) in the mother's blood and confirmed by ultrasound and high concentrations of AFP and acetylcholinesterase in the amniotic fluid. After birth, screening ultrasound may be used with magnetic resonance imaging to confirm less dramatic underlying spinal abnormalities.

Treatment and Prevention

Neonates with myelomeningocele must undergo operative closure of the open spinal defects (fetal or postnatal surgery) and often require treatment of hydrocephalus by placement of a ventriculoperitoneal shunt. Compared to postnatal surgery, fetal surgery prior to 26 weeks of gestation to close the myelomeningocele reduces the need for cerebrospinal fluid (CSF) shunting and improves neurodevelopmental outcomes. Toddlers and children with lower spinal cord dysfunction require physical therapy, bracing of the lower extremities, and intermittent bladder catheterization. In the absence of associated brain anomalies, most survivors have normal intelligence, but learning problems and epilepsy are more common than in the general population.

Spina bifida can be prevented in many cases by **folate** administration to the pregnant mother. Because the defect occurs so early in gestation, all women of childbearing age are advised to take oral folic acid daily.

CONGENITAL MALFORMATIONS OF THE BRAIN

Defective closure of the rostral neural tube produces anencephaly or encephaloceles. Neonates with **anencephaly** have a rudimentary brainstem or midbrain, but no cortex or cranium. This is rapidly fatal after delivery. Patients with **encephalocele** usually have a skull defect and exposure of meninges alone or meninges and brain. The recurrence risk in subsequent pregnancies for either cranial or spinal neural tube defects is 3–4%. Within a family, an anencephalic birth may be followed by the birth of a child affected with a lumbosacral myelomeningocele. The inheritance of neural tube defects is polygenic.

Agensis of the corpus callosum may be partial or complete and may occur in an isolated fashion or in association with other anomalies of cellular migration. **Dandy-Walker malformation** is diagnosed on the basis of the classic triad: complete or partial agensis of the cerebellar vermis, cystic dilation of the fourth ventricle, and enlarged posterior fossa. There may be associated hydrocephalus, absence of the corpus callosum, and neuronal migration abnormalities. Intelligence may be normal or impaired, depending on the degree of associated cerebral dysgenesis.

Holoprosencephaly represents varying degrees of failure of the forebrain (prosencephalon) to divide into two distinct cerebral hemispheres. Holoprosencephaly is often associated with midline facial defects (hypotelorism, cleft lip, cleft palate). This anomaly may be isolated or associated with a chromosomal or genetic disorder. The prognosis for infants with severe (alobar) holoprosencephaly is uniformly poor, but those with milder forms (semilobar, lobar) may have less severe neurologic outcomes. Children with trisomy 13 and trisomy 18 characteristically have varying degrees of holoprosencephaly.

Hydranencephaly is a condition in which the brain presumably develops normally, but then is destroyed by an

intrauterine, probably vascular, insult. The result is virtual absence of the cerebrum with an intact skull. The thalamus, brainstem, and some occipital cortex are typically present. Children may have a normal external appearance at the time of birth but do not achieve developmental milestones.

Macrocephaly and Microcephaly

Macrocephaly represents a head circumference above the 97th percentile and may be the result of **macrocrania** (increased skull thickness), **hydrocephalus** (enlargement of the ventricles; see Chapter 184), or **megalencephaly** (enlargement of the brain). Diseases of bone metabolism or hypertrophy of the bone marrow causes macrocrania. Megalencephaly may be the result of a significant disorder of brain development or an accumulation of abnormal metabolic substances (Table 187.1). Most often, however, macrocephaly is a familial trait of no clinical significance. If the child is developmentally normal but has macrocephaly, plotting the parents' head circumference on a growth chart can provide reassurance and help to avoid unnecessary neurodiagnostic testing.

Microcephaly represents a head circumference below the 3rd percentile. A myriad of syndromes and metabolic disorders are associated with microcephaly, some of which are hereditary (Table 187.2). In most instances, a small head circumference is a reflection of a small brain. Brain growth is rapid during the perinatal period, and any insult (e.g., infectious, metabolic, toxic, vascular) sustained during this period or during early infancy is likely to impair brain growth and result in microcephaly. Rarely, a small head is the result of premature closure of one or more skull sutures, called **craniosynostosis**. In patients with craniosynostoses, the shape of the head depends on which of the major sutures has prematurely

TABLE 187.1 Common Causes of Macrocephaly

Macrocrania (increased skull thickness)
Achondroplasia
Hypochondroplasia
Fragile X syndrome
Osteopetrosis
Chronic, severe anemia
Hydrocephalus (enlargement of the ventricles; Chapter 184)
Masses
Cysts
Arteriovenous malformations
Subdural fluid collections/hematoma
Neoplasm
Megalencephaly (enlargement of the brain)
Embryologic disorder causing abnormal proliferation of brain tissue (e.g., neurofibromatosis, tuberous sclerosis)
• Accumulation of abnormal metabolic substances (e.g., Alexander disease, Canavan disease, mucopolysaccharidoses)
Benign causes
Benign extracerebral collections of infancy
Familial macrocephaly

TABLE 187.2 Common Causes of Microcephaly

PRIMARY MICROCEPHALY	SECONDARY (ACQUIRED) MICROCEPHALY
Genetic microcephalies*	Infections (congenital)
Trisomy 21	Rubella
Trisomy 13	Cytomegalovirus
Trisomy 18	Toxoplasmosis
Angelman syndrome	Syphilis
Prader-Willi syndrome	HIV
Smith-Lemli-Opitz syndrome	Zika virus
Cornelia de Lange syndrome	Infections (noncongenital)
Rett syndrome	Meningitis
Central nervous system (CNS) malformation	Encephalitis
Holoprosencephaly	Stroke
Encephalocele	Toxic
Hydranencephaly	Radiation exposure—fetal
CNS migrational disorder	Fetal alcohol syndrome
Lissencephaly	Maternal phenylketonuria
Schizencephaly	Hypoxic-ischemic or other severe brain injury
Pachygyria	Periventricular leukomalacia
Micropolygyria	Severe chronic illness resulting in poor nutrition
	Craniosynostosis totalis

*Genetic microcephalies are nearly always present at birth, with the exception of Rett syndrome.

closed (e.g., metopic, coronal, sagittal, lambdoid). To accommodate the growing brain, compensatory skull growth occurs parallel to the affected suture. This diagnosis is readily made by the abnormal shape of the skull. Posterior plagiocephaly caused by craniosynostosis may be confused with positional plagiocephaly (skull flattening). Positional plagiocephaly has increased, in part because of supine sleep positioning recommendations. As a rule, macrocephaly and microcephaly raise a concern about cognitive ability, but head circumference alone should never be used to establish a prognosis for intellectual development.

Disorders of Neuronal Migration

Many malformations result from the failure of normal migration of neurons from the periventricular germinal matrix zone to the cortical surface at 1–5 months of gestation. Multiple malformations may exist in the same patient. Neurologic development with these anomalies varies and depends on the type and extent of the malformation. Many children with disorders of neuronal migration have treatment-resistant epilepsy.

Schizencephaly is characterized by clefts within the cerebral hemispheres that extend from the cortical surface to the ventricular cavity. Unilateral clefts can cause isolated congenital hemiparesis, whereas bilateral schizencephaly causes spastic quadriplegia and associated intellectual disability. Affected individuals are at high risk for focal epilepsy.

A severe defect in cortical migration, **lissencephaly** results in a smooth brain without sulcation (agyria). The normal six-layered cortex does not develop. Affected children have difficult-to-control seizures and profound developmental delay. This anomaly most commonly is part of a genetic disorder, which may be X linked (*DCX* mutations) or caused by de

novo autosomal dominant gene mutations (*LIS1* mutations). In **pachygyria**, the gyri are few in number and too broad. In **polymicrogyria**, the gyri are too many and too small. Sometimes pachygyria and polymicrogyria affect an entire hemisphere, producing enlargement of that hemisphere and a clinical syndrome of severe, medically intractable seizures that begin in early infancy. **Gray matter heterotopias** are abnormal islands within the central white matter of neurons that have never completed the migratory process.

PEARLS FOR PRACTITIONERS

CHAPTER 179

Neurology Assessment

- The pediatric neurologic examination varies with age; the newborn is unique, with many transient and primitive reflexes, which provide assessment of the functional integrity of the brainstem and basal ganglia.
- Careful evaluations of social, cognitive, language, fine motor and gross motor skills, and their age appropriateness are key in the neurologic assessment of children.
- Watching a child creep, crawl, cruise, or walk is the best global assessment for the motor and coordination systems.

CHAPTER 180

Headache and Migraine

- There are four temporal patterns of childhood headache: acute, acute recurrent, chronic progressive, and chronic nonprogressive or chronic daily.
- Additional investigation is warranted for headaches in the presence of an abnormal neurologic exam (especially papilledema), signs or symptoms of increased intracranial pressure, atypical headache, progressive chronic headache, or “worst headache of my life.”
- Symptoms of increased intracranial pressure include early-morning vomiting or headache that awakens the child from sleep.

CHAPTER 181

Seizures

- Focal aware seizures (previously termed *simple partial seizures*) arise from a specific anatomic focus.
 - Clinical symptoms include motor (tonic, clonic, myoclonic), sensory, psychic, or autonomic abnormalities, but consciousness is preserved.
- Focal seizures with impaired awareness (previously termed *complex partial seizures*) can have similar sensorimotor signs but also have associated alteration of consciousness.
- The clinical hallmark of absence seizures is a brief (<15 sec) loss of awareness accompanied by eyelid fluttering or simple automatisms, such as fumbling with the fingers and lip smacking. Absence seizures usually begin between 4 and 6 years of age.
- Children with febrile seizures have an excellent prognosis; daily antiseizure medication to prevent febrile seizures is not recommended.
- Infantile spasms are clusters of brief contractions of the neck, trunk, and arm muscles, followed by a phase of

sustained muscle contraction lasting less than 2 seconds. Rapid initiation of effective therapy offers the best chance for favorable neurodevelopmental outcomes.

- Initial management of status epilepticus is with a benzodiazepine and should begin if the seizure persists longer than 5 minutes.
 - If the seizure does not resolve after two doses of benzodiazepine, a second-line agent must be administered, typically phenobarbital for newborns and infants and intravenous fosphenytoin, valproic acid, or levetiracetam for older children.
- Psychogenic nonepileptic events (PNEE) is a type of functional neurologic symptom (conversion disorder).
 - Children with epilepsy may also have concurrent PNEE.
 - Careful assessment and intervention for abuse, as well as other social stressors, is a key component of the care of children with PNEE.

CHAPTER 182

Weakness and Hypotonia

- Weakness is a decreased ability to voluntarily and actively move muscles; hypotonia is a state of low muscle resistance to movement.
- An upper motor neuron pattern of weakness with increased deep tendon reflexes, spasticity, and extensor plantar responses may be caused by tumors, traumatic brain injury, infections, stroke, demyelinating syndromes, spinal cord trauma or mass, metabolic diseases, or neurodegenerative diseases.
- Acute spinal cord lesions, such as infarction or compression, may produce a flaccid, areflexic paralysis that mimics lower motor neuron disease. Lesions of the spinal cord are best delineated with magnetic resonance imaging.
- Spinal muscular atrophy is a genetic disease characterized by progressive degeneration of anterior horn cells, which results in weakness.
- Guillain-Barré syndrome (acute inflammatory demyelinating polyradiculoneuropathy) is a postinfectious autoimmune peripheral neuropathy that can occur after an infection and is the most common cause of acute flaccid paralysis in children. It presents with areflexia, flaccidity, and symmetric ascending weakness.
- Muscular dystrophies are characterized by progressive myofiber degeneration and the gradual replacement of muscle by fibrotic tissue. Duchenne muscular dystrophy is the most common muscular dystrophy.
- The acute onset of focal neurologic deficits in a child is stroke until proven otherwise.
 - The most common causes of pediatric stroke are vasculopathies, infection, cardioembolic infarcts due to congenital heart disease, sickle cell anemia, or coagulation disorders, dehydration, and head trauma.

CHAPTER 183

Ataxia and Movement Disorders

- The most common causes of acute ataxia in childhood are postinfectious acute cerebellar ataxia and drug intoxications.
- Movement disorders in children are typically hyperkinetic.
- Tics are rapid, purposeless, involuntary, stereotyped movements and typically involve the face, eyes, shoulder, and arm. Approximately 25% of children have transient tics.
- A child who is unsteady and has erratic eye movements may have opsoclonus myoclonus and should be evaluated for occult neuroblastoma.

CHAPTER 184

Altered Mental Status

- In childhood, the most common causes of coma are toxins, infections, head trauma, hypoxia-ischemia (e.g., cardiac arrest, near-drowning), and seizures.
- Computed tomography is the preferred head imaging technique in emergency situations because it can be performed rapidly without sedation and accurately identifies acute hemorrhages and mass lesions.
- Cerebral herniation is a medical emergency. Signs include altered mental status, signs of increased intracranial pressure (ICP) with dilated pupil or miosis, hemiparesis, decorticate or decerebrate posturing, and irregular respirations.
- Lumbar puncture is contraindicated in the setting of an intracranial mass lesion or clear hydrocephalus because withdrawal of cerebrospinal fluid (CSF) can change pressures between the intracranial compartments and promote brainstem shifts and herniation.
- Head trauma may result in concussion, posttraumatic intracranial hemorrhage, skull fractures, or cranial nerve or cervical spine injuries.
 - Concussion is the rapid onset of short-lived neurologic impairment that typically resolves spontaneously.
 - Symptoms may include headache, slowed reaction times, emotional lability, drowsiness, loss of consciousness, or amnesia.
 - Epidural, subdural, parenchymal, and subarachnoid intracranial hemorrhages can occur following head trauma.
 - Intracranial bleeding accompanied by neurologic deterioration requires prompt assessment for likely evacuation of the blood.

CHAPTER 185

Neurodegenerative Disorders

- Neurodegenerative disorders encompass a large heterogeneous group of diseases that result from specific genetic and biochemical defects and varied unknown causes.
 - Neuronal degenerative disorders affect gray matter.
 - Early signs are seizures and intellectual impairment.
 - Leukodystrophies affect white matter.
 - Early signs include upper motor neuron signs and progressive spasticity.
- Mitochondrial diseases represent a clinically heterogeneous group of disorders in oxidative phosphorylation.
 - Abrupt symptoms often manifest during physiologic stress (e.g., febrile illness, fasting).

CHAPTER 186

Neurocutaneous Disorders

- Abnormalities of skin, teeth, hair, and nails may indicate abnormal brain development, as all are derived from ectoderm.

CHAPTER 187

Congenital Malformations of the Central Nervous System

- Central nervous system malformations include disorders of the spinal cord, neural tube formation, structure specification (neuronal migration), brain growth, and skull growth and shape.
 - Spina bifida is the defective closure of the caudal neural tube and ranges in severity from insignificant defects of vertebral arches to myelomeningocele.
 - An elevated α -fetoprotein in the mother's blood suggests myelomeningocele in the fetus.
 - Children with myelomeningocele often have an associated Chiari type II malformation.
- Defective closure of the rostral neural tube produces anencephaly or encephaloceles.
 - Holoprosencephaly represents varying degrees of failure of the forebrain to divide into two distinct cerebral hemispheres.
- Hydranencephaly is a condition in which the brain presumably develops normally but is destroyed by an intrauterine, probably vascular, accident.
- Schizencephaly and lissencephaly are disorders of neuronal migration that result in abnormal neurologic development and often are associated with treatment-resistant epilepsy.

DERMATOLOGY

Nicole S. Stefanko | Yvonne E. Chiu

CHAPTER 188

Dermatology Assessment

Approximately one in three Americans of any age has at least one recognizable skin disorder at any time. The most common cutaneous diseases encountered in community settings are dermatophytosis, acne vulgaris, seborrheic dermatitis, atopic dermatitis (eczema), verrucae (warts), tumors, psoriasis, vitiligo, and infections such as herpes simplex and impetigo. The most common diagnoses in children attending pediatric dermatology clinics include atopic dermatitis, seborrheic dermatitis, impetigo, tinea capitis, acne vulgaris, verrucae vulgaris, and molluscum contagiosum.

HISTORY

The age of the patient, onset, duration, progression, associated cutaneous symptoms (pain, pruritus), previous treatments, and associated systemic signs or symptoms (fever, malaise, weight loss) are important clues. Obtaining an accurate description of the original lesion improves diagnostic accuracy. Patients often do not consider over-the-counter remedies, especially topical medications, as treatment, so it is important to probe about these specifically as they may alter the appearance of a rash. Other important information includes a history of allergies, environmental exposure, travel history, previous treatment, affected contacts, and family history.

PHYSICAL EXAMINATION

A careful examination of the skin requires a visual and a tactile assessment. Examination of the skin over the entire body must be performed systematically. Mucous membranes, hair, nails, and teeth, all of ectodermal origin, also may be involved in cutaneous disorders and should be assessed.

COMMON MANIFESTATIONS

A descriptive nomenclature of skin lesions helps with generating a differential diagnosis and with communication between health care providers. Determination of the primary lesion and secondary change is the cornerstone of dermatologic diagnosis. A **primary lesion** is defined as the basic lesion that arises de novo and is most characteristic of the disease process (Table 188.1; Fig. 188.1). Primary lesions may not be present on a patient at the time of presentation, as some are altered by

TABLE 188.1 Primary Skin Lesions

LESION	DESCRIPTION
Macule	Flat, nonpalpable lesion <1 cm in diameter
Patch	Similar to macule, but >1 cm in diameter
Papule	Elevated, solid lesion <1 cm in diameter
Plaque	Similar to papule, but >1 cm in diameter; has a flat and broad surface in contrast to a nodule
Nodule	Similar to papule, but >1 cm in diameter; has a rounded surface in contrast to a plaque
Tumor	Similar to nodule, but implies a neoplastic growth rather than an inflammatory process
Vesicle	Fluid-filled (usually clear or straw-colored) epidermal lesion <1 cm in diameter
Bulla	Similar to vesicle, but >1 cm in diameter
Pustule	Pus-filled epidermal lesion, which often is surrounded by erythema
Purpura	Red-purple macule or papule resulting from extravasated blood into the skin; does not blanch with pressure
Petechia	Similar to purpura, but less than a few millimeters in diameter
Ecchymosis	Larger, hemorrhagic patch or plaque resulting from extravasated blood
Wheal (hive)	Pink, edematous papules and plaques that vary greatly in size and configuration; characterized by transient nature with individual lesions resolving within 24 hr
Telangiectasia	Collection of small superficial red blood vessels
Milia	Superficial, white, small epidermal keratin cysts
Comedo	Plug of keratin and sebum within the orifice of a hair follicle, which can be open (blackhead) or closed (whitehead); characteristic lesion of acne vulgaris
Cyst	Papule or nodule with an epidermal lining and filled with solid material

time or external factors such as medication applied, secondary infection, or physical manipulation (e.g., scratching). A search for the primary lesion often proves worthwhile and focuses the differential diagnosis to a category of lesion that is specific for the underlying diagnosis. On occasion, two different types

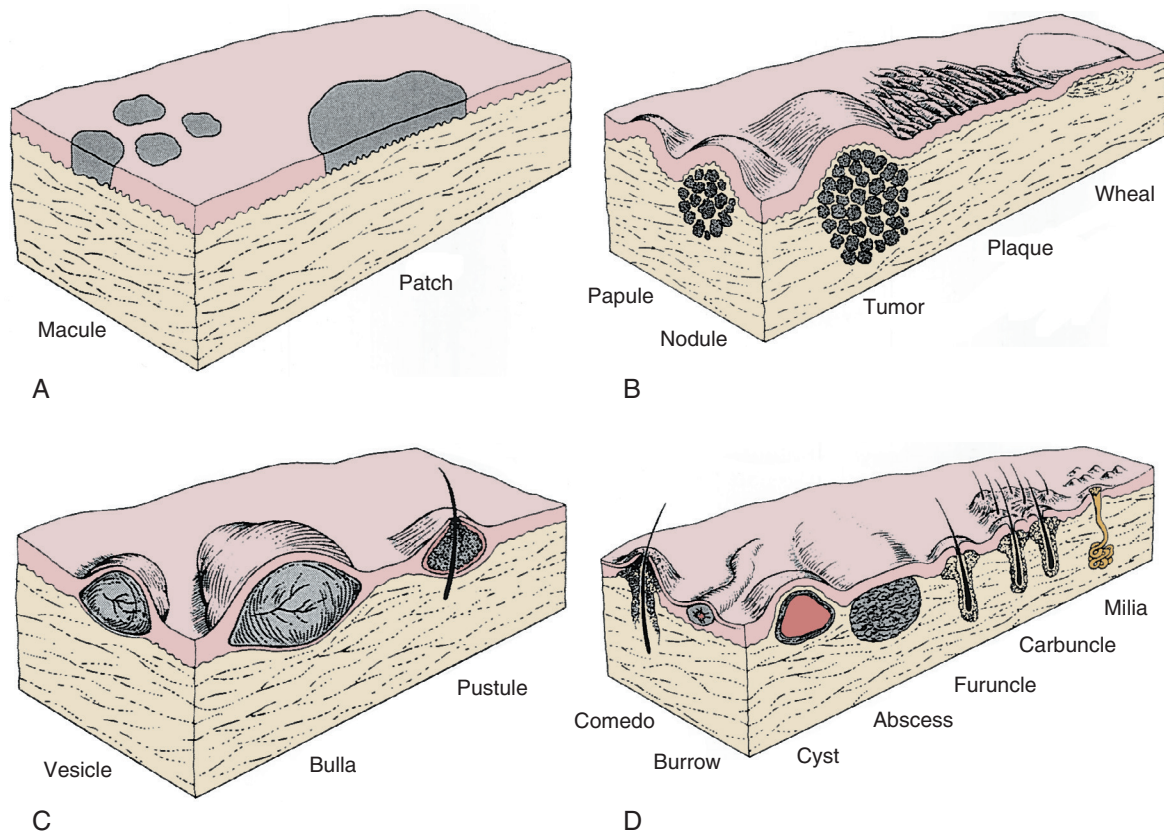

FIGURE 188.1 Morphology of primary skin lesions. (A) Flat lesions. (B) Palpable lesions. (C) Fluid-filled lesions. (D) Special primary lesions. (From Swartz MH. *Textbook of Physical Diagnosis: History and Examination*. Philadelphia: WB Saunders; 1989.)

of primary lesions may be present. **Secondary lesions** are the result of the effects of the primary lesion and may be seen in the absence of a primary lesion (Table 188.2).

The color, texture (e.g., rough, smooth), configuration (e.g., annular, serpiginous, linear), location, and distribution (e.g., localized, widespread, symmetric, dermatomal) of the lesion should be recorded. Lesions on mucous membranes are usually short lived and harder to definitively diagnose. Lesions in thick-skinned areas, such as the palms and soles, may be particularly difficult to characterize.

INITIAL DIAGNOSTIC EVALUATION AND TESTS

A thorough history and physical examination are usually sufficient for diagnosis because of the visibility of the skin. Adjunctive tests at the time of examination include potassium hydroxide (KOH) examination for fungi and dermatophytes, skin scrapings for scabies, cytologic examination (Tzanck test) for herpesvirus and varicella-zoster virus infection, and Wood light examination for the yellowish-gold fluorescence of tinea versicolor, depigmentation (e.g., vitiligo), or hypopigmentation (e.g., ash leaf macules of tuberous sclerosis). A skin biopsy, either shave or punch, may be performed to help with the diagnosis, and both are simple in-office procedures. Occasionally, laboratory or imaging studies are necessary.

TABLE 188.2		Secondary Skin Lesions
LESION	DESCRIPTION	
Scale	Results from abnormal keratinization; may be fine or sheetlike	
Crust	Dried collection of serum and cellular debris	
Erosion	Shallow depression with loss of the superficial epidermis	
Ulcer	Deeper depression with loss of the entire epidermis into dermis; heals with scarring	
Atrophy	Thinning of epidermis (surface appears shiny and translucent) or dermis (skin is depressed with epidermis intact)	
Scar	Thickened, firm, and discolored collection of connective tissue that results from dermal damage; initially pink, but lightens with time	
Sclerosis	Circumscribed or diffuse hardening of skin	
Lichenification	Accentuated skin lines/markings that result from thickening of the epidermis due to rubbing	
Excoriation	Superficial linear erosion that is caused by scratching	
Fissure	Linear break within the skin surface that usually is painful	

PEARLS FOR PRACTITIONERS

See *Dermatology: Pearls for Practitioners* at the end of this section.

CHAPTER 189

Acne Vulgaris

ETIOLOGY

Acne vulgaris (or acne) is a chronic inflammatory disorder that affects areas with the greatest concentration of sebaceous glands, such as the face, chest, and back. Gender, age, genetic factors, and environment are all major contributing pathogenic factors. Stress may trigger acne, possibly by affecting hormone levels. A high glycemic diet and milk intake, low-fat/skim milk in particular, may be associated with acne, although they remain controversial as potential causes.

Acne is caused by chronic inflammation of the pilosebaceous unit (hair follicle with an associated sebaceous gland). The primary event in all acne lesions is the development of the **microcomedo**, which results from the obstruction of the hair follicle with keratin, increased sebum production from sebaceous glands, and overgrowth of normal skin flora, leading to pilosebaceous occlusion and enlargement. Androgens are a potent stimulus of the sebaceous gland. The subsequent inflammatory component and pustule formation results from proliferation of *Cutibacterium acnes* (formerly *Propionibacterium acnes*), a commensal organism of the skin. The pathogenesis of acne involves three components: increased sebum production, hyperkeratosis, and bacterial proliferation. Effective treatment focuses on minimizing these factors.

EPIDEMIOLOGY

Acne is the most common skin disorder in adolescents, occurring in 85% of teenagers. The incidence is similar in both sexes, although boys often are more severely affected. Acne may begin as early as 6–8 years of age and may continue into adulthood.

CLINICAL MANIFESTATIONS

Acne primarily affects areas with increased sebaceous gland density, such as the face, upper chest, and back. Superficial plugging of the pilosebaceous unit results in noninflammatory small (1- to 2-mm) **open (blackhead)** and **closed (whitehead) comedones**. Rupture of a comedo into adjacent dermis and proliferation of *C. acnes* induce an inflammatory response and development of inflammatory **papules** and **pustules**. Larger, skin-colored or red cysts and nodules represent deeper plugging and **cystic acne**. Increased and persistent inflammation, especially with rupture of a deep cyst, increases the risk of scarring.

The diagnosis of acne is usually not difficult because of the characteristic and chronic lesions. Laboratory studies and imaging studies are usually not necessary to diagnose acne. Screening tests may be necessary if there are signs of hyperandrogenism due to polycystic ovarian syndrome (irregular menses, hirsutism, insulin resistance) or an underlying

androgen-secreting tumor (irregular menses, hirsutism, deepening voice, clitoromegaly).

TREATMENT

The mainstays of treatment of acne are topical comedolytic agents and topical antibiotics. Creams, lotions, gels, foams, and solutions are available. Gels and solutions are commonly used because acne skin is generally greasier, and these agents tend to be drying; however, they also have the tendency to be irritating and may not be as well tolerated. Creams and lotions are better tolerated but may not be as effective as the corresponding gel or solution.

The comedolytic agents (salicylic acid, azelaic acid, tretinoin, adapalene, tazarotene) produce superficial desquamation and, subsequently, relieve follicular obstruction. They are a mainstay of first-line therapy. The topical retinoids (tretinoin, adapalene, tazarotene) are based on the vitamin A molecule. They decrease keratin and sebum production and have some antiinflammatory and antibacterial activity; thus they can be the most effective when used as monotherapy.

Topical antimicrobials (benzoyl peroxide, dapson) and topical antibiotics (erythromycin, clindamycin) are antiinflammatory and inhibit *C. acnes* proliferation. Erythromycin efficacy has decreased as *C. acnes* has become increasingly resistant to this antibiotic and should no longer be used. Topical antibiotics should be combined with an antimicrobial, such as benzoyl peroxide, to prevent the development of resistance. Combination therapy of a topical comedolytic agent and a topical antimicrobial is more effective than either agent alone for inflammatory acne.

Oral antibiotics are typically used for deeper cystic lesions but should always be used in combination with a topical regimen. Tetracyclines are the most effective antibiotics because of their significant antiinflammatory activity but should not be used in children 8 years of age and younger. As with topical erythromycin, oral erythromycin is no longer used because of bacterial resistance. Given their increased risk of bacterial resistance and reported associations with inflammatory bowel disease, *Candida*, and *Clostridium difficile* infections, judicious use of systemic antibiotics is important.

For recalcitrant or severe nodulocystic acne, oral isotretinoin may be instituted. Isotretinoin, an oral analog of vitamin A, normalizes follicular keratinization, reduces sebum production, and decreases 5 α -dihydrotestosterone formation and androgen receptor-binding capacity. A course of isotretinoin is the only medication that can permanently alter the course of acne and induce a durable remission. Isotretinoin therapy requires careful patient selection, pretreatment counseling, and laboratory monitoring and should be used only by physicians familiar with the medication and monitoring requirements. It is teratogenic and must not be used immediately before or during pregnancy.

For females, hormonal agents can also be considered for anti-acne therapy. These include the estrogen-containing combined oral contraceptives (although use should be limited to those without contraindications) and spironolactone.

COMPLICATIONS

Acne has significant and frequently devastating effects on an adolescent's body image and self-esteem. There may be little correlation between severity and psychosocial impact. Scarring may result in permanent morbidity.

PROGNOSIS

Classically, acne lasts 3–5 years, although some individuals may have disease for 15–20 years. Only early treatment with isotretinoin may alter the natural course of acne. Acne lesions often heal with temporary postinflammatory erythema and hyperpigmentation. Depending on the severity, chronicity, and depth of involvement, pitted, atrophic, or hypertrophic scars may develop. **Cystic acne** has the highest incidence of scarring because rupture of a deep cyst induces the greatest inflammation, although scarring may be caused by milder pustular or even comedonal acne.

PREVENTION

Comedogenic hair and skin products should be avoided because they exacerbate preexisting acne. There are no effective means for preventing acne, although a low-milk or low-glycemic diet may improve acne. Repetitive cleansing with soap and water or use of astringents or abrasives removes only surface lipids; their use makes the skin appear less oily but does not prevent formation of microcomedones and may paradoxically worsen acne.

PEARLS FOR PRACTITIONERS

See *Dermatology: Pearls for Practitioners* at the end of this section.

CHAPTER 190

Atopic Dermatitis

ETIOLOGY

Atopic dermatitis is a chronic inflammatory disease with no known cure. It is associated with significant psychosocial morbidity and decreased health-related quality of life. For many affected individuals, atopic dermatitis is the skin manifestation of atopy accompanied by asthma and allergic rhinitis.

Atopic dermatitis manifests with a defective skin barrier, reduced innate immune responses, and exaggerated immune responses to allergens and microbes. Both genetic predisposition and environmental factors play a role in the development of atopic dermatitis. Genes associated with skin barrier dysfunction and inflammation have been linked with atopic dermatitis. Inflammatory mediators involved include predominantly T helper (T_H) cells, with the T_H2 pathway implicated early in acute lesions and a T_H1 predominance found in chronic lesions. Langerhans cells, immunoglobulin E (IgE), and eosinophils play a prominent role, as well as many other inflammatory mediators. Environmental and contact allergens, infections, irritants, extremes of temperature, sweat, and lack of humidity can exacerbate the condition, as can scratching or rubbing. Triggers are somewhat variable from individual to individual.

EPIDEMIOLOGY

Atopic dermatitis is the most common skin disease in children, with an estimated prevalence of up to 20% of children. Only 1–2% of adults manifest disease. In addition to genetic factors, an environmental influence contributes. Atopic dermatitis

occurs more frequently in non-White children, urban areas, and higher socioeconomic classes. Prevalence is lower in areas where industrial pollution is less and where eosinophil-mediated infections such as helminthic infections are endemic.

Patients generally have a family history of atopy. Children with atopic dermatitis are predisposed to the development of asthma and allergic rhinitis, referred to as the *atopic march*. Asthma develops in up to half of children with atopic dermatitis, and allergic rhinitis develops even more frequently. Food allergies are commonly present in children with atopic dermatitis but are a rare cause of atopic dermatitis itself.

CLINICAL MANIFESTATIONS

Atopic dermatitis is a chronic, relapsing skin disease characterized by xerosis, pruritus, and characteristic skin findings. The condition generally improves with age and remits in adulthood, although some childhood cases will continue into adulthood.

Characteristic lesions of atopic dermatitis are erythematous papules or plaques with ill-defined borders and overlying scale or hyperkeratosis. Weeping may be present in acute stages, which then develops into yellow crust. Lesions can be secondarily excoriated and result in hemorrhagic crusting and lichenification in older lesions. Formation of fissures is common in both acute and chronic lesions. Temporary hypo- and hyperpigmentation can be seen after lesions resolve, but atopic dermatitis is not usually scarring unless secondary features become severe (e.g., infection or scratching).

Characteristic locations vary with the age of the patient. Infantile atopic dermatitis typically affects the face and extensor surfaces of the extremities and is often generalized. Childhood lesions predominate in flexural surfaces (ante-cubital and popliteal fossae), wrists, ankles, hands, and feet (Fig. 190.1). The adult phase occurs after puberty and manifests

FIGURE 190.1 Atopic dermatitis (arm).

FIGURE 190.2 Atopic dermatitis with *Staphylococcus* superinfection.

in the flexural areas, including the neck, as well as predominant involvement on the face, hands, fingers, toes, and upper arms and back.

Secondary bacterial infection, most commonly with *Staphylococcus aureus* or less commonly with *Streptococcus pyogenes*, is frequently present. Patients can develop disseminated skin infections with viruses such as herpes simplex virus (HSV; eczema herpeticum), varicella-zoster virus, coxsackievirus (eczema coxsackium), smallpox virus (eczema vaccinatum), and molluscum contagiosum. Atopic skin is more susceptible to fungal infections as well. Signs of concomitant infection include acute worsening of disease in an otherwise well-controlled patient, resistance to standard therapy, fever, and presence of pustules, fissures, punched out erosions, or exudative or crusted lesions (Fig. 190.2). Eczema herpeticum and eczema vaccinatum can be life threatening if not treated.

LABORATORY AND IMAGING STUDIES

Diagnosis of atopic dermatitis is based on clinical signs and symptoms. Skin biopsy findings are generally characteristic but not exclusively diagnostic and can overlap with other skin conditions. Peripheral blood eosinophilia and elevated IgE levels can be found but are not specific and not routinely obtained. Skin prick testing or measurement of specific IgE antibody levels can detect sensitization to food and environmental allergens, although false-positive findings occur.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of atopic dermatitis is extensive, but the history of a relapsing pruritic condition in the setting of atopy and skin lesions in a characteristic distribution is typical.

The lesions of **seborrheic dermatitis** have circumscribed and well-defined borders. The scale or hyperkeratosis is thicker, greasy, and yellowish. The distribution of seborrheic dermatitis is different from that of atopic dermatitis, typically involving the scalp, eyebrows, perinasal region, upper chest, and back. The two conditions occasionally coexist, especially in infants.

Psoriasis tends to localize on the elbows, knees, lower back, and scalp. The lesions of psoriasis on exposed surfaces are

salmon colored at the base with an overlying hyperkeratosis that is much thicker with silver coloration. They are generally very well-demarcated, oval or round, thick plaques.

Allergic contact dermatitis has a distribution limited to one area of the body corresponding to contact with the allergen. The lesions generally make well-demarcated, bizarre, linear, square, or angulated shapes corresponding to the source. **Nickel dermatitis** is common and results from contact sensitization to nickel in metals. It occurs in characteristic locations such as the periumbilical area (where metal from pant buttons rubs against skin), on the ear lobule or neck (where earrings contact skin), circumferentially around the neck (necklaces), and under rings or wristbands. Patients with atopic dermatitis can have concomitant contact dermatitis as well.

TREATMENT

Ideal therapy for atopic dermatitis includes three main components: frequent liberal use of bland moisturizers to restore the skin barrier, avoidance of triggers of inflammation, and use of topical antiinflammatory medication to affected areas of skin when needed. Control of pruritus and infection should be considered on an individual basis. If topical therapy and these measures are inadequate, systemic therapy with immunosuppressive agents or ultraviolet (UV) light therapy may be indicated.

Up to once daily short baths with warm but not hot water are generally recommended. A moisturizing cream or ointment should be applied to the entire body immediately afterward to trap moisture. Application of topical medications is also most effective immediately after bathing. Additional information for patients and families can be found at the website of the National Eczema Association for Science and Education (<http://www.nationaleczema.org>).

Common triggers of inflammation in atopic dermatitis include rubbing or scratching, saliva, contact with acidic foods, soaps and detergents, wool or other harsh materials, fragranced products, sweat, highly chlorinated pools, low humidity, tobacco smoke, dust mites, animal dander, environmental pollen, and molds. Exposure to these triggers should be limited whenever possible. Infections that are unrelated to skin disease, such as an upper respiratory infection, can also exacerbate atopic dermatitis. Food allergy is commonly seen in patients with atopic dermatitis but typically presents with urticaria or anaphylaxis rather than exacerbation of the atopic dermatitis.

Topical corticosteroids are the mainstay of antiinflammatory therapy for atopic dermatitis. Hundreds of topical corticosteroids are available and are classified according to strength from I to VII. Class I is the highest potency and class VII is the lowest potency. Potency varies according to the steroid molecule (active ingredient), and, for a given ingredient, strength can vary according to relative concentration and vehicle base. Enhanced penetration occurs in areas of natural occlusion (flexures such as axillae and groin), with external occlusion (diapers or bandages), in areas of open skin (excoriations), and with heat or hydration. Use of wet wraps with topical corticosteroid application takes advantage of this principle of heat and hydration for enhanced penetration for recalcitrant lesions. Class I and II steroids are typically avoided in young children or in areas of thinner skin or enhanced penetration.

Corticosteroids are available in different vehicles. In general, ointments are preferred because of their increased efficacy,

occlusive nature, and tolerability. Creams may be slightly less effective for a given steroid ingredient but may be more cosmetically acceptable for older patients or in warmer climates. Lotions may cause more irritation and are generally less potent. Sprays, foams, solutions, and gels can be especially useful for hair-bearing areas. Creams, lotions, sprays, solutions, and gels can be particularly irritating when applied to atopic skin and should generally be avoided on areas of open skin.

Topical corticosteroids should be used in conjunction with adequate skin care, such as avoiding triggers of inflammation and frequent application of moisturizers. Twice-daily application of corticosteroids is recommended. The goal is to limit the need for antiinflammatory medications and thereby avoid the potential for adverse effects. Local side effects such as skin atrophy, striae, and acne are related to corticosteroid potency, site of application, and duration of application. While hyper- or hypopigmentation can rarely result from topical corticosteroid use, pigmentation changes are much more likely to be caused by inflammation secondary to atopic dermatitis itself. Systemic side effects of adrenal suppression or Cushing syndrome can result with application of a potent topical corticosteroid to large surface areas or occluded areas at risk of enhanced penetration.

Topical immune modulators such as topical calcineurin inhibitors (tacrolimus and pimecrolimus) or topical phosphodiesterase-4 inhibitor (crisaborole) may be part of the treatment regimen for atopic dermatitis. There is no potential for skin atrophy; thus these agents are particularly useful for face or genital lesions. They are currently approved for intermittent therapy as second-line treatments for mild to moderate atopic dermatitis.

Sedating antihistamines (e.g., diphenhydramine, hydroxyzine) have only mild effect on pruritus but can decrease sleeplessness due to scratching during the night. A dose before bedtime is most effective. Additional daytime doses can be added on an individual basis when needed. Nonsedating antihistamines are of little benefit in controlling the pruritus of atopic dermatitis.

Short-term administration of systemic corticosteroids is rarely indicated for cases of severe disease. Rebound flare of atopic dermatitis is common following withdrawal of corticosteroids and should be anticipated to avoid misinterpretation of the natural disease severity. Long-term and frequent repeated courses should be avoided to prevent adverse effects such as growth retardation and adrenal insufficiency.

UV light therapy with narrowband UVB can be an option for moderate to severe cases in older children. Typically, light therapy is administered two to three times weekly until improvement is seen and then is tapered or discontinued once the acute flare has resolved. More frequent use of light therapy in children is hindered by requirements for frequent office visits, ability to cooperate with standing in a light box while wearing protective goggles, and risk of long-term skin damage, including the potential for skin cancer development with excessive UV light exposure.

Systemic immunosuppressants such as cyclosporine, methotrexate, azathioprine, or mycophenolate mofetil can be effective therapies for atopic dermatitis in severe cases. Dupilumab, a monoclonal IgG4 antibody that inhibits interleukin 4 and 13, is approved for the treatment of moderate to severe atopic dermatitis in children ages 6 and older. Many immune targeting agents are currently being studied for the treatment of atopic dermatitis.

COMPLICATIONS

An increased tendency toward bacterial, viral, and fungal skin infections is due to an impaired skin barrier and decrease in innate immune proteins in the skin as well as maladaptive secondary immune responses.

Secondary impetigo with *S. aureus* is the most common secondary skin infection found in atopic dermatitis, followed by group A streptococcus infection. Infection manifests with pustules, erythema, crusting, flare of disease, or lack of response to adequate antiinflammatory therapy. Localized lesions can be treated with topical mupirocin. Widespread and generalized lesions require oral antibiotic therapy, most commonly with a first-generation cephalosporin such as cephalexin. Methicillin-resistant *S. aureus* infection is increasingly common, and antibiotic therapy should be tailored based on local resistance rates and patient factors. Diagnosis of superinfection may be made clinically, but a superficial bacterial culture can confirm the diagnosis and provide antimicrobial susceptibilities. Treatment should include a concomitant atopic skin care routine including the continued use of topical corticosteroids. Although secondary skin infection with *S. aureus* is common, progression to cellulitis or septicemia is unusual. Rarely, intravenous antibiotics may be required. Children with colonization and frequent infections may benefit from dilute bleach baths two to three times weekly; one-fourth to one-half cup of household bleach is added to a half-full or full bathtub.

Eczema herpeticum (Kaposi varicelliform eruption) is one of the potentially serious infectious complications in atopic dermatitis. After HSV infection, an eruption of multiple pruritic, vesiculopustular lesions occurs in a disseminated pattern, both within plaques of atopic dermatitis and on normal-appearing skin. These characteristically rupture and form crusted umbilicated papules and punched-out hemorrhagic erosions (Fig. 190.3). Irritability, anorexia, and fever can also be seen. Systemic and central nervous system disease have been reported. Bacterial superinfection of eroded areas of the skin often occurs. Diagnosis can be made rapidly from a scraping of the skin lesion stained with Giemsa or Wright stain

FIGURE 190.3 Eczema herpeticum (hand).

(Tzanck test) looking for multinucleated giant cells, although these are not highly sensitive. Vesicle fluid can also be sent for polymerase chain reaction (PCR) detection of HSV DNA or rapid direct fluorescent antibody testing, both of which are faster and more sensitive than viral culture. Laboratory confirmation of infection is important because similar clinical manifestations can occur with bacterial infections.

The psychosocial impact of atopic dermatitis can be significant. There is often disfigurement, lack of sleep from pruritus resulting in irritability and fatigue, and limitations on participation in sports. Significant time, as well as financial strain, is involved in caring for a child with atopic dermatitis. Thus management should address these potential issues and provide adequate anticipatory guidance.

PROGNOSIS

Atopic dermatitis frequently remits during childhood and is much less common after puberty. The condition is generally most severe and widespread in infancy and early childhood. Relapse of disease in adults can occur and commonly manifests as face or hand dermatitis. Patients with atopic dermatitis can also develop asthma and allergic rhinitis. Asthma is more commonly associated with more severe skin disease.

PREVENTION

Individual flares of atopic dermatitis can be prevented by avoiding triggers of inflammation and can be lessened with frequent moisturizer application. Evidence suggests that exclusive breastfeeding for at least 3–4 months decreases the incidence and severity of infantile atopic dermatitis in the first 2 years of life. It was previously thought that the use of partially or exclusively hydrolyzed formula in infants not exclusively breastfed might delay or prevent the onset of atopic dermatitis, but this is not supported by recent evidence. There is no convincing evidence that an antigen avoidance diet in pregnant or lactating mothers prevents the development of atopic disease. Early introduction of peanuts among children at high risk for this allergy (i.e., infants with severe eczema, egg allergy, or both) significantly decreased the frequency of the development of peanut allergy in these infants in one large randomized study.

PEARLS FOR PRACTITIONERS

See Dermatology: Pearls for Practitioners at the end of this section.

FIGURE 191.1 Irritant diaper dermatitis.

boys. **Allergic contact dermatitis** is a cell-mediated immune reaction, also called type IV or delayed-type hypersensitivity. The antigens, or haptens, involved in allergic contact dermatitis readily penetrate the epidermis and are bound by Langerhans cells, the antigen-presenting cells of the skin. The hapten is presented to T lymphocytes, and an immune cascade follows.

CLINICAL MANIFESTATIONS

Irritant contact dermatitis is characterized by ill-defined, scaly, pink or red patches and plaques (Fig. 191.1) localized to skin surfaces that are exposed to the irritant. Irritant contact dermatitis is observed frequently on the dorsal surfaces of the hands, often from repeated handwashing or exposure to irritating chemicals.

Diaper dermatitis is a common problem in infants and most commonly is a form of irritant contact dermatitis. The dermatitis is caused by irritation from urine and feces, typically affecting the perianal region and the buttocks while sparing the protected groin folds and other occluded areas. Secondary infection by *Candida albicans* or bacterial pathogens may complicate diaper dermatitis as well.

Allergic contact dermatitis may be acute (such as *Rhus* dermatitis) or chronic (such as nickel dermatitis). Acute lesions are bright pink, pruritic patches, often in linear or sharply margined, bizarre configurations. Within the patches are clear vesicles and bullae (Fig. 191.2). Signs and symptoms of the disease may be delayed for 7–14 days after exposure if the patient has not been sensitized previously. On re-exposure, symptoms begin within hours and are usually more severe. The eruption may persist for weeks. Chronic lesions are pink, scaly, pruritic plaques, often mimicking atopic dermatitis. Even intermittent exposure can result in a persistent dermatitis.

LABORATORY AND IMAGING STUDIES

The diagnosis is established by clinical presentation and history of exposure to a recognized irritant or allergen. Skin-prick testing and serum immunoglobulin E levels are not helpful in determining the cause of allergic contact dermatitis. Patch testing may be used to determine the allergen causing the reaction in difficult cases.

DIFFERENTIAL DIAGNOSIS

The distribution and appearance of the dermatitis and a detailed exposure history are the most useful diagnostic tools.

CHAPTER 191

Contact Dermatitis

ETIOLOGY AND EPIDEMIOLOGY

Inflammation in the top layers of the skin, caused by direct contact with a substance, is divided into two subtypes: irritant contact dermatitis and allergic contact dermatitis. **Irritant contact dermatitis** is observed after the skin surface is exposed to an irritating chemical or substance. Contact dermatitis may occur in any age, and girls are more frequently affected than

FIGURE 191.2 Allergic contact dermatitis to tincture of benzoin.

Involvement of the lower legs and distal arms suggests exposure to plants of the *Rhus* species (poison ivy or poison oak), especially when linear configurations of lesions are present. Dermatitis of the ears (earrings), wrist (bracelet or watch), or periumbilical region (belt buckle or pant buttons) suggests a metal allergy to nickel. Topical antibiotics (neomycin) and fragrances (soaps, perfumes, cosmetics) are frequent causes of allergic contact dermatitis.

Diaper rashes caused by *Candida* are quite common. Irritant contact dermatitis primarily affects the prominent, exposed surfaces, whereas *Candida* primarily affects intertriginous areas. The two are frequently present simultaneously, as secondary *Candida* infection may complicate irritant dermatitis.

Psoriasis, seborrheic dermatitis, and Langerhans cell histiocytosis can present with an erythematous rash in the diaper area. Referral to a dermatologist should be considered for any child with a severe rash or with a diaper rash that does not respond to conventional therapy.

TREATMENT

Topical corticosteroids are effective in treatment of allergic and irritant contact dermatitis. High-potency corticosteroids, and even short courses of oral corticosteroids, may be necessary for severe reactions of allergic contact dermatitis. Oral antihistamines may be required to control itching.

Treatment of candidal diaper dermatitis consists of topical nystatin or topical azole antifungals. Low-potency topical corticosteroids are frequently used in addition to topical antifungal therapy to treat the irritant component of the diaper dermatitis when present concomitantly.

COMPLICATIONS

In addition to superinfection of diaper dermatitis by *C. albicans*, bacterial superinfection may complicate any form of contact dermatitis. This is especially common if the skin barrier is no longer intact because of blistering or scratching.

PREVENTION

Every effort should be made to identify the trigger of allergic or irritant contact dermatitis. With allergic contact dermatitis, re-exposure often leads to increasingly severe reactions.

PEARLS FOR PRACTITIONERS

See *Dermatology: Pearls for Practitioners* at the end of this section.

CHAPTER 192

Seborrheic Dermatitis

ETIOLOGY

Seborrheic dermatitis is a common, chronic inflammatory disease that has different clinical presentations at different ages. Seborrheic dermatitis classically presents in infants as cradle cap or dermatitis in the intertriginous areas of the axillae, groin, antecubital and popliteal fossae, and umbilicus. It is seen in adolescents as dandruff. The pathogenesis of seborrheic dermatitis is unclear, but it is theorized that there is an abnormal inflammatory response to commensal *Malassezia* species in sebum-rich areas. Areas prone to seborrheic dermatitis include the scalp, eyebrows, eyelids, nasolabial folds, external auditory canals, and posterior auricular folds.

CLINICAL MANIFESTATIONS

Seborrheic dermatitis in infants begins during the first month and persists during the first year of life. It is also called **cradle cap** because of the thick, greasy and waxy, yellow-white scaling and crusting of the scalp (Fig. 192.1). Greasy, scaly, erythematous, nonpruritic patches and plaques may extend to the face and posterior auricular folds, sometimes involving the entire body. Diaper and intertriginous areas can have sharply demarcated, shiny, erythematous patches with minimal scale. Hypopigmentation may persist after the inflammation has faded. The eruption is usually asymptomatic, which helps differentiate it from infantile atopic dermatitis, which is pruritic.

FIGURE 192.1 Seborrheic dermatitis (cradle cap).

Classic seborrheic dermatitis during adolescence is typically localized to the scalp. The mild form is commonly known as **dandruff**, a fine, white, dry scaling of the scalp with minor itching. Additional findings of seborrheic dermatitis vary from diffuse, brawny scaling to focal areas of thick, oily, yellow crusts with underlying erythema. The external auditory canals, eyebrows, eyelids, and intertriginous areas may be involved as well. Pruritus may be minimal or severe.

LABORATORY AND IMAGING STUDIES

Laboratory studies and imaging studies are not necessary to diagnose seborrheic dermatitis. Fungal cultures and potassium hydroxide studies may be necessary to help differentiate seborrheic dermatitis of the scalp from tinea capitis (see Chapter 98).

DIFFERENTIAL DIAGNOSIS

Seborrheic dermatitis in an infant may be difficult to differentiate from atopic dermatitis, and in fact, some cases may represent an overlap. In a teenager, seborrheic dermatitis of the scalp and psoriasis of the scalp may have very similar clinical findings; it may be very difficult to differentiate the two disorders, especially if there are no other cutaneous findings to provide additional clues. Intractable, severe, generalized seborrheic dermatitis could suggest Langerhans cell histiocytosis.

TREATMENT

Seborrheic dermatitis of the scalp is usually asymptomatic and generally does not require treatment. Minor amounts of scale can be removed easily by frequent shampooing. For infants with cradle cap, oil (such as mineral oil or olive oil) may be gently massaged into the scalp and left on for a few minutes before gently brushing out the scale and shampooing. Daily shampooing with ketoconazole, zinc pyrithione, selenium sulfide, or salicylic acid shampoos can treat scalp scale. Seborrheic dermatitis with inflamed lesions responds rapidly to treatment with low-potency steroids two times daily.

The response to treatment is usually rapid. Secondary bacterial infection can occur but is uncommon. Intractable disease and other complications warrant further evaluation for other etiologies.

PROGNOSIS

Cradle cap is self-limited and resolves during the first year of life. Seborrheic dermatitis does not cause permanent hair loss. For teenagers, continued use of an antiseborrheic shampoo is often required for control of dandruff.

PREVENTION

Frequent shampooing, especially with early signs of seborrheic dermatitis, may help prevent progression.

OTHER PAPULOSQUAMOUS DERMATOSES

Pityriasis Rosea

Pityriasis rosea is a benign, self-limited eruption that may occur at any age, with peak incidence during adolescence. A solitary 2- to 5-cm, pink, oval patch with central clearing, the

so-called **herald patch**, is the first manifestation of the eruption. The herald patch typically is found on the trunk or proximal thigh and is often misdiagnosed as fungal or eczematous in origin. One to 2 weeks later, a generalized eruption occurs on the torso and proximal extremities. Multiple 0.5- to 2-cm, oval to oblong, red or tan macules with a fine, branlike scale are characteristically arranged parallel to skin tension lines (**Christmas tree pattern**). Rarely, the eruption may have an inverse distribution involving the axillae and groin or a papular or papulovesicular appearance. Mild prodromal symptoms may be present with the appearance of the herald patch, and pruritus is present in 25% of cases. The eruption lasts 4–14 weeks, with gradual resolution. Residual hyperpigmentation or hypopigmentation can take additional months to clear. Treatment is unnecessary, though pruritus can be managed with oral antihistamines, phototherapy, and low-potency topical corticosteroids.

Psoriasis

Psoriasis is a common papulosquamous condition characterized by well-demarcated, erythematous, scaling papules and plaques. Psoriasis occurs at all ages, including infancy, with onset of 30% of cases during childhood. The disease is characterized by a chronic and relapsing course, although spontaneous remissions can occur. Infections (especially *Streptococcus pyogenes*), stress, trauma, and medications may cause disease exacerbations. Various subtypes of psoriasis exist. The most common variety is **plaque-type psoriasis (psoriasis vulgaris)**, which can be localized or generalized. The lesions consist of round, well-demarcated, pink to red plaques measuring 1–7 cm with micaceous scale, which is distinctive in its thick, silvery appearance with pinpoint bleeding points revealed on removal of the scales (**Auspitz sign**). The lesions of psoriasis have a distinctive distribution involving the extensor aspect of the elbows and knees, posterior occipital scalp, periumbilical region, lumbosacral region, and intergluteal cleft. Children often have facial lesions involving the superomedial aspect of the eyelids. Nail plate involvement is common and includes pitting, onycholysis, subungual hyperkeratosis, and oil staining (reddish brown subungual macular discoloration). **Guttate** (numerous small papules and plaques diffusely distributed on the torso), **erythrodermic** (covering large body surface areas), **inverse** (moist red patches affecting body folds), and **pustular** forms may occur. Children with psoriasis are at increased risk for several comorbidities, including obesity, hypertension, hyperlipidemia, metabolic syndrome, diabetes mellitus, depression, and anxiety.

The foundation of therapy is topical corticosteroids. Because of the risk of atrophy, striae, and telangiectases, especially when potent fluorinated corticosteroid preparations are administered long term, the goal is to use the least potent corticosteroid necessary. Topical vitamin D analogs, calcineurin inhibitors, salicylic acid, and tar preparations are useful adjuncts to topical corticosteroids. Phototherapy with narrow-band ultraviolet B (UVB) light can be useful as secondary therapy in older children. Extensive plaque or guttate, erythrodermic, and pustular psoriasis may necessitate systemic treatments. Until recently, the most common systemic therapies included methotrexate, cyclosporine, and acitretin. However, the benefit of more targeted biologic therapies has become increasingly recognized. Tumor necrosis factor- α antagonists

and interleukin 12 (IL-12), IL-23, and IL-17 inhibitors are used, with the first two having pediatric approval. Disease triggers such as infection or medications should be identified and removed. Treatment of psoriasis with oral corticosteroids can induce pustular psoriasis and should be avoided.

PEARLS FOR PRACTITIONERS

See Dermatology: Pearls for Practitioners at the end of this section.

CHAPTER 193

Pigmented Lesions

Birthmark is a term that describes congenital anomalies of the skin. It should not be used as a definitive diagnosis because congenital skin lesions vary greatly in their appearance and prognosis. The differential diagnosis of various birthmarks is listed in Table 193.1.

DERMAL MELANOCYTOSIS

The most frequently encountered pigmented lesion is **dermal melanocytosis**, which occurs in 70–95% of African, Hispanic, Asian, and Native American infants and in approximately 5% of White infants. This is a congenital lesion caused by entrapment of melanocytes in the dermis during their migration from the neural crest into the epidermis. Although most of these lesions are found in the lumbosacral area (Mongolian spot), they also occur at other sites, such as the buttocks, flank, extremities, or (rarely) the face (Fig. 193.1). Single or multiple poorly demarcated, gray-blue patches up to 10 cm in size may be present. Most lesions gradually disappear during the first few years of life; aberrant lesions in unusual sites are more likely to persist.

CAFÉ-AU-LAIT MACULES

Café-au-lait macules are pigmented macules or patches, which may be present in a newborn but tend to develop during childhood (Fig. 193.2). They range in color from very light brown to a chocolate brown. Up to five café-au-lait macules are found in 1.8% of newborns and 25–40% of normal children and have

TABLE 193.1 Common Birthmarks

COLOR/LESION	BIRTHMARK	LOCATION	OTHER FEATURES
Brown/macule or patch	Café-au-lait macule	Variable	May be associated with genetic syndromes
Brown (<40 cm)/patch or plaque	Congenital melanocytic nevus	Variable	Low risk of melanoma
Brown (>40 cm)/patch or plaque	Giant congenital melanocytic nevus	Trunk most common	Risk of melanoma and neuromelanosis
Brown or skin colored/plaque	Epidermal nevus	Variable, trunk and neck	May enlarge with time
Red/patch	Port-wine stain (nevus flammeus)	Variable, face most common	May be associated with Sturge-Weber syndrome
Red/patch	Salmon patch (nevus simplex)	Glabella, eyelids, nape of neck	Improves or resolves with time
Red/papule or plaque	Hemangioma	Variable	May be associated with liver hemangiomas, airway hemangiomas, and PHACE syndrome
Gray-blue/patch	Dermal melanocytosis	Lower trunk (Mongolian spot); face (nevus of Ota); posterior shoulder (nevus of Ito)	Nevus of Ota may be associated with ocular pigmentation
Blue-purple/plaque	Venous, lymphatic, or mixed malformation	Variable	Intermittent swelling and pain
Yellow-orange/plaque	Nevus sebaceus	Head and neck	Malignant and benign tumors may arise within
Yellow-orange/papule	Juvenile xanthogranuloma	Head and neck most common	Spontaneously involutes
Yellow-brown/papule or plaque	Mastocytoma	Variable	Spontaneously involutes
Hypertrichosis/plaque	Smooth muscle hamartoma	Trunk	
Hypertrichosis/tumor	Plexiform neurofibroma	Trunk most common	Associated with neurofibromatosis type 1
White/patch	Nevus anemicus	Variable	Surrounding redness and telangiectasia
White/patch	Nevus depigmentosus	Variable	

FIGURE 193.1 Dermal melanocytosis (back).

FIGURE 193.2 Café-au-lait spots (leg).

no significance. Children with six or more café-au-lait macules (0.5 cm in diameter before puberty or >1.5 cm in diameter after puberty), especially when accompanied by **axillary or inguinal freckling**, should be evaluated carefully for additional stigmata of neurofibromatosis type 1. Other disorders also associated with café-au-lait macules include the other

FIGURE 193.3 Congenital melanocytic nevus (buttock).

FIGURE 193.4 Hairy congenital melanocytic nevus.

forms of neurofibromatosis, Legius syndrome, tuberous sclerosis, McCune-Albright syndrome, Noonan syndrome, and Russell-Silver syndrome.

CONGENITAL MELANOCYTIC NEVI

Approximately 1–6% of newborns have **congenital melanocytic nevi**. Lesions are categorized based on their anticipated diameter in adulthood, with small lesions generally defined as less than 1.5 cm, medium 1.5–20 cm, large more than 20–40 cm, and giant more than 40 cm. Small and medium congenital melanocytic nevi may resemble café-au-lait macules initially, but darker pigmentation, variegated speckles, textural changes, and elevation develop with time and help to differentiate these lesions (Fig. 193.3). Thick, dark, coarse hair frequently is associated with congenital melanocytic nevi (Fig. 193.4). These lesions vary in site and size but are most often solitary. Small and medium-size congenital melanocytic nevi pose a very slightly increased risk for the development of malignant melanoma, usually during adulthood, with risk proportional to the size of the nevus. Surgical removal may be considered to improve the cosmetic appearance or to reduce the likelihood of malignant transformation in difficult-to-monitor lesions, although some patients and physicians elect for observation. Excisional biopsy is indicated when malignant change is suspected.

GIANT CONGENITAL MELANOCYTIC NEVI

Giant congenital melanocytic nevi are defined as nevi that would be approximately 40 cm in length in adulthood. These

lesions appear as color variegated, light brown to black patches or plaques, sometimes with additional smaller macules and papules (**satellite nevi**). The affected skin may be smooth, nodular, or leathery. Prominent, dark hypertrichosis is often present. **Neuromelanosis**, the presence of melanocytes in the central nervous system, may be associated with giant congenital melanocytic nevi, referred to as neurocutaneous melanocytosis. Affected patients may be asymptomatic or have hydrocephalus and seizures; in symptomatic patients, death often results during early childhood. **Malignant melanoma** develops in approximately 2–10% of patients with giant congenital melanocytic nevi, in either the cutaneous lesion or the neural melanocytes. In contrast to small and medium-sized congenital melanocytic nevi, melanoma is more likely to develop within the first 10 years of life. Surgical excision may be considered for resectable lesions. The use of tissue expansion techniques has greatly improved the capability for surgical removal of large lesions.

ACQUIRED MELANOCYTIC NEVI

Acquired melanocytic nevi are common skin lesions. Melanocytic nevi may occur at any age; however, the lesions develop most rapidly in prepubertal children and teenagers. Melanocytic nevi are well-delineated, round to oval, brown macules and papules. Lesions are most common on the face, upper torso, and arms. Family history, fair skin, and sun exposure are considered major risk factors. Irregular pigmentation, rapid growth, bleeding, and a change in configuration or borders suggest signs of malignant degeneration, and biopsy should be performed. Malignant melanoma is rare in childhood; however, there is an alarming increase in incidence in adolescence, especially in those who use indoor tanning. Education of parents and children regarding the risks of sun exposure, appropriate sun protection, and recognition of worrisome lesions is important.

PEARLS FOR PRACTITIONERS

See *Dermatology: Pearls for Practitioners* at the end of this section.

FIGURE 194.1 Hemangioma (chest).

infants. Hemangiomas occur predominantly in females (3:1) and have an increased incidence in low birthweight infants. In newborns, hemangiomas may originate as a pale white macule with threadlike telangiectasia. When the tumor proliferates, it assumes its most recognizable form as a bright red, lobulated plaque or nodule (superficial type) (Fig. 194.1). Hemangiomas that lie deeper in the skin are soft, warm masses with a blue discoloration (deep type). Frequently, hemangiomas have both a superficial and a deep component (mixed type). They range from a few millimeters to several centimeters in diameter and are usually solitary; 20% of affected children have multiple lesions.

Approximately 65% have precursor lesions present at birth; the rest develop in the first weeks of life. Superficial hemangiomas reach their maximal size by 5 months with the most rapid growth occurring before 8 weeks of life, but deep hemangiomas may grow for longer. Hemangiomas then undergo slow, spontaneous involution, which takes 3–10 years.

Despite the benign nature of most cutaneous hemangiomas, there may be the risk of functional compromise or permanent disfigurement, depending on the location and extent. Ulceration, the most frequent complication, can be painful and increases the risk of infection, hemorrhage, and scarring. Areas frequently associated with complications include the periorcular region, lip, nasal tip, beard, face (large lesions), groin, and buttocks. **Periorbital hemangiomas** pose considerable risk to vision and should be monitored carefully. Amblyopia can result from the hemangioma, causing obstruction of the visual axis or pressure on the globe, resulting in astigmatism. If there is any concern, the patient should have urgent evaluation by an ophthalmologist. Treatment may be indicated to prevent blindness. **Subglottic hemangiomas** manifest as hoarseness and stridor; progression to respiratory failure may be rapid. Symptomatic airway hemangiomas develop in more than 50% of infants with extensive facial hemangiomas on the chin and jaw (beard distribution); any infant with a beard hemangioma should be urgently referred for laryngoscopy. Multiple cutaneous (diffuse hemangiomatosis) and large facial hemangiomas may be associated with visceral hemangiomas. Liver ultrasound is recommended to evaluate for hepatic infantile hemangiomas in infants who have at least five cutaneous infantile hemangiomas. Segmental cervicofacial hemangiomas may be associated with PHACE syndrome, characterized by posterior fossa malformations,

CHAPTER 194

Vascular Anomalies

Vascular anomalies can be divided into two major categories: tumors and malformations. Vascular tumors are characterized by hypercellularity, proliferation, and growth. Vascular malformations, however, are developmental defects derived from the capillary, venous, arterial, or lymphatic vessels. In contrast to hemangiomas, vascular malformations remain relatively static and grow very slowly over time. Differentiating between these entities is important because they have different prognoses and clinical implications.

VASCULAR TUMORS

Infantile Hemangiomas

Infantile hemangiomas are the most common soft tissue tumors of infancy, occurring in approximately 4–5% of

hemangiomas, arterial anomalies, coarctation of aorta and cardiac defects, and eye abnormalities. Magnetic resonance imaging (MRI) and magnetic resonance angiography of the head, neck, and aortic arch, as well as echocardiogram and ophthalmology evaluation are recommended for all infants with a segmental cervicofacial hemangioma. **Lumbosacral hemangiomas** suggest an occult spinal dysraphism with or without anorectal and urogenital anomalies (LUMBAR syndrome). MRI of the spine is indicated in all patients with large midline cutaneous hemangiomas in the lumbosacral area.

Most hemangiomas do not necessitate medical intervention and involute spontaneously; however, if complications arise and treatment is warranted, oral propranolol or topical timolol are the mainstays of therapy.

Pyogenic Granuloma

A pyogenic granuloma is an acquired, benign vascular tumor commonly seen in children. Initially, the lesions appear as friable, granulation tissue-like, pink-red papules that often arise after minor trauma, growing rapidly over a period of weeks into a 2- to 10-mm, bright red, vascular, often pedunculated papule. They may occur anywhere on the body, but the head, neck, and upper extremities are most commonly affected. When traumatized, these lesions may bleed profusely, often requiring emergent medical attention. Surgical excision is the most definitive treatment option, although pulsed dye laser, cryosurgery, electrodesiccation, and topical β blockers can be useful.

VASCULAR MALFORMATIONS

Port-Wine Stain

Port-wine stains (nevus flammeus, capillary malformation) are malformations of the superficial capillaries of the skin. These lesions are present at birth, permanent in nature, and grow with the child. A port-wine stain may be localized to any body surface, but facial lesions are the most common. They are pink or red macules and patches in infancy (Fig. 194.2). With time, they darken to a purple or *port-wine* color and may develop

FIGURE 194.2 Port-wine stain (face).

a pebbly or slightly thickened surface. Vascular blebs may form within the lesions and become symptomatic or bleed. The most successful treatment modality in use is the pulsed dye laser, which can result in 80–90% improvement in these lesions after a series of treatment sessions and can avoid future complications associated with vascular dilation. Treatment is more effective if undertaken in infancy. Overgrowth of underlying muscle and bone can occur and is frequently seen with facial lesions. Affected patients often need maxillofacial intervention from malalignment that develops.

Most port-wine stains occur as isolated defects and do not indicate systemic malformations. Rarely, they may suggest ocular defects or specific neurocutaneous syndromes. **Sturge-Weber syndrome** (encephalotrigeminal angiomatosis) may occur with a facial port-wine stain, usually in the cutaneous distribution of the first branch of the trigeminal nerve. Other features include leptomeningeal angiomatosis, mental retardation, seizures, contralateral hemiparesis, ipsilateral intracortical calcification, and frequent ocular manifestations such as buphthalmos, glaucoma, angioma of the choroid, hemianoptic defects, and optic atrophy. Anticonvulsant therapy and neurosurgical procedures have been of value in some patients. Glaucoma can occur in association with port-wine stains located on the eyelid, even in the absence of Sturge-Weber syndrome, and these patients need lifelong monitoring of ocular pressures. **Klippel-Trénaunay-Weber** syndrome is characterized by the triad of capillary and venous malformations, venous varicosities, and hyperplasia of the soft tissues—and often bone—of the involved area. The lower limb is most commonly affected. A port-wine stain overlying the spine may rarely be a marker of spinal dysraphism or an intraspinal vascular malformation.

Nevus Simplex

A nevus simplex (salmon patch, stork bite, angel's kiss) is a vascular birthmark that is present in up to 80% of newborns. They are light pink or red, irregular patches resulting from dilation of dermal capillaries and are usually found on the nape of the neck, the eyelids, and the glabella. Most of the facial lesions fade by 1 year of age, but lesions on the neck may persist for life.

PEARLS FOR PRACTITIONERS

See *Dermatology: Pearls for Practitioners* at the end of this section.

CHAPTER 195**Erythema Multiforme, Reactive Infectious Mucocutaneous Eruption, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis**

Erythema multiforme (EM), reactive infectious mucocutaneous eruption (RIME), Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN) are acute hypersensitivity reactions characterized by cutaneous and mucosal necrosis.

These syndromes represent a hypersensitivity reaction to a precipitating cause, usually infectious organisms or drugs. These disorders were historically thought to represent a spectrum of the same disease process, and inconsistent use of these disease names led to further confusion. A consensus definition was published in 1993, and current literature favors that EM is distinct from the SJS/TEN spectrum of disease. The differential diagnosis of vesiculobullous eruptions is listed in Table 195.1.

ERYTHEMA MULTIFORME

EM is a common, self-limiting, acute hypersensitivity syndrome characterized by the abrupt onset of round, deep red, well-demarcated macules and papules with a dusky gray or bullous center. The size may vary, but most lesions are approximately 1 cm in diameter. The classic **target lesion** consists of three concentric rings: The outermost is red, the intermediate is white, and the center is a dusky red or purple. These can progress to edematous plaques or bullae. If blistering occurs,

ENTITY	CLINICAL CLUES	ENTITY	CLINICAL CLUES
INFECTIOUS			
Bacterial			
Staphylococcal scalded skin syndrome	Generalized, tender erythema Nikolsky sign Occasionally associated with underlying infection such as osteomyelitis, septic arthritis, pneumonia Desquamation and moist erosions observed, especially in intertriginous areas More common in children <5yr of age	Stevens-Johnson syndrome and toxic epidermal necrolysis	Prodrome of fever, headache, malaise, sore throat, cough, vomiting, diarrhea Extensive epidermal necrosis with mucosal involvement Frequently related to drugs (e.g., sulfonamides, anticonvulsants) Nikolsky sign
Bullous impetigo	Localized blisters from staphylococcal infection	EXTRINSIC	
Viral			
Herpes simplex	Grouped vesicles on erythematous base May be recurrent at same site—lips, eyes, cheeks, hands Reactivated by fever, sunlight, trauma, stress	Contact dermatitis	Irritant or allergic Distribution dependent on the irritant or allergen Distribution helpful in identifying cause
Varicella	Crops of vesicles on erythematous base (“dewdrops on rose petal”) Highly contagious May see multiple stages of lesions simultaneously Associated with fever	Insect bites	Occur occasionally following flea or mosquito bites May be hemorrhagic bullae Often in linear or irregular clusters Very pruritic
Herpes zoster	Grouped vesicles on erythematous base limited to one or several adjacent dermatomes Thoracic dermatomes most commonly involved in children May be varicella vaccine associated Usually unilateral Burning, pruritus	Burns	Irregular shapes and configurations May be suggestive of abuse Bullae with second- and third-degree injuries
Hand-foot-mouth syndrome (coxsackievirus infection)	Prodrome of fever, anorexia, sore throat Oval blisters in acral distribution, usually few in number Shallow, oral erosions on erythematous base in oral mucosa Highly infectious Peak incidence in late summer and in fall	Friction	Usually on acral surfaces May be related to footwear Often activity-related
HYPERSENSITIVITY			
Erythema multiforme	Target lesions on acral sites May have involvement of mucosal surfaces Associated with herpes simplex virus infection	MISCELLANEOUS	
Reactive infectious mucocutaneous eruption	Prodrome of fever and cough Severe mucositis of 2+ mucosal surfaces Scarce/absent rash Associated with <i>Mycoplasma pneumoniae</i> , <i>Chlamydochila pneumoniae</i> , or viral respiratory infection	Urticaria pigmentosa	Red-brown macules and papules; bullous lesions are rare Darier sign Lesions appear in infancy and spontaneously resolve in childhood
		Miliaria crystallina	Clean, 1- to 2-mm superficial vesicles occurring in crops Rupture spontaneously Intertriginous areas, especially neck and axillae
		Hereditary: epidermolysis bullosa, incontinentia pigmenti, epidermolytic hyperkeratosis	
		Autoimmune: linear immunoglobulin A disease, bullous pemphigoid, dermatitis herpetiformis	

it is circumscribed and involves less than 10% of the body surface area. Cutaneous lesions are symmetrically distributed and commonly involve acral areas such as the hands, feet, elbows, and knees. Involvement of the ocular, oral, and genital mucosa can be seen in some cases.

Most EM cases in children are precipitated by herpes simplex virus infection, although the infection may no longer be apparent by the time EM develops. Symptomatic treatment is usually sufficient. Oral antihistamines help suppress pruritus, stinging, and burning. The use of systemic corticosteroids is controversial but may be considered for severe mucosal disease. Antiviral medications targeting herpes simplex virus do not alter the course of the EM, although children with recurrent EM may be candidates for prophylactic antivirals. The prognosis is excellent, with most lesions lasting no more than 2 weeks. Healing occurs without scarring.

REACTIVE INFECTIOUS MUCOCUTANEOUS ERUPTION

RIME is a newly recognized disorder characterized by a respiratory illness prodrome including fever and cough, severe mucositis (most often involving at least two mucosal surfaces), and a scarce to absent rash. When present, the rash associated with RIME is most often targetoid, but varying morphologies have been described. In contrast to SJS/TEN, which is caused by medications, RIME is caused by infection with *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, or respiratory viruses such as rhinovirus, enterovirus, influenza, parainfluenza, and human metapneumovirus. While most patients with RIME fully recover, the disorder can be associated with severe infection/sepsis requiring monitoring and treatment in an intensive care unit. Ocular and urogenital complications can occur as the result of the mucosal ulceration and subsequent scarring.

STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

SJS, TEN, and SJS/TEN overlap are severe, life-threatening disorders thought to represent the same disease continuum. They are usually preceded by a prodrome of fever, malaise, and upper respiratory symptoms 1–14 days before the onset of cutaneous lesions. Red macules appear suddenly and tend to coalesce into large patches, with a predominant distribution over the face and trunk. Atypical targets may be present, causing diagnostic confusion initially with EM, although the atypical targets lack the characteristic three zones. Skin lesions evolve rapidly into bullae and areas of necrosis. SJS is defined as epidermal detachment of less than 10% of the body surface area, whereas SJS/TEN overlap has 10–30% and TEN has greater than 30% body surface area involvement.

Any mucosal surface may be involved. The upper and lower lips are generally swollen and bright red with erosions and hemorrhagic crusts. The remainder of the oral mucosa may also be involved. Early in the disease process, there is bilateral conjunctival injection; this usually progresses to conjunctival erosions. There may be erosions of the penile, vaginal, or perianal mucosa. Urogenital, esophageal, and tracheal surfaces may be involved in the most severe cases.

Drugs are the most common cause of SJS/TEN in children. The most common drugs implicated are nonsteroidal

antiinflammatory drugs, sulfonamides, anticonvulsants, and antibiotics. Infections may be precipitating factors in some cases, and the relationship to RIME in these situations is controversial.

SJS/TEN can occur at any age. The diagnosis of SJS/TEN is clinical; there are no diagnostic tests. Confusion with EM, RIME, Kawasaki disease, and bacterial toxin-mediated diseases (scarlet fever, toxic shock syndrome, and staphylococcal scalded skin syndrome) may occur. Patients with Kawasaki disease may also have conjunctival injection and hyperemia of the mucous membranes; however, necrosis of the mucosal surfaces does not occur, and blistering, erosions, and severe crusting are not observed. The mucosal changes of staphylococcal scalded skin syndrome are minor, and the blistering of the skin is more superficial and favors intertriginous regions.

SJS/TEN is a serious illness with a mortality rate as high as 37% for severe cases of TEN. Prompt discontinuation of the offending agent is key, and a multidisciplinary care team is often necessary. Controlled clinical trials are limited, although intravenous immunoglobulin, cyclosporine, and etanercept are sometimes used. Sepsis is the major cause of morbidity and mortality, so meticulous wound care is crucial, with stringent surveillance for cutaneous infections and use of antibiotics as warranted. Parenteral or nasogastric feeding should be instituted early to accelerate the healing process, and monitoring of fluid and electrolyte status is critical. Ocular complications are a major cause of long-term morbidity, making early involvement of an ophthalmologist important.

PEARLS FOR PRACTITIONERS

See Dermatology: Pearls for Practitioners at the end of this section.

CHAPTER 196

Cutaneous Infestations

Arthropods are common in the environment. Although many can bite or sting humans, only a few infest humans. Arachnids (mites) are the most common, parasitizing humans and animals by burrowing into the skin and depositing eggs within the skin.

SCABIES

Scabies is caused by the mite *Sarcoptes scabiei*. The female mite burrows into the epidermis and deposits her eggs, which mature in 10–14 days. The disease is highly contagious, as infested humans do not manifest the typical signs or symptoms for 3–4 weeks, facilitating transmission. An immunocompetent person with scabies typically harbors only 10–12 mites.

The clinical presentation varies depending on the age of the patient, duration of infestation, and immune status of the patient. Severe and paroxysmal itching is the hallmark, with complaints of itching that is frequently worse than the eruption would suggest. Most children exhibit an eczematous eruption composed of red, excoriated papules and nodules. The classic linear papule or burrow is often difficult to find. Distribution is the most diagnostic finding; the papules are found in the

FIGURE 196.1 Scabies (hand).

axillae, umbilicus, groin, penis, wrist, instep of the foot, and web spaces of the fingers and toes (Fig. 196.1). Infants infested with scabies have diffuse erythema, scaling, and pinpoint papules, along with pustules, vesicles, and nodules. The face and scalp usually are spared in adults and older children, but these areas are usually involved in infants. Nodular lesions may represent active infection or prolonged hypersensitivity lesions following resolution of infestation. Immunocompromised or neurologically impaired persons may develop a severe form of the disease known as **Norwegian** or **crusted scabies**, with infestation of 2 million live mites at one time.

The diagnosis of scabies can be confirmed by microscopic visualization of the mite, eggs, larvae, or feces in scrapings of papules or burrows examined under oil immersion. Skin biopsy is rarely necessary but may be useful if lesions have become nodular.

Curative treatment is achieved by permethrin 5% cream applied to the entire body and left on for 12 hours. Because permethrin is not effective against the eggs, the treatment should be repeated 1 week later to kill any subsequently hatched larvae. All household members and close contacts should be treated simultaneously, even if asymptomatic. Bed linens, towels, and clothes worn for the previous 2 days before treatment should be machine-washed in hot water and machine-dried using high heat; heat is the most effective scabicide. Items that are not washable may be dry-cleaned or placed in a sealed plastic bag for 7 days.

Secondary bacterial infection may occur but is uncommon. In contrast to the pediculoses, scabies is not a vector for infections. Pruritus may persist for 7–14 days after successful therapy because of a prolonged hypersensitivity reaction, which does not indicate treatment failure. Inadequate treatment or reinfestation should be suspected if new lesions develop after treatment.

PEDICULOSES

Three species of lice infest humans: *Pediculus humanus capitis*, the **head louse**; *Pthirus pubis*, the **pubic louse** or **crab louse**; and *Pediculus humanus humanus* (also known as *Pediculus humanus corporis*), the **body louse**. Lice are wingless insects 2–4 mm in length that cannot fly or jump. Transmission usually occurs by direct contact with another infested individual. Indirect spread through contact with fomites or personal belongings, such as hairbrushes, combs, or caps, is much less frequent.

Pediculosis differs from scabies infestation in that the louse resides on the hair or clothing and intermittently feeds on the host by piercing the skin. The *bite* causes small urticarial papules and itching. Head lice live close to the skin and may live for 30 days, depositing 100–400 eggs as **nits** on hair shafts, usually within 6 mm of the scalp.

Head lice are seen most frequently in early school-age children. Head lice infestations are unrelated to hygiene and are not more common among children with long hair or with dirty hair. It is estimated that 6–12 million persons in the United States and 1–3% of persons in developed countries are infested with head lice each year. In the United States, head lice infestation is rare among Blacks.

Pubic lice are transmitted by sexual contact. Their presence in children may be a sign of child abuse. Body lice are firm evidence of poor hygiene, such as infrequent washing and clothing changes.

Itching is the primary symptom. Pediculosis capitis usually causes pruritus behind the ears or on the nape of the neck, or a crawling sensation in the scalp. Pediculosis pubis usually causes pruritus in the groin. Eyelash involvement in children may cause crusting and blepharitis. Pediculosis corporis causes pruritus that, because of repeated scratching, may result in lichenification or secondary bacterial infection. Excoriations and crusting, with or without associated regional lymphadenopathy, may be present.

Infestation with the head louse may be asymptomatic and has little morbidity. The diagnosis can be confirmed by visualizing a live louse. A fine-toothed comb to trap lice is more effective than simply looking at the hair. Wet combing is more time consuming, but dry combing produces static that may propel the lice away from the comb.

Nits represent the outer casing of the louse ova. Viable nits have an intact operculum (cap) on the nonattached end and a developing louse within the egg. **Brown nits** located on the proximal hair shaft suggest active infestation. **White nits** located on the hair shaft 4 cm or farther from the scalp indicate previous infestation. Because nonviable nits can remain stuck in the hair for weeks to months after an infestation has resolved, many children with nits do not have active lice infestation.

The treatment of head lice is variable because of resistance to many established options. Permethrin (1%) and pyrethrin-based products (0.17–0.33%) (pyrethroids) are over-the-counter options, but drug resistance is on the rise. Because 20–30% of eggs may survive one treatment, a second treatment should be applied in 9–10 days. Malathion (0.5%) lotion, benzyl alcohol (5%) lotion, spinosad (0.9%) topical suspension, and ivermectin (0.5%) lotion may be used as alternatives for resistant cases.

To reduce the risk of reinfestation, everyone in the family should be checked for head lice and treated if live lice are found. Bed linens, towels, and clothes worn for the previous 2 days before treatment should be machine-washed in hot water and machine-dried using high heat. Items that are not washable may be dry-cleaned or placed in a sealed plastic bag for 2 weeks. Brushes and combs should be soaked in dish detergent or rubbing alcohol for 1 hour. Rugs, furniture, mattresses, and car seats should be vacuumed thoroughly.

Manual removal of nits after treatment is not necessary to prevent spread. Children treated for head lice should return to school immediately after completion of the first effective treatment or first wet combing, regardless of the presence of remaining nits. There is no evidence that *no nit* or *nit-free*

policies reduce transmission of head lice. If required for return to school, nit removal is best achieved by wetting the hair and combing with a fine-toothed metal comb.

Excoriations can become secondarily infected with skin bacteria, usually *Staphylococcus* and *Streptococcus*. The body louse functions as a vector for potentially serious infectious diseases, including **epidemic typhus**, caused by *Rickettsia prowazekii*; **louse-borne relapsing fever**, caused by *Borrelia recurrentis*; and **trench fever**, caused by *Bartonella quintana*. These louse-borne infections are rare in the United States. In contrast to body lice, head lice and pubic lice are not associated with transmission of other infections.

PEARLS FOR PRACTITIONERS

CHAPTER 188

Dermatology Assessment

- Common cutaneous conditions in pediatrics include atopic dermatitis, impetigo, tinea capitis, acne vulgaris, verrucae vulgaris, and seborrheic dermatitis.
- Obtaining a thorough history including the age of the patient, onset, duration, progression, associated cutaneous symptoms (pain, pruritus), previous treatments, and associated systemic signs or symptoms (fever, malaise, weight loss) is important.
- Characterizing and describing the primary and secondary skin lesions is important for diagnosis and communication with other health care providers.

CHAPTER 189

Acne Vulgaris

- Acne vulgaris is the most common skin condition in adolescents.
- The pathogenesis of acne involves increased sebum production, hyperkeratosis, and bacterial proliferation. Treatment is aimed at decreasing these factors.

CHAPTER 190

Atopic Dermatitis

- Atopic dermatitis is the most common chronic skin disease in children and is associated with allergic rhinitis, asthma, and food allergies. Both genetic and environmental factors play a role in the development of atopic dermatitis.

- Treatment of atopic dermatitis is aimed at decreasing inflammation.
- Complications of atopic dermatitis include secondary impetigo and eczema herpeticum.

CHAPTER 191

Contact Dermatitis

- Contact dermatitis is a delayed type IV hypersensitivity reaction that occurs when the skin is directly exposed to irritating chemicals or substances (irritant contact dermatitis) or allergens in predisposed individuals.
- Diaper dermatitis is commonly due to irritant contact dermatitis from urine and feces, frequently complicated by secondary candida and bacterial infections.
 - Differential diagnosis for diaper dermatitis includes psoriasis, seborrheic dermatitis, and Langerhans cell histiocytosis. Referral to a pediatric dermatologist should be made in recalcitrant, difficult-to-treat cases.
- Treatment of contact dermatitis is generally avoidance of irritating substances and allergens and use of barriers and topical corticosteroids.

CHAPTER 192

Seborrheic Dermatitis

- Seborrheic dermatitis is a common, chronic inflammatory disease that presents as cradle cap or dermatitis in intertriginous areas in infants and dandruff in adolescents.
- The pathogenesis of seborrheic dermatitis is unclear, but it is theorized that there is an abnormal inflammatory response to commensal *Malassezia* species in sebum-rich areas.

- Treatment for seborrheic dermatitis is generally not needed, but oils, shampoos, and topical steroids can be used if needed.
- Pityriasis rosea is a benign, self-limited eruption that starts with a herald patch, which precedes a generalized eruption on the torso and extremities in a Christmas tree pattern.
- Psoriasis is a common papulosquamous disorder with various subtypes, including plaque-type psoriasis (psoriasis vulgaris), guttate, erythrodermic, and pustular.
 - Treatments for psoriasis include topical corticosteroids, topical vitamin D analogs, salicylic acid, tar preparations, phototherapy, systemic immunosuppressants, and biologics.

CHAPTER 193

Pigmented Lesions

- Dermal melanocytosis is the most frequently encountered pigmented lesion. The gray-blue lesions are typically found in the lumbosacral area, buttocks, flank, extremities, or (rarely) the face.
- Café-au-lait macules are light to chocolate brown pigmented macules or patches that can be found in normal newborns and children.
 - Children with six or more café-au-lait macules (0.5 cm in diameter before puberty or >1.5 cm in diameter after puberty), especially when accompanied by axillary or inguinal freckling, should be evaluated carefully for additional stigmata of neurofibromatosis type 1.
 - Other disorders also associated with café-au-lait macules include the other forms of neurofibromatosis, Legius syndrome, tuberous sclerosis, McCune-Albright syndrome, Noonan syndrome, and Russell-Silver syndrome.
- There is an increased risk of neuromelanosis and malignant melanoma when congenital melanocytic nevi are giant (>40 cm in length in adulthood).

CHAPTER 194

Vascular Anomalies

- Infantile hemangiomas are the most common soft tissue tumors of infancy and present as superficial, deep, or mixed types.
 - They undergo spontaneous involution after a rapid growth phase.
 - They do not need to be treated unless they are symptomatic and/or pose risks that can lead to functional compromise or permanent disfigurement, in which case oral propranolol and topical timolol are the mainstays of therapy.
- Infantile hemangiomas can have visceral involvement and be associated with other underlying anomalies.

- Evaluation for airway hemangiomas should be undertaken in infants with a beard hemangioma.
- Large lumbosacral hemangiomas should be investigated with a magnetic resonance imaging (MRI) of the spine.
- Evaluation with echocardiogram, MRI/MR angiography of the head, neck, and aortic arch, and ophthalmology exam should be performed in infants with large segmental infantile hemangiomas of the head at risk for PHACE syndrome.

CHAPTER 195

Erythema Multiforme, Reactive Infectious Mucocutaneous Eruption, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis

- Erythema multiforme (EM) is a common, self-limiting, acute hypersensitivity syndrome characterized by the abrupt onset of round, deep red, well-demarcated macules and papules with a dusky gray or bullous center (targetoid).
 - EM can be precipitated by infections (most commonly herpes simplex virus) or medications.
- Reactive infectious mucocutaneous eruption (RIME) is characterized by a prodrome with fever and cough, severe mucositis (most often involving at least two mucosal surfaces), and a scarce to absent rash. RIME is caused by infection with *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*, or respiratory viruses.
- Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and SJS/TEN overlap are severe, life-threatening disorders thought to represent the same disease continuum. They are precipitated by medications.
- SJS is defined as epidermal detachment of <10% of the body surface area, whereas SJS/TEN overlap has 10–30% and TEN has >30% body surface area involvement.

CHAPTER 196

Cutaneous Infestations

- Scabies is caused by the mite *Sarcoptes scabiei*.
 - Curative treatment for scabies is achieved by a 12-hour (overnight) application of permethrin 5% cream applied to the entire body and repeated in 1 week. All household members and close contacts should be treated for scabies simultaneously, even if asymptomatic.
- Household treatment for scabies and pediculosis includes machine washing (in hot water) and machine drying (using high heat) all bed linens, towels, and clothes worn in the previous 2 days. Items that are not washable may be dry-cleaned or placed in a sealed plastic bag for 7 days (scabies) and 14 days (pediculosis).

ORTHOPEDICS

Kevin D. Walter | Benjamin G. Escott

CHAPTER 197

Orthopedics Assessment

It is important to understand the growth and development of the musculoskeletal system as well as common orthopedic terms (Table 197.1). Providers should recognize common mechanisms for congenital and acquired orthopedic disorders (Table 197.2).

TABLE 197.1 Common Orthopedic Terminology	
ABDUCTION	MOVEMENT AWAY FROM MIDLINE
Adduction	Movement toward or across midline
Apophysis	Bone growth center that has a muscular insertion but is not considered a growth plate (e.g., tibial tubercle)
Arthroscopy	Surgical exploration of a joint using an arthroscope
Arthroplasty	Surgical reconstruction of a joint
Arthrotomy	Surgical incision into a joint; an “open” procedure
Deformation	Changes in limb, trunk, or head due to mechanical force
Dislocation	Displacement of bones at a joint
Disruption	Normally developing structure that is destroyed, removed, or stops developing
Equinus	Plantar flexion of the forefoot, hindfoot, or entire foot
Femoral anteversion	Increased angulation of the femoral head and neck with respect to the frontal plane
Malformation	Defect in development that occurs during fetal life (e.g., syndactyly)
Osteotomy	Surgical division of a bone
Pes cavus	High medial arch of the foot
Pes planus	Flat foot
Rotation, internal	Inward rotation (toward midline)
Rotation, external	Outward rotation (away from midline)
Subluxation	Incomplete loss of contact between two joint surfaces

TABLE 197.1 Common Orthopedic Terminology—cont’d	
ABDUCTION	MOVEMENT AWAY FROM MIDLINE
Tibial torsion	Rotation of the tibia in an internal or external fashion
Valgus/valgum	Angulation of a bone or joint in which the apex is toward the midline (e.g., knock-knee)
Varus/varum	Angulation of a bone or joint in which the apex is away from the midline (e.g., bowlegs)

TABLE 197.2 Mechanisms of Common Pediatric Orthopedic Problems		
CATEGORY	MECHANISM	EXAMPLE(S)
CONGENITAL		
Malformation	Teratogenesis <12 wk of gestation	Spina bifida
Disruption	Amniotic band constriction	Extremity amputation
	Fetal varicella infection	Limb scar/atrophy
Deformation	Neck compression	Torticollis
Dysplasia	Abnormal cell growth or metabolism	Osteogenesis imperfecta Skeletal dysplasias
ACQUIRED		
Infection	Pyogenic-hematogenous spread	Septic arthritis, osteomyelitis
Inflammation	Antigen-antibody reaction Immune mediated	Systemic lupus erythematosus Juvenile idiopathic arthritis
Trauma	Mechanical forces, overuse	Child abuse, sports injuries, unintentional injury, fractures, dislocations, tendinitis
Tumor	Primary bone tumor	Osteosarcoma
	Metastasis to bone from other site	Neuroblastoma
	Bone marrow tumor	Leukemia, lymphoma

GROWTH AND DEVELOPMENT

The ends of the long bones contain a much higher proportion of cartilage in the skeletally immature child than in an adult (Figs. 197.1 and 197.2). The high cartilage content allows for a unique vulnerability to trauma and infection (particularly in the metaphysis).

The physis is responsible for the longitudinal growth of the long bones. Articular cartilage allows the ends of the bone to enlarge and accounts for growth of smaller bones, such as the tarsals. The periosteum provides for circumferential growth. Trauma, infection, nutritional deficiency (e.g., rickets), inborn errors of metabolism (e.g., mucopolysaccharidoses), and other disorders (e.g., renal tubular acidosis, hypothyroid) may affect each of the growth processes and produce distinct aberrations.

DEVELOPMENTAL MILESTONES

Neurologic maturation, marked by achievement of developmental motor milestones, is important for normal musculoskeletal development (see Section 2). A neurologic disorder may cause a secondary musculoskeletal abnormality (e.g., extremity contractures in Duchenne muscular dystrophy). Thus, normal motor development must be included in the definition of a normal musculoskeletal system.

FIGURE 197.1 Schematic of long bone structure.

FIGURE 197.2 The ends of long bones at various ages. Lightly stippled areas represent cartilage composition, whereas heavily darkened areas are zones of ossification. (From Tachjian MO. *Congenital Dislocation of the Hip*. New York: Churchill Livingstone; 1982:105.)

Infants

In utero positioning of the fetus may affect the angular and torsional alignment (temporary or permanent) of the skeletal system, especially of the lower extremity (Fig. 197.3). A newborn has externally rotated hips and commonly has pes planus and genu varum. The flexed posture of an infant usually decreases to neutral within the first 4–6 months. The foot is often flat and *tucked under* at birth; the ankle will be inverted, and the forefoot is adducted when compared with the hind-foot. The lateral border of the foot must straighten out, even with dorsiflexion, to be considered secondary to in utero positioning.

The head and neck may also be distorted by in utero positioning. The spine and upper extremities are less likely to be affected. By the age of 3–4 years, the effects of in utero positioning have usually resolved.

Gait

Normal gait has a stance phase and swing phase; each leg should have symmetric timing with each phase. The stance phase represents 60% of the gait and begins with foot contact (usually the heel strike) and ends with the toe-off. During the swing phase (40%), the foot is off the ground. The gait cycle is the interval between stance phases on the same limb.

Toddlers will generally walk independently by 18 months of age. Their externally rotated gait is usually inconsistent, is characterized by short, rapid steps, and does not have the reciprocal arm swing. Gait coordination improves over time, with a normal gait usually achieved by the time a child enters elementary school.

Limping Child

The differential diagnosis for a limping child is often categorized by age and presence or absence of a painful limp (Table 197.3). The gluteus medius muscle stabilizes the pelvis during the stance phase, preventing the pelvis from dropping toward the leg in swing phase. An **antalgic gait** is a painful limp; the stance phase and stride of the affected limb are shortened to decrease the discomfort of weight bearing on the affected limb. The **Trendelenburg gait** has a normal stance phase but excessive swaying of the trunk. **Waddling gait** refers to a bilateral decrease in function of the gluteus muscles.

Toe walking is a common complaint in early walkers. A physician should evaluate any child older than 3 years of age who still toe walks. Although this is most likely habit, a neuromuscular disorder (e.g., cerebral palsy, tethered cord), Achilles tendon contracture (heel cord tightness), or a leg-length discrepancy should be considered.

PEARLS FOR PRACTITIONERS

See *Orthopedics: Pearls for Practitioners* at the end of this section.

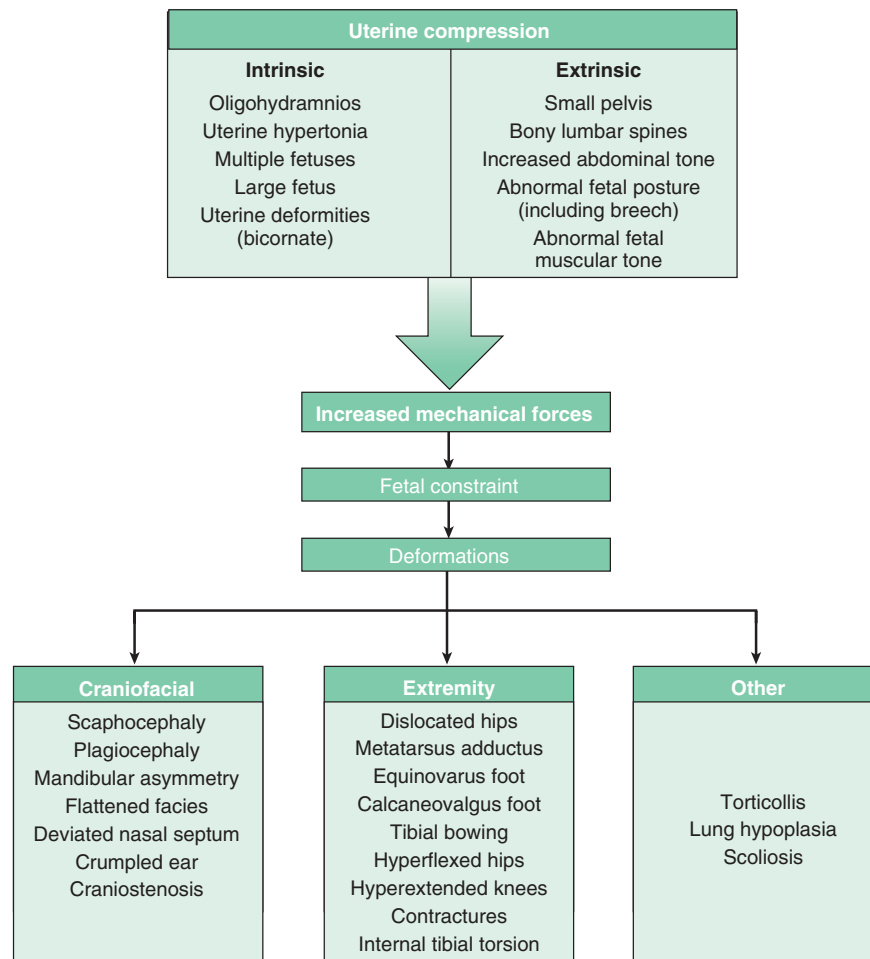

FIGURE 197.3 Deformation abnormalities resulting from uterine compression.

TABLE 197.3 Differential Diagnosis of Limping in Children			
AGE GROUP	DIAGNOSTIC CONSIDERATIONS	AGE GROUP	DIAGNOSTIC CONSIDERATIONS
Early walker: 1–3yr of age	<i>Painful limp</i>	Adolescent: 11 yr of age to maturity	<i>Painful limp</i>
	Septic arthritis and osteomyelitis Transient monarticular synovitis Occult trauma (“toddler’s fracture”) Spondylodiscitis Malignancy		Septic arthritis, osteomyelitis, myositis Trauma Rheumatologic disorder Slipped capital femoral epiphysis: acute; unstable Malignancy

CHAPTER 198

Fractures

Fractures account for 10–15% of all childhood injuries. The anatomic, biomechanical, and physiologic differences in children account for unique fracture patterns and management. Fracture terminology helps describe fractures (Table 198.1).

The pediatric skeleton has a higher proportion of cartilage and a thicker, stronger, and more active periosteum capable of producing a larger callus more rapidly than in an adult. The thick periosteum may decrease the rate of displaced fractures and stabilize fractures after reduction. Because of the higher proportion of cartilage, the skeletally immature patient can withstand more force before deformation or fracture than adult bone. As children mature into adolescence, the rate of healing slows and approaches that of adults.

PEDIATRIC FRACTURE PATTERNS

Buckle or torus fractures occur after compression of the bone; the bony cortex does not truly break. These fractures will typically occur in the metaphysis and are stable fractures that heal in approximately 4 weeks with immobilization. A common example is a fall onto an outstretched arm causing a buckle fracture in the distal radius; removable wrist splints have been effective for management of these fractures.

Complete fractures occur when both sides of bony cortex are fractured. This is the most common fracture and may be classified as comminuted, oblique, transverse, or spiral, depending on the direction of the fracture line.

Greenstick fractures occur when a bone is angulated beyond the limits of plastic deformation. The bone fails on the tension side and sustains a bend deformity on the compression side. The force is insufficient to cause a complete fracture (Fig. 198.1).

TABLE 198.1	Useful Fracture Terminology
Complete	The bone fragments separate completely
Incomplete	The bone fragments are still partially joined
Linear	Referring to a fracture line that is parallel to the bone's long axis
Transverse	Referring to a fracture line that is at a right angle to the bone's long axis
Oblique	Referring to a fracture line that is diagonal to the bone's long axis
Spiral	Referring to a twisting fracture
Comminution	A fracture that results in several fragments
Compaction	The bone fragments are driven into each other
Angulation	The fragments of bone are at an angle to each other
Rotation	The fragments spun (rotated) on each other when the bone broke
Shortening	The fractured ends of the bones overlap
Open	A fracture in which the bone has pierced the skin

FIGURE 198.1 The greenstick fracture is an incomplete fracture. (Modified from White N, Sty R. Radiological evaluation and classification of pediatric fractures. *Clin Pediatr Emerg Med.* 2002;3:94–105.)

Bowing fractures demonstrate no fracture line evident on radiographs, but the bone is bent beyond its limit of plastic deformation. This is not a true fracture but will heal with periosteal reaction.

Physeal Fractures

Fractures involving the growth plate constitute about 20% of all fractures in the skeletally immature patient. These fractures are twice as common in males. The peak incidence is 13–14 years in males and 11–12 years in females. The distal radius, distal tibia, and distal fibula are the most common locations.

Ligaments frequently insert onto epiphyses. Thus, traumatic forces to an extremity may be transmitted to the physis, which is not as biomechanically strong as the metaphysis; it may fracture with mechanisms of injury that may cause sprains in the adult. The growth plate is most susceptible to torsional and angular forces.

Physeal fractures are described using **Salter-Harris classification**, which allows for prognostic information regarding premature closure of the growth plate and poor functional outcomes. The higher the type number, the more likely the patient will have complications. There are five main groups (Fig. 198.2):

- Type I: transverse fracture through the physis; growth disturbance is unusual
- Type II: fracture through a portion of the physis and metaphysis; most common type of Salter-Harris fracture (75%)
- Type III: fracture through a portion of the physis and epiphysis into the joint that may result in complication because of intraarticular component and because of disruption of the growing or hypertrophic zone of the physis
- Type IV: fracture through the metaphysis, physis, and epiphysis with a high risk of complication
- Type V: a crush injury to the physis with a poor functional prognosis

Types I and II fractures can often be managed by closed reduction and do not require perfect alignment. A major exception is the type II fracture of the distal femur, which is associated with a poor outcome unless proper anatomic

FIGURE 198.2 The types of growth plate injury as classified by Salter and Harris. See text for descriptions of types I to V. (From Salter RB, Harris WR. Injuries involving the epiphyseal plate. *J Bone Joint Surg Am.* 1963;45:587–622.)

alignment is obtained. Types III and IV fractures require anatomic alignment for successful treatment. Type V fractures are rare and often result in premature closure of the physis.

MANAGEMENT OF PEDIATRIC FRACTURES

The majority of pediatric fractures can be managed with closed methods. Some fractures need closed reduction to improve alignment. Approximately 4% of pediatric fractures require internal fixation. Patients with open physes are more likely to require internal fixation if they have one of the following fractures:

- Displaced epiphyseal fractures
- Displaced intraarticular fractures
- Fractures in a child with multiple injuries
- Open fractures
- Unstable fractures

The goal of internal fixation is to improve and maintain anatomic alignment. This is usually done with Kirschner wires, Steinmann pins, and cortical screws with subsequent external immobilization in a cast until healing is satisfactory. After healing, the hardware is frequently removed to prevent incorporation into the callus and prevent physal damage.

External fixation without casting may be necessary for pelvic fractures causing hemodynamic instability. Fractures associated with soft tissue loss, burns, and neurovascular damage may benefit from external fixation.

SPECIAL CONCERNS

Remodeling

Fracture remodeling occurs because of a combination of periosteal resorption and new bone formation. Many pediatric fractures do not need perfect anatomic alignment for proper healing. Younger patients have greater potential for fracture remodeling. Fractures that occur in the metaphysis, near the growth plate, may undergo more remodeling. Fractures angulated in the plane of motion also remodel very well. Intraarticular fractures, angulated or displaced diaphyseal fractures, rotated fractures, and fracture deformity not in the plane of motion tend not to remodel as well.

Overgrowth

Overgrowth occurs in long bones as the result of increased blood flow associated with fracture healing. Femoral fractures

in children younger than 10 years of age will frequently overgrow 1–3 cm. This is the reason end-to-end alignment for femur and long-bone fractures may not be indicated. After 10 years of age, overgrowth is less of a problem, so end-to-end alignment is recommended.

Progressive Deformity

Fractures and injuries to the physis can result in premature closure. If it is a partial closure, the consequence may be an angular deformity. If it is a complete closure, limb shortening may occur. Commonly affected locations are the distal femur and the distal and proximal tibia.

Neurovascular Injury

Fractures and dislocations may damage adjacent blood vessels and nerves. The most common location is the distal humerus (**supracondylar fracture**) and the knee (dislocation and physal fracture). It is necessary to perform and document a careful neurovascular examination distal to the fracture (pulse, sensory, and motor function).

Compartment Syndrome

Compartment syndrome is an **orthopedic emergency** that results from hemorrhage and soft tissue swelling within the tight fascial compartments of an extremity. This can result in muscle ischemia and neurovascular compromise unless it is surgically decompressed. The most common sites are the lower leg (tibial fracture) and arm (supracondylar fracture).

Swollen and tight compartments and pain with passive stretching are present. Affected patients have severe pain not well controlled with prescribed medication and may eventually have decreased sensation in the dermatomes supplied by the nerves located in the compartment or decreased perfusion of the extremity if not promptly identified and treated. This can happen underneath a cast and may occur when a cast is applied too tightly; for this reason, many casts are split on each side (bivalved) in the post-reduction period to allow room for swelling. It is important to educate all patients with fractures on the signs of compartment syndrome and ensure that they realize it is an emergency.

Toddler's Fracture

This is an oblique fracture of the distal tibia without a fibula fracture. There is often no significant trauma. Patients are usually 1–3 years old but can be as old as 6 years and present with limping and pain with weight bearing. There may be minimal swelling and pain. Initial radiographs do not always show the fracture. If symptoms persist, a repeat x-ray in 7–10 days may be helpful; an oblique view on x-ray may also show the fracture.

Child Abuse

Child abuse must always be considered in the differential diagnosis of a child with fractures, especially in younger children (see [Chapter 22](#)). Common fracture patterns that should increase the index of suspicion include multiple fractures in different stages of radiographic healing, metaphyseal corner fractures (caused by twisting and shaking), fractures too severe for the history, or fractures in non-ambulatory infants. Although spiral fractures of long bones were historically considered pathognomonic for abuse, they may be seen in non-abuse situations.

When there is concern for child abuse, the child should have a full evaluation, which often includes admission to the hospital. A thorough and well-documented physical examination should focus on soft tissue injuries, the cranium, and a fundoscopic examination for retinal hemorrhages or detachment. A skeletal survey may be helpful in identifying other fractures. If suspicious fractures are identified, careful evaluation should be performed to rule out metabolic bone disease (e.g., osteogenesis imperfecta).

PEARLS FOR PRACTITIONERS

See Orthopedics: Pearls for Practitioners at the end of this section.

CHAPTER 199

Hip

The hip is a ball (femoral head) and socket (acetabulum) joint that is important for skeletal stability. The femoral head and acetabulum are interdependent for normal growth and development. The femoral neck and head, which contain the capital femoral epiphysis, are intraarticular. The blood supply to this region is unique because the blood vessels are extraosseous and lie on the surface of the femoral neck, entering the epiphysis peripherally. Thus, the blood supply to the femoral head is vulnerable to trauma, infection, and other causes that may increase intraarticular pressure. Damage to the blood supply can lead to **avascular necrosis** and permanent deformity of the hip.

DEVELOPMENTAL DYSPLASIA OF THE HIP

In developmental dysplasia of the hip (DDH), the hips may be dislocated or dislocatable at birth. The femoral head and acetabulum develop from the same mesenchymal cells; by

11 weeks of gestation, the hip joint is formed. There are two types of DDH: teratologic and typical. **Teratologic dislocations** occur early in utero and are usually associated with neuromuscular disorders (e.g., spina bifida, arthrogryposis). **Typical dislocations** occur in the neurologically normal infant and can occur before or after birth. The true incidence of DDH is unknown, but it may be as high as 1.5 cases per 1,000 infants.

Etiology

Newborn infants have ligamentous laxity that, if significant enough in the hip, may lead to spontaneous dislocation and reduction of the femoral head. Persistence of this spontaneous pattern can lead to pathologic changes, such as flattening of the acetabulum, muscle contractures that limit motion, and joint capsule tightening. The left hip is affected three times as often as the right hip, possibly because of in utero positioning.

Physiologic risk factors for DDH include a generalized ligamentous laxity, perhaps from maternal hormones that are associated with pelvic ligament relaxation (estrogen and relaxin). Female infants are at higher risk (9:1); family history is positive in 20% of all patients with DDH.

Other risk factors include breech presentation, firstborn child (60%), oligohydramnios, and intrauterine and postnatal infant positioning. In breech presentations, the fetal pelvis is situated in the maternal pelvis. This can increase hip flexion and limit overall fetal hip motion, causing further stretching of the already lax joint capsule and exposing the posterior aspect of the femoral head. The altered relationship between the acetabulum and femoral head causes abnormal acetabular development. Postnatal positioning of the hips in a tight swaddle with the hips adducted and extended can displace the hip joint.

Congenital muscular torticollis, metatarsus adductus, and clubfoot are associated with DDH. An infant with any of these three conditions should receive a careful examination of the hips.

Clinical Manifestations

Every newborn requires a screening physical examination for DDH; further evaluation through at least the first 18 months of life is part of the physical examination for toddlers. DDH evolves over time, so the examination may change as the patient ages. The examination starts with inspection for asymmetric thigh and gluteal folds with the hips and knees flexed. A relative shortening of the femur with asymmetric skinfolds is a positive **Galeazzi sign** and indicates DDH. Range of motion should be assessed with the pelvis stabilized and the child supine on the examining table, not in the parent's lap (Fig. 199.1). Hip abduction should easily reach or exceed 75 degrees, and hip adduction should reach 30 degrees. Limitations may indicate contractures associated with DDH, especially decreased abduction.

The **Barlow test** attempts to dislocate an unstable hip (Fig. 199.2). The examiner should stabilize the infant's pelvis with one hand and grasp the abducted and flexed thigh in the other hand. The hip should be flexed to 90 degrees. Next, begin to adduct the hip while applying a posterior force to the anterior hip. A hip that can be dislocated in this method is readily felt (clunk feeling) and is a positive test. It may reduce

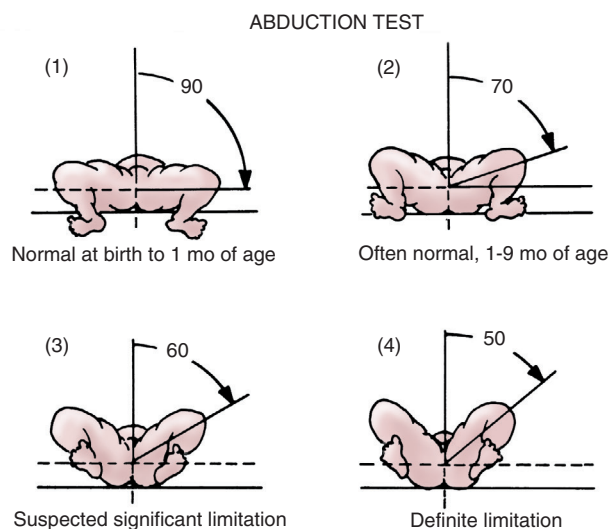

FIGURE 199.1 Hip abduction test. Place the infant supine, flex the hips 90 degrees, and fully abduct the hips. Although the normal abduction range is broad, hip disease should be suspected in any patient who lacks more than 30–45 degrees of abduction. (From Chung SMK. *Hip Disorders in Infants and Children*. Philadelphia: Lea & Febiger; 1981:69.)

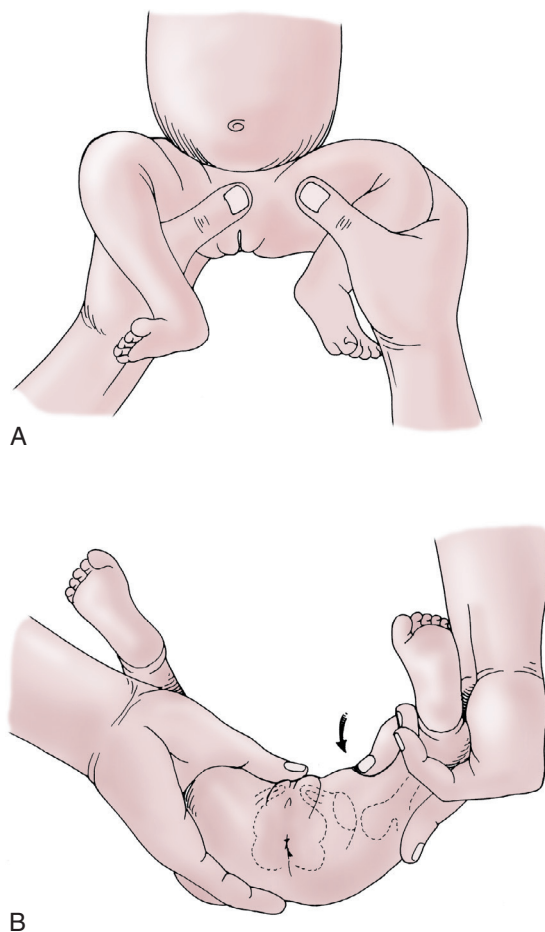

FIGURE 199.2 Barlow (dislocation) test. Reverse of Ortolani test. If the femoral head is in the acetabulum at the time of examination, the Barlow test is performed to discover any hip instability. (A) The infant's thigh is grasped as shown and adducted with gentle downward pressure. (B) Dislocation is palpable as the femoral head slips out of the acetabulum. Diagnosis is confirmed with the Ortolani test.

FIGURE 199.3 Ortolani (reduction) test. With the infant relaxed and content on a firm surface, the hips and knees are flexed to 90 degrees. The hips are examined one at a time. The examiner grasps the infant's thigh with the middle finger over the greater trochanter and lifts the thigh to bring the femoral head from its dislocated posterior position to opposite the acetabulum. Simultaneously the thigh is gently abducted, reducing the femoral head in the acetabulum. In a positive finding, the examiner senses reduction by a palpable, nearly audible *clunk*.

spontaneously once the posterior force is removed, or the examiner may need to perform the Ortolani test.

The **Ortolani test** attempts to reduce a dislocated hip (Fig. 199.3). The examiner should stabilize the pelvis and hold the leg in the same method as for the Barlow test. The infant's hip should be in 90 degrees of flexion. Abduct the hip while applying anterior pressure to the lateral thigh over the greater trochanter. A positive test is the palpable reduction of the dislocation, which may be felt (*clunk*). After 2 months of age, the hip may develop muscular contractures, preventing positive Ortolani tests.

These tests should be performed with only gentle force and done one hip at a time. The test may need to be repeated multiple times, as they can be difficult to interpret. A click, which is not pathologic, may occur from breaking the surface tension of the hip joint or snapping gluteal tendons.

Bilateral fixed dislocations present a diagnostic dilemma because of the symmetry on exam. The **Klisc test** is useful in this situation; it is done by placing the third finger over the greater trochanter and the index finger over the anterior superior iliac spine, then drawing an imaginary line between the two. The line should point to the umbilicus in a normal child. However, in a dislocated hip, the greater trochanter is elevated, which causes the line to project lower (between the umbilicus and pubis). This test is helpful in identifying bilateral DDH, which can otherwise be difficult to diagnose because of the symmetry found on examination.

Older children with unrecognized DDH may present with limping. A patient with increased lumbar lordosis and a waddling gait may have an unrecognized bilateral DDH.

Radiographic Evaluation

Ultrasound is used for initial evaluation of infants with DDH and should be done for females with a positive family history or breech presentation in both sexes. Ultrasound should be obtained after 6 weeks of age in the absence of abnormal examination findings to avoid confusion with physiologic laxity. Because the femoral head doesn't begin to ossify until 4–6 months of age, plain radiographs can be misleading until

patients are older. Plain radiographs are the imaging study of choice once the child reaches 6 months of age.

Treatment

The treatment of DDH is individualized and depends on the child's age at diagnosis. The goal of treatment is a stable reduction that results in normal growth and development of the hip. If DDH is suspected, the child should be sent to a pediatric orthopedic specialist.

The **Pavlik harness** is an effective treatment up to 6 months of age. It provides hip flexion to just over 90 degrees and limits adduction to no more than neutral. This positioning redirects the femoral head toward the acetabulum. The hip must be reduced within 1–2 weeks of beginning the Pavlik harness, although the infant will need more time in the device. The Pavlik harness is successful in treating approximately 95% of dysplastic or subluxated hips, and 80% successful for treatment of true dislocations. Persistently dislocated hips should not remain in a Pavlik harness for more than 2 weeks for fear of iatrogenic acetabular damage. Patients failing the Pavlik harness warrant treatment with a rigid abduction orthosis.

Children over 6 months or those who have failed nonoperative treatment should undergo closed reduction using a hip spica cast. This is done under general anesthesia; reduction is evaluated with an intraoperative arthrogram then confirmed by postoperative computed tomography (CT) or magnetic resonance imaging (MRI). If closed reduction fails, open reduction is indicated. Patients over 18 months of age may require a pelvic and femoral osteotomy.

Complications

The most important and severe complication of DDH is iatrogenic avascular necrosis of the femoral head. This can occur from excessive flexion or abduction during positioning of the Pavlik harness or hip spica cast. Infants under 6 months of age are at highest risk. Pressure ulcers can occur with prolonged casting. Redislocation or subluxation of the femoral head and residual acetabular dysplasia can occur.

TRANSIENT MONOARTICULAR SYNOVITIS

Transient synovitis, also known as **toxic synovitis**, is a common cause of limping in children. It is a diagnosis of exclusion because **septic arthritis** and **osteomyelitis** of the hip must be excluded (see [Chapters 117](#) and [118](#)).

Etiology and Epidemiology

The etiology of transient synovitis is uncertain; possible causes are viral illness and nonspecific inflammatory reactions. Approximately 70% of children diagnosed with transient synovitis have an upper respiratory tract viral infection in the preceding 7–14 days. Biopsies may reveal nonspecific synovial hypertrophy. Hip joint aspirations, when necessary, are negative for bacterial culture or signs of bacterial infection.

The mean age at onset is 6 years, with a range of 3–8 years. It is twice as common in male children.

Clinical Manifestations and Evaluation

An acute onset of pain in the groin/hip, anterior thigh, or knee occurs. Irritation of the obturator nerve can cause referred pain in the thigh and knee when the pathology is at the hip.

TABLE 199.1 Differences Between Bacterial Infection and Transient Synovitis

BACTERIAL INFECTION*	TRANSIENT SYNOVITIS
Elevated joint fluid WBC count	Joint fluid WBC count <15,000 cells/mm ³
Fever—temperature >38.5°C	Afebrile
Leukocytosis	Normal WBC count
ESR >20mm/hr	Normal ESR and CRP
Refusal to walk	Painful limp
Hip held in external rotation, abduction, and flexion	Hip held normally
Severe pain and tenderness	Moderate pain and mild tenderness

*Examples: Septic arthritis, osteomyelitis of hip. CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; WBC, white blood cell.

Patients with transient synovitis are often afebrile, walk with a painful limp, and have normal to minimally elevated white blood cell count (WBC), C-reactive protein (CRP), and erythrocyte sedimentation rate (ESR) compared with bacterial diseases of the hip ([Table 199.1](#)). [Table 197.3](#) lists the differential diagnosis of a limping child.

Anteroposterior and frog-leg radiographs of the hip are usually normal. Ultrasonography may reveal a joint effusion. Presence of an effusion along with refusal to bear weight, fever, or elevated WBC or ESR should prompt evaluation for septic arthritis with a joint aspiration that is sent for Gram stain, bacterial culture, and cell count; MRI imaging is also indicated under these circumstances.

Treatment

The mainstay of treatment is bed rest and minimal weight bearing until the pain resolves. Nonsteroidal antiinflammatory medication is usually sufficient to decrease pain. Limiting strenuous activity and exercise for 1–2 weeks following recovery is helpful. Follow-up will help ensure that there is no deterioration. Lack of improvement necessitates further evaluation for more serious disorders.

LEGG-CALVE-PERTHES DISEASE

Etiology and Epidemiology

Legg-Calve-Perthes disease (LCPD) is idiopathic **avascular necrosis (osteonecrosis)** of the capital epiphysis of the femoral head. The etiology is unclear, but it is likely caused by an interruption of the blood supply to the capital femoral epiphysis. There may be an associated hypercoagulability state (e.g., factor V Leiden mutation).

LCPD commonly presents in patients 3–12 years of age, with a mean age of 7 years. It is four to five times more common in boys.

Clinical Manifestations

Patients may not present for several weeks because of minimal discomfort; the classic presentation is a child with an atraumatic, painless limp. There may be mild or intermittent

hip/groin, anterior thigh, or knee pain. Decreased internal rotation and abduction with some discomfort, thigh muscle spasm, and anterior thigh muscular atrophy may be present. Patients have delayed bone age.

Radiologic Evaluation

Anteroposterior and frog-leg radiographs of both hips are usually adequate for diagnosis and management. It is necessary to document the extent of the disease and follow its progression. MRI is helpful to diagnose early LCPD.

Treatment and Prognosis

LCPD is usually a self-limited disorder that should be followed by a pediatric orthopedist. Initial treatment focuses on pain control and restoration of hip range of motion. The goal of treatment is prevention of complications, such as femoral head deformity and secondary osteoarthritis (OA).

Containment is important in treating LCPD; the femoral head is contained inside the acetabulum, which acts like a mold for the capital femoral epiphysis as it reossifies. Nonsurgical containment uses abduction casts and orthoses, whereas surgical containment is accomplished with osteotomies of the proximal femur and pelvis.

The short-term prognosis is determined by the magnitude of the femoral head deformity after healing has completed. It is improved by early diagnosis, good follow-up, and compliance with the treatment plan. Older children and children with a residual femoral head deformity are more likely to develop OA. The incidence of OA in patients who developed LCPD after 10 years of age is close to 100%; it is negligible in children with onset before 5 years of age. Patients between 6 and 9 years of age have a risk of OA of less than 40%.

SLIPPED CAPITAL FEMORAL EPIPHYSIS

Etiology and Epidemiology

Slipped capital femoral epiphysis (SCFE) is an adolescent hip disorder that is an orthopedic emergency. The incidence is 10.8 per 100,000, and it is slightly higher in males. Black and Hispanic populations are at higher risk. Approximately 20% of patients with SCFE will have bilateral involvement at presentation, and another 20–40% may progress to bilateral

involvement. The average age is 10–16 years, with a mean of 12 years in males and 11 years in females. Additional risk factors for SCFE include obesity, trisomy 21, and endocrine disorders (e.g., hypothyroid, pituitary tumor, growth hormone deficiency).

Classification

SCFE is classified as stable or unstable. Unstable patients refuse to ambulate even with crutches. Stable patients have an antalgic gait. SCFE can also be characterized as acute (symptoms <3 weeks) or chronic (symptoms >3 weeks). Acute-on-chronic SCFE is seen when more than 3 weeks of symptoms are accompanied by an acute exacerbation of pain and difficulty/inability to bear weight.

Clinical Manifestation

The presentation is variable, based on severity and type of slip. Patients will often report hip, thigh, or knee pain; limp or inability to ambulate; and decreased hip range of motion. There may or may not be a traumatic event. *Any knee pain mandates an examination of the hip, as hip pathology can cause referred pain to the anterior thigh and knee along the obturator nerve.* The patient usually holds the affected extremity in external rotation. As the hip is flexed, it will progressively externally rotate (obligate external rotation). There is usually a limitation of internal rotation, but there may also be a loss of flexion and abduction. If the patient can bear weight, it is typically an antalgic gait with the affected leg in external rotation. It is important to examine both hips given the high rate of bilateral involvement.

Radiologic Evaluation

Anteroposterior and frog-leg radiographs are indicated. Patients with known SCFE or with a high index of suspicion should not undergo frog-leg lateral radiographs. Instead, a cross-table lateral radiograph reduces the risk of iatrogenic progression. The earliest sign of SCFE is blurring or widening of the physis without slippage (**pre-slip condition**). Klein's line, a straight line drawn along the superior cortex of the femoral neck (Fig. 199.4), is helpful in assessing the anteroposterior

FIGURE 199.4 Slipped capital femoral epiphysis. (A) Anteroposterior radiograph reveals a widened physis (small arrows) and decreased height of the epiphysis on the left. In addition, there is loss (large arrow) of the Capener triangle (c) (normal double density of the medial metaphysis superimposed on the posterior acetabular rim on right) and an abnormal lateral femoral neck line (normal on right). (B) Frog, lateral view confirms the inferomedial position of the slipped capital femoral epiphysis. (From Blickman H. *Pediatric Radiology, the Requisites*. 2nd ed. St Louis: Mosby; 1998:244.)

radiograph for SCFE. The slippage can be classified radiographically as type I (0–33% displacement), type II (34–50%), or type III (>50%). The likelihood of complications increases with degree of displacement.

Treatment

Patients with SCFE should be immediately made non-weight bearing and referred to a pediatric orthopedist. The goal is to prevent further slippage, enhance physeal closure, and minimize complications, which is usually accomplished with internal fixation in situ with a single cannulated screw. More severe cases may require surgical hip dislocation and reduction to realign the epiphysis. There is controversy surrounding the prophylactic fixation of the non-affected side. Assessment for endocrine disorders is important, particularly in children outside the range of 10–16 years of age.

Complications

The two most serious complications of SCFE are **chondrolysis** and **avascular necrosis**. Chondrolysis is destruction of the articular cartilage. It is associated with more severe slips and with intraarticular penetration of operative hardware. This can lead to severe OA and disability. Avascular necrosis occurs when there is a disruption of the blood supply to the capital femoral epiphysis. This usually happens at the time of injury but may occur during forced manipulation or reduction of an unstable slip. Avascular necrosis may occur in up to 50% of unstable SCFEs and may lead to OA.

PEARLS FOR PRACTITIONERS

See *Orthopedics: Pearls for Practitioners* at the end of this section.

TABLE 200.1 Common Causes of In-Toeing and Out-Toeing

IN-TOEING	OUT-TOEING
Internal femoral torsion or anteversion	External femoral torsion or retroversion
Internal tibial torsion	External tibial torsion
Metatarsus adductus	Calcaneovalgus feet
Talipes equinovarus (clubfoot)	Hypermobility pes planus (flatfoot)
Developmental dysplasia	Slipped capital femoral epiphysis

In-Toeing

Femoral Anteversion

Internal femoral torsion or femoral anteversion is the most common cause of in-toeing in children 2 years or older (Table 200.1). The rotation is maximal between 4 and 6 years of age, and then decreases. It occurs twice as often in females. Many cases are associated with generalized ligamentous laxity. The etiology of femoral anteversion is likely congenital and is common in individuals with abnormal sitting habits such as *W-sitting*.

Clinical Manifestations. The family may give a history of *W-sitting*, and there may be a family history of similar concerns when the parents were younger. The child may have *kissing kneecaps* due to increased internal rotation of the femur. While walking, the entire leg will appear internally rotated, and with running, the child may appear to have an *egg-beater* gait where the lower legs circle laterally during the swing phase. The flexed hip will have internal rotation increased to 80–90 degrees (normal 60–70 degrees) with corresponding external rotation limitations to about 10 degrees. Radiographic evaluation is usually not indicated.

Internal Tibial Torsion

Internal (medial) tibial torsion is the most common cause of in-toeing in a child *younger* than 2 years old. When it is the result of in utero positioning, it may be associated with metatarsus adductus (see Chapter 201).

Clinical Manifestations. The child will present with a history of in-toeing. **Thigh-foot angle** (Fig. 200.1) is used to measure the degree of tibial torsion. The patient lies prone with the knee flexed to 90 degrees. The long axis of the foot is compared with the long axis of the thigh. An inwardly rotated foot represents internal tibial torsion and is measured as a negative angle. If follow-up is warranted, measurements should be taken at each visit.

Treatment of In-Toeing

It is critical to identify patients who have pathologic reasons for in-toeing and provide reassurance and follow-up to document improvement for patients with femoral anteversion and internal tibial torsion. Correction may not occur until 7–8 years of age, so it is important to inform families of the appropriate timeline. Braces (Denis Browne splint) do not improve or hasten outcomes. Fewer than 1% of all patients with in-toeing will need surgical intervention because of functional disability or cosmetic appearance.

CHAPTER 200

Lower Extremity and Knee

Torsional (in-toeing and out-toeing) and **angular** (physiologic bowlegs and knock knees) variations in the legs are common reasons that parents seek medical attention for their child. Most of these concerns are physiologic and resolve with normal growth. Understanding the natural history allows physicians to reassure the family and to identify non-physiologic disorders that necessitate further intervention. Physiologic disturbances are referred to as variations; pathologic disturbances are called deformities.

TORSIONAL VARIATIONS

The femur is internally rotated (anteversion) about 30 degrees at birth, decreasing to about 10 degrees at maturity. The tibia begins with up to 30 degrees of internal rotation at birth and can decrease to a mean of 15 degrees at maturity.

Torsional variations should not cause a limp or pain. Unilateral torsion raises the index of suspicion for a neurologic (hemiplegia) or neuromuscular disorder.

FIGURE 200.1 Thigh-foot angle measurement. The thigh-foot angle is useful for assessment of tibial torsion. The patient lies prone, with knees flexed to 90 degrees. The long axis of the thigh is compared to the long axis of the foot to determine the thigh-foot angle. Negative angles are associated with internal tibial torsion, and positive angles are associated with external tibial torsion.

Out-Toeing

External Tibial Torsion

External tibial torsion is the most common cause of out-toeing and may be associated with a calcaneovalgus foot (see Chapter 201). This is often related to in utero positioning. It may improve over time, but because the tibia rotates externally with age, external tibial torsion can worsen. It may be an etiologic factor for patellofemoral pain syndrome, especially when combined with femoral anteversion. Thigh-foot angle is used to measure external tibial torsion. Treatment is usually observation and reassurance, but patients with functional disability and cosmetic concerns may benefit from surgical intervention.

ANGULAR VARIATIONS

The majority of patients who present with knock-knees (**genu valgum**) or bowlegs (**genu varum**) are normal variations (Fig. 200.2). Infants are born with maximum genu varum. The lower extremity straightens out around 18 months of age, then typically progresses to maximal genu valgum around 4 years. Further growth and development usually end with the legs straight to a slight genu valgum in adulthood.

It is important to inquire about family history and assess overall height. A child who is 2 standard deviations below normal height with angular deformities may have skeletal dysplasia. Dietary history should be obtained, as rickets (see Chapter 31) may cause angular deformities. For genu valgum, measure the intermalleolar distance (distance between the two tibial medial malleoli with the knees touching). Measure intercondylar distance (the distance between the medial femoral condyles with the medial malleoli touching) for genu varum. These measurements should be followed to track improvement

FIGURE 200.2 Bowleg and knock-knee deformities. (A) Bowleg deformity. Bowlegs are referred to as varus angulation (**genu varum**) because the knees are tilted away from the midline of the body. (B) Knock-knee or valgus deformity of the knees. The knee is tilted toward the midline. (From Scoles P. *Pediatric Orthopedics in Clinical Practice*. Chicago: Year Book Medical Publishers; 1982:84.)

or progression. For accurate radiographic measurement, it is important to have the patella, not the feet, facing forward. In the child with external tibial torsion, having the feet facing forward gives the false appearance of bowlegs.

Genu Valgum

Physiologic knock-knees are most common in 3–4 year olds and usually resolve between 5 and 8 years of age. Patients with asymmetric genu valgum or severe deformity may have underlying disease causing their knock-knees (e.g., renal osteodysplasia, skeletal dysplasia). Treatment is based on reassurance; however, surgical intervention may be indicated for severe deformities, gait dysfunction, pain, and cosmesis.

Genu Varum

Physiologic bowlegs are most common in children older than 18 months with symmetric genu varum. This generally improves as the child approaches 2 years of age. The most important consideration for genu varum is differentiating between physiologic genu varum and Blount disease (tibia vara).

Tibia Vara (Blount Disease)

Tibia vara is the most common pathologic disorder associated with genu varum. It is characterized by abnormal growth of the medial aspect of the proximal tibial epiphysis, resulting in a progressive varus deformity. Blount disease is classified according to age of onset:

- Infantile (1–3 years)
- Juvenile (4–10 years)
- Adolescent (>11 years)

Late-onset Blount disease is less common than infantile disease. The etiology is unknown but thought to be secondary to

growth suppression from increased compressive forces across the medial knee. There may also be a genetic component.

Clinical Manifestations

Infantile tibia vara is more common in Blacks, females, and obese patients. Many patients are early walkers. Nearly 80% of infantile Blount disease is bilateral. It is usually painless. Patients will often have significant internal tibial torsion and lower extremity leg-length discrepancy (LLD). There may also be a palpable medial tibial metaphyseal beak.

Late-onset Blount disease is more common in Blacks, males, and markedly obese patients or patients with a rapid weight gain. Only 50% have bilateral involvement; adolescent Blount disease is usually unilateral. The initial presentation is often painful bowlegs. Late-onset Blount disease is usually not associated with palpable metaphyseal beaking, significant internal tibial torsion, or significant LLD.

Radiologic Evaluation

Weight-bearing anteroposterior and lateral radiographs of both legs are necessary for the diagnosis of tibia vara. Fragmentation, wedging, and metaphyseal beak deformities of the proximal medial tibia are the major radiologic features of infantile Blount disease. In late-onset Blount disease, the medial deformity may not be as readily noticeable. It can be very difficult to tell the difference between physiologic genu varum and infantile Blount disease on radiographs in patients younger than 2 years of age.

Treatment

Treatment of Blount disease should begin immediately. In children younger than 3 years of age with a mild deformity, orthotics to unload the medial compressive forces can be used, but compliance with this regimen can be difficult. Most cases of Blount disease require surgical management. Patients older than 4 years, patients with moderate to severe deformity, or patients with mild deformity that fail orthotic treatment should undergo surgical intervention. Proximal tibia/fibula osteotomy or distal femur osteotomy or eiphysiodesis (surgical physeal closure) are the usual procedures.

LEG-LENGTH DISCREPANCY

LLD may be due to differences in the femur, tibia, or both bones. The differential diagnosis is extensive, but common causes are listed in Table 200.2. The majority of the lower extremity growth comes from the distal femur (38%) and the proximal tibia (27%) physes.

Measuring Leg-Length Discrepancy

Clinical measurements using bony landmarks (anterior superior iliac spine to medial malleolus) are inaccurate. Measuring the LLD through imaging is more accurate. The **teloradiograph** is a single radiograph of both legs that can be done in very young children. Historically, in older patients, the **orthoradiograph** (three slightly overlapping exposures of the hips, knees, and ankles) or the **scanogram** (three standard radiographs of the hips, knees, and ankles with a ruler next to the extremities) have been used. **Computed tomography (CT) scanogram** is an accurate measure of LLD but also has the highest radiation exposure. Technology known as EOS/

TABLE 200.2 Common Causes of Leg-Length Discrepancy

Congenital	Coxa vara Clubfoot Hypoplasia
Developmental	Developmental dysplasia of the hip Legg-Calve-Perthes disease
Neuromuscular	Hemiplegia Cerebral palsy
Infectious	Physeal injury secondary to osteomyelitis
Tumors	Fibrous dysplasia Physeal injury secondary to irradiation or neoplastic infiltration Overgrowth
Trauma	Physeal injury with premature closure Malunion (shortening of extremity) Overgrowth of healing fracture
Syndromes	Neurofibromatosis Beckwith-Wiedemann syndrome Klippel-Trenaunay syndrome (KTS) PROS: <i>PIK3CA</i> related (vascular malformation) overgrowth spectrum including KTS

slot scanning is an extremely accurate, reduced-radiation alternative to CT scan. The measured discrepancy is followed using Moseley and Green-Anderson graphs.

Treatment

Treating LLD is complex. The physician must take into account the estimated adult height, discrepancy measurements, skeletal maturity, and psychologic aspects of the patient and family. LLD greater than 2 cm usually requires treatment. Shoe lifts can be used, but they often cause psychosocial problems and may make the shoes heavier and less stable. Surgical options include shortening of the longer extremity, lengthening of the shorter extremity, or a combination of the two procedures. Discrepancies less than 5 cm are treated by epiphysiodesis of the affected side, whereas discrepancies greater than 5 cm are treated by lengthening. Use of removable implants, which permit growth modulation without permanent impact on growth plates, has allowed for early and more accurate treatment.

KNEE

The knee joint is constrained by soft tissues rather than the usual geometric fit of articulating bones. The medial and lateral collateral ligaments as well as the anterior and posterior cruciate ligaments maintain knee stability. Weight and force transmission crosses articular cartilage and the meniscus. The patellofemoral joint is the extensor mechanism of the knee and a common site of injury in the adolescent (Fig. 200.3).

Knee effusion, or intraarticular swelling, is a common sign of injury. When the fluid accumulates rapidly after an injury, it is usually a hemarthrosis (blood in the joint) and may indicate a fracture, ligamentous disruption (often the anterior cruciate ligament [ACL]), or meniscus tear. Unexplained knee effusion may occur with arthritis (e.g., septic, Lyme disease, viral, postinfectious, juvenile idiopathic arthritis, systemic lupus erythematosus). It may also occur as a result of overactivity and hypermobile joint syndrome (ligamentous laxity). An

FIGURE 200.3 Diagram of the knee extensor mechanism. The major force exerted by the quadriceps muscle tends to pull the patella laterally out of the intercondylar sulcus. The vastus medialis muscle pulls medially to keep the patella centralized. (Modified from Smith JB. Knee problems in children. *Pediatr Clin North Am.* 1986;33:1439.)

aspiration and laboratory evaluation of unexplained effusion can help expedite a diagnosis.

Discoid Lateral Meniscus

Each meniscus is normally semilunar in shape; rarely the lateral meniscus will be disk shaped. A normal meniscus is attached at the periphery and glides anteriorly and posteriorly with knee motion. The discoid meniscus is less mobile and may tear more easily. When there is inadequate posterolateral attachment, the discoid meniscus can displace anteriorly with knee flexion, causing an audible click. Most commonly, patients are asymptomatic for years before presenting in late childhood or early adolescence after an injury with knee pain and swelling. The anteroposterior radiographs can show increased joint space and a squared-off appearance of the lateral femoral condyle; magnetic resonance imaging (MRI) can confirm the diagnosis. Treatment is usually arthroscopic excision of tears and reshaping of the meniscus.

Popliteal Cyst

A popliteal cyst (**Baker cyst**) is commonly seen in the middle childhood years. The cause is the distension of the gastrocnemius and semimembranous bursa along the posteromedial aspect of the knee by synovial fluid. In adults, Baker cysts are associated with meniscus tears. In childhood, the cysts are usually painless and benign. They often spontaneously resolve, but it may take several years. Knee radiographs are normal. The diagnosis can be confirmed by ultrasound or MRI. Treatment is reassurance; aspiration or surgical excision is indicated only for progressive cysts or cysts that cause disability.

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) occurs when an area of bone near the articular cartilage suffers a vascular insult and separates from the adjacent bone. It most commonly affects the lateral aspect of the medial femoral condyle. Patients may complain of knee pain or swelling. The lesions can be seen on

anteroposterior, lateral, and tunnel view radiographs. MRI can be helpful in determining the extent of the injury. In young patients with intact articular cartilage, the lesion will often revascularize and heal with crutch use and rest from activities. The healing process often takes several months and requires serial radiographic imaging to document healing. With increasing skeletal maturity, the risk for articular cartilage damage and separation of the bony fragment increases. Older patients are more likely to need surgical intervention. Patients of any age with a fracture through the articular cartilage are unlikely to improve without surgical intervention. Patients with OCD should be referred to a specialist.

Osgood-Schlatter Disease

Osgood-Schlatter disease is a common cause of knee pain at the insertion of the patellar tendon on the tibial tubercle. The stress from a contracting quadriceps muscle is transmitted through the developing tibial tubercle, which can cause microfractures and apophysitis. It usually occurs after a growth spurt and is more common in boys. The age at onset is typically 11 years for females and 13–14 years for males.

Patients will present with pain during and after activity and often have tenderness and local swelling over the tibial tubercle. Radiographs may be necessary to rule out infection, tumor, or avulsion fracture.

Rest and activity modification are paramount for treatment. Medication and icing may provide pain control. Treatment centers on rest from offending activity and rehabilitation exercises, particularly lower extremity flexibility and strengthening exercise programs. The course is usually benign, but symptoms frequently last 1–2 years. Complications can include bony enlargement of the tibial tubercle and avulsion fracture of the tibial tubercle.

Patellofemoral Disorders

The patellofemoral joint is a complex joint that depends on a balance between restraining ligaments of the patella, muscular forces around the knee, and alignment for normal function. The interior surface of the patella has a V-shaped bottom that moves through a matching femoral groove called the trochlea. When the knee is flexed, the patellar ligaments and the majority of the quadriceps muscular forces pull the patella laterally. The vastus medialis muscle counteracts the lateral motion, pulling the patella toward the midline. Problems with function of this joint usually result in anterior knee pain.

Idiopathic anterior knee pain is a common complaint in adolescents. It is particularly prevalent in adolescent female athletes. Previously, this was referred to as chondromalacia of the patella, but this term is incorrect as the joint surfaces of the patella are often normal. It is now known as **patellofemoral pain syndrome** (PFPS). The patient will present with anterior knee pain that worsens with activity, going up and down stairs, and soreness after sitting in one position for an extended time. There is usually no associated swelling. The patient may complain of a grinding sensation under the kneecap. Palpating and compressing the patellofemoral joint with the knee extended elicits pain. Patients often have weak hip musculature and/or poor lower extremity flexibility. Radiographs are rarely helpful but may be indicated to rule out other diagnoses such as OCD.

Treatment is focused on correcting the biomechanical problems that are causing the pain. A rehabilitation exercise program emphasizing hip girdle and vastus medialis strengthening with lower extremity stretching can be helpful. Activity modification, ice, and antiinflammatory medication may also be helpful. Persistent cases should be referred to an orthopedic or sports medicine specialist.

One must exclude **recurrent patellar subluxation and dislocation** when evaluating a patient with PFPS. Acute traumatic dislocation will usually cause significant pain, swelling, and disability. Patients with recurrent dislocations often have associated ligamentous laxity, genu valgum, and femoral anteversion. The initial treatment is nonoperative and may involve a brief period of immobilization, followed by an aggressive physical therapy program designed to strengthen the quadriceps and improve function of the patellofemoral joint. Continued subluxation or recurrent dislocation is failure of this treatment plan, and surgical repair is usually necessary.

Anterior Cruciate Ligament Tears

Increased sports participation and intensity of training have led to increased prevalence of pediatric ACL injuries, especially in females. The majority of ACL tears occur as noncontact injuries; patients often report feeling a pop followed by sudden onset of pain. Exam is significant for a positive anterior drawer sign or Lachman test. The Lachman test is performed when an anteriorly directed force is applied to the proximal tibia; a firm end-point is felt with an intact ACL, while a torn ACL will have an indistinct end-point. Radiographs should be obtained to rule out other injuries, but MRI is ultimately needed for diagnosis. Treatment varies based on the severity of the ACL tear and should be discussed with a pediatric orthopedic surgeon.

PEARLS FOR PRACTITIONERS

See *Orthopedics: Pearls for Practitioners* at the end of this section.

CHAPTER 201

Foot

In newborns and non-weight-bearing infants, the difference between posturing and deformity is important. Posturing is the habitual position in which the infant holds the foot; passive range of motion is normal. Deformity produces an appearance similar to posturing, but passive motion is restricted. Most pediatric foot disorders are painless. Foot pain is more common in older children (Table 201.1).

CLUBFOOT (TALIPES EQUINOVARUS)

A clubfoot deformity involves the entire leg, not just the foot. It affects 1 in 1,000 newborns and is bilateral in one-half of cases. The tarsals in the affected foot are hypoplastic; the talus is most affected. The muscles of the limb are hypoplastic because of the abnormal tarsal interactions, which leads to a generalized limb hypoplasia, mainly affecting and shortening the foot. There is usually atrophy of the calf musculature.

TABLE 201.1 Differential Diagnosis of Foot Pain by Age

AGE GROUP	DIAGNOSTIC CONSIDERATIONS
0–6 years	Poorly fitting shoes Fracture Puncture wound Foreign body Osteomyelitis Cellulitis Juvenile idiopathic arthritis Hair tourniquet Dactylitis Leukemia
6–12 years	Poorly fitting shoes Trauma (fracture, sprain) Juvenile idiopathic arthritis Puncture wound Sever disease Accessory tarsal navicular bone Hypermobility flatfoot Tarsal coalition Oncologic (Ewing sarcoma, leukemia)
12–18 years	Poorly fitting shoes Stress fracture Trauma (fracture, sprain) Foreign body Ingrown toenail Metatarsalgia Plantar fasciitis Achilles tendinopathy Accessory ossicles (navicular, os trigonum) Tarsal coalition Avascular necrosis of metatarsal (Freiberg infarction) or navicular (Kohler disease) Plantar warts

Etiology

Family history is important. Clubfoot can be congenital or teratologic. Although congenital clubfoot (75% of all cases) is usually an isolated abnormality, every infant should be assessed for developmental dysplasia of the hip. Teratologic clubfoot is associated with a neuromuscular disorder, such as myelomeningocele, arthrogyrosis, or other syndromes. Positional foot deformities that occur due to abnormal positioning in utero can be differentiated from clubfoot as they typically resolve without treatment in the early months of life.

Clinical Manifestations

The diagnosis is seldom confused with other disorders (Fig. 201.1). The presence of clubfoot should prompt a careful search for other abnormalities. The infant will have midfoot cavus, forefoot adduction, hindfoot equinus and varus, and varying degrees of rigidity. All are secondary to the abnormalities of the talonavicular joint. Calf atrophy and foot shortening are more noticeable in older children.

Radiologic Evaluation

In infants, radiographs and advanced imaging are rarely necessary for assessment because their tarsals have incomplete or absent ossification. The navicular ossifies at about 3 years of age for females and 4 years for males. As children age, radiographs can be used to follow the tibial calcaneal and lateral talocalcaneal angles and to assess navicular positioning.

FIGURE 201.1 Clinical picture demonstrating clubfoot deformity. (From Kliegman RM, Behrman RE, Jenson HB, et al. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:2778.)

Treatment

The goal of treatment is to correct the deformity and preserve mobility and function. The gold-standard for the treatment of clubfoot is the Ponseti method of serial casting. Treatment includes a percutaneous tenotomy of the Achilles tendon to help correct the equinus deformity near the end of casting. An abduction brace is initiated after casting and is an essential part of the treatment of clubfoot. Children who are unable to achieve good compliance with bracing recommendations demonstrate high rates of recurrence and need for further casting or surgery.

The two most common procedures performed for recurrent clubfoot include a repeat Achilles lengthening and a tibialis anterior tendon transfer. Rarely, more aggressive surgical procedures may need to be done. Complications of untreated clubfoot include severe disability. Complications of treated clubfoot include recurrence and stiffness.

METATARSUS ADDUCTUS

Metatarsus adductus is the most common foot disorder in infants. It is characterized by a convexity of the lateral foot (Fig. 201.2) and is caused by in utero positioning. It is bilateral in half of cases. Occurring equally in males and females, it is more common in first-born children because of the smaller primigravid uterus. Two percent of infants with metatarsus adductus have developmental dysplasia of the hip.

Clinical Manifestations

The forefoot is adducted and sometimes supinated, but the midfoot and hindfoot are normal. The lateral border of the foot is convex, while the medial border is concave. Normal ankle dorsiflexion and plantar flexion differentiate this deformity

FIGURE 201.2 Clinical picture of metatarsus adductus with a normal foot on opposite side. (From Kliegman RM, Behrman RE, Jenson HB, et al. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:2777.)

from clubfoot. With the midfoot and hindfoot stabilized, the deformity can be pushed beyond a neutral position (into abduction). Older children may present with an in-toeing gait.

Treatment

True metatarsus adductus resolves spontaneously over 90% of the time without treatment, so reassurance is all that is needed. Metatarsus adductus that does not improve within 2 years needs evaluation by a pediatric orthopedist. Persistent cases may benefit from serial casting or bracing, and, potentially, surgery. The deformity is not associated with a disability.

It is important to differentiate among metatarsus adductus, **metatarsus varus**, and **skewfoot**. Metatarsus varus looks like metatarsus adductus, but it is an uncommon rigid deformity that will need serial casting. Skewfoot is an uncommon deformity that is characterized by hindfoot plantar flexion, midfoot abduction, and forefoot adduction, giving the foot a Z or serpentine appearance. This needs to be managed very carefully with serial casting and surgery to help reduce the risk of disability in adulthood.

CALCANEVALGUS FOOT

The calcaneovalgus foot is another common foot disorder in newborns that is secondary to in utero positioning. It is characterized by a hyperdorsiflexed foot with forefoot abduction and heel valgus, but it is not a rigid deformity like congenital vertical talus. It is usually unilateral and is often associated with developmental dysplasia of the hip. Simulated weight-bearing radiographs may be necessary for questionable diagnoses. The calcaneovalgus foot will appear normal or have flexible hind-foot valgus.

This disorder requires no treatment beyond reassurance. Parents can be taught passive stretching exercises for their infant's foot. Most affected infants realign by 2 years. A calcaneovalgus foot can be associated with bowing of the tibia, which resolves spontaneously, but a leg length discrepancy may persist.

HYPERMOBILE PES PLANUS (FLEXIBLE FLATFOOT)

Hypermobile or pronated feet are seen in 15% of adults. The child with flatfeet is usually asymptomatic and has no activity limitations. Newborn and toddler flatfoot are the result of

ligamentous laxity and fat in the medial longitudinal arch. This is called **developmental flatfoot** and usually improves by 6 years of age. In older children, flatfoot is typically the result of generalized ligamentous laxity or tightness of the Achilles tendon, and there is often a positive family history. Hypermobile flatfoot can be thought of as a normal variant.

Clinical Manifestations

In the non-weight-bearing position, the older child with a flexible flatfoot will have a medial longitudinal arch. When weight bearing, the foot pronates (arch collapse) with varying degrees of hindfoot valgus. Subtalar motion (essentially all ankle motion except plantar and dorsiflexion) is normal and allows varus positioning of the hindfoot on heel rise. Any loss of subtalar motion may indicate a rigid flatfoot, which can be related to tarsal coalition or neuromuscular disorders (cerebral palsy). Radiographs of hypermobile flatfeet are usually not indicated.

Treatment

Hypermobile pes planus cannot be diagnosed until after 6 years of age; before that, it is developmental pes planus. Reassurance that this is a normal variant is very important. Patients who are symptomatic with activity may require education on proper, supportive footwear, orthotics/arch supports, and heel cord stretching.

TARSAL COALITION

Patients with tarsal coalition will usually present with a **rigid flatfoot** (loss of inversion and eversion at the subtalar joint). Coalition is produced by a congenital fusion or failure of segmentation of two or more tarsal bones. The attachment may be fibrous, cartilaginous, or osseous. Tarsal coalition can be unilateral or bilateral and will often become symptomatic in early adolescence with progressive ossification of the tarsal bones. The most common forms of tarsal coalition are **calcaneonavicular** and **talocalcaneal**.

Clinical Manifestations

Presentation will depend on the location of the coalition. Talocalcaneal coalitions will usually present with hindfoot pain, which may radiate laterally because of peroneal muscle spasm. Calcaneonavicular coalitions can also present with dorsolateral pain over the site of the coalition. Symptoms are exacerbated by sports, and young athletes can present with frequent ankle sprains. There is a familial component. Pes planus is usually present in both weight-bearing and non-weight-bearing positions. There is usually a loss of subtalar motion, and passive attempts at joint motion may produce pain.

Radiologic Evaluation

Anteroposterior, lateral, and oblique radiographs should be obtained, but they may not always clearly identify the disorder. The oblique view often identifies the calcaneonavicular coalition. Computed tomography (CT) is the gold standard for diagnosis of tarsal coalition. Even patients with obvious calcaneonavicular coalition on plain radiographs should have a CT scan to rule out a second coalition.

Treatment

Coalitions that are asymptomatic (the majority) do not need treatment. Nonoperative treatment for patients with pain consists of cast immobilization for a few weeks and foot orthotics. The symptoms will often return with a return to physical activities, necessitating surgery. Surgical excision of the coalition and soft tissue interposition to prevent reossification can be very effective.

CAVOVARUS FOOT

Cavovarus foot is characterized by increased height of the medial longitudinal arch (**high arch**) and frequently hindfoot varus. It can be classified as physiologic or neuromuscular. Most patients with physiologic cavovarus foot are asymptomatic and have a family history of similar foot deformity. A thorough neurologic examination on all patients with a cavovarus foot is important. Patients with painful high arches have a high risk of neurologic (tethered cord) and neuromuscular disease, and there is a strong association with **Charcot-Marie-Tooth disease**, a familial neuropathy. Unilateral cavovarus foot deformity should raise concern for an underlying intraspinal anomaly, while bilateral disease suggests an underlying muscle or neurologic cause. The underlying disorder should be treated first to halt progression. Nonoperative treatment using orthotics is usually not helpful. Progressive, symptomatic cavovarus foot will likely need surgical reconstruction.

IDIOPATHIC AVASCULAR NECROSIS

Kohler disease (tarsal navicular) and **Freiberg disease** (head of the second metatarsal) are uncommon and due to avascular necrosis. Patients will present with pain at the affected site with activity and weight bearing. Infection, fracture, and neoplasm should be excluded. Treatment consists of immobilization and activity restriction. The majority of patients will improve upon subsequent revascularization and re-formation of bone.

SEVER DISEASE (CALCANEAL APOPHYSITIS)

Sever disease is a common cause of heel pain among active young people. The mean age of presentation for girls is about 9 years of age and for boys about 11–12 years. Approximately 60% of cases are bilateral. Sever disease is caused by the forces of the calf musculature through the Achilles tendon at the calcaneal apophysis, causing microfracture. As the child ages and the apophysis closes, the pain disappears.

Clinical Manifestations

The common presentation is a young athlete who develops heel pain with activity that decreases with rest. Swelling is rare, but limping may be associated with Sever disease. The child will have pain on palpation of the posterior calcaneus and often tight heel cords. Radiographs are rarely indicated, but with persistent pain radiographs help to exclude infection or tumor.

Treatment

Activity modification, icing, and antiinflammatory medications can be helpful. A program designed to improve heel cord flexibility and overall ankle strength may decrease symptoms. Heel elevation using heel wedges or heel cups can be helpful.

	Fanconi pancytopenia
	Trisomy 21
	Trisomy 13
	Trisomy 18

TOE DEFORMITIES

Curly toes are the most common deformity of the lesser toes. The third, fourth, and fifth toes are most commonly affected. Curly toes are characterized by flexion at the proximal interphalangeal joint with lateral rotation of the toe. It is caused by contractures of the flexor digitorum brevis and longus tendons. Some curly toes will spontaneously resolve by 3–4 years of age. Persistent deformity may be treated by surgical tenotomy.

Polydactyly (extra toes) is usually found on the initial newborn physical examination. When the extra toe is adjacent to the fifth toe and attached by only a stalk of soft tissue or skin, simple ligation or amputation is effective. When the deformity involves the great toe or middle toes, or when the extra digit has cartilage or bone, delayed surgical intervention is indicated. **Syndactyly** (fusion of toes) is more common than polydactyly. It is usually a benign cosmetic problem. Both syndactyly and polydactyly may be associated with malformation syndromes (Table 201.2).

PEARLS FOR PRACTITIONERS

See *Orthopedics: Pearls for Practitioners* at the end of this section.

CHAPTER 202

Spine

SPINAL DEFORMITIES

A simplified classification of the common spinal abnormalities, scoliosis and kyphosis, is presented in Table 202.1.

Clinical Manifestations

Most patients will present for evaluation of an asymmetric spine, which is usually pain free. A complete physical examination is necessary for any patient with a spinal deformity because the deformity can indicate an underlying disease. The back is examined from behind (Fig. 202.1). First, the levelness of the pelvis is assessed. Leg-length discrepancy produces pelvic obliquity, which often results in **compensatory scoliosis**. When the pelvis is level, the spine is examined for symmetry

and spinal curvature with the patient upright. Cutaneous lesions (hemangioma, skin dimple, or hair tuft) should be noted. The spine should be palpated for areas of tenderness.

The patient is then asked to bend forward with the hands directed between the feet (**Adams forward bend test**). The examiner should inspect for asymmetry in the spine. The presence of a thoracic prominence in this position is the hallmark for scoliosis. The area opposite the thoracic prominence is usually depressed because of spinal rotation. Scoliosis is a rotational malalignment of one vertebra on another, resulting in rib elevation in the thoracic spine and paravertebral muscle elevation in the lumbar spine. With the patient still in the forward flexed position, inspection from the side can reveal the degree of roundback. A sharp forward angulation in the thoracolumbar region indicates a **kyphotic deformity**. It is important to examine the skin for café-au-lait spots

FIGURE 202.1 Clinical evaluation of a patient with scoliosis.

(neurofibromatosis), hairy patches, and nevi (**spinal dysraphism**). Abnormal extremities may indicate skeletal dysplasia, whereas heart murmurs can be associated with Marfan syndrome. It is essential to do a full neurologic examination to determine whether the scoliosis is idiopathic or secondary to an underlying neuromuscular disease, and to assess whether the scoliosis is producing any neurologic sequelae.

Radiologic Evaluation

Initial radiographs should include a posteroanterior and lateral standing film of the entire spine. The entire pelvis including iliac crests should be visible to help determine skeletal maturity. The degree of curvature is measured from the most tilted or end vertebra of the curve superiorly and inferiorly to determine the Cobb angle (Fig. 202.2). Newer imaging modalities

FIGURE 202.2 Cobb method of scoliotic curve measurement. Determine the end vertebrae of the curve: They are at the upper and lower limits of the curve and tilt most severely toward the concavity of the curve. Draw two perpendicular lines, one from the bottom of the lower body and one from the top of the upper body. Measure the angle formed. This is the accepted method of curve measurement according to the Scoliosis Research Society. Curves of 0–20 degrees are mild; 20–40 degrees, moderate; and greater than 40 degrees, severe.

such as slot scanning (e.g., EOS) provide the ability to obtain accurate measurements with much lower radiation.

SCOLIOSIS

Alterations in normal spinal alignment that occur in the antero-posterior plane are termed scoliosis. Most scoliotic deformities are idiopathic. Scoliosis may also be congenital, neuromuscular, or compensatory from a leg-length discrepancy.

Idiopathic Scoliosis

Etiology and Epidemiology

Idiopathic scoliosis is the most common form of scoliosis. It occurs in healthy, neurologically normal children. Approximately 20% of patients have a positive family history. The incidence is slightly higher in females than males, and the condition is more likely to progress and require treatment in females. There is some evidence that progressive scoliosis may have a genetic component as well.

Idiopathic scoliosis can be classified in three categories: **infantile** (birth–3 years), **juvenile** (4–10 years), and **adolescent** (>11 years). Idiopathic adolescent scoliosis is the most common cause (80%) of spinal deformity. The right thoracic curve is the most common pattern. Juvenile scoliosis is uncommon but may be underrepresented because many patients do not seek treatment until they are adolescents. In any patient younger than 11 years of age, there is a greater likelihood that scoliosis is not idiopathic.

Clinical Manifestations

Idiopathic scoliosis is a painless disorder 70% of the time. A patient with pain requires careful evaluation. Any patient presenting with a *left-sided thoracic curve* has a high incidence of intraspinal pathology (syrinx or tumor). Evaluation of the

spine with magnetic resonance imaging (MRI) is indicated in these cases.

Treatment

Treatment of idiopathic scoliosis is based on the skeletal maturity of the patient, the size of the curve, and whether the spinal curvature is progressive or nonprogressive. Initial treatment for scoliosis is likely observation and repeat radiographs to assess for progression. No treatment is indicated for nonprogressive deformities. The risk factors for curve progression include gender, curve location, and curve magnitude. Girls are five times more likely to progress than boys. Younger patients are more likely to progress than older patients.

Typically, curves under 25 degrees are observed. Progressive curves between 20 and 50 degrees in a skeletally immature patient are treated with bracing. A radiograph in the orthotic device is important to evaluate correction. Curves greater than 50 degrees usually require surgical intervention.

Congenital Scoliosis

Abnormalities of the vertebral formation during the first trimester may lead to structural deformities of the spine that are evident at birth or early childhood. Congenital scoliosis can be classified as follows (Fig. 202.3):

Partial or complete failure of vertebral formation (wedge vertebra or hemivertebra)

Partial or complete failure of segmentation (unsegmented bars)
Mixed

More than 60% of patients have other associated abnormalities, such as VACTERL association (vertebral defects, imperforate anus, cardiac anomalies, tracheoesophageal fistula, renal anomalies, limb abnormalities such as radial agenesis) or Klippel-Feil syndrome. Renal anomalies occur in 20–40% of children with congenital scoliosis, with renal agenesis being the most common; 6% of children have a silent, obstructive uropathy suggesting the need for evaluation with ultrasonography. Congenital heart disease occurs in about 12% of patients. **Spinal dysraphism** (tethered cord, intradural lipoma, syringomyelia, diplomyelia, and diastematomyelia) occurs in approximately 20% of children with congenital scoliosis. These disorders are frequently associated with cutaneous lesions on the back and abnormalities of the legs and feet (e.g., cavus foot, neurologic changes, calf atrophy). MRI is indicated in evaluation of spinal dysraphism.

The risk of spinal deformity progression in congenital scoliosis is variable and depends on the growth potential of the malformed vertebrae. A unilateral unsegmented bar typically progresses, but a block vertebra has little growth potential. About 75% of patients with congenital scoliosis will show some progression that continues until skeletal growth is complete, and about 50% will require some type of treatment. Progression can be expected during periods of rapid growth (<2 years and >10 years).

Treatment of congenital scoliosis hinges on early diagnosis and identification of progressive curves. Orthotic treatment is not helpful in congenital scoliosis. Early spinal surgery should be performed once progression has been documented. This can help prevent major deformities. Patients with large curves that cause thoracic insufficiency should undergo surgery immediately.

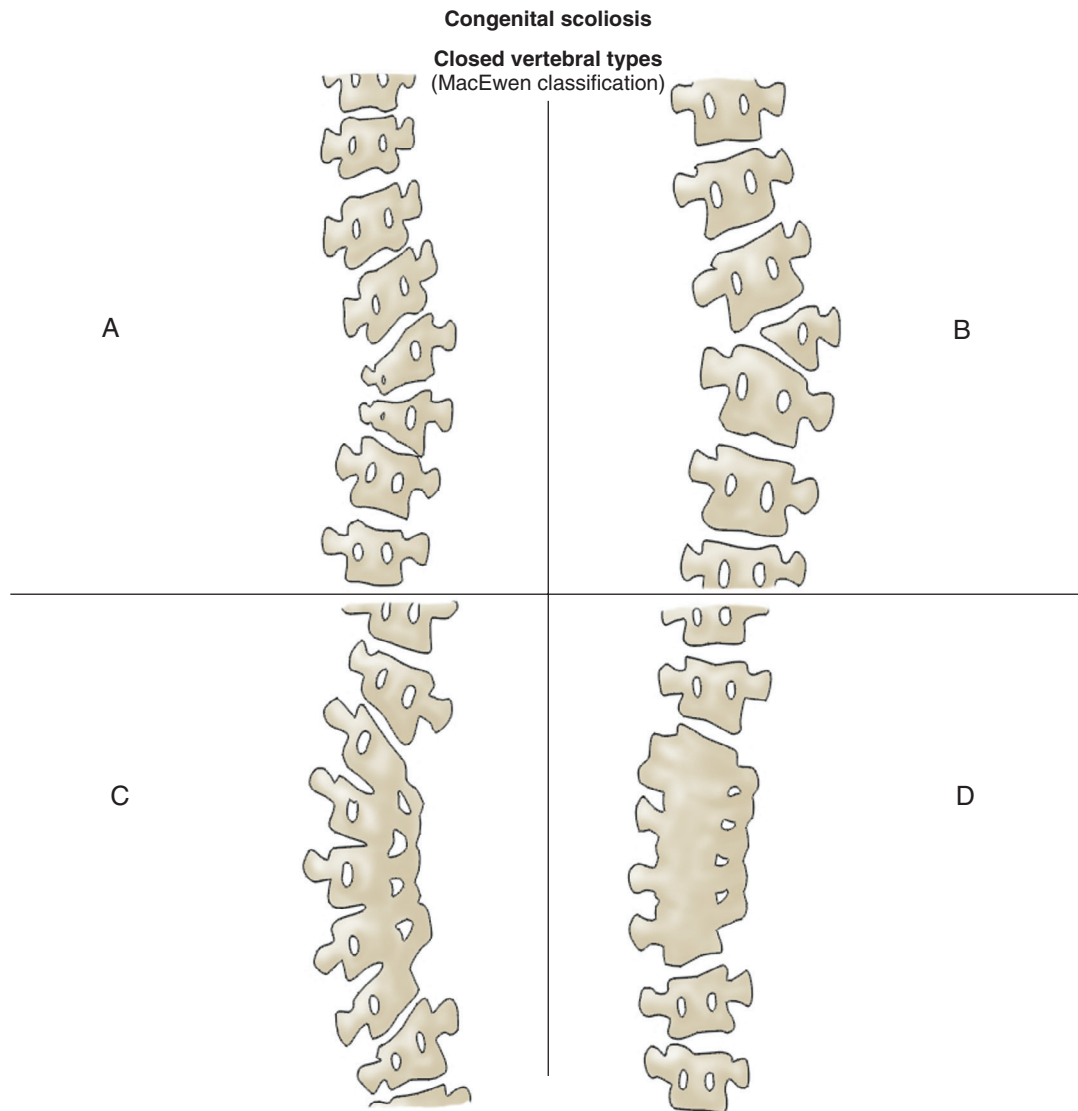

FIGURE 202.3 Types of closed vertebral and extravertebral spinal anomalies that result in congenital scoliosis. (A) Partial unilateral failure of formation (wedge vertebra). (B) Complete unilateral failure of formation (hemivertebra). (C) Unilateral failure of segmentation (congenital bar). (D) Bilateral failure of segmentation (block vertebra).

Neuromuscular Scoliosis

Progressive spinal deformity is a common and potentially serious problem associated with many neuromuscular disorders, such as cerebral palsy, Duchenne muscular dystrophy, spinal muscular atrophy, and spina bifida. Spinal alignment must be part of the routine examination for a patient with neuromuscular disease. Once scoliosis begins, progression is usually continuous. The magnitude of the deformity depends on the severity and pattern of weakness, whether the underlying disease process is progressive, and the amount of remaining musculoskeletal growth. Nonambulatory patients have a higher incidence of spinal deformity than ambulatory patients. In nonambulatory patients, the curves tend to be long and sweeping, produce pelvic obliquity, involve the cervical spine, and also produce restrictive lung disease. If the child cannot stand, then a supine or seated anteroposterior radiograph of the entire spine, rather than a standing posteroanterior view, is indicated.

The goal of **treatment** is to prevent progression and loss of function. Nonambulatory patients are more comfortable and independent when they can sit in a wheelchair without external support. Progressive curves can impair sitting balance, which affects quality of life. Pulmonary dysfunction may be seen as collapse of the spine, which causes the pelvis to impinge on the rib cage. Orthotic treatment is usually ineffective in neuromuscular scoliosis. Surgical intervention may be necessary with frequent fusion to the pelvis.

Compensatory Scoliosis

Adolescents with a leg-length discrepancy (see [Chapter 200](#)) may have a positive screening examination for scoliosis. Before correction of the pelvic obliquity, the spine curves in the same direction as the obliquity. However, with identification and correction of any pelvic obliquity, the curvature should resolve, and treatment should be directed at the leg-length

discrepancy. Thus, it is important to distinguish between a structural and compensatory spinal deformity.

KYPHOSIS

Kyphosis refers to a roundback deformity or to increased angulation of the thoracic or thoracolumbar spine in the sagittal plane. Kyphosis can be postural, structural (Scheuermann kyphosis), or congenital.

Postural Kyphosis

Postural kyphosis is secondary to poor posture. It is voluntarily corrected in the standing and prone positions. The patient may also have increased lumbar lordosis. Radiographs are usually unnecessary if the kyphosis fully corrects. If not, radiographs will reveal no vertebral abnormalities. Treatment, if needed, is aimed at improving the child's posture.

Scheuermann Kyphosis

Scheuermann disease is the second most common cause of pediatric spinal deformity. It occurs equally in males and females. The etiology is unknown, but there may be hereditary factors. Scheuermann kyphosis is differentiated from postural kyphosis on physical examination and by radiographs.

A patient with Scheuermann disease cannot correct the kyphosis with standing or lying prone. When viewed from the side in the forward flexed position, patients with Scheuermann disease will have an abrupt angulation in the mid to lower thoracic region (Fig. 202.4), and patients with postural kyphosis show a smooth, symmetric contour. In both conditions, lumbar lordosis is increased. However, half of patients with Scheuermann disease will have atypical back pain, especially with thoracolumbar kyphosis. The classic radiologic findings of Scheuermann kyphosis include the following:

- Narrowing of disk space

- Loss of anterior height of the involved vertebrae producing wedging of 5 degrees or more in at least three consecutive vertebrae

- Irregularities of the vertebral endplates

FIGURE 202.4 Note the sharp break in the contour of a child with kyphosis. (From Behrman RE. *Nelson Textbook of Pediatrics*. 14th ed. Philadelphia: WB Saunders; 1992.)

Schmorl nodes (disc material herniating into adjacent vertebral bodies)

Treatment of Scheuermann kyphosis is similar to idiopathic scoliosis. It is dependent on the degree of deformity, skeletal maturity, and the presence or absence of pain. Nonoperative treatment begins with bracing. Surgical fusion is done for patients who have completed growth, have a severe deformity, or have intractable pain.

Congenital Kyphosis

Congenital kyphosis is a failure of the formation of all or part of the vertebral body (with preservation of posterior elements) or failure of anterior segmentation of the spine, or both. Severe deformities are found at birth and tend to rapidly progress. Progression will not cease until the end of skeletal growth. A progressive spine deformity may result in neurologic deficit. Treatment of congenital kyphosis is often surgical.

TORTICOLLIS

Etiology and Epidemiology

Torticollis is usually first identified in newborns because of a head tilt. Torticollis is usually secondary to a shortened sternocleidomastoid muscle (muscular torticollis). This may result from in utero positioning or birth trauma. Acquired torticollis may be related to upper cervical spine abnormalities or central nervous system pathology (mass lesion). It can also occur in older children during a respiratory infection (potentially secondary to lymphadenitis) or local head or neck infection, and it may herald psychiatric diagnoses.

Clinical Manifestations and Evaluation

Infants with muscular torticollis have the ear tilted toward the clavicle on the ipsilateral side. The face will look upward toward the contralateral side. There may be a palpable swelling or fibrosis in the body of the sternocleidomastoid shortly after birth, which is often the precursor of a contracture. Congenital muscular torticollis is associated with skull and facial asymmetry (**plagiocephaly**) and developmental dysplasia of the hip.

After a thorough neurologic examination, anteroposterior and lateral radiographs should be obtained. The goal is to rule out a nonmuscular etiology. A computed tomography (CT) scan or MRI of the head and neck is necessary for persistent neck pain, neurologic symptoms, and persistent deformity.

Treatment

Treatment of muscular torticollis is aimed at increasing the range of motion of the neck and correcting the cosmetic deformity. Stretching exercises of the neck can be very beneficial for infants. Surgical management is indicated if patients do not improve with adequate stretching exercises in physical therapy. Postoperative physical therapy is needed to decrease the risk of recurrence. Treatment in patients with underlying disorders should target the disorder.

BACK PAIN IN CHILDREN

Etiology and Epidemiology

Back pain in the pediatric population should always be approached with care. In contrast to adults, in whom back pain is frequently mechanical or psychologic, back pain in children

may be the result of organic causes, especially in preadolescents. Back pain lasting longer than a week requires a detailed investigation. In the pediatric population, approximately 85% of children with back pain for greater than 2 months have a specific lesion: 33% are post-traumatic (spondylolysis, occult fracture), 33% are developmental (kyphosis, scoliosis), and 18% have an infection or tumor. In the remaining 15%, the diagnosis is undetermined.

Clinical Manifestations and Management

The history must include the onset and duration of symptoms. The location, character, and radiation of pain are important. Neurologic symptoms (muscle weakness, sensory changes, gait disturbance, and bowel or bladder dysfunction) must be reviewed. Medical history and family history should be obtained with a focus on back pain, rheumatologic disorders, and neoplastic processes. The review of systems should include detailed questions on overall health, fever, chills, recent weight loss, and recent illnesses. Physical examination should include a complete musculoskeletal and neurologic evaluation. Spinal alignment, range of motion, areas of tenderness, and muscle spasm should be noted. **Red flags** for childhood back pain include persistent or increasing pain, systemic findings (e.g., fever, weight loss), neurologic deficits, bowel or bladder dysfunction, young age (<4 years is strongly associated with tumor), night waking, pain that restricts activity, and a painful left thoracic spinal curvature.

Anteroposterior and lateral standing films of the entire spine with bilateral oblique views of the affected area should be obtained. Secondary imaging with CT scan or MRI are often necessary for diagnosis. MRI is very useful for suspected intraspinal pathology. Laboratory studies, such as a complete blood count, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and specialized testing for juvenile idiopathic arthritis and ankylosing spondylitis, may be indicated.

The differential diagnosis of pediatric back pain is extensive (Table 202.2). Treatment depends on the specific diagnosis. If serious pathology has been ruled out and no definite diagnosis has been established, an initial trial of physical therapy with close follow-up for reevaluation is recommended.

SPONDYLOLYSIS AND SPONDYLOLISTHESIS

Etiology and Epidemiology

Spondylolysis is a defect in the pars interarticularis. Spondylolisthesis refers to bilateral defects with anterior slippage of the superior vertebra on the inferior vertebra. The lesions are not present at birth, but about 5% of children will have the lesion by 6 years of age. It is most common in adolescent athletes, especially those involved in sports that involve repetitive back extension. Gymnasts, divers, football interior linemen (extension while blocking), soccer players (extension while shooting), and basketball players (extension while rebounding) are examples of athletes at higher risk. The most common location of spondylolysis is L5 on S1, followed by L4 on L5.

Spondylolisthesis is classified according to the degree of slippage:

- Grade 1: less than 25%
- Grade 2: 25–50%

TABLE 202.2 Differential Diagnosis of Back Pain

INFECTIOUS DISEASES

Spondylodiscitis (most common before the age of 6 yr)
Vertebral osteomyelitis (pyogenic or tuberculous)
Spinal epidural abscess
Pyelonephritis

RHEUMATOLOGIC DISEASES

Juvenile idiopathic arthritis
Reactive arthritis
Ankylosing spondylitis
Psoriatic arthritis
Inflammatory bowel disease

DEVELOPMENTAL DISEASES

Scheuermann kyphosis
Scoliosis (left thoracic)
Spondylolysis
Spondylolisthesis
Syringomyelia

TRAUMATIC AND MECHANICAL ABNORMALITIES

Hip and pelvic abnormalities (sacroiliac joint dysfunction)
Herniated nucleus pulposus (intervertebral disk)
Overuse injuries (facet syndrome)
Vertebral stress fractures (spondylolysis, spondylolisthesis)
Vertebral compression fracture (steroid, sickle cell anemia)
Upper cervical spine instability (atlantoaxial instability)

NEOPLASTIC DISEASES

Primary vertebral tumors (osteogenic sarcoma)
Metastatic tumor (neuroblastoma)
Primary spinal tumor (astrocytoma)
Bone marrow malignancy (leukemia, lymphoma)
Benign tumors (eosinophilic granuloma, osteoid osteoma)

OTHER

Conversion disorder
Juvenile osteoporosis
Pancreatitis

- Grade 3: 50–75%
- Grade 4: 75–99%
- Grade 5: complete displacement or spondyloptosis

Clinical Manifestations

Patients will often complain of an insidious onset of low back pain persisting over 2 weeks. The pain tends to worsen with activity and with extension of the back and improves with rest. There may be some radiation of pain to the buttocks. A loss of lumbar lordosis may occur due to muscular spasm. Pain is present with extension of lumbar spine and with palpation over the lesion. Patients with spondylolisthesis may have a palpable *step-off* at the lumbosacral area. A detailed neurologic examination should be done especially because spondylolisthesis can have nerve root involvement.

Radiologic Evaluation

Anteroposterior, lateral, and oblique radiographs of the spine should be obtained. The oblique views may show the classic *Scotty dog* findings associated with spondylolysis. The lateral view will allow measurement of spondylolisthesis.

Unfortunately, plain radiographs do not regularly reveal spondylolysis, so advanced imaging may be needed. The most helpful form of advanced imaging among CT, single photon emission CT (SPECT), or MRI continues to be debated. MRI should be considered in patients with neurologic deficits.

Treatment

Spondylolysis

Painful spondylolysis requires activity restriction. Bracing is controversial but may help with pain relief. Patients benefit from an aggressive physical therapy plan to improve lower extremity flexibility and increase core strength and spinal stability. There is evidence that some patients with an acute spondylolysis can achieve bony union and that these patients have a decreased incidence of low back pain and degenerative change in the low back as they age when compared with spondylolysis patients with nonunion. Rarely, surgery is indicated for intractable pain and disability.

Spondylolisthesis

Patients with spondylolisthesis require periodic evaluation for progression of their slippage. Treatment of spondylolisthesis is based on grading:

- Grade 1: Same treatment as spondylolysis. Failure of nonoperative management may lead to surgical fusion.
- Grade 2: Trial of nonoperative management, but if the slippage is progressing, surgical intervention may be needed. Any patient with neurologic symptoms requires surgical intervention.
- Grades 3–5: Spinal fusion is usually required to prevent further slippage or damage.

SPONDYLODISKITIS

Diskitis begins as an intervertebral disk space infection that may also produce adjacent vertebral osteomyelitis (see Chapter 117). The most common organism is *Staphylococcus aureus*. The infection can occur at any age but is more common in patients under 6 years of age.

Clinical Manifestations

Children may present with back pain, abdominal pain, pelvic pain, irritability, and refusal to walk or sit. Fever is an inconsistent symptom. The child typically holds the spine in a straight or stiff position, generally has a loss of lumbar lordosis due to paravertebral muscular spasm, and refuses to flex the lumbar spine. The white blood cell count is normal or elevated; the ESR and CRP are usually high.

Radiologic Evaluation

Radiographic findings vary according to the duration of symptoms before diagnosis. Anteroposterior, lateral, and oblique radiographs of the lumbar or thoracic spine will typically show a narrow disk space with irregularity of the adjacent vertebral body end plates. In early cases, MRI may be helpful because they will be positive before findings are noticeable on plain radiographs. MRI can define the extent of disc space, vertebral bone, or epidural space involvement.

Treatment

Intravenous antibiotic therapy is the mainstay of treatment. Blood cultures may occasionally be positive and identify the infectious agent. Aspiration and needle biopsy are reserved for children who are not responding to empiric antibiotic treatment. Symptoms should resolve rapidly with antibiotics, but patients will still require a total of 4–6 weeks of treatment. Conversion from intravenous to oral antibiotics should be considered once the patient shows clear clinical improvement. Pain control can be obtained with medications and temporary orthotic immobilization of the back.

PEARLS FOR PRACTITIONERS

See *Orthopedics: Pearls for Practitioners* at the end of this section.

CHAPTER 203

Upper Extremity

SHOULDER

The shoulder actually comprises four joints:

- Glenohumeral joint (commonly referred to as the shoulder joint)
- Acromioclavicular joint
- Sternoclavicular joint
- Scapulothoracic joint

The glenohumeral joint has minimal geometric stability because the relatively small glenoid fossa articulates with the proportionately larger head of the humerus. The low level of intrinsic stability allows for a large range of motion. The rotator cuff muscles help give the glenohumeral joint more stability, but they need normal contact of the glenohumeral joint to be successful. The scapulothoracic movement also expands the range of motion of the shoulder, but like the glenohumeral joint, it requires strong, coordinated musculature to function efficiently.

Sprengel Deformity

Sprengel deformity is the congenital elevation of the scapula. There are varying degrees of severity; it is usually unilateral. There is restricted scapulothoracic motion (especially with abduction), so most of the shoulder motion is through the glenohumeral joint. There is usually associated hypoplasia of the periscapular muscles. Webbing of the neck and low posterior hairline can be associated problems. There is an association with congenital syndromes, such as Klippel-Feil anomaly, so a thorough history and examination are necessary. Mild forms with a cosmetic deformity and mild loss of shoulder motion do not need surgical correction. Severe forms may have a bony connection (omovertebral) between the scapula and lower cervical spine. Moderate and severe forms may need surgical repositioning of the scapula in early childhood to improve cosmesis and function.

Clavicular Fractures

Clavicle fractures may be seen in neonates as a result of birth injury (see [Chapter 58](#)) or in childhood with falls or direct

trauma to the clavicle. Fractures most commonly occur in the distal third of the clavicle. In the case of a posteriorly displaced medial clavicle fracture, computed tomography (CT) may be necessary to evaluate great vessels. A simple sling for 3–6 weeks is commonly effective. Surgery may be indicated for older adolescents with significant shortening or displacement, skin tenting, or neurovascular compromise.

Brachial Plexus Injuries

Obstetric brachial plexus palsy is discussed in Section 11. **Brachial plexopathy** is an athletic injury, commonly referred to as a **stinger** or **burner**. The symptoms are often likened to a *dead arm*. There is pain (often burning), weakness, and numbness in a single upper extremity. There are three mechanisms of injury:

1. Traction caused by lateral flexion of the neck away from the involved upper extremity
2. Direct impact to the brachial plexus at Erb point
3. Compression caused by neck extension and rotation toward the involved extremity

Symptoms are always unilateral and should resolve within 15 minutes. It is paramount to assess the *cervical spine* for serious injury. Bilateral symptoms, lower extremity symptoms, persistent symptoms, or recurrent injury are all signs of more serious injury requiring a more extensive work-up. Athletes may return to activity if there are no red flags on history or physical examination and the athlete has full pain-free range of motion and strength in the neck and affected extremity.

Glenohumeral Dislocation

Shoulder dislocation is uncommon in childhood but becomes more frequent in adolescence. The younger the patient is at presentation, the more likely it is that the patient will have recurrent dislocation. Anterior dislocation is the most common. If assessment of the neurovascular status of the affected extremity reveals any compromise, urgent reduction is needed to prevent further complications. Patients will need radiographs to assess for fractures of the glenoid (Bankhart lesion) and humeral head (Hill-Sachs lesion). Most patients will require a brief period of protection in a sling or shoulder immobilizer, as well as pain control. As symptoms resolve, a gentle range-of-motion program, followed by an aggressive strengthening program, should be done. Recurrence rate may be nearly 90% for contact sport athletes, so there is controversy surrounding early surgical intervention at the first dislocation; surgical intervention is needed for repeat dislocations.

Overuse Injuries

The incidence of overuse injuries is increasing because of increased year-round athletic participation as well as higher intensity levels during training. Soft tissue overuse injuries are inflammatory responses in tendons and bursae that are subjected to repetitive motions and trauma (e.g., rotator cuff tendinitis in swimmers). These injuries are more common in adolescents than younger children. Bony injury such as stress injury, physeal fracture, and apophysitis must be ruled out before making the diagnosis of a soft tissue overuse injury.

Overuse injuries in the shoulder can be provoked by joint laxity.

Patients often present with discomfort that worsens with activity over the affected area. Physical examination usually reveals tenderness to palpation and often weakness of the associated muscles due to pain. It is important to assess for glenohumeral stability. Radiographs may be indicated for acute trauma or when symptoms are not improving. Treatment consists of activity modification, icing, antiinflammatory medication, and a physical therapy program aimed at improving strength, flexibility, and posture.

Proximal Humeral Epiphysiolysis

Proximal humeral epiphysiolysis, often referred to as *Little Leaguer's shoulder*, commonly occurs in 9–14-year-olds who participate in overhead (e.g., tennis, volleyball) and throwing sports, particularly baseball pitchers. It is a stress injury that can progress to a fracture (epiphysiolysis) of the proximal humeral physis. Most patients present with pain during or after throwing. There may be tenderness to palpation over the proximal humerus; if the athlete has been resting for a few days, examination may be normal. Radiographs should include comparison views to assess the physis. There may be widening of the proximal humeral physis in the affected arm, but the imaging may be normal. Treatment is rest from the offending activity (typically for 6–8 weeks), followed by a rehabilitation program designed to improve strength in the shoulder girdle. Pitchers should also be encouraged to follow youth pitching guidelines published by Little League baseball.

ELBOW

The elbow consists of three articulations:

- Ulnar-humeral joint
- Radial-humeral joint
- Proximal radioulnar joint

Collectively, these joints produce a hinge-type joint that allows for supination (palm up) and pronation (palm down) positioning of the hand. The elbow has excellent bony stability, and the musculature around the elbow primarily produces flexion and extension.

Radial Head Subluxation

Radial head subluxation is more commonly known as **nursemaid's elbow**. Because the radial head is not as bulbous in infants and young children, the annular ligament that passes around it can partially slip off the radial head with traction forces (Fig. 203.1). The subluxation is usually caused by a quick pull on the extended elbow when a child is forcefully lifted by the hand or when the child falls while holding hands with an adult. After a subluxation, the child usually holds the hand in a pronated position and will refuse to use the hand or move the elbow. Moving the hand into the supinated position while applying pressure to the radial head will usually reduce the injury; hyperpronation is another effective reduction method. Usually radiographs are not necessary unless reduction cannot be obtained or there is concern for fracture (swelling and

FIGURE 203.1 Nursemaid's elbow. The annular ligament is torn when the arm is pulled. The radial head moves distally, and when traction is discontinued, the ligament is carried into the joint. (From Rang M. *Children's Fractures*. Philadelphia: JB Lippincott; 1974:121.)

bruising). Once the injury is reduced, the child will begin using the arm again without complaint. Parents should be educated about the mechanism of injury and encouraged to avoid that position. There is a high rate of recurrence for this injury. The problem generally resolves with maturation, but some children with high recurrence rates may benefit from casting or, rarely, surgical intervention.

Panner Disease

Panner disease is an osteochondrosis of the capitellum (lateral portion of distal humeral epiphysis) that occurs spontaneously in late childhood, usually prior to 10 years of age. Clinical features include elbow pain, decreased range of motion, and tenderness to palpation over the capitellum. Radiographs reveal an irregular epiphysis at the capitellum. Treatment is activity restriction and follow-up radiographs to demonstrate spontaneous reossification of the capitellum over several months. There is usually no need for further treatment or imaging studies. This is not to be confused with osteochondritis dissecans of the capitellum, which usually will occur in adolescents involved with throwing sports.

Throwing Injuries in the Elbow

The elbow is especially vulnerable to throwing injuries in the skeletally immature athlete. These occur from excessive and repetitive tension forces across the radial aspect of the elbow and compression forces across the lateral aspect of the elbow. These injuries are commonly known as *Little Leaguer's elbow*.

Although this injury is most common in baseball players, it also occurs in football quarterbacks and tennis players. Patients will usually complain of pain over the medial elbow with throwing that may last for a few days afterward. There may be associated swelling and lateral or posterior elbow pain. Radiation of pain may be secondary to ulnar neuropathy. There is often a flexion contracture of the elbow when compared to the opposite side. Palpation often reveals bony tenderness. Ulnar (medial) collateral ligament stability should be assessed. Radiographs should include the contralateral elbow

for comparison. Radiographic findings in Little Leaguer's elbow can vary and may include normal anatomy, medial humeral epicondyle apophyseal avulsion fracture, osteochondritis dissecans of the capitellum, radial head abnormalities, and foreign bodies in the elbow. Magnetic resonance imaging may be helpful.

Treatment depends on the underlying diagnosis but always includes pain control and rest from activity. *Classic Little Leaguer's elbow* refers to medial humeral epicondyle apophysitis. These athletes benefit from rest, ice, antiinflammatory medication, and a physical therapy program aimed at upper body strengthening. Throwing mechanics and the pitching guidelines published by Little League Baseball/Softball should be reviewed with these players. Switching players to a lower throwing position (e.g., first base) after rehabilitation, to avoid pitching for the remainder of the season, is often recommended.

WRIST AND HAND

Multiple small joints, a delicately balanced intrinsic muscle system, a powerful extrinsic muscle system, dense sensory innervation, and specialized skin combine to make the hand a highly mobile and sensitive yet powerful anatomic part. The extrinsic muscles originate in the forearm, and the intrinsic muscles are located in the hand and coordinate small, delicate movements. The movements of opening the hand, extending and spreading the fingers, and then clenching the hand into a fist require coordinated function of the intrinsic and extrinsic muscles. Tenderness of direct palpation of the bones raises the concern for fracture. **Scaphoid fracture** is the most common carpal bone fracture in the pediatric population and can be difficult to visualize on radiographs. Treatment of nondisplaced fractures requires immobilization in a thumb spica cast, whereas displaced fractures require surgical intervention. **Salter-Harris fractures of the distal radius** are also very common. In young gymnasts, there is increased risk for injury at the distal radial physis from repetitive impact and upper extremity weight bearing. This overuse injury is commonly called **gymnast's wrist** and requires absolute rest from impact and weight bearing to prevent premature closure of the growth plate.

Ganglion cysts are synovial fluid-filled cysts about the wrist. The most common location is the dorsum of the wrist near the radiocarpal joint, followed by the volar radial aspect of the wrist. The defect is in the joint capsule, which allows synovial fluid into the soft tissues with wrist use, where it can become walled off with fibrous tissue. Often, in skeletally immature patients, the process is benign and disappears over time. Large ganglion cysts or cysts that are painful and interfere with function may require more aggressive management. Aspiration and steroid injection into the cyst may be helpful, but many will recur. Surgical excision will remove the tract that attaches to the wrist joint, so it is usually curative.

Finger Abnormalities

Polydactyly (extra digits) occurs in simple and complex variants (see [Table 201.2](#)). Skin tags and digit remnants that occur near the metacarpophalangeal joint of the fifth digit and thumb

that do not have palpable bones or possess voluntary motion are categorized as simple. These may be excised or ligated in the nursery. Complex deformities should be referred to a pediatric hand surgeon for amputation. **Syndactyly** (fused digits) is concerning because of the possibility of shared structures and the tethering effects on bone growth (see [Table 201.2](#)). All patients with syndactyly should be referred for treatment options.

Trigger thumb and **trigger finger** are secondary to isolated thickening of the flexor tendons. As the thickened nodule enlarges, it may catch in a bent position, then snap or *trigger* straight as it passes through the first pulley that anchors the tendon. Ultimately, as it enlarges, it cannot pass through at all and produces a flexion deformity at the interphalangeal joints. The nodule may be palpable near the metacarpophalangeal joint. Children with these issues should be referred for surgical correction.

PEARLS FOR PRACTITIONERS

See *Orthopedics: Pearls for Practitioners* at the end of this section.

CHAPTER 204

Benign Bone Tumors and Cystic Lesions

Benign bone tumors and cystic lesions are common in childhood. Some represent fibrous dysplasia. Others are benign bone cysts (unicameral) or benign bone tumors (osteoid osteoma). Subacute osteomyelitis (**Brodie abscess**) and eosinophilic granulomas are lesions not associated with abnormal bone or cartilage growth. Some of these lesions can produce pain, limp, and pathologic fractures. Others can be incidental findings on radiographs. The prognosis is usually excellent. A brief differential diagnosis of bone tumors and their management is listed in Table 204.1. Malignant bone tumors are discussed in Section 21.

PEARLS FOR PRACTITIONERS

See *Orthopedics: Pearls for Practitioners* at the end of this section.

DISEASE	CHARACTERISTICS	RADIOGRAPHIC FINDINGS	TREATMENT	PROGNOSIS
Osteochondroma (osteocartilaginous exostosis)	Common; distal metaphysis of femur, proximal humerus, proximal tibia; painless, hard, nontender mass	Bony outgrowth, sessile or pedunculated	Excision, if symptomatic	Excellent; malignant transformation rare
Multiple hereditary exostoses	Osteochondroma of long bones; bone growth disturbances	As above	As above	Recurrences common
Osteoid osteoma	Pain relieved by NSAIDs; femur and tibia; found predominantly in boys	Dense sclerosis surrounds small radiolucent nidus, <1 cm	As above. Radiofrequency ablation may also be used	Excellent
Osteoblastoma (giant osteoid osteoma)	As above, but more destructive	Osteolytic component; size >1 cm	Excision or curettage	Excellent
Enchondroma	Tubular bones of hands and feet; pathologic fractures, swollen bone; Ollier disease if multiple lesions are present	Radiolucent diaphyseal or metaphyseal lesion; may calcify	Excision or curettage if symptomatic or large	Excellent; malignant transformation rare
Nonossifying fibroma	Silent; rare pathologic fracture; late childhood, adolescence	Incidental radiographic finding; thin sclerotic border, radiolucent lesion	None or curettage with fractures	Excellent; heals spontaneously
Eosinophilic granuloma	Age 5–10 yr; skull, jaw, long bones; pathologic fracture; pain	Small, radiolucent without reactive bone; punched-out lytic lesion	Biopsy, excision rare; irradiation	Excellent; may heal spontaneously
Brodie abscess	Insidious local pain; limp; suspected as malignancy	Circumscribed metaphyseal osteomyelitis; lytic lesions with sclerotic rim	Surgical debridement; antibiotics	Excellent
Unicameral bone cyst (simple bone cyst)	Metaphysis of long bone (femur, humerus); pain, pathologic fracture	Cyst in medullary canal, expands cortex; fluid-filled unilocular or multilocular cavity	Curettage; steroid injection into lesion	Recurrence in 50%; some heal spontaneously
Aneurysmal bone cyst	As above; contains blood, fibrous tissue	Expands beyond metaphyseal cartilage	Curettage, bone graft	Recurrence in 20%

NSAIDs, Nonsteroidal antiinflammatory drugs.

PEARLS FOR PRACTITIONERS

CHAPTER 197

Orthopedics Assessment

- Orthopedic rough guide to developmental milestones
 - Sit independently at 6 months
 - Pull to stand at 10 months
 - Cruising at 12 months
 - Walk at 18 months
- Lower extremity angular profile
 - Genu varum (bowlegs) at birth and begin to straighten out by 18 months
 - Genu valgum (knock knees)—maximum at 4 years old and resolves by 5–8 years of age
 - Pathologic genu verum: Blount disease (tibia vara) and rickets
- The limping child differential diagnosis
 - Painful
 - Septic arthritis, osteomyelitis, diskitis
 - Transient monoarticular synovitis
 - Toddler's fracture or trauma
 - Malignancy
 - Rheumatologic disorders in older children
 - Acute slipped capital femoral epiphysis (SCFE) in adolescents
 - Painless
 - Development dysplasia of the hip
 - Neuromuscular disorder
 - Leg length inequality
 - Legg-Calve-Perthes disease in older children
 - Muscular dystrophy in older children
 - Chronic, stable SCFE in adolescents

CHAPTER 198

Fractures

- Features unique to pediatric skeleton
 - Bone has higher collagen content (tend to undergo plastic deformation before complete fracture)
 - Thicker periosteum (aids healing and can stabilize fracture after reduction)
 - Ability to remodel some deformity

- Possible overgrowth following long-bone fractures (especially femur)
- Salter-Harris (physeal) fracture types
 - I—transverse through physis
 - II—through physis into metaphysis
 - III—through physis into epiphysis (joint)
 - IV—through both metaphysis and epiphysis
 - V—crush to the physis
- Signs/symptoms of acute compartment syndrome producing neurovascular injury:
 - Early findings: Pain out of proportion to the injury, pain with passive stretch or muscle contraction
 - Later findings: pallor, pulselessness, paresthesia, poikilothermy (cold)
 - Most common sites at risk: supracondylar humerus and tibia fractures

CHAPTER 199

Hip

- Development dysplasia of the hip
 - Risk factors: first born, female, breech, family history, oligohydramnios
 - Associated lesions include congenital torticollis, metatarsus adductus, and clubfoot
 - Ortolani test: reduces dislocated hip
 - Barlow test: dislocates unstable hip
 - Imaging: Ultrasound <6 months of age, x-ray >6 months of age
 - Treatment: Pavlik harness <6 months of age, spica cast or surgery >6 months or failed Pavlik harness
- Legg-Calve-Perthes disease
 - Avascular necrosis of the femoral head
 - Classic presentation is painless limp in elementary school-aged boy
 - Mean age: 7 years
 - Delayed treatment increases risk of arthritis
- Transient monoarticular synovitis often follows a recent viral illness; typically have no fever and normal to minimally elevated white blood cell (WBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP).
- Septic arthritis has elevated WBC, ESR, CRP, and elevated joint fluid cell count. Patients are usually febrile and hold hip in flexion and external rotation.

- Slipped capital femoral epiphysis
 - Mean age is 12 years in males and 11 years in females.
 - Risk factors: adolescent, obese, trisomy 21, endocrine disorder.
 - May present as isolated hip or knee pain.
 - Hip held externally rotated, especially when moved into hip flexion.
 - Treat as orthopedic emergency—non-weight bearing and immediate referral.

CHAPTER 200

Lower Extremity and Knee

- Apophysitis
 - Osgood-Schlatter disease at tibial tubercle
 - Sever disease at posterior calcaneus
 - Treat with rest, stretching, and ice; counsel family that symptoms may last for about 2 years.
- Rotational and angular variants
 - Internal tibial torsion is the most common cause of in-toeing in children <2 years of age.
 - Internal femoral torsion (anteversion) may be seen in children with W-sitting positions.
 - Unilateral rotational anomalies may be linked with neurologic or neuromuscular disorders.
- Acute swelling of the knee joint after injury may indicate a hemarthrosis (ACL tear or meniscus tear).
- Patellofemoral pain syndrome is anterior knee pain that worsens with activity such as going up and down stairs.
 - Treatment focuses on exercise program to correct biomechanics.

CHAPTER 201

Foot

- Clubfoot (talipes equinovarus) may be congenital or teratologic.
 - Treatment involves Ponseti serial casting, percutaneous heel cord lengthening, and bracing.
- Metatarsus adductus is a common foot disorder in infants; it resolves spontaneously in >90% of infants.
- Hypermobil pes planus (flatfoot) involves pronated feet associated with generalized ligamentous laxity in children >6 years of age.
- Rigid flat foot should be evaluated for tarsal coalition.
- A cavovarus foot (high arch) is associated with Charcot-Marie-Tooth disease (genetic neuropathy) and other spinal disorders (e.g., tethered cord).

CHAPTER 202

Spine

- Scoliosis
 - Coronal curvature is >10 degrees.
 - Adam forward bend test shows rotational deformity/asymmetry.
 - Congenital scoliosis has abnormal bony morphology.
 - Neuromuscular scoliosis is associated with underlying neurologic disorder.
 - Idiopathic scoliosis—no clear etiology
 - Treatment
 - Observation: <25 degrees
 - Bracing: 20–50 degree curve or if progressing
 - Spinal fusion surgery: >50 degrees
- Kyphosis
 - Postural—normal bony structure
 - Scheuermann kyphosis
 - >5-degree anterior wedging on three consecutive vertebral bodies
 - Treat with bracing if skeletally immature; observation or surgical correction if skeletally mature
- Congenital—abnormal bony structure that often requires bracing or surgery to treat

CHAPTER 203

Upper Extremity

- Brachial plexus injury
 - At birth, differential diagnosis includes clavicle or humerus fracture.
 - Athletic “stingers” are unilateral, any bilateral symptoms should be concerning for more severe cervical spine injury.
- Radial head subluxation (nursemaid’s elbow)
 - Mechanism—pulling the outstretched arm of a child
 - Treatment is reduction, usually with supination of forearm and flexion of elbow or hyperpronation
- Complex polydactyly and syndactyly require surgical correction.
- Nondisplaced scaphoid fractures require a thumb spica cast, while displaced may need surgical correction.

CHAPTER 204

Benign Bone Tumors and Cystic Lesions

- Often found incidentally; management depends on specific diagnosis but prognosis is usually excellent.

 Anorectal malformations, 508–509
 constipation due to, 496t
 Anorectal manometry, for Hirschsprung disease, 509
 Anorexia nervosa, 295–296, 295f
 clinical features of, 296
 delayed puberty due to, 675
 diagnostic criteria of, 296t
 differential diagnosis of, 296
 treatment and prognosis for, 296, 296t
 Anovulation, 289–290
 Antagonism, of antimicrobial drugs, 385
 Antalgic gait, 754
 Anterior cruciate ligament tears, 766
 Anterior pituitary gland, 652
 Anterior pituitary hormone function testing, 653t
 Anterior uveitis, 450t
 Anthrax, 457t–462t
 Anthropometric data, for obesity, 112
 Antiarrhythmics, for cardiomyopathies, 576t, 577t
 Antibiotic-lock therapy, 456
 Antibiotics
 for acne, 737
 for cystic fibrosis, 548
 for infectious diseases, 380
 for infective endocarditis, 426
 intravenous, 740
 for pneumonia, 425t
 prophylaxis, for severe combined immunodeficiency, 313
 Antibody deficiency disease, 307–309, 307f, 308t
 agammaglobulinemia as, 307, 308t
 autosomal recessive, 307
 X-linked, 307
 antibody deficiency syndrome as, 308t, 309
 common variable immunodeficiency as, 308, 308t
 IgA deficiency as, 308–309, 308t
 IgG subclass deficiency as, 308t, 309
 transient hypogammaglobulinemia of infancy as, 308t, 309
 Anti-CCP antibody, in juvenile idiopathic arthritis, 367
 Anticholinergics, toxicity, 169t
 Anticoagulant, for cardiomyopathies, 577t
 Anticongestive medications, in truncus arteriosus, 571
 Anticonvulsants
 for anxiety disorders, 66
 Anticonvulsants (Continued)
 for autism spectrum disorder, 74
 for bipolar disorders, 70
 Antidepressants
 for depressive disorders, 68–69
 for somatic symptom and related disorders, 63
 Antidiuretic hormone (ADH)
 in regulation of intravascular volume, 131
 in renal function, 633, 635f
 in sodium balance, 137–138
 Antidysrhythmic drugs, 564t
 Antiemetic medications, for vomiting, 493
 Antihistamines
 for allergic rhinitis, 339–340
 for atopic dermatitis, 740
 for urticaria and angioedema, 347
 Antiinfective therapy, 385
 antagonism in, 385
 definitive, 385
 drug-drug interactions and, 385
 drug susceptibilities in, 385
 empirical or presumptive, 385
 site and nature of the infection and, 385
 synergism, 385
 medications
 for Kawasaki disease, 365
 for pericarditis, 578
 Antimicrobial therapy, for pneumonia, 421t
 Antinuclear antibody
 in juvenile idiopathic arthritis, 367
 in systemic lupus erythematosus, 370
 Antioxidant, 123
 Antiphospholipid syndrome, maternal, 246
 Antipsychotics
 for autism spectrum disorder, 74
 for schizophrenia spectrum disorders, 75
 Anti-Rh-positive immune globulin (RhoGAM), 262
 Antithrombin, 606–607
 in hemostasis, 605
 Antithrombotic doses, for Kawasaki disease, 365
 α 1-Antitrypsin deficiency, 516
 Anuria, fluid therapy for, 133, 133t
 Anus
 anteriorly displaced, constipation due to, 496t
 imperforate, 508–509
 constipation due to, 496t
 Anxiety disorders, 63
 agoraphobia, 64
 attention-deficit/hyperactivity disorder and, 66
 bipolar and related disorders and, 70
 characteristics of, 64t
 defined, 63
 generalized anxiety disorder, 64–65
 management of, 65–66

 laboratory and imaging studies in, 45
 physical examination for, 45
 treatment of, 45–46
- Atypical hemolytic uremic syndrome, 319
- Atypical lymphocytes, 402
 in infectious diseases, 380
- Atypical pneumonia, 420
- Auditory brainstem response (ABR), 34
- Aura, migraine, 702
- Auscultation, in cardiovascular system
 assessment, 556
- Auspitz sign, in psoriasis, 743
- Autism, screening for, 18
- Autism spectrum disorder (ASD), 72, 73*t*

- Autoantibodies
 manifestations of, 361t
 in systemic lupus erythematosus, 369–370
- Autocrine action, of hormones, 652, 652f
- Autoimmune encephalitis, 407
- Autoimmune hemolytic anemia, 597
- Autoimmune hepatitis, 520t, 521
- Autoimmune polyglandular syndrome type I, 682–683
- Autoimmune polyglandular syndrome type II, 682–683
- Autoimmune regulator (*AIRE*) gene, in chronic mucocutaneous candidiasis, 312
- Autoimmune thrombocytopenic purpura of childhood (childhood ITP), 603
- Autonomic nerves, dysfunction of, in Guillain-Barré syndrome, 711
- Autonomic system, 661
- Autonomy, 4
 in early childhood, 15
 in end-of-life decision making, 8
- Autosomal dominant disorders, 178–179
 achondroplasia due to, 178t
 Crouzon syndrome with acanthosis nigricans due to, 178t
 hereditary angioneurotic edema due to, 178t
 Marfan syndrome due to, 178t
 myotonic dystrophy due to, 178t
 neurofibromatosis 1 due to, 178t
 neurofibromatosis 2 due to, 178t
 nonsyndromic craniosynostosis due to, 178t
 pedigree drawing of, 178f, 181f, 181f
 penetrance in, 178f, 179
 thanatophoric dysplasia due to, 178t
 variable expressivity of, 179
- Autosomal dominant (AD) inheritance, rules of, 179t
- Autosomal dominant polycystic kidney disease, 638
- Autosomal recessive agammaglobulinemia, 307
- Autosomal recessive disorders, 179–180
 consanguinity and, 185–186
 cystic fibrosis due to, 181t
 Friedreich ataxia due to, 181t
 Gaucher disease due to, 181t
 phenylketonuria due to, 181t
 sickle cell disease due to, 181t
- Autosomal recessive (AR) inheritance, rules of, 181t
- Autosomes, 177
- Avascular necrosis, 758, 762
 idiopathic, 768
- Avian influenza (bird flu), 420
- Avoidant restrictive food intake disorder (ARFID), 296, 296t
- Azathioprine, for ulcerative colitis, 511
- Azelaic acid, for acne, 737
- Azithromycin
 for *Chlamydia* infection, 440
 for pertussis, 418
 for streptococcal pharyngitis, 411
- B**
- B cells, 302
- B virus, 457t–462t
- Babesia*, 457t–462t, 458
- Babesiosis, 457t–462t
- Babinski reflex, 241, 698t, 700
- Baby bottle caries, 499
- Baby-cereals, as complementary food, 104
- Bacille Calmette-Guérin (BCG) vaccine, 473, 478
- Bacillus anthracis*, 457t–462t
- Back pain, 773–774, 774t
- Back to Sleep initiative, 24
- Back-to-sleep program, 536
- Bacteremia, 434
 catheter-associated, 455
 fever and, 386
 in nephrotic syndrome, 637
 occult, 387
- Bacterial colonization, of newborn, 232
- Bacterial conjunctivitis, 450t
- Bacterial diarrhea, fever due to, 386
- Bacterial diseases, zoonotic, 457t–462t
- Bacterial enteritis, gastrointestinal bleeding due to, 497t
- Bacterial gastroenteritis, vomiting due to, 493t
- Bacterial infections
 in immunocompromised person, 451
 superficial, 391–393
 cellulitis as, 397–398
 folliculitis as, 398
 impetigo as, 397
 perianal dermatitis as, 398
 viral infections vs., 381t, 386
- Bacterial meningitis, 722–723
 causes of, 404t
- Bacterial peritonitis, spontaneous, 523–524
- Bacterial tracheitis, 417
 upper airway obstruction due to, 537t
- Bacterial vaginosis, 435, 440t
- Bag/mask ventilation, for respiratory failure, 156
- Baker cyst, 765
- Balantidiasis, 457t–462t
Balantidium coli, 457t–462t
- Balloon angioplasty, for coarctation of aorta, 568
- Balloon atrial septostomy, for transposition of great arteries, 570–571
- Balloon valvuloplasty
 for aortic stenosis, 568
 for pulmonary stenosis, 567
- Barbiturates, maternal use of, 248t–251t
- Bardet-Biedl syndrome, obesity in, 110t
- Bare lymphocyte syndrome, 311
- Barium enema, for Hirschsprung disease, 509
- Barium esophagram, 531
- Barium upper gastrointestinal (GI) series, for gastroesophageal reflux, 501
- Barlow test, 241, 759f
- Bart hemoglobin, 593
- Bartonella henselae*, 401, 457t–462t
 conjunctivitis from, 448
- Bartonella* spp., 457t–462t
- Bartonellosis, 457t–462t
- Bartter syndrome, 142, 142t
- Basophilic stippling, 589
- Batten disease, 219–223
- Batteries, ingestion of, 169
- Battle sign, 725
- Baylisascariasis, 457t–462t
Baylisascaris procyonis, 457t–462t, 469t, 471
- Becker muscular dystrophy, 712
- Beckwith-Wiedemann syndrome, 193, 508, 663
- Beclomethasone HFA, for asthma, 334f
- Bed bug bites, allergic reactions to, 349
- Bed rest, for rheumatic fever, 575–576
- Bee stings, allergic reactions to, 348–349

 classification of, 664t
 clinical manifestations of, 661–663
 definition of, 661
 due to poisoning, 169t
 emergency management of, 666
 with fulminant liver failure, 519t
 in glycogen storage diseases, 209–210
 ketotic, due to inborn errors of metabolism, 203–205
 lack of awareness of, 660
 due to medications and intoxications, 666
 metabolic disorders of, 666
 neonatal seizures due to, 268
 pathophysiology of, 663–665
 disrupted metabolic response pathways, 665–666
 energy stores, 665
 hormonal signal in, 663–665
 counter-regulatory hormone defects, 665
 factitious hyperinsulinemia, 663
 and hyperinsulinemia, 663
 idiopathic ketotic hypoglycemia, 665
 sequelae, 661–663
 symptoms and signs of, 663t
 with type 1 diabetes mellitus, 659–660
- Hypoglycemic disorders, due to inborn errors of metabolism, 203t
- Hypogonadotropic hypogonadism, 673
- Hypoketotic hypoglycemia, 217–218
- Hypomagnesemia, 685–686
 neonatal seizures due to, 268
 in newborn, 245
- Hypomania, in bipolar I disorder (BD), 70
- Hyponatremia, 138–139, 138f
- Hyponatremic dehydration, 135
- Hypoparathyroidism
 primary, 685, 686t
 pseudo-, 670, 685, 686t
 transient, 685
- Hypoperfusion, 569t
- Hypophosphatemic rickets, 181
- Hypopituitarism
 acquired, 653
 diagnostic evaluation of, 653t
 idiopathic, 674
- Hypoplastic left heart syndrome, 572–573, 572f
- Hypoplastic nail, 193t
- Hypoplastic right ventricle, 571
- Hypospadias, 194–195, 648
- Hypothalamic corticotropin-releasing hormone (CRH), 690
- Hypothalamic dysfunction, obesity with, 110t
- Hypothalamic gliomas, 678
- Hypothalamic gonadotropin-releasing hormone (GnRH), 672
- Hypothalamic-pituitary axis, 652–653, 652f
 disorders of, 653–654
 interrelationships of, 680f
- Hypothalamus, 652, 680f
- Hypothyroidism, 675, 681–683
 acquired, 682–683
 causes of, 681t
 congenital, 681–682
 clinical manifestations of, 682
 obesity in, 110t
 symptoms and signs of, 682t
- Hypotonia, 699–700, 708. *See also* Weakness
 central (without significant weakness), 714
 neonatal and infantile, 714
- Hypoventilation
 congenital central, 534
 hypoxemia due to, 528t
- Hypovolemic hyponatremia, 138
- Hypoxemia
 causes of, 528t
 during drowning, 164
 in newborn, treatment of, 253–254
- Hypoxia
 disorders of consciousness with, 719
 perinatal, 242–243
- Hypoxic-ischemic encephalopathy, in newborn, 270–271
 clinical manifestations of, 271, 271t
 prognosis, 270
 seizures due to, 268–270
- Hypoxic-ischemic injury, due to drowning, 165
- Hypoxic pulmonary vasoconstriction, 528
- Hypoxic spells, in tetralogy of Fallot, 569
- Hypsarrhythmia, 706
- I**
- Ibuprofen, maternal use of, 248t–251t
- ICP. *See* Intracranial pressure
- Icteric phase, of viral hepatitis, 431–432
- Idiogenic osmoles, 135
- Idiopathic aplastic anemia, 591t
- Idiopathic hypopituitarism, 674
- Idiopathic intracranial hypertension, 723
- Idiopathic ketotic hypoglycemia, 665
- Idiopathic pulmonary hemosiderosis, 545
- Idiopathic scoliosis, 771
- Idiopathic thrombocytopenic purpura (ITP), 603
 bleeding disorder in newborn due to, 267
 clinical manifestations of, 603
 diagnosis of, 603
 etiology of, 603
 maternal, 246, 247t, 602–603
 maternal, neonatal thrombocytopenia due to, 267
 prognosis for, 603
 treatment of, 603

- Iduronate 2-sulfatase deficiency, 219–223
 α -L-Iduronidase deficiency, 219–223
 Ifosfamide, for cancer, 619t–620t
 Ig replacement therapy, for severe combined immunodeficiency, 313
 IgA nephropathy, 638
 IgA vasculitis, 361
 IGF-binding protein 3 (IGF-BP3), 667
 Ileal atresia, 237t
 Illness, 55t–56t
 Illness anxiety disorder, 61, 62t
 Illness Attitude Scales and Soma Assessment Interview, for somatic symptom and related disorders, 63
 Imatinib, for cancer, 619t–620t
 Imipramine, for enuresis, 49
 Immediate hypersensitivity reactions, 325, 325t
 Immobilization, physiologic changes due to, 686t
 Immune-mediated mechanisms, in thrombocytopenia resulting from peripheral destruction, 602–603
 Immunization, 381–384
 active, 381
 administration of, 382–383
 adverse events after, 384
 catch-up, 382
 schedules for, 383f
 contraindications to, 383–384
 informed consent for, 382–383
 passive, 381
 and prophylaxis, 381
 recommended schedules for, 382f
 Immunocompromised person, infection in, 451
 clinical manifestations of, 453
 differential diagnosis of, 454
 epidemiology of, 453
 etiology of, 451–453, 452t
 laboratory tests and imaging for, 453–454
 prevention of, 454–455
 treatment of, 454
 Immunodeficiency, 123
 common variable, 308, 308t
 fever due to, 389
 general management of, 313t
 severe combined, 310–311, 310t
 autosomal recessive, 311
 clinical manifestations of, 311
 due to deficiencies in adenosine deaminase and purine nucleoside phosphorylase, 311
 X-linked, 311
 Immunodeficiency diseases
 antibody deficiency disease, 307–309, 307f, 308t
 agammaglobulinemia as, 307, 308t
 X-linked, 307
 antibody deficiency syndrome as, 308t, 309
 autosomal recessive, 307
 common variable immunodeficiency as, 308, 308t
 IgA deficiency as, 308–309, 308t
 IgG subclass deficiency as, 308t, 309
 transient hypogammaglobulinemia of infancy as, 308t, 309
 assessment, 301
 adaptive immune system, 301
 clinical characteristics of, 304t
 diagnostic evaluation of, 304–306, 305f
 imaging in, 306
 laboratory tests in, 304–306, 306t
 differential diagnosis of, 303–304, 304t
 due to defects in anatomic-mucociliary barrier, 301, 302t
 history of, 302
 innate immune system and, 301, 303t
 physical examination for, 302–303
 Immunodeficiency diseases (*Continued*)
 combined, 309–313, 310t
 autosomal recessive, 311
 bare lymphocyte syndrome as, 310t, 311
 clinical manifestations of, 311
 DiGeorge syndrome as, 310t, 311
 hyper-IgM syndrome as, 310t
 autosomal recessive, 309–310
 due to defects in NEMO, 310
 X-linked, 309–310, 309f
 Omenn syndrome as, 310t, 311
 reticular dysgenesis as, 310t
 severe, 310–311, 310t
 autosomal recessive, 311
 clinical manifestations of, 311
 due to deficiencies in adenosine deaminase and purine nucleoside phosphorylase, 311
 X-linked, 311
 due to lymphocyte disorders. *See* Lymphocyte disorders
 secondary, 304t
 Immunoglobulin, intravenous, for autoimmune hemolysis, 598
 Immunoglobulin A (IgA) deficiency, 308–309, 308t
 Immunoglobulin E (IgE)
 disorders associated with elevated, 326, 326t
 in food allergies, 353t
 Immunoglobulin G (IgG) subclass deficiency, 308t, 309
 Immunomodulating drugs, topical, for atopic dermatitis, 342
 Immunophenotype, of leukemia, 621–622
 Immunosuppression, immunization and, 384
 Immunotherapy, for allergic rhinitis, 340
 Impact seizures, 725
 Imperforate anus, 508–509
 constipation due to, 496t
 Impetigo, 397
 bullous, 397, 748t
 nonbullous, 397
 Implanted venous access systems (Port-a-Cath), 455
 In-toeing, 762–763
 common causes of, 762t
 due to femoral anteversion, 762
 due to internal tibial torsion, 762
 treatment of, 762
 In vitro serum testing, for antigen-specific IgE, 326–327, 327t
 In vivo skin testing, for allergen-specific IgE, 326, 327t
 Inactivated poliovirus (IPV) vaccine, 382f, 383f
 Inborn errors of metabolism
 assessment of, 201
 clinical, and laboratory findings, 206, 206t
 ataxia due to, 717
 clinical presentation of, 201–206
 congenital malformations or dysmorphic features in, 205–206
 energy deficiency in, 202
 ketosis and ketotic hypoglycemia in, 202–205
 specific organ, 202, 205t
 storage disorders, 206
 toxic, 201–202
 genetic aspects of, 206–207
 identification of molecular pathology as, 207
 mechanisms of inheritance as, 206–207
 hyperammonemia in
 etiology of, 205t
 in later infancy and childhood, 202–205
 metabolic acidosis in, 201–202, 206t
 neonatal
 moderate, 202
 Inborn errors of metabolism (*Continued*)
 severe, 202
 incidence of, 202t
 metabolic acidosis due to, 146
 neonatal screening for, 207–208
 confirmatory testing principles of, 207
 disorders identified by, 207
 specialized laboratory and clinical testing after, 207–208, 208t
 strategy of, 207
 overview of treatment for, 208
 signs and symptoms of, 201
 Inclusion conjunctivitis, 448
 Incontinentia pigmenti, 181–182
 Individualized educational plan (IEP), 28
 Indomethacin, maternal use of, 248t–251t
 Induction chemotherapy, for leukemia, 622
 Infancy
 bonding and attachment in, 15
 obesity and, 112–113
 physical development in later, 14
 Infant(s)
 crying, 41. *See also* Crying
 ethical principles related to, 4–5
 genetic assessment of, 186
 hearing and vision screening of, 20
 low birth weight of, 228
 mortality, 2, 228
 very low birth weight of, 228–229
 Infant botulism, 712
 Infantile beriberi, 122
 Infantile hemangiomas, 746–747
 Infantile hypotonia, 714
 Infantile spasms, 706
 Infection(s)
 assessment, 301
 adaptive immune system, 301
 clinical characteristics of, 304t
 diagnostic evaluation of, 304–306, 305f
 imaging in, 306
 laboratory tests in, 304–306, 306t
 differential diagnosis of, 303–304, 304t
 due to defects in anatomic-mucociliary barrier, 301, 302t
 history of, 302
 innate immune system and, 301, 303t
 physical examination for, 302–303
 congenital (TORCH), 273, 275t
 with chlamydia, 276–277
 with *Chlamydia trachomatis*, 275t
 with COVID-19, 277
 with cytomegalovirus, 274
 with herpes simplex virus, 274, 275t
 with HIV, 275t
 with *Mycobacterium tuberculosis*, 275t
 with *Neisseria gonorrhoeae*, 275t, 276
 with parvovirus, 275t
 with rubella, 273–274, 275t
 with toxoplasmosis, 273
 with *Trypanosoma cruzi*, 275t
 with varicella-zoster virus, 275t
 with Zika virus, 277
 cutaneous (superficial)
 bacterial, 397–398
 cellulitis as, 397–398
 folliculitis as, 398
 impetigo as, 397
 perianal dermatitis as, 398
 fungal, 398, 399t
 viral, 398–400
 from herpes simplex virus, 398–399
 from human papillomaviruses (warts), 399–400
 molluscum contagiosum as, 400
 with fever and rash, 391

- Infection(s) (*Continued*)
- erythema infectiosum (fifth disease) as, 395
 - measles (rubeola) as, 391–393
 - roseola infantum (exanthem subitum), 394–395
 - rubella (German or 3-day measles), 393–394
 - varicella-zoster virus infection (chickenpox and zoster), 395–397
- in immunocompromised person, 451
- clinical manifestations of, 453
 - differential diagnosis of, 454
 - epidemiology of, 453, 453f
 - etiology of, 451–453, 452t
 - laboratory tests and imaging for, 453–454
 - prevention of, 454–455
 - treatment of, 454, 454t
- maternal
- effect on fetus or newborn, 247t
 - as teratogens, 185
- medical devices-associated, 455
- from central nervous system shunts, 456–457
 - peritoneal dialysis-associated infections as, 456
 - from urinary catheters, 456
 - from vascular devices, 455–456
 - ventilator-associated pneumonia as, 456
- with neutropenia, 316t
- orthopedic problems due to, 753t
 - in sickle cell disease, 595t
- Infectious arthritis, juvenile idiopathic arthritis vs., 369t
- Infectious diseases, 379
- assessment of, 379
 - diagnostic imaging in, 380–381
 - differential diagnosis in, 379
 - history in, 380t
 - initial diagnostic evaluation in, 379
 - physical examination in, 379
 - screening tests in, 379–380
 - localizing manifestations of, 381t
 - in transfusion reactions, 608
 - viral vs. bacterial, 381t, 386
- Infectious mononucleosis, 401
- Infectious peritonitis, 523–524
- Infectious pyogenic infection, synovial fluid findings in, 447t
- Infectious rhinitis, 338
- Infective endocarditis, 425
- causes of, 426t
 - clinical manifestations of, 426
 - complications and prognosis of, 430
 - culture-negative, 426
 - differential diagnosis of, 426
 - epidemiology of, 425–426
 - etiology of, 425
 - laboratory studies and imaging of, 426
 - modified Duke clinical criteria for, 426
 - prevention of, 431
 - treatment of, 426
- Inflammation
- orthopedic problems due to, 753t
 - of peritoneum, 523–524
- Inflammatory bowel disease (IBD), 510–511
- abdominal pain due to, 490t
 - clinical manifestations of, 510, 510t
 - epidemiology and etiology of, 510
 - gastrointestinal bleeding due to, 497t
 - juvenile idiopathic arthritis vs., 368t
 - laboratory and imaging studies for, 510, 511t
 - synovial fluid findings in, 447t
 - treatment of, 511
 - very early-onset, 510
- Inflammatory diseases, fever due to, 389
- Infliximab, for juvenile idiopathic arthritis, 368–369
- Influenza, avian, 420
- Influenza A (H5N1), 420
- Influenza vaccines, 382f
- for prevention of pneumonia, 424
- Infuse-a-Port (implanted venous access systems), infections associated with, 455
- Inhalants, acute effects of, 297t–298t
- Inhalation challenge tests, 531
- Inheritance patterns
- autosomal dominant disorders, 178–179, 178t
 - autosomal recessive disorders, 179–180
 - mitochondrial, 183, 184f
 - MELAS due to, 183
 - multifactorial disorders (polygenic inheritance), 182–183
 - hypertrophic pyloric stenosis as, 183
 - neural tube defects as, 183
 - uniparental disomy as, 183
 - pedigree drawing of, 177–178, 178f
- Inhibin, in puberty, 672
- Inhibitors, for hemophilia, 605
- Inhibitory factors, in hemostasis, 605
- Injury(ies), 2
- birth, 243–244
 - prevention of, 23t–24t, 161
 - educations for, 162
 - epidemiology of, 161–162
 - etiology of, 161–162
- Innate immune system, 301, 303t
- Innocent bystander, 597
- Innocent murmurs, 558, 558t
- Innominate artery, anomalous, extrinsic tracheal compression due to, 541
- Inotropic agents
- for cardiomyopathies, 577, 577t
 - for heart failure, 575t
- Insect allergies, 348
- Insect bites, vesiculobullous eruptions due to, 748t
- Insensible losses, 132
- Insomnia of childhood, 55t–56t

- Streptococcus pneumoniae* vaccine, 381–382
- Streptococcus pyogenes*, pharyngitis from, 409–410
- Streptomycin, as teratogen, 248t–251t
- Stridor, 530
 croup and, 416
 due to subglottic stenosis, 538
 due to upper airway obstruction, 537–538
 inspiratory, due to laryngomalacia, 538
- String sign, in pyloric stenosis, 505
- Stroke, 714–715
 clinical manifestations of, 714–715
 diagnostic tests and imaging for, 715
 differential diagnosis of, 715
 etiology of, 714, 715t
 hemorrhagic, 714
 in sickle cell disease, 595
 treatment of, 715
- Stroke volume, oxygen delivery and, 157
- Strongyloides stercoralis*, 469t
- Structured Communication Adolescent Guide (SCAG), 282f
- Stunting
 failure to thrive and, 79–80
 marasmus and, 116
 zinc deficiency and, 126–127
- Stupor, 719
- Sturge-Weber syndrome, 730, 747
- Styes, 449
- Subacute bacterial endocarditis prophylaxis, 570
- Subacute necrotizing encephalomyelopathy, 728
- Subacute sclerosing panencephalitis (SSPE), 393
- Subarachnoid hemorrhages, 724–725
 aneurysmal, 702f
 in newborn, 268–269
- Subconjunctival hemorrhage, in newborn, 243–244

- Subcutaneous nodules, due to heart failure, 575, 576t
- Subdural hematoma, in newborn, 270
- Subdural hemorrhages, 724–725
due to child abuse, 83, 84f
in newborn, 270
- Subependymal giant cell astrocytomas, 729–730
- Subependymal nodules, 729–730
- Subgaleal bleed, in newborn, 243–244
- Subglottic hemangioma, 746–747
- Subglottic space, 527
- Subglottic stenosis, 538–539
- Subluxation, 753t
- Substance abuse
by adolescents, 2, 297, 297t–298t
acute and chronic effects of, 297
acute overdose due to, 297, 297t–298t
treatment for, 297
maternal, during pregnancy, 92–93
- Substance/medication-induced psychotic disorders, 75
- Substernal retractions, 529–530
- Succimer acid, for lead poisoning, 172t
- Succinylacetone, urine or blood, 208t
- Sucking reflex, 14
- Sudden infant death syndrome (SIDS), 535–536
differential diagnosis of, 536t
etiology and epidemiology of, 535
with medium-chain acyl-CoA dehydrogenase deficiency, 217
prevention of, 536
- Sufentanil, as analgesia, 173t
- Suffocation, fatal injury due to, 162
- Sugar, added, 108
- Suicide, in bipolar disorders, 70–71
- Sulfadiazine, 470
- Sulfasalazine, for ulcerative colitis, 511
- Sulfatases deficiency, 219–223
- Sulfonamides, maternal use of, 248t–251t
- Superficial infections
bacterial, 397–398
cellulitis as, 397–398
folliculitis as, 398
impetigo as, 397
perianal dermatitis as, 398
fungal, 398, 399t
viral, 398–400
from herpes simplex virus as, 398–399
from human papillomaviruses (warts), 399–400
molluscum contagiosum as, 400
- Superficial venous thrombi (thrombophlebitis), 601
- Superior vena cava syndrome, oncologic emergencies, 618t
- Supplemental oxygen, 532
- Supportive care
for cancer, 620
for poisoning, 171
- Suppurative bursitis, 446
- Supraclavicular retractions, 529–530
- Supracondylar fracture, 757
- Supracristal septum, 565
- Suprasternal retractions, 537–538
- Supraventricular tachycardia (SVT), 563, 563t
- Susceptibilities, to anti-infective drugs, 385
- Sutures, of newborn, 240
- Swallowing study, videofluoroscopic, 540
- Sweat chloride test, for cystic fibrosis, 546
- Sweat test, for cystic fibrosis, 547–548, 547t
- Swimmer's ear, 415. *See also* Otitis externa
- Swinging flashlight test, 699
- Swyer-James syndrome, 424
- Sydenham chorea, due to rheumatic fever, 575, 576t
- Sympathomimetics, toxicity, 169t
- Symptomatic hyponatremia, 139
- Synchronized cardioversion, for dysrhythmias, 564
- Syncope, 560, 722
cardiac, 561t
carotid sinus, 561t
clinical manifestations of, 560
cough (deglutition), 561t
diagnostic studies for, 560
etiology of, 560, 561t
micturition, 561t
neurocardiogenic (vasopressor), 561t
- Syndactyly, 193t, 194
of finger, 777–778
of toes, 769, 769t
- Syndrome of inappropriate antidiuretic hormone (SIADH), 138–139
- Synergism, of antimicrobial drugs, 385
- Synophrys, 193t
- Synovial fluid findings, in various joint diseases, 447t
- Synovitis
in juvenile idiopathic arthritis, 366
in rheumatic diseases, 359
toxic or transient, 445
transient monoarticular, 760
clinical manifestations and evaluation of, 760, 760t
etiology and epidemiology of, 760
treatment for, 760
- Syphilis (*Treponema pallidum*), 437, 440–441
clinical features of, 439t
congenital, 274–276, 440–441
latent, 440–441
neuro-, 441
primary, 440–441
secondary, 440–441
tertiary, 440–441
- Syrup of ipecac, for poisoning, 171
- Systematic ignoring, for pediatric sleep disorders, 58
- Systemic capillary leak, due to burns, 166
- Systemic diseases, cardiac manifestations of, 556t
- Systemic inflammation, in juvenile idiopathic arthritis, 367
- Systemic inflammatory response syndrome (SIRS), 158
- Systemic lupus erythematosus (SLE), 369
clinical manifestations of, 370, 370t, 371f, 371t
complications of, 372
differential diagnosis of, 359, 372
epidemiology of, 370
etiology of, 369–370
laboratory and imaging studies for, 370–371
maternal, 246, 247t
prognosis for, 372
synovial fluid findings in, 447t
treatment of, 372
- Systolic murmurs, 556–557
ejection, 556–557
due to aortic stenosis, 568
in total anomalous pulmonary venous return, 572
in truncus arteriosus, 571
