*This book is dedicated to our patients, who inspire us to learn more;
our mentors; and, now more than ever, our colleagues,
the dedicated medical professionals whose curiosity and focus
on providing excellent care and who, even in the face of recent adversity,
spur the advancement of our medical practice.*

CONTRIBUTORS

Warren P. Bishop, MD

Professor of Pediatrics
University of Iowa Carver College of Medicine
University of Iowa Children's Hospital
Iowa City, Iowa
The Digestive System

Kim Blake, MD, MRCP, FRCPC

Professor of Medicine
Department of General Pediatrics
IWK Health;
Division of Medical Education
Dalhousie University
Halifax, Nova Scotia, Canada
Adolescent Medicine

Latasha Bagues, MD, FAAP

Associate Professor of Pediatrics
Morehouse School of Medicine
Atlanta, Georgia
Growth and Development

Brian R. Branchford, MD

Assistant Professor of Pediatrics
Division of Pediatric Hematology/Oncology/Bone Marrow
Transplant
Medical College of Wisconsin
Milwaukee, Wisconsin
Hematology

Amanda M. Brandow, DO, MS

Professor of Pediatrics
Division of Pediatric Hematology/Oncology/Bone Marrow
Transplant
Medical College of Wisconsin
Milwaukee, Wisconsin
Hematology

Margo Sheck Breilyn, MD

Assistant Professor of Pediatrics
Albert Einstein College of Medicine Children's Hospital at
Montefiore
Bronx, New York
Human Genetics and Dysmorphology

April O. Buchanan, MD

Associate Professor of Pediatrics
Associate Dean for Curriculum
University of South Carolina School of Medicine Greenville;
Pediatric Hospitalist
Children's Hospital of the Greenville Health System
Greenville, South Carolina
Pediatric Nutrition and Nutritional Disorders

Gray M. Buchanan, PhD

Associate Professor of Family Medicine
Medical University of South Carolina
Charleston, South Carolina;
Director, Behavioral Medicine
Family Medicine Residency Program
Self Regional Healthcare
Greenwood, South Carolina
Psychiatric Disorders

Asriani M. Chiu, MD

Professor of Pediatrics (Allergy and Immunology) and
Medicine
Director, Asthma and Allergy Clinic
Medical College of Wisconsin
Milwaukee, Wisconsin
Allergy

Yvonne E. Chiu, MD

Professor of Dermatology and Pediatrics
Medical College of Wisconsin
Milwaukee, Wisconsin
Dermatology

Claudia S. Crowell, MD, MPH

Kinderklinik von Haunersche
Ludwig Maximilian University
Munich, Germany
Infectious Diseases

Alison H. Downes, MD

Associate Professor of Pediatrics and Pathology
Albert Einstein College of Medicine
Children's Hospital at Montefiore
Bronx, New York
Human Genetics and Dysmorphology

Jackson T. Londeree, DO

Assistant Professor
Division of Pediatric Nephrology
Emory University School of Medicine
Children's Healthcare of Atlanta
Atlanta, Georgia
Fluids and Electrolytes

Erin W. MacKintosh, MD

Acting Assistant Professor of Pediatrics
University of Washington School of Medicine;
Division of Pediatric Pulmonary and
Sleep Medicine
Seattle Children's Hospital
Seattle, Washington
The Respiratory System

Karen J. Marcdante, MD

Professor of Pediatrics
Medical College of Wisconsin
Children's Hospital of Wisconsin
Milwaukee, Wisconsin
The Profession of Pediatrics

Maria L. Marquez, MD

Professor of Pediatrics
Georgetown University School of Medicine;
Medical Director
Mary's Center, Fort Totten
Washington, DC
Pediatric Nutrition and Nutritional Disorders

Susan G. Marshall, MD

Professor and Vice Chair for Education
Department of Pediatrics
University of Washington School of Medicine;
Director of Medical Education
Seattle Children's Hospital
Seattle, Washington
The Respiratory System

Thomas W. McLean, MD

Professor of Pediatrics
Section of Pediatric Hematology/Oncology
Atrium Health Wake Forest Baptist
Winston-Salem, North Carolina
Oncology

Michael Muriello, MD

Assistant Professor of Pediatrics
Division of Genetics
Medical College of Wisconsin
Milwaukee, Wisconsin
Metabolic Disorders

Erin E. Neil, DO

Assistant Professor of Pediatrics
Division of Pediatric Neurology
University of Michigan Medical School
Ann Arbor, Michigan
Neurology

Hiren P. Patel, MD

Clinical Associate Professor of Pediatrics
The Ohio State University College of Medicine;
Chief, Section of Nephrology
Medical Director, Kidney Transplant Program
Nationwide Children's Hospital
Columbus, Ohio
Nephrology and Urology

Caroline R. Paul, MD

Associate Professor of Pediatrics
University of Wisconsin School of Medicine and Public
Health
Madison, Wisconsin
Behavioral Disorders

Tara L. Petersen, MD, MSED

Associate Professor of Pediatrics
Division of Pediatric Critical Care
Medical College of Wisconsin
Milwaukee, Wisconsin
The Acutely Ill or Injured Child

John R. Routes, MD

Professor of Pediatrics (Allergy, Asthma & Immunology) and
Microbiology & Immunology
Chief, Section of Allergy and Clinical Immunology
Medical College of Wisconsin
Milwaukee, Wisconsin
Immunology

Thomas B. Russell, MD

Associate Professor of Pediatrics
Section of Pediatric Hematology/Oncology
Atrium Health Wake Forest Baptist
Winston-Salem, North Carolina
Oncology

Jocelyn Huang Schiller, MD

Professor of Pediatrics
University of Michigan Medical School
Ann Arbor, Michigan
Neurology

Daniel S. Schneider, MD

Associate Professor of Pediatrics
Division of Pediatric Cardiology
University of Virginia School of Medicine
Charlottesville, Virginia
The Cardiovascular System

Abigail M. Schuh, MD, MMHPE

Assistant Professor of Pediatrics
Division of Pediatric Emergency Medicine
Medical College of Wisconsin
Milwaukee, Wisconsin
The Acutely Ill or Injured Child

J. Paul Scott, MD

Professor of Pediatrics
Medical College of Wisconsin;
Medical Director
Wisconsin Sickle Cell Center
The Children's Research Institute of the Children's Hospital of
Wisconsin
Milwaukee, Wisconsin
Hematology

Paola Palma Sisto, MD

Associate Professor of Pediatrics
Department of Pediatrics
Division of Endocrinology
Medical College of Wisconsin

Kevin D. Walter, MD, FAAP

Associate Professor of Orthopedic Surgery and Pediatrics
Medical College of Wisconsin;
Program Director
Children's Wisconsin Sports Medicine
Medical Director
Children's Wisconsin Sports Rehabilitation
Milwaukee, Wisconsin
Orthopedics

PREFACE

This edition was created in the midst of several pandemics, one caused by a virus and one focused on advancing social justice to overcome structural and personal racism. The many challenges highlighted by these pandemics are resulting in acceleration of necessary changes in medical education. These changes must be built on a foundation of evidence-based knowledge and heightened awareness. Our goal as the editors and authors of this textbook is not only to provide the classic, foundational knowledge we use every day, but also to include recent advances in a readable, searchable, and concise text for medical learners at all levels. Mastering this knowledge, when combined with mindful experiences in the rapidly changing world of medicine, will allow our readers to develop the practical wisdom needed to serve our patients and their families.

We hope that this text will help you investigate the common and classic pediatric disorders in a time-honored, logical format, helping you to both acquire and apply knowledge needed to provide high value care. We are honored to be part of the journey of the thousands of learners who rotate through pediatrics, those who will become new providers of pediatric care in the years to come, and those who continue to build on their knowledge.

Karen J. Marcdante, MD
Abigail M. Schuh, MD, MMHPE
Robert M. Kliegman, MD

ACKNOWLEDGMENTS

The editors profusely thank Marybeth Thiel, Jennifer Shreiner, and Kristine Feeherty, as well as their teams, for their assistance and attention to detail. We also again thank our colleague, Carolyn Redman, whose prompting, organizing, and overseeing of the process helped us create this new edition. Finally, we thank our spouses for their patient support throughout the process.

CONTENTS

SECTION 1

THE PROFESSION OF PEDIATRICS

Ahmeneh Ghavam and Karen J. Marcdante

- 1 Population and Culture: The Care of Children in Society 1
- 2 Professionalism 3
- 3 Ethics and Legal Issues 4
- 4 Palliative Care and End-of-Life Issues 6

SECTION 2

GROWTH AND DEVELOPMENT

Latasha Bogues and David A. Levine

- 5 Normal Growth 11
- 6 Disorders of Growth 13
- 7 Normal Development 14
- 8 Disorders of Development 16
- 9 Evaluation of the Well Child 19
- 10 Evaluation of the Child with Special Needs 27

SECTION 3

BEHAVIORAL DISORDERS

Caroline R. Paul and Colleen M. Wallace

- 11 Crying and Colic 41
- 12 Temper Tantrums 42
- 13 Attention-Deficit/Hyperactivity Disorder 44
- 14 Control of Elimination 46
- 15 Normal Sleep and Pediatric Sleep Disorders 54

SECTION 4

PSYCHIATRIC DISORDERS

Gray M. Buchanan

- 16 Somatoform Disorders, Factitious Disorders, and Malingering 61
- 17 Anxiety and Phobias 63
- 18 Depression and Bipolar Disorders 66
- 19 Obsessive-Compulsive Disorder 71
- 20 Pervasive Developmental Disorders and Psychoses 72

SECTION 5

PSYCHOSOCIAL ISSUES

Kristine Fortin and Alison H. Downes

- 21 Failure to Thrive 79
- 22 Child Abuse and Neglect 81
- 23 Sexuality and Gender Identity 87
- 24 Family Structure and Function 90
- 25 Violence 93
- 26 Divorce, Separation, and Bereavement 96

SECTION 6

PEDIATRIC NUTRITION AND NUTRITIONAL DISORDERS

April O. Buchanan and Maria L. Marquez

- 27 Diet of the Normal Infant 101
- 28 Diet of the Normal Child and Adolescent 106
- 29 Obesity 109
- 30 Pediatric Undernutrition 114
- 31 Vitamin and Mineral Deficiencies 118

SECTION 7

FLUIDS AND ELECTROLYTES

Jackson T. Londeree and Larry A. Greenbaum

- 32 Maintenance Fluid Therapy 131
- 33 Dehydration and Replacement Therapy 132
- 34 Parenteral Nutrition 136
- 35 Sodium Disorders 137
- 36 Potassium Disorders 141
- 37 Acid-Base Disorders 145

SECTION 8

THE ACUTELY ILL OR INJURED CHILD

Tara L. Petersen and Abigail M. Schuh

- 38 Assessment and Resuscitation 151
- 39 Respiratory Failure 155
- 40 Shock 157
- 41 Injury Prevention 161
- 42 Major Trauma 161
- 43 Drowning 164
- 44 Burns 165
- 45 Poisoning 167
- 46 Sedation and Analgesia 172

SECTION 9

HUMAN GENETICS AND DYSMORPHOLOGY

Margo Sheck Breilyn and Paul A. Levy

- 47 Patterns of Inheritance 177
- 48 Genetic Assessment and Diagnosis 185
- 49 Chromosomal Disorders 189
- 50 Approach to the Dysmorphic Child 192

SECTION 10

METABOLIC DISORDERS

Michael Muriello

- 51 Metabolic Assessment 201
- 52 Carbohydrate Disorders 209
- 53 Amino Acid Disorders 211
- 54 Organic Acid Disorders 215
- 55 Fatty Acid Oxidation Disorders 217
- 56 Lysosomal and Peroxisomal Disorders 219
- 57 Mitochondrial Disorders 223

SECTION 11

FETAL AND NEONATAL MEDICINE

Clarence W. Gowen, Jr.

- 58 Assessment of the Mother, Fetus, and Newborn 227
- 59 Maternal Diseases Affecting the Newborn 246
- 60 Diseases of the Fetus 251
- 61 Respiratory Diseases of the Newborn 253
- 62 Anemia and Hyperbilirubinemia 260
- 63 Necrotizing Enterocolitis 267
- 64 Hypoxic-Ischemic Encephalopathy, Intracranial Hemorrhage, and Seizures 268
- 65 Sepsis and Meningitis 271
- 66 Congenital Infections 273

SECTION 12

ADOLESCENT MEDICINE

Kim Blake and Nancy Van Eyk

- 67 Overview and Assessment of Adolescents 281
- 68 Well-Adolescent Care 287
- 69 Adolescent Gynecology 288
- 70 Eating Disorders 295
- 71 Substance Abuse 297

SECTION 13

IMMUNOLOGY

John R. Routes and James W. Verbsky

- 72 Immunological Assessment 301
- 73 Lymphocyte Disorders 307
- 74 Neutrophil Disorders 314
- 75 Complement System 318
- 76 Hematopoietic Stem Cell Transplantation 320

SECTION 14

ALLERGY

Kristen K. Volkman and Asriani M. Chiu

- 77 Allergy Assessment 325
- 78 Asthma 327
- 79 Allergic Rhinitis 338
- 80 Atopic Dermatitis 340
- 81 Urticaria, Angioedema, and Anaphylaxis 343
- 82 Serum Sickness 348
- 83 Insect Allergies 348
- 84 Adverse Reactions to Foods 350
- 85 Adverse Reactions to Drugs 353

SECTION 15

RHEUMATIC DISEASES OF CHILDHOOD

Grant D. Syverson

- 86 Rheumatic Assessment 359
- 87 IgA Vasculitis (Henoch-Schönlein Purpura) 361
- 88 Kawasaki Disease 363
- 89 Juvenile Idiopathic Arthritis 366
- 90 Systemic Lupus Erythematosus 369
- 91 Juvenile Dermatomyositis 372
- 92 Musculoskeletal Pain Syndromes 373

SECTION 16

INFECTIOUS DISEASES

Matthew P. Kronman, Claudia S. Crowell, and Surabhi B. Vora

- 93 Infectious Disease Assessment 379
- 94 Immunization and Prophylaxis 381
- 95 Antiinfective Therapy 385
- 96 Fever Without a Focus 386
- 97 Infections Characterized by Fever and Rash 391
- 98 Cutaneous Infections 397
- 99 Lymphadenopathy 400
- 100 Meningitis 403
- 101 Encephalitis 406
- 102 The Common Cold 408
- 103 Pharyngitis 409
- 104 Sinusitis 411
- 105 Otitis Media 412
- 106 Otitis Externa 415
- 107 Croup (Laryngotracheobronchitis) 416
- 108 Pertussis 417
- 109 Bronchiolitis 418
- 110 Pneumonia 420
- 111 Infective Endocarditis 425
- 112 Acute Gastroenteritis 427
- 113 Viral Hepatitis 431
- 114 Urinary Tract Infection 433

- 119 Ocular Infections 448
- 120 Infection in the Immunocompromised Person 451
- 121 Infections Associated with Medical Devices 455
- 122 Zoonoses and Vector-Borne Infections 457
- 123 Parasitic Diseases 467
- 124 Tuberculosis 473
- 125 Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome 478

SECTION 17

THE DIGESTIVE SYSTEM

Dawn R. Ebach and Warren P. Bishop

- 126 Digestive System Assessment 487
- 127 Oral Cavity 499
- 128 Esophagus and Stomach 500
- 129 Intestinal Tract 507
- 130 Liver Disease 513
- 131 Pancreatic Disease 521
- 132 Peritonitis 523

SECTION 18

THE RESPIRATORY SYSTEM

BreAnna Kinghorn, Erin W. MacKintosh, and Susan G. Marshall

- 133 Respiratory System Assessment 527

- 134 Control of Breathing 533
- 135 Upper Airway Obstruction 536
- 136 Lower Airway, Parenchymal, and Pulmonary Vascular Diseases 539
- 137 Cystic Fibrosis 546
- 138 Chest Wall and Pleura 549

SECTION 19

THE CARDIOVASCULAR SYSTEM

Daniel S. Schneider

- 139 Cardiovascular System Assessment 555
- 140 Syncope 560
- 141 Chest Pain 561
- 142 Dysrhythmias 562
- 143 Acyanotic Congenital Heart Disease 564
- 144 Cyanotic Congenital Heart Disease 568
- 145 Heart Failure 573
- 146 Rheumatic Fever 575
- 147 Cardiomyopathies 576
- 148 Pericarditis 577

SECTION 20

HEMATOLOGY

Amanda M. Brandow, Brian R. Branchford, and J. Paul Scott

- 149 Hematology Assessment 581
- 150 Anemia 584
- 151 Hemostatic Disorders 598
- 152 Blood Component Therapy 607

SECTION 21

ONCOLOGY

Thomas B. Russell and Thomas W. McLean

- 153 Oncology Assessment 613
- 154 Principles of Cancer Treatment 617
- 155 Leukemia 621
- 156 Lymphoma 623
- 157 Central Nervous System Tumors 625
- 158 Neuroblastoma 626
- 159 Wilms Tumor 628
- 160 Sarcomas 629

SECTION 22

NEPHROLOGY AND UROLOGY

Hiren P. Patel and Beth A. Vogt

- 161 Nephrology and Urology Assessment 633
- 162 Nephrotic Syndrome and Proteinuria 636
- 163 Glomerulonephritis and Hematuria 637
- 164 Hemolytic Uremic Syndrome 639
- 165 Acute Kidney Injury and Chronic Kidney Disease 640
- 166 Hypertension 643
- 167 Vesicoureteral Reflux 644
- 168 Congenital and Developmental Abnormalities of the Urinary Tract 645
- 169 Other Urinary Tract and Genital Disorders 647

SECTION 23

ENDOCRINOLOGY

Paola Palma Sisto and Mary Kathleen Heneghan

- 170 Endocrinology Assessment 651
- 171 Diabetes Mellitus 654
- 172 Hypoglycemia 661
- 173 Short Stature 666
- 174 Disorders of Puberty 672
- 175 Thyroid Disease 679
- 176 Disorders of Parathyroid Bone and Mineral Endocrinology 685
- 177 Disorders of Sexual Development 686

THE PROFESSION OF PEDIATRICS

Ahmeneh Ghavam | Karen J. Marcdante

CHAPTER 1

Population and Culture: The Care of Children in Society

CARE OF CHILDREN IN SOCIETY

Health care professionals need to appreciate the interactions between medical conditions and social, economic, and environmental influences associated with the provision of pediatric care. New technologies and treatments improve morbidity, mortality, and the quality of life for children and their families, but the costs may exacerbate disparities in medical care. The challenge for pediatricians is to deliver care that is socially equitable; integrates psychosocial, cultural, and ethical issues into practice; and ensures that health care is available to all children.

CURRENT CHALLENGES

Challenges that affect children's health outcomes include access to health care; health disparities; supporting their social, cognitive, and emotional lives in the context of families and communities; and addressing environmental factors, especially poverty. Early experiences and environmental stresses interact with the genetic predisposition of every child and, ultimately, may lead to the development of diseases seen in adulthood. Pediatricians have the unique opportunity to address not only acute and chronic illnesses but also environmental and toxic stressors to promote wellness and health maintenance in children.

Many scientific advances have an impact on the growing role of pediatricians. Newer genetic technologies allow the diagnosis of diseases at the molecular level, aid in the selection of medications and therapies, and may provide information on prognosis. Prenatal diagnosis and newborn screening improve the accuracy of early diagnosis and treatment, even when a cure is impossible. Functional magnetic resonance imaging allows a greater understanding of psychiatric and neurologic problems.

Challenges persist due to the increasing incidence and prevalence of chronic illness. Chronic illness is now the most common reason for hospital admissions among children (excluding trauma and newborn admissions). In older children, mental illness is the main non-childbirth-related reason for hospitalization. Pediatricians must also address the increasing concern about environmental toxins and the prevalence of physical, emotional, and sexual abuse, and violence. World unrest, terrorism, and a global pandemic have caused an increased level of anxiety and fear for many families and children.

To address these ongoing challenges, many pediatricians now practice as part of a health care team that includes psychiatrists, psychologists, nurses, and social workers. This **patient-centered medical home model** of care is designed to provide continuous and coordinated care to maximize health outcomes. Other models, such as school-based health and retail medical facilities, may improve access but may not support continuity and coordination of care.

Childhood antecedents of adult health conditions, such as alcoholism, depression, obesity, hypertension, and hyperlipidemias, are increasingly recognized. Infants who are relatively underweight at birth due to maternal malnutrition are at higher risk of developing certain health conditions later in life, including diabetes, heart disease, hypertension, metabolic syndrome, and obesity. Improved neonatal care results in greater survival of preterm, low birthweight, or very low birthweight newborns, increasing the number of children with chronic medical conditions and developmental delays with their lifelong implications. Childhood exposure to adverse experiences such as abuse, divorce, and violence increases the risk of diabetes, cardiovascular disease, and mental health disorders in adults.

LANDSCAPE OF HEALTH CARE FOR CHILDREN IN THE UNITED STATES

Complex health, economic, and psychosocial challenges greatly influence the well-being and health outcomes of children. National reports from the Centers for Disease Control and Prevention (CDC) (e.g., <https://www.cdc.gov/nchs/data/hus/hus18.pdf>) provide information about many of these issues. Some of the key issues include the following:

- **Health insurance coverage.** Because of programs like Medicaid and the State Children's Health Insurance Program, children are more likely than adults to have health insurance coverage. For example, in 2018, 36% of children were covered by Medicaid. The continued decline in uninsured children nationally over the past decade left 5.2% of U.S. children lacking insurance in 2018.
- **Prenatal and perinatal care.** Nearly 75% of women begin prenatal care in the first trimester with lower rates noted in Hispanic and Black populations. Less than 1 in 10 women had delayed or no prenatal care.
- **Preterm births.** The incidence of preterm births (<37 weeks) has been rising since 2014 after an initial decrease in the rate from 2007 to 2014. In 2018, the preterm birth rate was 10% with continued racial and ethnic disparities. However, the rates of low birthweight infants ($\leq 2,500$ g [8.3% of all

births]) and very low birthweight infants ($\leq 1,500$ g [1.4% of all births]) are essentially unchanged since 2006.

- **Birthrate in adolescents.** The national birthrate among adolescents has been steadily dropping since 1990, reaching its lowest rate (17.4 births per 1,000) for 15- to 19-year-old adolescents in 2018.
- **Adolescent abortions.** The rate of abortions among adolescents has been decreasing since its peak in 1988 and is now at its lowest rate since abortion was legalized in 1973. In 2015, adolescents aged 15–19 years accounted for 9.8% of all reported abortions, with an abortion rate of 6.7 abortions per 1,000 adolescents that age.
- **Infant mortality.** In 2017, the overall infant mortality rate in the United States was 5.8 deaths per 1,000 live births demonstrating a continued slow, downward trend since 1995. However, disparity remains among ethnic groups. Infant mortality among non-Hispanic Black women is nearly double the national average. U.S. geographic variability persists with highest mortality rates in the South.
- **Initiation and maintenance of breast-feeding.** In 2015, 83.2% of newborn infants started breast-feeding after birth. That same year, rates of breast-feeding at 6 and 12 months were 57.6% and 35.9%. Breast-feeding rates vary by ethnicity (higher rates in non-Hispanic White and Hispanic mothers) and education (highest in women with a bachelor's degree or higher).
- **Cause of death in U.S. children.** The overall causes of death in all children (1–24 years of age) in the United States in 2018, in order of frequency, were unintentional injuries, congenital anomalies, suicide, homicide, and malignant neoplasms (Table 1.1). Death rates from all causes continue to slowly decline.
- **Hospital admissions for children and adolescents.** In 2018, 7% of children were admitted to a hospital at least once. Respiratory illnesses are the predominant cause of hospitalization for children 1–9 years of age, while mental illness is the most common cause of admission for adolescents.

TABLE 1.1 Causes of Death by Age in the United States, 2018

AGE GROUP (YEAR)	CAUSES OF DEATH IN ORDER OF FREQUENCY
1–4	Unintentional injuries (accidents) Congenital anomalies Homicide Malignant neoplasms Influenza/pneumonia Heart disease
5–14	Unintentional injuries (accidents) Malignant neoplasms Suicide Congenital anomalies Homicide Heart disease
15–24	Unintentional injuries (accidents) Suicide Homicide Malignant neoplasms Heart disease

From National Center for Health Statistics (US). *Health, United States, 2018*. https://www.cdc.gov/injury/images/lc-charts/leading-causes-of-death-by-age_group_2018_1100w850h.jpg.

- **Significant adolescent health challenges: substance use and abuse.** There is increasing substance use and abuse among U.S. adolescents. Fourteen percent of high school students report using some illicit or injection drugs, and 14% report using non-prescription opioids, both placing youth at risk for overdose and HIV infection. In 2017, 30% of surveyed high school students drank alcohol, 14% binge drank, and 17% rode in the car with someone who had been drinking. Tobacco cigarette use has declined among teens over the past decade, but the rate of e-cigarette use (or vaping) has increased from 1.5% in 2011 to 27.5% in 2019. Vaping has been proven to pose significant health risks to both users and nonusers.
- **Children in foster care.** In 2018, 437,000 children were in the foster care system and of those children 56% were reunited with families and 25% were adopted. Children leaving foster care often lack the emotional or financial support necessary to succeed in life and experience homelessness and/or joblessness and will not graduate from high school.

OTHER HEALTH ISSUES THAT AFFECT CHILDREN IN THE UNITED STATES

- **Obesity.** Obesity is the second leading cause of death in the United States (estimated 300,000 deaths annually). Rates of childhood obesity continue to rise. The prevalence of obesity among children aged 2–19 years was 18.5% in 2018. Obesity rates among Hispanic and Black populations were well above 20%.
- **Sedentary lifestyle.** With advancing technology, children spend more time in front of a screen (television, videogames, computer, etc.); some spend more than 7.5 hours for entertainment per day. This does not include additional time spent on a computer for educational purposes.
- **Motor vehicle accidents and injuries.** In 2017, 675 children 12 years of age or younger died in motor vehicle crashes, and more than 116,000 were injured. Thirty-five percent of those killed were not appropriately restrained. In 2017, 2,364 teens, aged 16–19, were killed in motor vehicle crashes. Drivers aged 16–19 are nearly three times more likely than drivers over age 20 to be involved in a fatal crash.
- **Child maltreatment.** In 2018, nearly 1,770 children died of abuse and neglect in the United States, with at least 1 in 7 children having experienced child abuse and/or neglect in the past year. Reportedly, 1 in 4 girls and 1 in 13 boys has experienced child sexual abuse at some point in their lifetime leading to both short- and long-term physical and mental health complications.
- **Toxic stress in childhood leading to adult health challenges.** The growing understanding of the interrelationship between biologic and developmental stresses, environmental exposure, and the genetic potential of patients is helping us recognize the adverse impact of toxic stressors on health and well-being. Screening for and acting upon factors that promote or hinder early development provides the best opportunity for long-term health. The field of epigenetics is demonstrating that exposure to environmental stress impacts genetic expression and can result in long-term effects on development, health, and behaviors.

- **Military deployment and children.** Current armed conflicts and political unrest affect millions of adults and their children. Active duty and National Guard/Reserve servicemen and servicewomen are parents to more than a million children. One third of troops returning from armed conflicts have a mental health condition (alcoholism, depression, and post-traumatic stress disorder) or have experienced a traumatic brain injury. Their children are affected by these morbidities as well as by the psychological impact of deployment. Child maltreatment is more prevalent in families of U.S.-enlisted soldiers during combat deployment than in non-deployed soldiers.

HEALTH DISPARITIES IN HEALTH CARE FOR CHILDREN

Health disparities are the differences that remain after accounting for patients' needs, preferences, and the availability of health care. Social conditions and inequity, discrimination, social stress, language barriers, and poverty are antecedents to and associated causes of health disparities. Disparities in infant mortality relate to poor access to prenatal care and the lack of access to appropriate health services for women.

- Infant mortality increases as the mother's level of education decreases.
- Children from poor families are less likely to be immunized and receive dental care at 4 years of age.
- Children with Medicaid/public coverage are less likely to be in excellent health than children with private health insurance.
- Children of ethnic minorities and those from poor families are less likely to have physician office or hospital outpatient visits and more likely to have hospital emergency department visits and higher rate of hospital admission.

CHANGING MORBIDITY: SOCIAL/EMOTIONAL ASPECTS OF PEDIATRIC PRACTICE

- **Changing morbidity** reflects the relationship among environmental, social, emotional, and developmental issues; child health status; and outcome. These observations are based on significant interactions of **biopsychosocial** influences on health and illness, such as school problems, learning disabilities, and attention problems; child and adolescent mood and anxiety disorders; adolescent suicide and homicide; firearms in the home; school violence; effects of media violence, obesity, and sexual activity; and substance use and abuse by adolescents.
- An estimated 1 in 5 children, ages 13–18 years, has a mental health condition. Half of all lifetime cases of mental illness begin by age 14 years. The average delay between onset of symptoms and intervention is 8–10 years. Suicide is the second leading cause of death for children ages 10–24 years, making early recognition of mental illness paramount. Children from poor families are twice as likely to have psychosocial problems as children from higher-income families. Nationwide, there is a lack of adequate mental health services for children.

Important influences on children's health, in addition to poverty, include homelessness, single-parent families, parental divorce, domestic violence, both parents working, and inadequate child care. Related pediatric challenges include

improving the quality of health care, social justice, equality in health care access, and improving the public health system. For adolescents, there are special concerns about sexuality, sexual orientation, pregnancy, substance use and abuse, violence, depression, and suicide.

CULTURE

The growing diversity of the United States requires that health care workers better understand the impact of health, illness, and treatment on the patient and family from their perspective. This requires open-ended questions, such as: "What *worries* you the most about your child's illness?" and "What do you *think* has caused your child's illness?" One must address concepts and beliefs about how patients/families interact with health professionals, as well as their spiritual and religious approach to health and health care from a cultural perspective, allowing incorporation of differences in perspectives, values, or beliefs into the care plan. Conflicts may arise because religious or cultural practices may lead to the possibility and/or perception of child abuse and neglect, which are required, by law, to be reported to social service authorities (see Chapter 22).

Complementary and alternative medicine (CAM) practices constitute a part of the broad cultural perspective. Therapeutic modalities for CAM include biochemical, lifestyle, biomechanical, and bioenergetic treatments, as well as homeopathy. It is estimated that 20–40% of healthy children and more than 60% of children with chronic illness use CAM and don't always reveal CAM use to their physician. Screening for CAM use can aid the pediatrician's counseling and minimize unintentional adverse interactions.

PEARLS FOR PRACTITIONERS

See *Profession of Pediatrics: Pearls for Practitioners at the end of this section.*

CHAPTER 2

Professionalism

CONCEPT OF PROFESSIONALISM

Society provides a profession with economic, political, and social rewards. Professions have specialized knowledge and responsibilities and exist as long as they fulfill responsibilities for the social good.

Today, the activities of medical professionals are subject to explicit public rules of accountability. Governmental and other authorities at city, state, and federal levels grant limited autonomy to professional organizations and their membership through regulations, licensing requirement, and standards of service (e.g., Medicare, Medicaid, and the Food and Drug Administration). The Department of Health and Human Services regulates physician behavior in conducting research with the goal of protecting human subjects. The National Practitioner Data Bank, created in 1986, contains information about physicians and other health care practitioners who have been disciplined by a state licensing board,

professional society, hospital, or health plan or named in medical malpractice judgments or settlements. Hospitals are required to review information in this data bank every 2 years as part of clinician re-credentialing. There are accrediting agencies for medical schools, such as the Liaison Committee on Medical Education (LCME), and postgraduate training, such as the Accreditation Council for Graduate Medical Education (ACGME).

Public trust in physicians is based on the physician's commitment to altruism, a cornerstone of the Hippocratic oath and an important rite of passage and part of medical school commencement ceremonies. The core of professionalism is embedded in the daily healing work of the physician and encompasses the patient-physician relationship. Professionalism includes an appreciation for the cultural and religious/spiritual health beliefs of the patient, incorporating the ethical and moral values of the profession (e.g., justice, courage, and wisdom) and the moral values of the patient. Professionalism also includes the understanding that dire circumstances may require physicians to provide care in uncertain situations, be it due to a natural disaster or a global pandemic. The ability of medical professionals to adapt in an ever-changing environment is a vital component of professionalism within medicine.

PROFESSIONALISM FOR PEDIATRICIANS

The American Board of Pediatrics (ABP) adopted professional standards in 2000, and the American Academy of Pediatrics (AAP) updated the policy statement and technical report on Professionalism in 2007, as follows:

- **Honesty/integrity** is the consistent regard for the highest standards of behavior and the refusal to violate one's personal and professional codes. Maintaining integrity requires awareness of situations that may result in conflict of interest or that may result in personal gain at the expense of the best interest of the patient.
- **Reliability/responsibility** includes accountability to one's patients, their families, society, and the medical community to ensure that all needs are addressed. There also must be a willingness to accept responsibility for errors.
- **Respect for others** requires the pediatrician to treat all persons with respect and regard for their individual worth and dignity; be aware of emotional, personal, family, and cultural influences on a patient's well-being, rights, and choices of medical care; and respect appropriate patient confidentiality.
- **Compassion/empathy** requires the pediatrician to listen attentively, respond humanely to patient/family concerns, and provide appropriate empathy for and relief of pain, discomfort, and anxiety as part of daily practice.
- **Self-improvement** is the pursuit of and commitment to providing the highest quality of health care through lifelong learning and education. This includes learning from errors, aspiring to excellence through self-evaluation, and accepting the critiques of others.
- **Self-awareness/knowledge of limits** includes recognition of the need for guidance and supervision when faced with new or complex responsibilities, the impact of behavior on others, and establishing appropriate professional boundaries.
- **Communication/collaboration** is crucial to providing the best care for patients. Pediatricians must work cooperatively and communicate effectively with patients, their

families, and all health care providers involved in the care of their patients.

- **Altruism/advocacy** refers to unselfish regard for and devotion to the welfare of others. It is a key element of professionalism. Self-interest or the interests of other parties should not interfere with the care of one's patients and their families.

PEARLS FOR PRACTITIONERS

See *Profession of Pediatrics: Pearls for Practitioners* at the end of this section.

CHAPTER 3

Ethics and Legal Issues

ETHICS IN HEALTH CARE

The ethics of health care and medical decision-making relies on **values**. Sometimes, ethical decision-making in medicine is a matter of choosing the least harmful option among many adverse alternatives. In the day-to-day practice of medicine, major ethical challenges are infrequent although always possible.

The legal system defines the minimal standards of behavior required of physicians and the rest of society through the legislative, regulatory, and judicial systems. Laws support the principle of **confidentiality** for teenagers who are competent to decide about medical issues. Using the concept of **limited confidentiality**, parents, teenagers, and the pediatrician may all agree to openly discuss serious health challenges, such as suicidal ideation and pregnancy. This reinforces the long-term goal of supporting the developing autonomy and identity of the teenager while encouraging appropriate conversations with parents.

Ethical problems usually derive from **value differences** among patients, families, and clinicians regarding choices and options in the provision of health care. Resolving these value differences involves several important ethical principles. **Autonomy**, based on the principle of **respect for persons**, means that competent adult patients can make choices about their health care after being appropriately informed about their health condition and the risks and benefits of alternative diagnostic tests and treatments. **Paternalism** challenges the principle of autonomy and involves the clinician deciding what is best for the patient. Under certain circumstances (e.g., when a patient has a life-threatening medical condition or a significant psychiatric disorder and is threatening self or others), paternalism is an accepted alternative to autonomy.

Other important ethical principles are those of **beneficence** (doing good), **nonmaleficence** (doing no harm or as little harm as possible), and **justice** (the values involved in the equal distribution of goods, services, benefits, and burdens to the individual, family, or society).

ETHICAL PRINCIPLES RELATED TO INFANTS, CHILDREN, AND ADOLESCENTS

Infants and young children do not have the capacity for making medical decisions, thus decision-making falls onto their parents. Parental decision-making should be guided by

what is in the best interest of the child. In certain older children, assent can be obtained for medical decision-making. Obtaining the **assent** of a child is the process in which the child is involved in decision-making with information appropriate to the child's capacity to understand. Most adolescents (<18 years of age) cannot legally provide informed consent for medical decisions; however, they can and should provide assent. Exceptions include medical decisions made by an adolescent for certain medical conditions, notably sexual and mental health. Emancipated minors are legally able to provide informed consent for medical decision-making.

The principle of shared medical decision-making is appropriate, but the process may be limited because of issues of confidentiality. A parent's concern about the side effects of immunization raises a conflict between the need to protect and support the health of the individual and of the public. Parental decisions that are clearly not in the child's best interest should be challenged.

LEGAL ISSUES

All competent patients of an age defined legally by each state (usually ≥ 18 years of age) are autonomous regarding their health decisions. To have decision-making capacity, patients must meet the following requirements:

- Understand the nature of the medical interventions and procedures, understand the risks and benefits of these interventions, and be able to communicate their decision.
- Reason, deliberate, and weigh the risks and benefits using their understanding about the implications of the decision on their own welfare.
- Apply a set of personal values to the decision-making process and show an awareness of the possible conflicts or differences in values as applied to the decisions to be made.

These requirements must be placed within the context of medical care and applied to each case with its unique characteristics. Most young children are not able to meet these requirements, hence parents serve as their legal surrogate decision-maker unless circumstances preclude them from making decisions in the child's best interest (e.g., abuse)

It is important to become familiar with state law as it, not federal law, determines when an adolescent can consent to medical care and when parents may access confidential adolescent medical information. In 2003, the Health Insurance Portability and Accountability Act (HIPAA) became effective, requiring a minimal standard of confidentiality protection. The law confers less confidentiality protection to minors than to adults. It is the pediatrician's responsibility to inform minors of their confidentiality rights and help them exercise these rights under the HIPAA regulations.

Under special circumstances, non-autonomous adolescents are granted the legal right to consent under state law when they are considered mature or emancipated minors or because of certain public health considerations, as follows:

- **Mature minors.** Some states recognize adolescents who meet the cognitive criteria and emotional maturity for competence and provide them with legal decision-making capacity. The Supreme Court has decided that pregnant, mature minors have the constitutional right to make decisions about abortion without parental consent. Although many state legislatures require parental notification,

pregnant adolescents wishing to have an abortion do not have to seek parental consent. The state must provide a judicial procedure to facilitate this decision-making for adolescents.

- **Emancipated minors.** Children who are legally emancipated from their parents may seek medical treatment without parental consent. The definition varies from state to state but generally includes children who have graduated from high school, are members of the armed forces, married, pregnant or have children, runaways, live apart from their parents, and are financially independent or declared emancipated by a court.
- **Interests of the state (public health).** State legislatures have concluded that minors with certain medical conditions, such as sexually transmitted infections and other contagious diseases, pregnancy (including prevention through the use of birth control), certain mental illnesses, and drug and alcohol abuse, may seek treatment for these conditions autonomously. States have an interest in limiting the spread of disease that may endanger the public health and in eliminating barriers to access for the treatment of certain conditions.

ETHICAL ISSUES IN PRACTICE

Clinicians should engage children and adolescents based on their developmental capacity in discussions about medical plans so that the child has a good understanding of the nature of the treatments and alternatives, the side effects, and expected outcomes. There should be an assessment of the patient's understanding of the clinical situation, how the patient is responding, and the factors that may influence the patient's decisions. Pediatricians should always listen to and appreciate patients' requests for confidentiality and their hopes and wishes. The goal is to help nourish a child's capacity to become as autonomous as is appropriate to their developmental stage.

Confidentiality

Confidentiality is crucial to the provision of medical care and is an important part of the basis for a trusting patient-family-physician relationship. Confidentiality means that information about a patient should not be shared without consent. If confidentiality is broken, patients may experience great harm and may not seek needed medical care. See [Chapter 67](#) for a discussion of confidentiality in the care of adolescents.

Ethical Issues in Genetic Testing and Screening in Children

The goal of **screening** is to identify diseases when there is no clinically identifiable risk factor for disease. Screening should take place only when there is a treatment available or when a diagnosis would benefit the child. **Testing** usually is performed when there is some clinically identifiable risk factor. Genetic testing and screening present special problems because test results have important implications. Some genetic screening (sickle cell anemia or cystic fibrosis) may reveal a carrier state, which may lead to choices about reproduction or create financial, psychosocial, and interpersonal problems (e.g., guilt, shame, social stigma, and discrimination in insurance and

jobs). Collaboration with, or referral to, a clinical geneticist is appropriate in helping the family with the complex issues of genetic counseling when a genetic disorder is detected or anticipated.

Newborn screening should not be used as a surrogate for parental testing. Examples of diseases that can be diagnosed by genetic screening, even though the manifestations of the disease process do not appear until later in life, are polycystic kidney disease; Huntington disease; certain cancers, such as breast cancer in some ethnic populations; and hemochromatosis. For their own purposes, parents may pressure the pediatrician to order genetic tests when the child is still young. Testing for these disorders should be delayed until the child has the capacity for informed consent or assent and is competent to make decisions, unless there is a direct benefit to the child at the time of testing.

Religious Issues and Ethics

The pediatrician is required to act in the best interests of the child, even when religious tenets may interfere with the health and well-being of the child. When an infant or child, whose parents have a religious prohibition against a blood transfusion, needs a transfusion to save the child's life, the courts always intervene to allow a transfusion. In contrast, parents with strong religious beliefs may refuse immunizations for their children. States may use the principle of **distributive justice** to require immunization of all during outbreaks or epidemics, including individuals who object on religious grounds.

Children as Human Subjects in Research

The goal of research is to develop new and generalized knowledge. Parents may give informed permission for children to participate in research under certain conditions. Children cannot give consent but may assent or dissent to research protocols, and these decisions should be respected. Special federal regulations have been developed to protect child and adolescent participants in human investigation. These regulations provide additional safeguards beyond those for adult participants while still providing the opportunity for children to benefit from the scientific advances of research.

Many parents with seriously ill children hope that the research protocol will have a direct benefit for their child. The researcher should be sensitive and compassionate in explaining to the parents that research does not guarantee a (better) treatment.

Ethical Issues Surrounding Scarce Resource Allocation

Medical resources are finite and under certain circumstances, notably a global pandemic, risk becoming a scarce resource. In such situations it is possible that allocation strategies need to be developed and implemented. The ethical principles of justice, beneficence, and nonmaleficence serve as guiding pillars to ensure that resources are allocated in a fair manner.

PEARLS FOR PRACTITIONERS

See *Profession of Pediatrics: Pearls for Practitioners* at the end of this section.

CHAPTER 4

Palliative Care and End-of-Life Issues

The death of a child is one of life's most difficult experiences. The **palliative care** approach is defined as patient- and family-centered care that optimizes quality of life by anticipating, preventing, and treating suffering. This approach should be instituted when medical diagnosis, intervention, and treatment cannot reasonably be expected to affect the imminence of death. Central to this approach is the willingness of clinicians to look beyond traditional medical goals of curing disease and preserving life and toward enhancing the life of the child with assistance from family members and close friends. High-quality palliative care is an expected standard at the end of life.

Palliative care in pediatrics is not simply end-of-life care. Children needing palliative care have been described as having conditions that fall into four basic groups based on the goal of treatment. These include conditions of the following scenarios:

- A cure is possible, but failure is not uncommon (e.g., cancer with a poor prognosis).
- Long-term treatment is provided with a goal of maintaining quality of life (e.g., cystic fibrosis).
- Treatment that is exclusively palliative after the diagnosis of a progressive condition is made (e.g., trisomy 13 syndrome).
- Treatments are available for severe, non-progressive disability in patients who are vulnerable to repeated health complications (e.g., severe spastic quadriplegia with difficulty in controlling symptoms).

These conditions present different timelines and different models of medical intervention while sharing the need to attend to concrete elements affecting the quality of a child's life and possible death and are mediated by medical, psychosocial, cultural, and spiritual concerns.

Palliative care can make important contributions to the end-of-life and bereavement issues for families without time to prepare for an unexpected death. This may become complicated in circumstances where the cause of the death must be fully explored such as possible child abuse or neglect, as this subjects the family to intense scrutiny and may create guilt and anger directed at the medical team.

PALLIATIVE AND END-OF-LIFE CARE

Palliative treatment is directed toward the relief of symptoms as well as assistance with anticipated adaptations that may cause distress and diminish the quality of life of the dying child. Elements of palliative care include pain management; expertise with feeding and nutritional issues at the end of life; and management of symptoms, such as minimizing nausea and vomiting, bowel obstruction, labored breathing, and fatigue. Psychologic elements of palliative care have a profound importance and include sensitivity to bereavement, a developmental perspective of a child's understanding of death, clarification of the goals of care, and ethical issues. Palliative care is delivered through a multidisciplinary approach, giving a broad range of expertise to patients and families as well as providing a supportive network for the caregivers. Caregivers

involved may be pediatricians, nurses, mental health professionals, social workers, and pastors.

A model of integrated palliative care rests on the following principles:

- **Respect for the dignity of patients and families.** The clinician should respect and listen to patient and family goals, preferences, and choices. School-age children can articulate preferences about how they wish to be treated. Adolescents can engage in decision-making (see Section 12). **Advanced care** (advance directives) should be discussed with the child and parents to determine what they would like as treatment options as the end of life nears. Differences of opinion between the family and pediatrician should be addressed by identifying the multiple perspectives, reflecting on possible conflicts, and altruistically coming to agreements that validate the patient and family perspectives yet reflect sound practice. **Hospital ethics committees** and consultation services are important resources for the pediatrician and family members.
- **Access to comprehensive and compassionate palliative care.** The clinician should address the physical symptoms, comfort, and functional capacity, with special attention to pain and other symptoms associated with the dying process while also responding empathically to psychologic distress and human suffering, and provide treatment options. Respite should be available at any time during the illness to allow the family caregivers to rest and renew.
- **Use of interdisciplinary resources.** Because of the complexity of care, no one clinician can provide all needed services. The team members may include primary and subspecialty physicians, nurses in the hospital/facility or for home visits, the pain management team, psychologists, social workers, pastoral ministers, schoolteachers, friends of the family, and peers of the child. The child and family should decide who should know what during all phases of the illness process.
- **Acknowledgment and support provisions for caregivers.** The primary caregivers of the child, family, and friends need opportunities to address their own emotional concerns. Team meetings to address thoughts and feelings of team members are crucial. Institutional support may include time to attend funerals, counseling for the staff, opportunities for families to return to the hospital, and scheduled ceremonies to commemorate the death of the child.
- **Commitment to quality improvement of palliative care through research and education.** Hospitals should develop support systems and staff to monitor the quality of care continually, assess the need for appropriate resources, and evaluate the responses of the patient and family members to the treatment program.

Hospice care is a treatment program for the end of life that provides the range of palliative care services by an interdisciplinary team including specialists in the bereavement and end-of-life process. In 2010, legislation was passed allowing children covered under Medicaid or the Children's Health Insurance Program (CHIP) to receive access simultaneously to hospice care and curative care.

BEREAVEMENT

Bereavement refers to the process of psychologic and spiritual accommodation to death on the part of the child and

the child's family. **Grief** has been defined as the emotional response caused by a loss which may include pain, distress, and physical and emotional suffering. It is a normal adaptive human response to death. Assessing the coping resources and vulnerabilities of the affected family before death occurs is central to the palliative care approach.

Parental grief is recognized as being more intense and sustained than other types of grief. Most parents work through their grief. Complicated grief, a pathologic manifestation of continued and disabling grief, is rare. Parents who share their problems with others during the child's illness, who have access to psychologic support during the last month of their child's life, and who have had closure sessions with the attending staff are more likely to resolve their grief. In the era of technology, some parents may find solace in connecting with other parents with similar experiences in an online forum.

A particularly difficult issue for parents is whether to talk with their child about the child's imminent death. Although evidence suggests that sharing accurate and truthful information with a dying child is beneficial, each individual case presents its own complexities based on the child's age, cognitive development, disease, timeline of disease, and parental psychologic state. Parents are more likely to regret not talking with their child about death than having done so.

COGNITIVE ISSUES IN CHILDREN AND ADOLESCENTS: UNDERSTANDING DEATH AND DYING

The pediatrician should communicate with children about what is happening to them while respecting the cultural and personal preferences of the family. A developmental understanding of children's concepts of health and illness helps frame the discussion and can help parents understand how their child is grappling with the situation. Piaget's theories of cognitive development, which help illustrate children's concepts of death and disease, are categorized as sensorimotor, preoperational, concrete operations, and formal operations.

For children up to 2 years of age (sensorimotor), death is seen as a separation without a specific concept of death. The associated behaviors in grieving children of this age usually include protesting and difficulty of attachment to other adults. The degree of difficulty depends on the availability of other nurturing people with whom the child has a good previous attachment.

Children from 3–5 years of age (preoperational; sometimes called *the magic years*) have trouble grasping the meaning of the illness and the permanence of the death. Their language skills at this age make understanding their moods and behavior difficult. Because of a developing sense of guilt, death may be viewed as punishment. If a child previously wished a sibling dead, the death may be seen psychologically as being caused by the child's wishful thinking. They can feel overwhelmed when confronted with the strong emotional reactions of their parents.

In children ages 6–11 years of age (late preoperational to concrete operational), the finality of death gradually comes to be understood. Magical thinking gives way to a need for detailed information to gain a sense of control. Older children in this range have a strong need to control their emotions by compartmentalizing and intellectualizing.

In adolescents older than 12 years of age (formal operations), death is a reality and seen as universal and irreversible.

Adolescents handle death issues at the abstract or philosophical level and can be realistic. They may also avoid emotional expression and information, instead relying on anger or disdain. Their wishes, hopes, and fears should be attended to and respected.

CULTURAL, RELIGIOUS, AND SPIRITUAL CONCERNS ABOUT PALLIATIVE CARE AND END-OF-LIFE DECISIONS

Understanding the family's religious/spiritual or cultural beliefs and values about death and dying can help the pediatrician work with the family to integrate these beliefs, values, and practices into the palliative care plan. Cultures vary regarding the roles family members have, the site of treatment for dying people, and the preparation of the body. Some ethnic groups expect the clinical team to speak with the oldest family member or only to the head of the family, outside of the patient's presence, while others involve the entire extended family in decision-making. For some families, dying at home can bring the family bad luck; others believe that the patient's spirit will become lost if the death occurs in the hospital. In some traditions, the health care team cleans and prepares the body, whereas in others, family members prefer to complete this ritual. Religious/spiritual or cultural practices may include prayer, anointing, laying on of the hands, an exorcism ceremony to undo a curse, amulets, and other religious objects placed on the child or at the bedside. Families differ in the idea of organ donation and the acceptance of autopsy. Decisions, rituals, and withholding of palliative or lifesaving procedures that could harm the child or are not in the best interests of the child should be addressed. Quality palliative care attends to this complexity and helps parents and families navigate the death of a child while honoring the familial, cultural, and spiritual values.

ETHICAL ISSUES IN END-OF-LIFE DECISION-MAKING

Before speaking with a child about death, the caregiver should assess the child's age, experience, and level of development; the child's understanding and involvement in end-of-life decision-making; the parents' emotional acceptance of death; their coping strategies; and their philosophical, spiritual, and cultural views of death. These may change over time. The use of open-ended questions to repeatedly assess these areas contributes to the end-of-life process. The care of a dying child can create **ethical dilemmas** involving **autonomy**, **beneficence** (doing good), **nonmaleficence** (doing no harm), truth telling, confidentiality, or the physician's duty. It is extremely difficult for parents to know when the burdens of continued medical care are no longer appropriate for their child and may, at times, rely on the medical team for guidance. The beliefs and values of what constitutes quality of life, when life ceases to be worth living, and religious/spiritual, cultural, and philosophical beliefs may differ between families and health care workers. The most important ethical principle is what is in the **best interest** of the child as determined through the process of **shared decision-making**, **informed consent** from the parents, and **assent** from the child. Sensitive and meaningful communication with the family, in their own terms, is essential. The physician, patient, and family must **negotiate**

the goals of continued medical treatment while recognizing the burdens and benefits of the medical intervention plan. There is no ethical or legal difference between withholding treatment and withdrawing treatment, although many parents and physicians see the latter as more challenging. Family members and the patient should agree about what are appropriate **do not resuscitate** (also called **DNR**) orders. Foregoing some measures does not preclude other measures being implemented based on the needs and wishes of the patient and family. When there are serious differences among parents, children, and physicians on these matters, the physician may consult with the **hospital ethics committee** or, as a last resort, turn to the legal system by filing a report about potential abuse or neglect.

ORGAN DONATION IN PEDIATRICS

The gap between supply and demand of transplantable organs in children is widening as more patients need a transplant without a concomitant increase in the organ donor pool. Organ donation can occur one of two ways: after fulfilling criteria for neurologic (brain) death or through a process of donation after circulatory death (DCD). DCD has only recently gained acceptance in pediatrics. Organ procurement, donation, and transplantation are strictly regulated by governmental agencies to ensure proper and fair allocation of donated organs for transplantation. It is important that pediatric medical specialists and pediatricians be well acquainted with the strategies and methods of organ donation to help acquaint both the donor family and the recipient family with the process and address expectations. Areas of concern within pediatric organ donation include availability of and access to donor organs; oversight and control of the process; pediatric medical and surgical consultation and continued care throughout the transplantation process; ethical, social, financial, and follow-up; insurance coverage; and public awareness of the need for organ donors. Organ donation and organ transplantation can provide significant life-extending benefits to a child who has a failing organ and is awaiting transplant, while at the same time place a high emotional impact on the donor family after the loss of a child.

PEARLS FOR PRACTITIONERS

PEARLS FOR PRACTITIONERS

CHAPTER 1

Population and Culture: The Care of Children in Society

- Pediatricians must continue to address major issues impacting children's health outcomes including access to care, health disparities, and environmental factors including toxic stressors such as poverty and violence.
- The significant increase in the number of children with a chronic medical condition (e.g., asthma, obesity, attention-deficit/hyperactivity disorder) affects both inpatient and outpatient care.
- Addressing the following as a part of routine health care allows pediatricians to impact health care outcomes:
 - Toxic stressors (e.g., maternal stress, poverty, exposure to violence)
 - The use of electronic nicotine delivery systems or e-cigarettes
 - The sedentary lifestyle as children spend an increased amount of time in front of a screen (television, video games, computers, cell phones)
 - Early recognition of mental illness (It is estimated that 1 in 5 adolescents has a mental health condition.)
 - Use of complementary and alternative medicine (to minimize unintended interactions)

CHAPTER 2

Professionalism

- The activities of medical professionals are subject to explicit public rules of accountability developed by governmental and other authorities.
- The public trust of physicians is based on the physician's commitment to altruism.
- Extreme circumstances, such as a natural disaster or global pandemic, may necessitate adaptability as physicians expand how they help others by using their medical knowledge and clinical skills in unique and uncertain situations.

- The policy statement on professionalism released by the American Board of Pediatrics emphasizes honesty/integrity, reliability/responsibility, respect for others, compassion/empathy, self-improvement, self-awareness/knowledge of limits, communication/collaboration, and altruism/advocacy.

CHAPTER 3

Ethics and Legal Issues

- Important ethical principles that help guide medical decision-making include autonomy, beneficence, non-maleficence, and justice.
- The ability to legally make medical decisions for oneself depends on the patient's age, maturity, and determination of competence. Parents serve as medical decision-makers for most children, and these decisions should always be made within the child's best interest.
- Key ethical principles in the care of pediatric patients include autonomy (addressing medical decision-making in children), informed consent by parents, assent by the child, and confidentiality.

CHAPTER 4

Palliative Care and End-of-Life Issues

- Children needing palliative care generally fall into four basic categories: (1) when a cure is possible but unlikely, (2) long-term treatment with a goal of maintaining quality of life (e.g., cystic fibrosis), (3) treatment that is exclusively palliative after the diagnosis of a progressive condition is made (e.g., trisomy 13), and (4) when treatments are available for severe, non-progressive disabilities.
- Organ donation can occur after fulfilling criteria for neurologic death or through donation after circulatory death.

GROWTH AND DEVELOPMENT

Latasha Bogues | David A. Levine

CHAPTER 5

Normal Growth

HEALTH MAINTENANCE VISIT

The frequent office visits for health maintenance in the first 2 years of life are more than physicals. Although a somatic history and physical examination are important parts of each visit, many other issues are discussed, including nutrition, behavior, development, safety, and **anticipatory guidance**.

Disorders of growth and development are often associated with chronic or severe illness or may be the only symptom of parental neglect or abuse. Although normal growth and development does not eliminate a serious or chronic illness, in general, it supports a judgment that a child is healthy except for acute, often benign illnesses.

The processes of growth and development are intertwined. However, it is convenient to refer to **growth** as the increase in size and **development** as an increase in function of processes related to body and mind. Being familiar with normal patterns of growth and development allows practitioners who care for children to recognize and manage abnormal variations.

The genetic makeup and the physical, emotional, and social environment of the individual determine how a child grows and develops throughout childhood. Helping each child achieve individual potential through periodically monitoring and screening for the normal progression or abnormalities of growth and development is one goal of pediatrics. The American Academy of Pediatrics recommends routine office visits in the first week of life (within 72 hours of routine nursery discharges); by 1 month of age; at 2, 4, 6, 9, 12, 15, and 18 months; at 2, 2 1/2, and 3 years; and then annually through adolescence/young adulthood (see Fig. 9.1; the *Bright Futures*’ “Recommendations for Preventive Pediatric Health Care” found at https://www.aap.org/en-us/documents/periodicity_schedule.pdf).

Deviations in growth patterns may be nonspecific or may be important indicators of serious and chronic medical disorders. An accurate measurement of length/height, weight, and head circumference (measure head circumference through age 24 months) should be obtained at every health supervision visit and compared with statistical norms on growth charts. Table 5.1 summarizes several convenient benchmarks to evaluate normal growth. Serial measurements that establish a growth trend are much more useful than single measurements for detecting abnormal growth patterns. A single

measurement may be within statistically defined normal limits (percentiles) while being at a vastly different percentile from previous measurements, representing a growth pattern that warrants further evaluation.

Growth is assessed by plotting accurate measurements on growth charts and comparing each set of measurements with previous measurements obtained at health visits. Please see examples in Figs. 5.1–5.4. Complete charts can be found at www.cdc.gov/growthcharts. The body mass index is defined as body weight in kilograms divided by height in meters squared; it is used to classify adiposity and is recommended as a screening tool for children and adolescents to identify those overweight or at risk for being overweight (see Chapter 29).

Normal growth patterns have spurts and plateaus, so some shifting on percentile graphs can be expected. Large shifts in percentiles warrant attention, as do large discrepancies in height, weight, and head circumference percentiles. When caloric intake is inadequate, the weight percentile falls first, then the height; the head circumference is last. Caloric intake may be poor as a result of inadequate feeding or because the child is not receiving adequate attention and stimulation (*nonorganic* failure to thrive [see Chapter 21]).

TABLE 5.1 Rules of Thumb for Growth

WEIGHT

Weight loss in first few days: 5–10% of birthweight

Return to birthweight: 7–10 days of age

Double birthweight: 4–5 months

Triple birthweight: 1 year

Daily weight gain:

20–30 g for first 3–4 months

15–20 g for rest of the first year

HEIGHT

Average length: 20 in. at birth, 30 in. at 1 year

At age 4 years, the average child is double birth length or 40 in.

HEAD CIRCUMFERENCE (HC)

Average HC: 35 cm at birth (13.5 in.)

HC increases: 1 cm per month for first year (2 cm per month for first 3 months, then slower)

FIGURE 5.1 Length-by-age and weight-by-age percentiles for boys, birth to 2 years of age. Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion. (From Centers for Disease Control and Prevention. *WHO Child Growth Standards*. Atlanta, GA: CDC; 2009. <http://www.cdc.gov/growthcharts>.)

FIGURE 5.2 Head circumference and weight-by-length percentiles for boys, birth to 2 years of age. (From Centers for Disease Control and Prevention. *WHO Child Growth Standards*. Atlanta, GA: CDC; 2009. <http://www.cdc.gov/growthcharts>.)

FIGURE 5.3 Stature-for-age and weight-for-age percentiles for girls, 2–20 years of age. Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion. (From Centers for Disease Control and Prevention. Atlanta, GA; 2001. <http://www.cdc.gov/growthcharts>.)

FIGURE 5.4 Body mass index-for-age percentiles for girls, 2–20 years of age. Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion. (From Centers for Disease Control and Prevention. Atlanta, GA; 2001. <http://www.cdc.gov/growthcharts>.)

Caloric intake also may be inadequate because of increased caloric needs. Children with chronic illnesses, such as heart failure or cystic fibrosis, may require a significantly higher caloric intake to sustain growth. An increasing weight percentile in the face of a falling height percentile suggests hypothyroidism. Head circumference may be disproportionately large when there is familial megaloccephaly, hydrocephalus, or merely *catch-up* growth in a neurologically normal premature infant. A child is considered microcephalic if the head circumference is less than the 3rd percentile, even if length and weight measurements also are proportionately low. Serial measurements of head circumference are crucial during infancy, a period of rapid brain development, and should be plotted regularly until the child is 2 years of age. Any suspicion of abnormal growth warrants at least a close follow-up, further evaluation, or both.

PEARLS FOR PRACTITIONERS

See Growth and Development: Pearls for Practitioners at the end of this section.

CHAPTER 6

Disorders of Growth

The most common reasons for deviant measurements are technical (i.e., faulty equipment and human errors). Repeating a deviant measurement is the first step. Separate growth charts are available and should be used for very low birthweight infants (weight <1,500 g) and for those with Turner syndrome, Down syndrome, achondroplasia, and various other dysmorphism syndromes.

Variability in body proportions occurs from fetal to adult life. Newborns' heads are significantly larger in proportion to the rest of their body. This difference gradually disappears. Certain growth disturbances result in characteristic changes in the proportional sizes of the trunk, extremities, and head. Patterns requiring further assessment are summarized in Table 6.1.

Evaluating a child over time, coupled with a careful history and physical examination, helps determine whether the growth pattern is normal or abnormal. Parental heights may be useful when deciding whether to proceed with a further evaluation. Children, in general, follow their parents' growth patterns, although there are many exceptions.

For a girl, midparental height is calculated as follows:

$$\frac{\text{Paternal height (inches)} + \text{Maternal height (inches)}}{2} - 2.5$$

For a boy, midparental height is calculated as follows:

$$\frac{\text{Paternal height (inches)} + \text{Maternal height (inches)}}{2} + 2.5$$

Actual growth depends on too many variables to make an accurate prediction from midparental height determination for every child. The growth pattern of a child with low weight, length, and head circumference is commonly associated with **familial short stature** (see Chapter 173). These children are genetically normal but are smaller than most children. A child who, by age, is preadolescent or adolescent and who starts puberty later than others may have the normal variant called **constitutional short stature** (see Chapter 173); careful

TABLE 6.1 Specific Growth Patterns Requiring Further Evaluation

PATTERN	REPRESENTATIVE DIAGNOSES TO CONSIDER	FURTHER EVALUATION
Weight, length, head circumference all <5th percentile	<ul style="list-style-type: none"> Familial short stature Constitutional short stature Intrauterine insult Genetic abnormality 	<ul style="list-style-type: none"> Midparental height Evaluation of pubertal development Examination of prenatal records Chromosome analysis
Discrepant percentiles (e.g., weight 5th, length 5th, head circumference 50th, or other discrepancies)	<ul style="list-style-type: none"> Normal variant (familial or constitutional) Endocrine growth failure Caloric insufficiency 	<ul style="list-style-type: none"> Midparental height Thyroid hormone Growth factors, growth hormone testing Evaluation of pubertal development
Declining percentiles	<ul style="list-style-type: none"> Catch-down growth Caloric insufficiency Endocrine growth failure 	<ul style="list-style-type: none"> Midparental height Complete history and physical examination Dietary and social history Growth factors, growth hormone testing

examination for abnormalities of pubertal development should be done. An evaluation for primary amenorrhea should be considered for any female adolescent who has not reached menarche by 15 years or has not done so within 3 years of thelarche (beginning of breast development). Lack of breast development by age 13 years also should be evaluated (see Chapter 174).

Starting out in high growth percentiles, many children assume a lower percentile between 6 and 18 months of age until they match their genetic programming; then they grow along new, lower percentiles. They usually do not decrease more than two major percentiles and have normal developmental, behavioral, and physical examinations. These children with *catch-down growth* should be followed closely, but no further evaluation is warranted.

Infants born small for gestational age, or prematurely, ingest more breast milk or formula and, unless there are complications that require extra calories, usually exhibit *catch-up growth* in the first 6 months. These infants should be fed on demand and provided as much as they want unless they are vomiting (not just spitting up [see Chapter 128]). Some may benefit from a higher caloric content formula. Many psychosocial risk factors that may have led to being born small or early may contribute to nonorganic failure to thrive (see Chapter 21). Conversely, infants who recover from being low birthweight or premature have an increased risk of developing childhood obesity.

Growth of the nervous system is most rapid in the first 2 years, correlating with increasing physical, emotional, behavioral, and cognitive development. There is again rapid change during adolescence. Osseous maturation (bone age) is determined from radiographs on the basis of the number and size of calcified epiphyseal centers; the size, shape, density, and sharpness of outline of the ends of bones; and the distance separating the epiphyseal center from the zone of provisional calcification.

PEARLS FOR PRACTITIONERS

See *Growth and Development: Pearls for Practitioners* at the end of this section.

CHAPTER 7

Normal Development

PHYSICAL DEVELOPMENT

Parallel to the changes in the developing brain (i.e., cognition, language, behavior) are changes in the physical development of the body.

NEWBORN PERIOD

Observation of any asymmetric movement or altered muscle tone and function may indicate a significant central nervous system abnormality or a nerve palsy resulting from the delivery and requires further evaluation. Primitive neonatal reflexes are unique in the newborn period and can further elucidate or eliminate concerns over asymmetric function. The most important reflexes to assess during the newborn period are as follows:

The **Moro reflex** is elicited by allowing the infant's head to gently move back suddenly (from a few inches off of the mattress onto the examiner's hand), resulting in a startle, then abduction and upward movement of the arms followed by adduction and flexion. The legs respond with flexion.

The **rooting reflex** is elicited by touching the corner of the infant's mouth, resulting in lowering of the lower lip on the same side with tongue movement toward the stimulus. The face also turns toward the stimulus.

The **sucking reflex** occurs with almost any object placed in the newborn's mouth. The infant responds with vigorous sucking. The sucking reflex is replaced later by voluntary sucking.

The **asymmetric tonic neck reflex** is elicited by placing the infant supine and turning the head to the side. This placement results in ipsilateral extension of the arm and the leg into a "fencing" position. The contralateral side flexes as well.

A delay in the expected disappearance of the reflexes may also warrant an evaluation of the central nervous system.

See Sections 11 and 26 for additional information on the newborn period.

LATER INFANCY

With the development of gross motor skills, the infant is first able to control posture, then proximal musculature, and, last, distal musculature. As the infant progresses through these stages, the parents may notice orthopedic deformities (see Chapters 202 and 203). The infant also may have deformities that are related to intrauterine positioning. Physical examination should indicate whether the deformity is fixed or can be moved passively into the proper position. When a joint held in an abnormal fashion can be moved passively into the proper position, there is a high likelihood of resolving with the progression of gross motor development. Fixed deformities warrant immediate pediatric orthopedic consultation (see Section 26).

Evaluation of vision and ocular movements is important to prevent the serious outcome of strabismus. The cover test and light reflex should be performed at early health

maintenance visits; interventions after age 2 decrease the chance of preserving binocular vision or normal visual acuity (see Chapter 179).

SCHOOL AGE/PREADOLESCENT

In addition to routine health supervision, older school-age children who begin to participate in competitive sports should have a comprehensive sports history and physical examination that includes a careful evaluation of the cardiovascular system. The American Academy of Pediatrics 5th edition sports preparticipation form is excellent for documenting cardiovascular and other risks. The patient and parent should complete the history form and be interviewed to assess cardiovascular risk. Any history of heart disease or a murmur must be referred for evaluation by a pediatric cardiologist. A child with a history of dyspnea or chest pain on exertion, irregular heart rate (i.e., skipped beats, palpitations), or syncope should also be referred to a pediatric cardiologist. A family history of a primary (immediate family) or secondary (immediate family's immediate family) atherosclerotic disease (myocardial infarction or cerebrovascular disease) before 50 years of age or sudden unexplained death at any age also requires additional assessment.

Children interested in contact sports should be assessed for special vulnerabilities. Similarly, vision should be assessed as a crucial part of the evaluation before participation in sports.

ADOLESCENCE

Adolescents need annual comprehensive health assessments to ensure progression through puberty without major problems (see Chapters 67 and 68). Sexual maturity is an important issue in adolescents, and all adolescents should be assessed to monitor progression through sexual maturity rating stages (see Chapter 67). Other issues in physical development include scoliosis, obesity, and common orthopedic growth issues (e.g., Osgood Schlatter; see Chapters 29 and 203). Most scoliosis is mild and requires only observation for resolution. Obesity may first manifest during childhood and is a growing public health concern for many adolescents.

DEVELOPMENTAL MILESTONES

The use of milestones to assess development focuses on discrete behaviors that the clinician can observe or accept as present by parental report. This approach is based on comparing the patient's behavior with that of many normal children whose behaviors evolve in a uniform sequence within specific age ranges (see Chapter 8). The development of the neuromuscular system, similar to that of other organ systems, is determined first by genetic endowment and then is molded by environmental influences.

Although a sequence of specific, easily measured behaviors can adequately represent some areas of development (**gross motor**, **fine motor**, and **language**), other areas, particularly social and emotional development, are not as easy to assess. Easily measured developmental milestones are well established through age 6 years only. Other types of assessment (e.g., intelligence tests, school performance, and personality profiles) that expand the developmental milestone approach are available for older children.

PSYCHOSOCIAL ASSESSMENT

Bonding and Attachment in Infancy

The terms *bonding* and *attachment* describe the affective relationships between parents and infants. **Bonding** occurs shortly after birth and reflects the feelings of the parents toward the newborn (unidirectional). **Attachment** involves reciprocal feelings between parent and infant and develops gradually over the first year.

Attachment of infants outside of the newborn period is crucial for optimal development. Infants who receive extra attention, such as parents responding immediately to any crying or fussiness in the first 4 months, show less crying and fussiness at the end of the first year. **Stranger anxiety** develops between 9 and 18 months of age, when infants normally become insecure about separation from the primary caregiver. The infant's new motor skills and attraction to novelty may lead to headlong plunges into new adventures that result in fright or pain followed by frantic efforts to find and cling to the primary caregiver. The result is dramatic swings from stubborn independence to clinging dependence that can be frustrating and confusing to parents. With secure attachment, this period of ambivalence may be shorter and less tumultuous.

Developing Autonomy in Early Childhood

Toddlers build on attachment and begin developing autonomy that allows separation from parents. In times of stress, toddlers often cling to their parents, but in their usual activities they may be actively separated. Ages 2–3 years are a time of major accomplishments in fine motor skills, social skills, cognitive skills, and language skills. The dependency of infancy yields to developing independence and the “I can do it myself” age. Limit setting is essential to a balance of the child's emerging independence.

Early Childhood Education

There is a growing body of evidence that notes that children who are in high-quality early learning environments are more prepared to succeed in school. Every dollar invested in early childhood education may save taxpayers up to 13 dollars in future costs. These children commit fewer crimes and are better prepared to enter the workforce after school. Early Head Start (<3 years), Head Start (3–4 years), and prekindergarten programs (4–5 years) all demonstrate better educational attainment, although the earlier the start, the better the results.

School Readiness

Readiness for preschool depends on the development of autonomy and the ability of the parent and the child to separate for hours at a time. Preschool experiences help children develop socialization skills; improve language; increase skill building in areas such as colors, numbers, and letters; and increase problem solving (puzzles).

Readiness for school (kindergarten) requires emotional maturity, peer group and individual social skills, cognitive abilities, and fine and gross motor skills (Table 7.1). Other issues include chronological age and gender. Children tend to do better in kindergarten if their fifth birthday is at least 4–6 months before the beginning of school. Girls usually are ready earlier than boys. If the child is in less than the average developmental

TABLE 7.1 Evaluating School Readiness

PHYSICIAN OBSERVATIONS (BEHAVIORS OBSERVED IN THE OFFICE)

Ease of separation of the child from the parent

Speech development and articulation

Understanding of and ability to follow complex directions

Specific pre-academic skills

Knowledge of colors

Counts to 10

Knows age, first and last name, address, and phone number

Ability to copy shapes

Motor skills

Stand on one foot, skip, and catch a bounced ball

Dresses and undresses without assistance

PARENT OBSERVATIONS (QUESTIONS ANSWERED BY HISTORY)

Does the child play well with other children?

Does the child separate well, such as a child playing in the backyard alone with occasional monitoring by the parent?

Does the child show interest in books, letters, and numbers?

Can the child sustain attention to quiet activities?

How frequent are toilet-training accidents?

range, the child should not be forced into early kindergarten. Holding a child back for reasons of developmental delay, in the false hope that the child will catch up, can also lead to difficulties. The child should enroll on schedule, and educational planning should be initiated to address any deficiencies.

Physicians should be able to identify children at risk for school difficulties, such as those who have developmental delays or physical disabilities. These children may require specialized school services in an individualized education plan (IEP) and/or environment accommodations in a 504 plan.

Adolescence

Some define adolescence as 10–25 years of age, but adolescence is perhaps better characterized by the developmental stages (*early*, *middle*, and *late* adolescence) that all teens must negotiate to develop into healthy, functional adults. Different behavioral and developmental issues characterize each stage. The age at which each issue manifests and the importance of these issues vary widely among individuals, as do the rates of cognitive, psychosexual, psychosocial, and physical development.

During **early adolescence**, attention is focused on the present and on the peer group. Concerns are primarily related to the body's physical changes and normality. Strivings for independence are ambivalent. These young adolescents are difficult to interview because they often respond with short, clipped conversation and may have little insight. They are just becoming accustomed to abstract thinking.

Middle adolescence can be a difficult time for adolescents and the adults who have contact with them. Cognitive processes

are more sophisticated. Through abstract thinking, middle adolescents can experiment with ideas, consider things as they might be, develop insight, and reflect on their own feelings and the feelings of others. As they mature, these adolescents focus on issues of identity not limited solely to the physical aspects of their body. They explore their parents' and culture's values, sometimes by expressing the contrary side of the dominant value. Many middle adolescents explore these values in their minds only; others do so by challenging their parents' authority. Many engage in high-risk behaviors, including unprotected sexual intercourse, substance abuse, or dangerous driving. The strivings of middle adolescents for independence, limit testing, and need for autonomy often distress their families, teachers, or other authority figures. These adolescents are at higher risk for morbidity and mortality from accidents, homicide, or suicide.

Late adolescence usually is marked by formal operational thinking, including thoughts about the future (e.g., educational, vocational, and sexual). Late adolescents are usually more committed to their sexual partners than are middle adolescents. Unresolved separation anxiety from previous developmental stages may emerge, at this time, as the young person begins to move physically away from the family of origin to college or vocational school, a job, or military service.

MODIFYING PSYCHOSOCIAL BEHAVIORS

Child behavior is determined by heredity and by the environment. Behavioral theory postulates that behavior is primarily a product of external environmental determinants and that manipulation of the environmental antecedents and consequences of behavior can be used to modify maladaptive behavior and increase desirable behavior (operant conditioning). The four major methods of operant conditioning are positive reinforcement, negative reinforcement, extinction, and punishment. Many common behavioral problems of children can be ameliorated by these methods.

Positive reinforcement increases the frequency of a behavior by following the behavior with a favorable event (e.g., praising a child for excellent school performance). Sometimes this reinforcement may occur unintentionally, increasing the frequency of an undesirable behavior. For example, a toddler may purposely try to stick a pencil in a light socket to obtain attention, whether it be positive or negative. **Negative reinforcement** increases the frequency of a behavior by removal, cessation, or avoidance of an unpleasant event (e.g., no longer having to sit at table once vegetables are eaten). **Extinction** occurs when there is a decrease in the frequency of a previously reinforced behavior because the reinforcement is withheld. Extinction is the principle behind the common advice to ignore behavior such as crying at bedtime or temper tantrums, which parents may unwittingly reinforce through attention and comforting. While reinforcement increases behavior frequency, **punishment** decreases the frequency of a behavior through unpleasant consequences. Punishment can be positive (undesired event is increased or introduced) or negative (desired event is decreased).

Positive reinforcement is more effective than punishment. Punishment is more effective when combined with positive reinforcement. A toddler who draws on the wall with a crayon may be punished, but the child learns much quicker when positive reinforcement is given for the proper use of the crayon—on paper, not the wall. Interrupting and modifying behaviors are discussed in detail in [Section 3](#).

TEMPERAMENT

Significant individual differences exist within the normal development of temperament (behavioral style). Temperament must be appreciated because, if an expected pattern of behavior is too narrowly defined, normal behavior may be inappropriately labeled as abnormal or pathologic. Three common constellations of temperamental characteristics are as follows:

1. The **easy child** (about 40% of children) demonstrates regularity of biologic functions (consistent, predictable times for eating, sleeping, and elimination), a positive approach to new stimuli, high adaptability to change, mild or moderate intensity in responses, and a positive mood.
2. The **difficult child** (about 10%) demonstrates irregularity of biologic functions, negative withdrawal from new stimuli, poor adaptability, intense responses, and a negative mood.
3. The **slow to warm up child** (about 15%) demonstrates a low activity level, withdrawal from new stimuli, slow adaptability, mild intensity in responses, and a somewhat negative mood.

The remaining 35% of children have more mixed temperaments. The individual temperament of a child has important implications for parenting and for the advice a pediatrician may give in anticipatory guidance or behavioral problem counseling.

Although temperament may be hardwired (*nature*) in each child to some degree, the environment (*nurture*) in which the child grows has a strong effect on the child's adjustment. Social and cultural factors can have marked effects on the child through differences in parenting style, educational approaches, and behavioral expectations.

PEARLS FOR PRACTITIONERS

See *Growth and Development: Pearls for Practitioners at the end of this section*.

CHAPTER 8

Disorders of Development

**DEVELOPMENTAL SURVEILLANCE
AND SCREENING**

Developmental and behavioral problems are more common than any other category of problems in pediatrics, except acute infections and trauma. In 2008, 15% of children ages 3–7 had a developmental disability and others had behavioral disabilities. As many as 25% of children have serious psychosocial problems. Parents often neglect to mention these problems because they think the physician is uninterested or cannot help. It is necessary to monitor development and screen for the presence of these problems at health supervision visits, particularly in the years before preschool or early childhood learning center enrollment.

Development surveillance, done at every office visit, is an informal process comparing skill levels to lists of milestones. If suspicion of developmental or behavioral issues recurs, further evaluation is warranted (Table 8.1). Surveillance does not have a standard, so screening tests are necessary.

Developmental screening involves the use of standardized screening tests to identify children who require further diagnostic assessment. The American Academy of Pediatrics

TABLE 8.1 Developmental Milestones

AGE	GROSS MOTOR	FINE MOTOR-ADAPTIVE	PERSONAL-SOCIAL	LANGUAGE	OTHER COGNITIVE
2 wk	Moves head side to side	—	Regards face	Alerts to bell	—
2 mo	Lifts shoulder while prone	Tracks past midline	Smiles responsively	Cooing Searches for sound with eyes	—
4 mo	Lifts up on hands Rolls front to back If pulled to sit from supine, no head lag	Reaches for object Raking grasp	Looks at hand Begins to work toward toy	Laughs and squeals	—
6 mo	Sits alone Rolls back to front	Transfers object hand to hand	Feeds self Holds bottle	Babbles	—
9 mo	Pulls to stand Gets into sitting position	Starting to pincer grasp Bangs two blocks together	Waves bye-bye Plays pat-a-cake	Says <i>Dada</i> and <i>Mama</i> , but nonspecific Two-syllable sounds	—
12 mo	Walks Stoops and stands	Puts block in cup	Drinks from a cup Imitates others	Says <i>Mama</i> and <i>Dada</i> , specific Says one to two other words	—
15 mo	Walks backward Stoops and recovers	Scribbles Stacks two blocks	Uses spoon and fork Helps in housework	Says three to six words Follows commands	—
18 mo	Runs	Stacks four blocks Kicks a ball	Removes garment “Feeds” doll	Says at least six words	—
2yr	Walks up and down stairs Throws overhand	Stacks six blocks Copies line	Washes and dries hands Brushes teeth Puts on clothes	Puts two words together Points to pictures Knows body parts	Understands concept of <i>today</i>
3yr	Walks steps alternating feet Broad jump	Stacks eight blocks Wiggles thumb	Uses spoon well, spilling little Puts on T-shirt	Names pictures Speech understandable to stranger 75% Says three-word sentences	Understands concepts of <i>tomorrow</i> and <i>yesterday</i>
4yr	Balances well on each foot Hops on one foot	Copies <i>O</i> , maybe + Draws person with three parts	Brushes teeth without help Dresses without help	Names colors Understands adjectives	—
5yr	Skips Heel-to-toe walks	Copies □	—	Counts Understands opposites	—
6yr	Balances on each foot 6sec	Copies Δ Draws person with six parts	—	Defines words	Begins to understand <i>right</i> and <i>left</i>

Mo, Month; sec, second; wk, week; yr, year.

recommends the use of validated standardized screening tools at three of the health maintenance visits: 9 months, 18 months, and 30 months. Clinics and offices that serve a higher risk patient population (e.g., children living in poverty) often perform a screening test at *every* health maintenance visit. A child who fails to pass a developmental screening test requires more comprehensive evaluation but does not necessarily have a delay; definitive testing must confirm. Developmental evaluations for children with suspected delays and intervention services for children with diagnosed disabilities are available free to families. A combination of U.S. state and federal funds provides these services.

Screening tests can be categorized as general screens that cover all behavioral domains or as targeted screens that focus on one area of development. Some may be administered in the office by professionals, while others may be completed at home (or in a waiting room) by parents. Good developmental/behavioral screening instruments have a sensitivity of 70–80% in detecting suspected problems and a specificity of 70–80% in detecting normal development. Although 30% of children

screened may be *over-referred* for definitive developmental testing, this group also includes children whose skills are below average and who may benefit from testing that may help address relative developmental deficits. The 20–30% of children who have disabilities that are not detected by the single administration of a screening instrument are likely to be identified on repeat screening at subsequent health maintenance visits.

The Denver Developmental Screening Test II was the first test used by general pediatricians, but it is now out of date, and the company has closed. The test required observation of objective behavior and was difficult to administer consistently.

Today's most used developmental screening tools include **Ages and Stages Questionnaires** (developmental milestone driven) and **Parents' Evaluation of Developmental Status (PEDS)**. The latter is a simple, 10-item questionnaire that parents complete at office visits based on concerns with function and progression of development. Parent-reported screens have good validity compared to office-based screening measures. Many offices combine PEDS with developmental surveillance to track milestone attainment.

AGE (YR)	SPEECH PRODUCTION	ARTICULATION (AMOUNT OF SPEECH UNDERSTOOD BY A STRANGER)	FOLLOWING COMMANDS
1	One to three words	—	One-step commands
2	Two- to three-word phrases	One half	Two-step commands
3	Routine use of sentences	Three fourths	—
4	Routine use of sentence sequences; conversational give-and-take	Almost all	—
5	Complex sentences; extensive use of modifiers, pronouns, and prepositions	Almost all	—

Autism screening is mandated for all children at 18 and 24 months of age. Although there are several tools, many pediatricians use the **Modified Checklist for Autism in Toddlers—Revised (M-CHAT-R)**. M-CHAT-R is an office-based questionnaire that asks parents about typical behaviors, some of which are more predictive than others for autism or other pervasive developmental disorders. If the child demonstrates more than two predictive or three total behaviors, further assessment with an interview algorithm is indicated to distinguish normal variant behaviors from those children needing a referral for definitive testing. The test is freely distributed on the Internet and is available at <https://www.m-chat.org> (see Chapter 20).

Language screening correlates best with cognitive development in the early years. Table 8.2 provides some rules of thumb for language development that focus on speech production (expressive language). Although expressive language is the most obvious language element, the most dramatic changes in language development in the first years involve recognition and understanding (receptive language).

Whenever there is a speech and/or language delay, a **hearing deficit** must be considered and screened for. If hearing is abnormal and not addressed, speech cannot develop appropriately or appropriately respond to therapy. The implementation of universal newborn hearing screening detects many, if not most, of these children in the newborn period, and appropriate early intervention services may be provided. Conditions that present a high risk of an associated hearing deficit are listed in Table 8.3. Dysfluency (*stuttering*) is common in a 3- and 4-year-old child. Unless the dysfluency is severe, is accompanied by tics or unusual posturing, or occurs after 4 years of age, parents should be counseled that it is normal and transient and to accept it calmly and patiently.

After the child's sixth birthday and until adolescence, developmental assessment is initially done by inquiring about school performance (academic achievement and behavior). Inquiring about concerns raised by teachers or other adults who care for the child (after-school program counselor, coach,

Congenital hearing loss in first cousin or closer relative
Bilirubin level of ≥ 20 mg/dL
Congenital rubella or other nonbacterial intrauterine infection
Defects in the ear, nose, or throat
Birthweight of $\leq 1,500$ g
Multiple apneic episodes
Exchange transfusion
Meningitis
Five-minute Apgar score of ≤ 5
Persistent fetal circulation (primary pulmonary hypertension)
Treatment with ototoxic drugs (e.g., aminoglycosides and loop diuretics)

religious leader) is prudent. Formal developmental testing of these older children is beyond the scope of the primary care pediatrician. Nonetheless, the health care provider should be the coordinator of the testing and evaluation performed by other specialists (e.g., psychologists, psychiatrists, developmental pediatricians, and educational professionals).

OTHER ISSUES IN ASSESSING DEVELOPMENT AND BEHAVIOR

Ignorance of environmental influences on child behavior may result in ineffective or inappropriate management (or both). Adverse childhood experiences (ACEs) are traumatic experiences, including witnessed or experienced abuse or neglect, that occur prior to age 18. Social determinants of health (SDOH) are conditions of where a person is born, grows, works, and lives. ACEs and SDOH can greatly affect growth and development so should be asked about and addressed. Table 8.4 lists some contextual factors that should be considered in the etiology of a child's behavioral or developmental problem.

Building rapport with the parents and the child is a prerequisite for obtaining the often-sensitive information that is essential for understanding a behavioral or developmental issue. Rapport usually can be established quickly if the parents sense that the clinician respects them and is genuinely interested in listening to their concerns. The clinician develops rapport with the child by engaging in developmentally appropriate conversation or play, perhaps providing toys while interviewing the parents, and being sensitive to the fears the child may have. Too often, the child is ignored until it is time for the physical examination. Similar to their parents, children feel more comfortable if they are greeted by name and involved in pleasant interactions before they are asked sensitive questions or threatened with examinations. Young children can be engaged in conversation on the parent's lap, which provides security and places the child at the eye level of the examiner.

With adolescents, emphasis should be placed on building a physician-patient relationship that is distinct from the relationship with the parents. The parents should not be excluded; however, the adolescent should have the opportunity to express

TABLE 8.4 Context of Behavioral Problems

CHILD FACTORS
Health (past and current)
Developmental status
Temperament (e.g., difficult, slow to warm up)
Coping mechanisms
PARENTAL FACTORS
Misinterpretations of stage-related behaviors
Mismatch of parental expectations and characteristics of child
Mismatch of personality style between parent and child
Parental characteristics (e.g., depression, lack of interest, rejection, overprotective, coping)
ENVIRONMENTAL FACTORS
Stress (e.g., marital discord, unemployment, personal loss, perceived racism)
Support (e.g., emotional, material, informational, child care)
Poverty—including poor housing, poorer education facilities, lack of access to healthy foods (food deserts), unsafe environments, toxic stress, poor access to primary care
Racism

concerns and ask questions of the physician in confidence. Two intertwined issues must be taken into consideration—consent and confidentiality. Although laws vary from state to state, in general, adolescents who are able to give informed consent (i.e., mature minors) may consent to visits and care related to high-risk behaviors (i.e., depression and mental health issues, substance abuse; sexual health, including prevention, detection, and treatment of sexually transmitted infections; and pregnancy). Most states support the physician who wishes the visit to be confidential. Physicians should become familiar with the governing law in the state where they practice (see <https://www.guttmacher.org>). Providing confidentiality is crucial, allowing for optimal care (especially for obtaining a history of risk behaviors). When assessing development and behavior, confidentiality can be achieved by meeting with the adolescent alone for at least part of each visit. However, parents must be informed when the clinician has significant and immediate concerns about the health and safety of the child. Often, the clinician can convince the adolescent to inform the parents directly about a problem or can reach an agreement with the adolescent about how the parents will be informed by the physician (see [Chapter 67](#)).

EVALUATING DEVELOPMENTAL AND BEHAVIORAL ISSUES

Responses to open-ended questions often provide clues to underlying, unstated problems and identify the appropriate direction for further, more directed questions. Histories about developmental and behavioral problems are often vague and confusing; to reconcile apparent contradictions, the interviewer frequently must request clarification, more detail, or mere repetition. By summarizing an understanding of the

information at frequent intervals and by recapitulating at the close of the visit, the interviewer and patient and family can ensure that they understand each other.

If the clinician's impression of the child differs markedly from the parent's description, there may be a crucial parental concern or issue that has not yet been expressed, either because it may be difficult to talk about (e.g., marital problems), because it is unconscious, or because the parent overlooks its relevance to the child's behavior. Alternatively, the physician's observations may be atypical, even with multiple visits. The observations of teachers, relatives, and other regular caregivers may be crucial in sorting out this possibility. The parent also may have a distorted image of the child, rooted in parental psychopathology. A sensitive, supportive, and non-critical approach to the parent is crucial to appropriate intervention. More information about referral and intervention for behavioral and developmental issues is covered in [Chapter 10](#).

PEARLS FOR PRACTITIONERS

See [Growth and Development: Pearls for Practitioners](#) at the end of this section.

CHAPTER 9

Evaluation of the Well Child

Health maintenance or supervision visits should consist of a comprehensive assessment of the child's health and of the parent's/guardian's role in providing an environment for optimal growth, development, and health. The American Academy of Pediatrics' (AAP) Bright Futures information standardizes each of the health maintenance visits and provides resources for working with the children and families of different ages (see <https://brightfutures.aap.org>). Elements of each visit include evaluation and management of parental concerns; inquiry about any interval illness since the last physical, growth, development, and nutrition; anticipatory guidance (including safety information and counseling); physical examination; screening tests; and immunizations (Table 9.1). The Bright Futures Recommendations for Preventive Pediatric Health Care, found at https://www.aap.org/en-us/Documents/periodicity_schedule.pdf, summarizes requirements and indicates the ages that specific prevention measures should be undertaken, including risk screening and performance items for specific measurements. Bright Futures is now the enforced standard for the Medicaid and the Children's Health Insurance Program, along with many insurers, including Patient Protection and Affordable Care Act (PPACA) insurers. Health maintenance and immunizations now are covered without copays for insured patients as part of the PPACA.

SCREENING TESTS

Children usually are quite healthy and only the following screening tests are recommended: newborn metabolic screening with hemoglobin electrophoresis, hearing and vision evaluation, anemia and lead screening, tuberculosis testing, and dyslipidemia screening. (Items marked by a *star* in the Bright Futures Recommendations should be performed if a risk factor

TABLE 9.1 Topics for Health Supervision Visits	
FOCUS ON THE CHILD	
Concerns (parent's or child's)	
Past problem follow-up	
Immunization and screening test update	
Routine care (e.g., eating, sleeping, elimination, and health habits)

Caregiving schedule for caregiver who lives at home	
Parent-child and sibling-child interactions	
Extended family role	
Family stresses (e.g., work, move, finances, illness, death, marital, and other interpersonal relationships)	
Family supports (relatives, friends, groups)	
Screening and intervention in the Social Determinants of Health	
Community	
Caregivers outside of the family	
Peer interaction	
School and work	
Recreational activities	
Physical Environment	
Appropriate stimulation	
Safety	

is found, while items marked with a *dot* should be done universally.) Sexually experienced adolescents should be screened for sexually transmissible infections and have an HIV test at least once between 16 and 18. When an infant, child, or adolescent begins with a new physician, the pediatrician should perform any missing screening tests and immunizations.

Newborn Screening

Metabolic Screening

Every state in the United States mandates newborn metabolic screening. Each state determines its own priorities and procedures, but the following diseases are usually included in metabolic screening: phenylketonuria, galactosemia, congenital hypothyroidism, maple sugar urine disease, and organic aciduria (see Section 10). Many states now screen for cystic fibrosis (CF) by testing for immunoreactive trypsinogen. If that test is positive, then a DNA analysis for the most common CF mutations is performed. This is not a perfect test due to the myriad of mutations that lead to CF. Clinical suspicion warrants evaluation even if there were no CF mutations noted on the DNA analysis.

Hemoglobin Electrophoresis

Children with hemoglobinopathies are at higher risk for infection and complications from anemia, which early detection may prevent or ameliorate. Infants with sickle cell disease are begun on oral penicillin prophylaxis to prevent sepsis, which is the major cause of mortality in these infants (see Chapter 150).

Critical Congenital Heart Disease Screening

Newborns with cyanotic congenital heart disease may be missed if the ductus arteriosus is still open; when the ductus closes, these children become profoundly cyanotic, leading to complications and even death. The AAP now mandates screening with pulse oximetry of the right hand and foot. The baby passes screening if the oxygen saturation is 95% or greater in the right hand and foot and the difference is three percentage points or less between the right hand and foot. The screen is immediately failed if the oxygen saturation is less than 90% in the right hand and foot. Equivocal tests are repeated, or echocardiography and pediatric cardiology consultation are warranted (see Chapters 143 and 144).

Hearing Evaluation

Because speech and language are central to a child's cognitive development, the hearing screening is performed before discharge from the newborn nursery. An infant's hearing is tested by placing headphones over the infant's ears and electrodes on the head. Standard sounds are played, and the transmission of the impulse to the brain is documented. If abnormal, a further evaluation using evoked response technology of sound transmission is indicated. A newborn should have a hearing screen by 1 month of age with follow-up testing for abnormal results by 3 months of age and interventions if indicated by 6 months of age.

Hearing and Vision Screening of Older Children

Infants and Toddlers

Inferences about hearing are drawn from asking parents about responses to sound and speech and by examining speech and language development closely. Inferences about vision may be made by examining gross motor milestones (children with vision problems may have a delay) and by physical examination of the eye. Parental concerns about vision should be sought until the child is 3 years of age and about hearing until the child is 4 years of age. If there are concerns, definitive testing should be arranged. Hearing can be screened by auditory evoked responses, as mentioned for newborns. For toddlers and older children who cannot cooperate with formal audiologic testing with headphones, behavioral audiology may be used. Sounds of a specific frequency or intensity are provided in a standard environment within a soundproof room, and responses are assessed by a trained audiologist. Vision may be assessed by referral to a pediatric ophthalmologist and by visual evoked responses.

Children 3 Years of Age and Older

At various ages, hearing and vision should be screened objectively using standard techniques as specified in the Bright Futures Recommendations. Asking the family and child about any concerns or consequences of poor hearing or vision accomplishes subjective evaluation. At 3 years of age, children are screened for vision for the first time if they are

developmentally able to be tested. Many children at this age do not have the interactive language or interpersonal skills to perform a vision screen; these children should be re-examined within 6 months to ensure that their vision is normal. Because most of these children do not yet identify letters, using a Snellen eye chart with standard shapes is recommended. When a child is able to identify letters, the more accurate letter-based chart should be used. Audiologic testing of sounds with headphones should begin on the fourth birthday (although Head Start requires that pediatricians attempt the hearing screening at 3 years of age). Any suspected audiologic problem should be evaluated by a careful history and physical examination with referral for comprehensive testing. Children who have a documented vision problem, failed screening, or parental concern should be referred, preferably to a pediatric ophthalmologist.

Anemia Screening

Children are screened for anemia at ages when there is a higher incidence of iron-deficiency anemia. Infants are screened at birth and again at 4 months if there is a documented risk, such as low birthweight or prematurity. All infants are screened at 12 months of age because this is when a high incidence of iron deficiency is noted. Children are assessed at other visits for risks or concerns related to anemia (denoted by a star in the Bright Futures Recommendations at https://downloads.aap.org/AAP/PDF/periodicity_schedule.pdf). Any abnormalities detected should be evaluated for etiology. Anemic infants do not perform as well on standard developmental testing. When iron deficiency is strongly suspected, a therapeutic trial of iron may be used (see Chapter 150).

Lead Screening

Lead intoxication may cause developmental and behavioral abnormalities that are not reversible, even if the hematologic and other metabolic complications are treated. Although the Centers for Disease Control and Prevention (CDC) recommends environmental investigation at blood lead levels of 20 µg/dL on a single visit or persistent 15 µg/dL over a 3-month period, levels of 5–10 µg/dL may cause learning problems. Risk factors for lead intoxication include living in older homes with cracked or peeling lead-based paint, industrial exposure, use of foreign remedies (e.g., a diarrhea remedy from Central or South America), and use of pottery with lead paint glaze. Because of the significant association of lead intoxication with poverty, the CDC recommends routine blood lead screening at 12 and 24 months. In addition, standardized screening questions for risk of lead intoxication should be asked for all children between 6 months and 6 years of age (Table 9.2). Any positive or suspect response is an indication for obtaining a blood lead level. Capillary blood sampling may produce false-positive results; thus, in most situations, a venous blood sample should be obtained or a process implemented to get children tested with a venous sample if they had an elevated capillary level. County health departments, community organizations, and private companies provide lead inspection and detection services to determine the source of the lead. Standard decontamination techniques should be used to remove the lead while avoiding aerosolizing the toxic metal that a child might breathe or creating dust that a child might ingest (see Chapters 149 and 150).

TABLE 9.2 Lead Poisoning Risk Assessment Questions to Be Asked Between 6 Months and 6 Years

Does the child live in or regularly visit a home built before 1950?
Does the child spend any time in a building built before 1978 with recent or ongoing painting, repair work, remodeling, or damage?
Is there a brother, sister, housemate, playmate, or community member being followed or treated (or even rumored to be) for lead poisoning?
Does the child live with an adult whose job or hobby involves exposure to lead (e.g., lead smelting and automotive radiator repair)?
Does the child live near an active lead smelter, battery recycling plant, or other industry likely to release lead?
Does the family use home remedies or pottery from another country?

TABLE 9.3 Groups at High Risk for Tuberculosis

Close contacts with persons known to have tuberculosis (TB), positive TB test, or suspected to have TB
Foreign-born persons from areas with high TB rates (Asia, Africa, Latin America, Eastern Europe, Russia)
Health care workers
High-risk racial or ethnic minorities or other populations at higher risk (Asian, Pacific Islander, Hispanic, Black, Native American, groups living in poverty [e.g., Medicaid recipients], migrant farm workers, homeless persons, substance abusers)
Children <5 years of age
Immunocompromised individuals

Tuberculosis Testing

The prevalence of tuberculosis is increasing largely as a result of the adult HIV epidemic. Children often present with serious and multisystem disease (miliary tuberculosis). All children should be assessed for risk of tuberculosis at health maintenance visits at 1 month, 6 months, 12 months, and then annually. The high-risk groups, as defined by the CDC, are listed in Table 9.3. In general, the standardized purified protein derivative intradermal test is used with evaluation by a health care provider 48–72 hours after injection. The size of induration, not the color of any mark, denotes a positive test; 15 mm of induration is a positive test in anyone. For most patients with risk factors, 10 mm of induration is a positive test. For HIV-positive patients, those with recent tuberculosis contacts, patients with evidence of old healed tuberculosis on chest film, or immunosuppressed patients, 5 mm is a positive test (see Chapter 124). The QuantiFERON-TB Gold blood test is a newer test that has the advantage of needing one office visit only, but it also has a higher cost.

Cholesterol

Children and adolescents who have a family history of cardiovascular disease or have at least one parent with a high blood cholesterol level are at increased risk of having high blood cholesterol levels as adults and increased risk of coronary heart disease. The AAP recommends dyslipidemia screening in the

TABLE 9.4 Cholesterol Risk Screening Recommendations

Risk screening at ages 2, 4, 6, 8, and annually in adolescence:

1. Children and adolescents who have a family history of high cholesterol or heart disease
2. Children whose family history is unknown
3. Children who have other personal risk factors: obesity, high blood pressure, or diabetes

Universal screening at ages 9–11 and ages 17–21 (once per age range)

context of regular health care for at-risk populations (Table 9.4) by obtaining a fasting lipid profile. The recommended screening levels are the same for all children 2–18 years. Total cholesterol of less than 170 mg/dL is normal, 170–199 mg/dL is borderline, and greater than 200 mg/dL is elevated. In addition, in 2011, the AAP endorsed the National Heart, Lung, and Blood Institute of the National Institutes of Health recommendation to test all children at least once between ages 9 and 11.

Sexually Transmitted Infection Testing

Annual office visits are recommended for adolescents. A full adolescent psychosocial history should be obtained in confidential fashion (see Section 12). Part of this evaluation is a comprehensive sexual history that often requires creative questioning. Not all adolescents identify oral sex as sex, and some adolescents misinterpret the term *sexually active* to mean that one has many sexual partners or is very vigorous during intercourse. The questions, “Are you having sex?” and “Have you ever had sex?” should be asked. In the Bright Futures Guidelines, any child or adolescent who has had any form of sexual intercourse should have at least an annual evaluation (more often if there is a history of high-risk sex) for sexually transmitted diseases by physical examination (genital warts, genital herpes, and pediculosis) and laboratory testing (chlamydia, gonorrhea, syphilis, and HIV) (see Chapter 116). Young women should be assessed for human papillomavirus and precancerous lesions by Papanicolaou smear at 21 years of age.

Depression Screening

All adolescents, starting at age 11, should have annual depression screening with a validated tool. The Patient Health Questionnaires (PHQ) are commonly used. Both the short PHQ2 and its slightly longer PHQ9 are available on the Bright Futures website in the Tool and Resource Kit at https://toolkits.solutions.aap.org/ss/screening_tools.aspx.

Immunizations

Immunization records should be checked at each office visit regardless of the reason. Appropriate vaccinations should be administered (see Chapter 94).

DENTAL CARE

Many families in the United States, particularly poor and ethnic minority families, underuse dental health care. Pediatricians may identify gross abnormalities, such as large caries, gingival inflammation, or significant malocclusion. All

children 1 year and older should have a dental examination by a dentist at least annually and a dental cleaning by a dentist or hygienist every 6 months. Dental health care visits should include instruction about preventive care practiced at home (brushing and flossing). Other prophylactic methods shown to be effective at preventing caries are concentrated fluoride topical treatments (dental varnish) and acrylic sealants on the molars. Bright Futures now recommends that pediatricians apply dental fluoride varnish to infants and children every 3–6 months between 9 months and 5 years. Pediatric dentists recommend beginning visits at age 1 year to educate families and to screen for milk bottle caries. Fluoridation of water or fluoride supplements in communities that do not have fluoridation are important in the prevention of cavities (see Chapter 127).

NUTRITIONAL ASSESSMENT

Plotting a child’s growth on the standard charts is a vital component of the nutritional assessment. A dietary history should be obtained because the content of the diet may suggest a risk of nutritional deficiency (see Chapters 27 and 28).

ANTICIPATORY GUIDANCE

Anticipatory guidance is information conveyed to parents verbally, in written materials, or even directing parents to certain Internet websites to assist them in facilitating optimal growth and development for their children. Anticipatory guidance that is age relevant is another part of the Bright Futures Guidelines. The Bright Futures Tool and Resource Kit includes the topics and one-page handouts for families (and for older children) about the highest yield issues for the specific age. Table 9.5 summarizes representative issues that might be discussed. It is important to briefly review the safety topics previously discussed at other visits for reinforcement. Age-appropriate discussions should occur at each visit.

Safety Issues

The most common cause of death for infants 1 month to 1 year of age is **motor vehicle crashes**. No newborn should be discharged from a nursery unless the parents have a functioning and properly installed car seat. Many automobile dealerships and fire departments offer services to parents to ensure that safety seats are installed properly in their specific model. Most states have laws that mandate the use of safety seats until the child reaches 4 years of age or at least 40 pounds in weight. The following are age-appropriate recommendations for car safety:

1. Infants and toddlers should ride in a **rear-facing safety seat** until they are at least 2 years old. It is considered safest for children to remain rear-facing after 2 years old for as long as possible while within weight and height limits set by the safety seat manufacturer.
2. Toddlers and preschoolers over age 2 or who have outgrown the rear-facing car seat should use a **forward-facing car seat** with harness for as long as possible up to the highest weight or height recommended by the manufacturer.
3. School-age children, whose weight or height is above the forward-facing limit for their car seat, should use a **belt-positioning booster seat** until the vehicle seat belt fits properly, typically when they have reached 4 ft 9 in. in height and are between 8 and 12 years of age.

TABLE 9.5 Anticipatory Guidance Topics Suggested by Age

AGES	INJURY PREVENTION	VIOLENCE PREVENTION	NUTRITIONAL COUNSELING	FOSTERING OPTIMAL DEVELOPMENT
Birth and/or 3–5 days	Crib safety Hot water heaters <120°F Car safety seats Smoke detectors Back to sleep	Assess bonding and attachment Identify family strife, lack of support, pathology Educate parents on nurturing	Exclusive breast-feeding encouraged Formula as a second-best option	Discuss parenting skills Refer for parenting education
2 weeks or 1 month	Falls Back to sleep	Reassess* Discuss sibling rivalry Assess if guns in the home	Assess breast-feeding and offer encouragement, problem solving	Recognize and manage postpartum blues Child care options
2 months	Burns/hot liquids Back to sleep	Reassess firearm safety		Parent getting enough rest and managing returning to work
4 months	Infant walkers Choking/suffocation Back to sleep	Reassess	Introduction of solid foods	Discuss central to peripheral motor development Praise good behavior
6 months	Burns/hot surfaces Childproofing	Reassess	Assess status	Consistent limit-setting vs “spoiling” an infant Praise good behavior
9 months	Water safety Home safety review Ingestions/poisoning Car seat safety (rear-facing until ≥2 yr)	Assess parents’ ideas on discipline and “spoiling”	Avoiding juice Begin to encourage practice with cup drinking	Assisting infants to sleep through the night if not accomplished Praise good behavior
12 months	Firearm hazards Auto-pedestrian safety Car seat safety (rear-facing until ≥2 yr)	Discuss time-out vs corporal punishment Avoiding media violence Review firearm safety	Introduction of whole cow’s milk (and constipation with change discussed) Assess anemia, discuss iron-rich foods	Safe exploration Proper shoes Praise good behavior
15 months	Review and reassess topics	Encourage nonviolent punishments (time-out or natural consequences)	Discuss decline in eating with slower growth Assess food choices and variety	Fostering independence Reinforce good behavior Ignore annoying but not unsafe behaviors
18 months	Review and reassess topics	Limit punishment to high yield and major transgressions Parents consistent in discipline	Discuss food choices, portions, “finicky” feeders	Preparation for toilet training Reinforce good behavior
2 years	Falls—play equipment	Assess and discuss any aggressive behaviors in the child	Assess body proportions and recommend low-fat milk Assess family cholesterol and atherosclerosis risk	Toilet training and resistance
3 years	Review and reassess topics	Review, especially avoiding media violence	Discuss optimal eating and the food pyramid Healthy snacks	Read to child Socializing with other children Head Start if possible
4 years	Booster seat vs seat belts		Healthy snacks	Read to child Head Start or pre-K options
5 years	Bicycle safety Water/pool safety	Developing consistent, clearly defined family rules and consequences Avoiding media violence	Assess for anemia Discuss iron-rich foods	Reinforcing school topics Read to child Library card Chores begun at home
6 years	Fire safety	Reinforce consistent discipline Encourage nonviolent strategies Assess domestic violence Avoiding media violence	Assess content, offer specific suggestions	Reinforcing school topics After-school programs Responsibility given for chores (and enforced)

Continued

AGES	INJURY PREVENTION	VIOLENCE PREVENTION	NUTRITIONAL COUNSELING	FOSTERING OPTIMAL DEVELOPMENT
7–10 years	Sports safety Firearm hazard	Reinforcement Assess domestic violence Assess discipline techniques Avoiding media violence Walking away from fights (either victim or spectator)	Assess content, offer specific suggestions	Reviewing homework and reinforcing school topics After-school programs Introduce smoking and substance abuse prevention (concrete)
11–13 years	Review and reassess	Discuss strategies to avoid interpersonal conflicts Avoiding media violence Avoiding fights and walking away Discuss conflict resolution techniques	Junk food vs healthy eating	Reviewing homework and reinforcing school topics Smoking and substance abuse prevention (begin abstraction) Discuss and encourage abstinence; possibly discuss condoms and contraceptive options Avoiding violence Offer availability
14–16 years	Motor vehicle safety Avoiding riding with substance abuser	Establish new family rules related to curfews, school, and household responsibilities	Junk food vs healthy eating	Review school work Begin career discussions and college preparation (PSAT) Review substance abuse, sexuality, and violence regularly Discuss condoms, contraception options, including emergency contraception Discuss sexually transmitted diseases, HIV Providing “no questions asked” ride home from at-risk situations
17–21 years	Review and reassess	Establish new rules related to driving, dating, and substance abuse	Heart healthy diet for life	Continuation of above topics Off to college or employment New roles within the family

*Reassess means to review the issues discussed at the prior health maintenance visit.
PSAT, Preliminary scholastic aptitude test.

4. Older children should always use **lap and shoulder seat belts** for optimal protection. All children younger than 13 years should be restrained in the rear seats of vehicles for optimal protection. This is specifically to protect them from airbags, which may cause more injury than the crash in young children.

The **Back to Sleep initiative** has reduced the incidence of sudden infant death syndrome (SIDS). Before the initiative, infants routinely were placed prone to sleep. Since 1992, when the AAP recommended this program, the annual SIDS rate has decreased by more than 50%. Another initiative is aimed at day care providers, because 20% of SIDS deaths occur in day care settings.

Fostering Optimal Development

See Table 9.5 as well as the Bright Futures Recommendations (Fig. 9.1; also found at http://brightfutures.aap.org/clinical_practice.html) for presentation of age-appropriate activities that the pediatrician may advocate for families.

Discipline means to teach, not merely to punish. The ultimate goal is the child's self-control. Overbearing punishment to control a child's behavior interferes with the learning process and focuses on external control at the expense of the development of self-control. Parents who set too few reasonable

limits may be frustrated by children who cannot control their own behavior. Discipline should teach a child exactly what is expected by supporting and reinforcing positive behaviors and responding appropriately to negative behaviors with proper limits. It is more important and effective to reinforce good behavior than to punish bad behavior.

Parenting styles are important because a caregiver's interactions with a child influences the child's growth, development, and eventual adult behavior. Parenting styles vary in the level of expectations and number of rules set for a child (demandingness), and in the level of warmth, communication, and consideration of the child's opinions (responsiveness). There are four recognized parenting styles: authoritative (high demandingness, high responsiveness), authoritarian (high demandingness, low responsiveness), permissive (low demandingness, high responsiveness), and uninvolved (low demandingness, low responsiveness). Authoritative parenting is regarded as the style most likely to result in a child who is happy, successful, and self-disciplined.

Commonly used techniques to control undesirable behaviors in children include scolding, physical punishment, and threats. These techniques have potential adverse effects on children's sense of security and self-esteem. The effectiveness of scolding diminishes the more it is used. Scolding should not be allowed to expand from an expression of displeasure about

FIGURE 9.1, cont'd

a specific event to derogatory statements about the child. Scolding also may escalate to the level of psychological abuse. It is important to educate parents that they have a *good child who does bad things from time to time*, so parents do not think and tell the child that they are “bad.”

Frequent mild physical punishment (corporal punishment) may become less effective over time and tempt the parent to escalate the physical punishment, increasing the risk of child abuse. Corporal punishment teaches a child that in certain situations it is proper to strike another person. Commonly, in households that use spanking, older children who have been raised with this technique are seen responding to younger sibling behavioral problems by hitting their siblings.

Threats by parents to leave or to give up the child are perhaps the most psychologically damaging ways to control a child's behavior. Children of any age may remain fearful and anxious about loss of the parent long after the threat is made; however, many children are able to see through empty threats. Threatening a mild loss of privileges (no video games for 1 week or grounding a teenager) may be appropriate, but the consequence must be enforced if there is a violation.

Parenting involves a dynamic balance between **setting limits** on the one hand and allowing and encouraging freedom of expression and exploration on the other. A child whose behavior is out of control improves when clear limits on the behavior are set and enforced. However, parents must agree on where the limit will be set and how it will be enforced. The limit and the consequence of breaking the limit must be clearly presented to the child. Enforcement of the limit should be consistent and firm. Too many limits are difficult to learn and may thwart the normal development of autonomy. The limit must be reasonable in terms of the child's age, temperament, and developmental level. To be effective, both parents (and other adults in the home) must enforce limits. Otherwise, children may effectively *split* the parents and seek to test the limits with the more indulgent parent. In all situations, to be effective, punishment must be brief and linked directly to a behavior. More effective behavioral change occurs when punishment also is linked to praise of the intended behavior.

Extinction is an effective and systematic way to eliminate a frequent, annoying, and relatively harmless behavior by ignoring it. First parents should note the frequency of the behavior to realistically appreciate the magnitude of the problem and to evaluate progress. Parents must determine what reinforces the child's behavior and what needs to be consistently eliminated. An appropriate behavior is identified to give the child a positive alternative that the parents can reinforce. Parents should be warned that the annoying behavior usually increases in frequency and intensity (and may last for weeks) before it decreases when the parent ignores it (removes the reinforcement). A child who has an attention-seeking temper tantrum should be ignored or placed in a secure environment. This action may anger the child more, and the behavior may get louder and angrier. Eventually with no audience for the tantrum, the tantrums decrease in intensity and frequency. In each specific instance, when the child's behavior has become appropriate, the child should be praised, and extra attention should be given. This is an effective technique for early toddlers, before their capacity to understand and adhere to a time-out develops.

The **time-out** consists of a short period of isolation *immediately* after a problem behavior is observed. Time-out interrupts the behavior and immediately links it to an unpleasant

consequence. This method requires considerable effort by the parents because the child does not wish to be isolated. A parent may need to hold the child physically in time-out. In this situation, the parent should become *part of the furniture* and should not respond to the child until the time-out period is over. When established, a simple isolation technique, such as making a child stand in the corner or sending a child to the bedroom, may be effective. If such a technique is not helpful, a more systematic procedure may be needed. One effective protocol for the time-out procedure involves interrupting the child's play when the behavior occurs and having the child sit in a dull, isolated place for a brief period, measured by a portable kitchen timer (the clicking noises document that time is passing, and the bell alarm at the end signals the end of the punishment). Time-out is simply punishment and is not a time for a young child to *think* about the behavior (these children do not possess the capacity for abstract thinking) or a time to de-escalate the behavior. The amount of time-out should be appropriate to the child's short attention span. One minute per year of a child's age is recommended. This inescapable and unpleasant consequence of the undesired behavior motivates the child to learn to avoid the behavior.

PEARLS FOR PRACTITIONERS

See Growth and Development: Pearls for Practitioners at the end of this section.

CHAPTER 10

Evaluation of the Child with Special Needs

Children with disabilities, severe chronic illnesses, congenital defects, and health-related educational and behavioral problems are **children with special health care needs (SHCN)**. Many of these children share a broad group of experiences and encounter similar problems, such as school difficulties and family stress. The term *children with special health care needs* defines these children noncategorically, without regard to specific diagnoses, in terms of increased service needs. Approximately 19% of children in the United States younger than 18 years of age have a physical, developmental, behavioral, or emotional condition requiring services of a type or amount beyond those generally required by most children.

The goal in managing a child with SHCN is to maximize the child's potential for productive adult functioning by treating the primary diagnosis and by helping the patient and family deal with the stresses and secondary impairments incurred because of the disease or disability. Whenever a chronic disease is diagnosed, family members typically grieve, show anger, denial, negotiation (in an attempt to forestall the inevitable), and depression. Because the child with SHCN is a constant reminder of the object of this grief, it may take family members a long time to accept the condition. A supportive physician can facilitate the process of acceptance by education and by allaying guilty feelings and fear. To minimize denial, it is helpful to confirm the family's observations about the child. The family may not be able to absorb any additional

information initially, so written material and the option for further discussion at a later date should be offered.

The primary physician should provide a **medical home** to maintain close oversight of treatments and subspecialty services, provide preventive care, and facilitate interactions with school and community agencies. A major goal of *family-centered care* is for the family and child to feel in control. Although the medical management team usually directs treatment in the acute health care setting, the locus of control should shift to the family as the child moves into a more routine, home-based life. Treatment plans should allow the greatest degree of normalization of the child's life. As the child matures, self-management programs that provide health education, self-efficacy skills, and techniques such as symptom monitoring help promote good long-term health habits. These programs should be introduced at 6 or 7 years of age or when a child is at a developmental level to take on chores and benefit from being given responsibility. Self-management minimizes *learned helplessness* and the *vulnerable child syndrome*, both of which occur commonly in families with chronically ill or disabled children.

MULTIFACETED TEAM ASSESSMENT OF COMPLEX PROBLEMS

When developmental screening and surveillance suggest the presence of significant developmental lags, the physician should take responsibility for coordinating the further assessment of the child by the team of professionals and provide continuity of care. The physician should become aware of local facilities and programs for assessment and treatment. If the child is at high risk for delay (e.g., prematurity), a structured follow-up program to monitor the child's progress may already exist. Under federal law, all children are entitled to assessments if there is a suspected developmental delay or a risk factor for delay (e.g., prematurity, failure to thrive, and parental intellectual disability [ID]). Early intervention programs for children up to 3 years of age are developed by states to implement this policy. Developmental interventions are arranged in conjunction with third-party payers with local programs funding the cost only when there is no insurance coverage. After 3 years of age, development programs usually are administered by school districts. Federal laws mandate that special education programs be provided for all children with developmental disabilities from birth through 21 years of age.

Children with special needs may be enrolled in pre-K programs with a therapeutic core, including visits to the program by therapists, to work on challenges. Children who are of traditional school age (kindergarten through secondary school) should be evaluated by the school district and provided an **individualized education plan (IEP)** to address any deficiencies. An IEP may feature individual tutoring time (resource time), placement in a special education program, placement in classes with children with severe behavioral problems, or other strategies to address deficiencies. As part of the comprehensive evaluation of developmental/behavioral issues, all children should receive a thorough medical assessment. A variety of other specialists may assist in the assessment and intervention, including subspecialists (e.g., child neurology, pediatric orthopedics, child and adolescent psychiatry, developmental/behavioral pediatricians), therapists (e.g., occupational, physical, oral-motor), and others (e.g., psychologists, early childhood development specialists).

Medical Assessment

The physician's main goals in team assessment are to identify the cause of the developmental dysfunction if possible (often a specific cause is not found) and identify and interpret other medical conditions that have a developmental impact. The comprehensive history (Table 10.1) and physical examination (Table 10.2) include a careful graphing of growth parameters and an accurate description of dysmorphic features. Many causative diagnoses are rare or unusual diseases or syndromes. Many of these diseases and syndromes are discussed further in Sections 9 and 24.

Motor Assessment

The comprehensive neurologic examination is an excellent basis for evaluating motor function, but it should be supplemented by an adaptive functional evaluation (see Chapter 179). Observing the child at play aids assessment of function. Specialists in early childhood development and therapists (especially occupational and physical therapists who have experience with children) can provide excellent input into the evaluation of age-appropriate adaptive function.

Psychologic Assessment

Psychologic assessment includes the testing of cognitive ability (Table 10.3) and the evaluation of personality and emotional well-being. The IQ and mental age scores, taken in isolation, are only partially descriptive of a person's functional abilities, which are a combination of cognitive, adaptive, and social skills. Tests of achievement are subject to variability based on culture, educational exposures, and experience and must be standardized for social factors. Projective and nonprojective tests are useful in understanding the child's emotional status. Although a child should not be labeled as having a problem solely based on a standardized test, these tests provide important and reasonably objective data for evaluating a child's progress within a particular educational program.

Educational Assessment

Educational assessment involves the evaluation of areas of specific strengths and weaknesses in reading, spelling, written expression, and mathematical skills. Schools routinely screen children with grouped tests to aid in problem identification and program evaluation. For the child with special needs, this screening ultimately should lead to individualized testing and the development of an IEP that would enable the child to progress comfortably in school. Diagnostic teaching, in which the child's response to various teaching techniques is assessed, also may be helpful.

Social Environment Assessment

Assessments of the environment in which the child is living, working, playing, and growing are important in understanding the child's development. A home visit by a social worker, community health nurse, and/or home-based intervention specialist can provide valuable information about the child's social milieu. Often, the home visitor can suggest additional adaptive equipment or renovations if there are challenges at home. If there is a suspicion of inadequate parenting, and,

TABLE 10.1 Information to Be Sought During the History Taking of a Child with Suspected Developmental Disabilities

ITEM	POSSIBLE SIGNIFICANCE	ITEM	POSSIBLE SIGNIFICANCE
Parental concerns	Parents are quite accurate in identifying development problems in their children.	Mental functioning	Increased hereditary and environmental risks
Current levels of developmental functioning	Should be used to monitor child's progress	Illnesses (e.g., metabolic diseases)	Hereditary illness associated with developmental delay
Temperament	May interact with disability or may be confused with developmental delay	Family member died young or unexpectedly	May suggest inborn error of metabolism or storage disease
PRENATAL HISTORY		Family member requires special education	Hereditary causes of developmental delay
Alcohol ingestion	Fetal alcohol syndrome; index of caregiving risk	SOCIAL HISTORY	
Exposure to medication, illegal drug, or toxin	Development toxin (e.g., phenytoin); may be an index of caregiving risk	Resources available (e.g., financial, social support)	Necessary to maximize child's potential
Radiation exposure	Damage to CNS	Educational level of parents	Family may need help to provide stimulation
Nutrition	Inadequate fetal nutrition	Mental health problems	May exacerbate child's conditions
Prenatal care	Index of social situation	High-risk behaviors (e.g., illicit drugs, sex) in parent(s) or adolescents	Increased risk for HIV infection; index of caregiving risk
Injuries, hyperthermia	Damage to CNS	Other stressors (e.g., marital discord)	May exacerbate child's conditions or compromise care
Smoking	Possible CNS damage	OTHER HISTORY	
HIV exposure	Congenital HIV infection	Gender of child	Important for X-linked conditions
Maternal illness (so-called "TORCH" infections)	Toxoplasmosis, Syphilis (Other in the mnemonic), Rubella, Cytomegalovirus, Herpes simplex virus infections	Developmental milestones	Index of developmental delay; regression may indicate progressive condition.
PERINATAL HISTORY		Head injury	Even moderate trauma may be associated with developmental delay or learning disabilities.
Gestational age, birthweight	Biologic risk from prematurity and small for gestational age	Serious infections (e.g., meningitis)	May be associated with developmental delay
Labor and delivery	Hypoxia or index of abnormal prenatal development	Toxic exposure (e.g., lead)	May be associated with developmental delay
APGAR scores	Hypoxia, cardiovascular impairment	Physical growth	May indicate malnutrition; obesity, short stature, genetic syndrome
Specific perinatal adverse events	Increased risk of CNS damage	Recurrent otitis media	Associated with hearing loss and abnormal speech development
NEONATAL HISTORY		Visual and auditory functioning	Sensitive index of impaired vision and hearing
Illness—seizures, respiratory distress, hyperbilirubinemia, metabolic disorder	Increased risk of CNS damage	Nutrition	Malnutrition during infancy may lead to delayed development.
Malformations	May represent genetic syndrome or new mutation associated with developmental delay	Chronic conditions such as renal disease	May be associated with delayed development or anemia
FAMILY HISTORY			
Consanguinity	Autosomal recessive condition more likely		

CNS, Central nervous system.

Modified and updated from Liptak G. *Mental retardation and developmental disability*. In: Kliegman RM, ed. *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia: WB Saunders; 1996.

especially, if there is a suspicion of neglect or abuse (including emotional abuse), the child and family must be referred to the local child protection agency. Information about reporting hotlines and local child protection agencies can be found at <https://www.childwelfare.gov/organizations/> (see Chapter 22).

MANAGEMENT OF DEVELOPMENTAL PROBLEMS

Intervention in the Primary Care Setting

The clinician must decide whether a problem requires referral for further diagnostic work-up and management or whether

TABLE 10.2 Information to Be Sought During the Physical Examination of a Child with Suspected Developmental Disabilities

ITEM	POSSIBLE SIGNIFICANCE	ITEM	POSSIBLE SIGNIFICANCE
General appearance	May indicate significant delay in development or obvious syndrome	LIVER	
STATURE		Hepatomegaly	Fructose intolerance, galactosemia, glycogenosis types I to IV, mucopolysaccharidosis I and II, Niemann-Pick disease, Tay-Sachs disease, Zellweger syndrome, Gaucher disease, ceroid lipofuscinosis, gangliosidosis
Short stature	Williams syndrome, malnutrition, Turner syndrome; many children with severe intellectual disability have associated short stature.	GENITALIA	
Obesity	Prader-Willi syndrome	Macro-orchidism (usually not noted until puberty)	Fragile X syndrome
Large stature	Sotos syndrome	Hypogenitalism	Prader-Willi syndrome, Klinefelter syndrome, CHARGE association
HEAD		EXTREMITIES	
Macrocephaly	Alexander syndrome, Sotos syndrome, gangliosidosis, hydrocephalus, mucopolysaccharidosis, subdural effusion	Hands, feet, dermatoglyphics, and creases	May indicate specific entity such as Rubinstein-Taybi syndrome or be associated with chromosomal anomaly
Microcephaly	Virtually any condition that can retard brain growth (e.g., malnutrition, Angelman syndrome, Cornelia de Lange syndrome, fetal alcohol effects)	Joint contractures	Sign of muscle imbalance around joints (e.g., with meningomyelocele, cerebral palsy, arthrogryposis, muscular dystrophy; also occurs with cartilaginous problems such as mucopolysaccharidosis)
FACE		SKIN	
Coarse, triangular, round, or flat face; hypotelorism or hypertelorism, slanted or short palpebral fissure; unusual nose, maxilla, and mandible	Specific measurements may provide clues to inherited, metabolic, or other diseases such as fetal alcohol syndrome, cri du chat syndrome (5p-syndrome), or Williams syndrome.	Café-au-lait spots	Neurofibromatosis, tuberous sclerosis, Bloom syndrome
EYES		Eczema	Phenylketonuria, histiocytosis
Prominent	Crouzon syndrome, Seckel syndrome, fragile X syndrome	Hemangiomas and telangiectasia	Sturge-Weber syndrome, Bloom syndrome, ataxia-telangiectasia
Cataract	Galactosemia, Lowe syndrome, prenatal rubella, hypothyroidism	Hypopigmented macules, streaks, adenoma sebaceum	Tuberous sclerosis, hypomelanosis of Ito
Cherry-red spot in macula	Gangliosidosis (GM ₁), metachromatic leukodystrophy, mucopolipidosis, Tay-Sachs disease, Niemann-Pick disease, Farber lipogranulomatosis, sialidosis III	HAIR	
Chorioretinitis	Congenital infection with cytomegalovirus, toxoplasmosis, or rubella	Hirsutism	Cornelia de Lange syndrome, mucopolysaccharidosis, fetal phenytoin effects, cerebro-oculo-facio-skeletal syndrome, trisomy 18 syndrome
Corneal cloudiness	Mucopolysaccharidosis I and II, Lowe syndrome, congenital syphilis	NEUROLOGIC	
EARS		Asymmetry of strength and tone	Focal lesion, cerebral palsy
Pinnae, low set or malformed	Trisomies such as 18, Rubinstein-Taybi syndrome, Down syndrome, CHARGE association, cerebro-oculo-facio-skeletal syndrome, fetal phenytoin effects	Hypotonia	Prader-Willi syndrome, Down syndrome, Angelman syndrome, gangliosidosis, early cerebral palsy
Hearing	Loss of acuity in mucopolysaccharidosis; hyperacusis in many encephalopathies	Hypertonia	Neurodegenerative conditions involving white matter, cerebral palsy, trisomy 18 syndrome
HEART		Ataxia	Ataxia-telangiectasia, metachromatic leukodystrophy, Angelman syndrome
Structural anomaly or hypertrophy	CHARGE association, CATCH-22, velocardiofacial syndrome, glycogenosis II, fetal alcohol effects, mucopolysaccharidosis I; chromosomal anomalies such as Down syndrome; maternal phenylketonuria; chronic cyanosis may impair cognitive development.		

CATCH-22, Cardiac defects, abnormal face, thymic hypoplasia, cleft palate, hypocalcemia, defects on chromosome 22; CHARGE, coloboma, heart defects, atresia choanae, retarded growth, genital anomalies, ear anomalies (deafness).

TABLE 10.3 Tests of Cognition		
TEST	AGE RANGE	SPECIAL FEATURES
INFANT SCALES		
Bayley Scales of Infant Development (3rd ed.)	1–42 mo	Mental, psychomotor scales, behavior record; weak intelligence predictor
Cattell Infant Intelligence Scale	2–30 mo	Used to extend Stanford-Binet downward
Gesell Developmental Observation-Revised (GDO-R)	Birth–3 yr	Used by many pediatricians
Ordinal Scales of Infant Psychological Development	Birth–24 mo	Six subscales; based on Piaget's stages; weak in predicting later intelligence
PRESCHOOL SCALES		
Stanford-Binet Intelligence Scale (4th ed.)	2 yr–adult	Four area scores, with subtests and composite IQ score
McCarthy Scales of Children's Abilities	2–8 yr	6–18 subtests; good at defining learning disabilities; strengths/weaknesses approach
Wechsler Primary and Preschool Test of Intelligence–Revised (WPPSI-R)	2½–7¼ yr	11 subtests; verbal, performance IQs; long administration time; good at defining learning disabilities
Merrill-Palmer Scale of Mental Tests	18 mo–4 yr	19 subtests cover language skills, motor skills, manual dexterity, and matching ability
Differential Abilities Scale—II (2nd ed.)	2½–<18 yr	Special nonverbal composite; short administration time
SCHOOL-AGE SCALES		
Stanford-Binet Intelligence Scale (4th ed.)	2 yr–adult	Four area scores, with subtests and composite IQ score
Wechsler Intelligence Scale for Children (5th ed.) (WISC V)	6–16 yr	See comments on WPPSI-R
Leiter International Performance Scale, Revised	2–20 yr	Nonverbal measure of intelligence ideal for use with those who are cognitively delayed, non-English speaking, hearing impaired, speech impaired, or autistic
Wechsler Adult Intelligence Scale (WAIS-IV)	16 yr–adult	See comments on WPPSI-R
Differential Abilities Scale—II (2nd ed.)	2½–<18 yr	Special nonverbal composite; short administration time
ADAPTIVE BEHAVIOR SCALES		
Vineland Adaptive Behavior Scale—II (2nd ed.)	Birth–90 yr	Interview/questionnaire; typical persons and blind, deaf, developmentally delayed, and intellectually disabled
American Association on Intellectual and Developmental Disabilities Diagnostic Adaptive Behavior Scale (DABS)	4–21 yr	Measures conceptual, social, and practical skills needed for daily functioning. Significant limitations in these domains is needed to diagnose ID.

management in the primary care setting is appropriate. Counseling roles required in caring for these children are listed in Table 10.4. When a child is young, much of the counseling interaction takes place between the parents and the clinician, and as the child matures, direct counseling shifts increasingly toward the child.

The assessment process may itself be therapeutic. By assuming the role of a nonjudgmental, supportive listener, the clinician creates a climate of trust, allowing the family to express difficult or painful thoughts and feelings. Expressing emotions may allow the parent or caregiver to move on to the work of understanding and resolving the problem.

Interview techniques may facilitate clarification of the problem for the family and for the clinician. The family's ideas about the causes of the problem and attempts at coping can provide a basis for developing strategies for problem management that are much more likely to be implemented successfully because they emanate, in part, from the family. The clinician

shows respect by endorsing the parent's ideas when appropriate; this can increase self-esteem and sense of competency.

Educating parents through anticipatory guidance about normal and aberrant development and behavior may prevent problems through early detection and communicates the physician's interest in hearing parental concerns. Early detection allows intervention before the problem becomes entrenched and associated problems develop.

The severity of developmental and behavioral problems ranges from variations of normal to problematic responses to stressful situations to frank disorders. The clinician must try to establish the severity and scope of the patient's symptoms so that appropriate intervention can be planned.

Counseling Principles

For the child, behavioral change must be learned, not simply imposed. It is easiest to learn when the lesson is simple, clear, and consistent and presented in an atmosphere free of fear or

TABLE 10.4 Primary Care Counseling Roles

Coordinate care and interpret reports after referrals

intimidation. Parents often try to impose behavioral change in an emotionally charged atmosphere, most often at the time of a behavioral *violation*. Similarly, clinicians may try to *teach* parents with hastily presented advice when the parents are distracted by other concerns or not engaged in the suggested behavioral change.

Apart from management strategies directed specifically at the problem behavior, regular times for positive parent-child interaction should be instituted. Frequent, brief, affectionate physical contact over the day provides opportunities for positive reinforcement of desirable child behaviors and for building a sense of competence in the child and the parent.

Most parents feel guilty when their children have a developmental/behavioral problem. Guilt may be caused by the fear that the problem was caused by inadequate parenting or by previous angry responses to the child's behavior. If possible and appropriate, the clinician should find ways to alleviate guilt, which may be a serious impediment to problem solving.

Interdisciplinary Team Intervention

In many cases, a team of professionals is required to provide the breadth and quality of services needed to appropriately serve the child who has SHCN. The primary care physician should monitor the progress of the child and continually reassess that the requisite therapy is being accomplished.

Educational intervention for a young child begins as home-based infant stimulation, often with an early childhood specialist (e.g., nurse/therapist), providing direct stimulation for the child and training the family to provide the stimulation. As the child matures, a center-based early learning center program may be indicated. For the school-age child, special services may range from extra attention in the classroom to a self-contained special education classroom.

Psychologic intervention may be directed to the parent or family or, with an older child, primarily the child. Examples of therapeutic approaches are guidance therapies, such as directive advice giving, counseling to create their own solutions to problems, psychotherapy, behavioral management techniques, psychopharmacologic methods (from a psychiatrist), and cognitive-behavioral therapy.

Motor intervention may be performed by a physical or occupational therapist. *Neurodevelopmental therapy* (NDT),

the most commonly used method, is based on the concept that nervous system development is hierarchic and subject to some plasticity. The focus of NDT is on gait training and motor development, including daily living skills; perceptual abilities, such as eye-hand coordination; and spatial relationships. *Sensory integration therapy* is also used by occupational therapists to structure sensory experience from the tactile, proprioceptive, and vestibular systems to allow for adaptive motor responses.

Speech-language intervention by a speech and language therapist/pathologist (oral-motor therapist) is usually part of the overall educational program and is based on the tested language strengths and weaknesses of the child. Children needing this type of intervention may show difficulties in reading and other academic areas and develop social and behavioral problems because of their difficulties in being understood and in understanding others. **Hearing intervention**, performed by an audiologist (or an otolaryngologist), includes monitoring hearing acuity and providing amplification when necessary via hearing aids.

Social and environmental intervention generally includes nursing or social work involvement with the family. Frequently, the task of coordinating services falls to these specialists. Case managers may be in the private sector, from the child's insurance or Medicaid plan, or part of a child protection agency.

Medical intervention for a child with a developmental disability involves providing primary care as well as specific treatment of conditions associated with the disability. Although curative treatment often is not possible, functional impairment can be minimized through thoughtful medical management. Certain general medical problems are found more frequently in delayed and developmentally disabled people (Table 10.5), especially if the delay is part of a known syndrome. Some children may have a limited life expectancy. Supporting the family through palliative care, hospice, and bereavement is another important role of the primary care pediatrician.

SELECTED CLINICAL PROBLEMS: THE SPECIAL NEEDS CHILD

Intellectual Disability

ID is defined as significantly subnormal intellectual functioning for a child's developmental stage, existing concurrently with deficits in adaptive behaviors (self-care, home living, communication, and social interactions). ID is defined statistically as cognitive performance that is two standard deviations below the mean (roughly below the 3rd percentile) of the general population as measured on standardized intelligence testing. The prevalence of ID in the United States is approximately 2%. ICD-10 categorization of levels of ID is shown in Table 10.6. Caution must be exercised in interpretation because these categories do not reflect actual functional level of the tested individual. The American Association on Intellectual and Developmental Disabilities and the American Psychiatric Association recommend classifying ID based on adaptive functioning (daily life activities) and not on IQ alone.

The etiology of the central nervous system insult resulting in ID may involve genetic disorders, teratogenic influences, perinatal insults, acquired childhood disease or injury, and environmental and social determinants of health (Table 10.7). Mild ID correlates with socioeconomic status, although profound ID does not. Although a single organic cause may be found, each individual's performance should be considered a function of the interaction of environmental influences with the individual's

TABLE 10.5 Recurring Medical Issues in Children with Developmental Disabilities	
PROBLEM	ASK ABOUT OR CHECK
Motor	Range of motion examination; scoliosis check; assessment of mobility; interaction with orthopedist, physical medicine and rehabilitation, and physical therapist/occupational therapist as needed
Diet	Dietary history, feeding observation, growth parameter measurement and charting, supplementation as indicated by observations, oro-motor therapist as needed
Sensory impairments	Functional vision and hearing screening; interaction as needed with ophthalmologist, audiologist
Dermatologic	Examination of <i>all</i> skin areas for decubitus ulcers or infection
Dentistry	Examination of teeth and gums; confirmation of access to dental care (preferably with ability to use sedation)
Behavioral problems	Aggression, self-injury, pica; sleep problems; psychotropic drug levels and side effects
Seizures	Major motor, absence, other suspicious symptoms; monitoring of anticonvulsant levels and side effects
Infectious diseases	Ear infections, diarrhea, respiratory symptoms, aspiration pneumonia, immunizations (especially hepatitis B and influenza)
Gastrointestinal problems	Constipation, gastroesophageal reflux, gastrointestinal bleeding (stool for occult blood)
Sexuality	Sexuality education, preventing abuse, hygiene, contraception, menstrual suppression, genetic counseling
Other syndrome-specific problems	Ongoing evaluation of other "physical" problems as indicated by known intellectual disability/developmental disability etiology
Advocacy for services and enhancing access to care	Educational program, family supports, financial supports, legislative advocacy to support programs

TABLE 10.6 Levels of Intellectual Disability	
LEVEL OF DISABILITY	ICD-10 IQ SCORE
Mild	50–55 to 70
Moderate	35–40 to 50–55
Severe	20–25 to 35–40
Profound	<20 to 25

ICD-10, *International Classification of Diseases, Tenth Revision*.

organic substrate. Behavioral difficulties resulting from ID itself and from the family's reaction to the child and the condition are common. More severe forms of ID can be traced to biologic factors. The earlier the cognitive slowing is recognized, the more severe the deviation from normal is likely to be.

TABLE 10.7 Differential Diagnosis of Intellectual Disability	
EARLY ALTERATIONS OF EMBRYONIC DEVELOPMENT	
Sporadic events affecting embryogenesis, usually a stable developmental challenge	
Chromosomal changes (e.g., trisomy 21 syndrome)	
Prenatal influences (e.g., substance abuse, teratogenic medications, intrauterine TORCH infections) [†]	
UNKNOWN CAUSES	
No definite issue is identified, or multiple elements present, none of which is diagnostic (may be multifactorial)	
ENVIRONMENTAL AND SOCIAL PROBLEMS	
Dynamic influences, commonly associated with other challenges	
Deprivation (neglect)	
Parental mental illness	
Environmental intoxications (e.g., significant lead intoxication)*	
PREGNANCY PROBLEMS AND PERINATAL MORBIDITY	
Impingement on normal intrauterine development or delivery; neurologic abnormalities frequent, challenges are stable or occasionally worsening	
Fetal malnutrition and placental insufficiency	
Perinatal complications (e.g., prematurity, birth asphyxia, birth trauma)	
HEREDITARY DISORDERS	
Preconceptual origin, variable expression in the individual infant, multiple somatic effects, frequently a progressive or degenerative course	
Inborn errors of metabolism (e.g., Tay-Sachs disease, Hunter disease, phenylketonuria)	
Single-gene abnormalities (e.g., neurofibromatosis or tuberous sclerosis)	
Other chromosomal aberrations (e.g., fragile X syndrome, deletion mutations such as Prader-Willi syndrome)	
Polygenic familial syndromes (pervasive developmental disorders)	
ACQUIRED CHILDHOOD ILLNESS	
Acute modification of developmental status, variable potential for functional recovery	
Infections (all can ultimately lead to brain damage, but most significant are encephalitis and meningitis)	
Cranial trauma (accidental and child abuse)	
Accidents (e.g., near-drowning, electrocution)	
Environmental intoxications (prototype is lead poisoning)	

*Some health problems fit in several categories (e.g., lead intoxication may be involved in several areas).

[†]This also may be considered as an acquired childhood disease.

TORCH, *Toxoplasmosis, other (congenital syphilis), rubella, cytomegalovirus, and herpes simplex virus*.

The first step in the diagnosis and management of a child with ID is to identify functional strengths and weaknesses for purposes of medical and rehabilitative therapies. A history and physical examination may suggest a diagnosis that might be confirmed by laboratory testing and/or imaging. Frequently

used laboratory tests include chromosomal analysis and magnetic resonance imaging of the brain. Almost one third of individuals with ID do not have readily identifiable reasons for their disability.

Vision Impairment

Significant visual impairment is a problem in many children. **Partial vision** (defined as visual acuity between 20/70 and 20/200) occurs in 1 in 500 school-age children in the United States. **Legal blindness** is defined as distant visual acuity of 20/200 or worse and affects about 35,000 children in the United States. Such impairment can be a major barrier to optimal development.

The most common cause of **severe visual impairment** in children is retinopathy of prematurity (see [Chapter 61](#)). Congenital cataracts may lead to significant amblyopia. Cataracts also are associated with other ocular abnormalities and developmental disabilities. **Amblyopia** is a pathologic alteration of the visual system characterized by a reduction in visual acuity in one or both eyes with no clinically apparent organic abnormality that completely accounts for the visual loss. Amblyopia is due to a distortion of the normal clearly formed retinal image (from congenital cataracts or severe refractive errors); abnormal binocular interaction between the eyes, as one eye competitively inhibits the other (strabismus); or a combination of both mechanisms. Albinism, hydrocephalus, congenital cytomegalovirus infection, and birth asphyxia are other significant contributors to blindness in children.

Children with **mild to moderate visual impairment** usually have an uncorrected refractive error. The most common presentation is myopia or nearsightedness. Other causes are hyperopia (farsightedness) and astigmatism (alteration in the shape of the cornea leading to visual distortion). In children younger than 6 years, high refractive errors in one or both eyes also may cause amblyopia, aggravating visual impairment.

The diagnosis of severe visual impairment commonly is made when an infant is 4–8 months of age. Clinical suspicion is based on parental concerns aroused by unusual behavior, such as lack of smiling in response to appropriate stimuli, the presence of nystagmus, other wandering eye movements, or motor delays in beginning to reach for objects. Fixation and visual tracking behavior can be seen in most infants by 6 weeks of age. This behavior can be assessed by moving a brightly colored object (or the examiner's face) across the visual field of a quiet but alert infant at a distance of 1 ft. The eyes also should be examined for red reflexes and pupillary reactions to light. Optical alignment (binocular vision with both eyes consistently focusing on the same spot) should not be expected until the infant is beyond the newborn period. Persistent nystagmus is abnormal at any age. If ocular abnormalities are identified, referral to a pediatric ophthalmologist is indicated.

During the newborn period, vision may be assessed by physical examination and by **visual evoked response**. This test evaluates the conduction of electrical impulses from the optic nerve to the occipital cortex of the brain. The eye is stimulated by a bright flash of light or with an alternating checkerboard of black-and-white squares, and the resulting electrical response is recorded from electrodes strategically placed on the scalp, similar to an electroencephalogram.

There are many developmental implications of visual impairment. Perception of body image is abnormal, and imitative

behavior, such as smiling, is delayed. Delays in mobility may occur in children who are visually impaired from birth, although their postural milestones (ability to sit) usually are achieved appropriately. Social bonding with the parents also is often affected.

Visually impaired children can be helped in various ways. Classroom settings may be augmented with resource-room assistance to present material in a nonvisual format. Fine motor activity development, listening skills, and Braille reading and writing are intrinsic to successful educational intervention for a child with severe visual impairment.

Hearing Impairment

The clinical significance of hearing loss varies with its type (conductive vs. sensorineural), its frequency, and its severity as measured in the number of decibels heard or the number of decibels of hearing lost. The most common cause of mild to moderate hearing loss in children is a conduction abnormality caused by acquired middle ear disease (acute and chronic otitis media). This abnormality may have a significant effect on the development of speech and language development, particularly if there is chronic fluctuating middle ear fluid. If hearing impairment is more severe, sensorineural hearing loss is more common. Causes of sensorineural deafness include congenital infections (e.g., rubella and cytomegalovirus), meningitis, birth asphyxia, kernicterus, ototoxic drugs (especially aminoglycoside antibiotics), and tumors and their treatments. Genetic deafness may be either dominant or recessive in inheritance; this is the main cause of hearing impairment in schools for the deaf. In Down syndrome, there is a predisposition to conductive loss caused by middle-ear infection and sensorineural loss caused by cochlear disease. Any hearing loss may have a significant effect on the child's developing communication skills. These skills then affect all areas of the child's cognitive and skills development ([Table 10.8](#)).

It is sometimes quite difficult to accurately determine the presence of hearing in infants and young children. Inquiring about a newborn's or infant's response to sounds or even observing the response to sounds in the office is unreliable for identifying hearing-impaired children. Universal screening of newborns is required prior to nursery discharge and includes the following:

1. **Auditory brainstem response (ABR)** measures how the brain responds to sound. Clicks or tones are played through soft earphones into the infant's ears. Three electrodes placed on the infant's head measure the brain's response.
2. **Otoacoustic emissions** measure sound waves produced in the inner ear. A tiny probe is placed just inside the infant's ear canal. It measures the response (echo) when clicks or tones are played into the infant's ears.

Both of these tests are quick (5–10 minutes), painless, and may be performed while the infant is sleeping or lying still. The tests are sensitive but not as specific as more definitive tests. Infants who do not pass these tests are referred for more comprehensive testing. Many of these infants have normal hearing on definitive testing. Infants who do not have normal hearing should be immediately evaluated or referred for etiologic diagnosis and early intervention.

For children not screened at birth (such as children of immigrant parents) or children with suspected acquired hearing loss, later testing may allow early appropriate intervention. Hearing can be screened by means of an office audiogram, but

SEVERITY OF HEARING LOSS	POSSIBLE ETIOLOGIC ORIGINS	COMPLICATIONS			
		SPEECH-LANGUAGE	EDUCATIONAL	BEHAVIORAL	TYPES OF THERAPY
<i>Slight</i> 15–25 dB (ASA)	Chronic otitis media/middle ear effusions	Difficulty with hearing distant or faint speech	Possible auditory learning dysfunction	Usually none	May require favorable class setting, speech therapy, or auditory training
	Perforation of tympanic membrane		May reveal a slight verbal deficit		Possible value in hearing aid, surgery
	Sensorineural loss				Favorable class setting
	Tympanosclerosis				Favorable class setting
<i>Mild</i> 25–40 dB (ASA)	Chronic otitis media/middle ear effusions	Difficulty with conversational speech over 3–5 ft	May miss 50% of class discussions	Psychologic problems	Special education resource help, surgery
	Perforation of tympanic membrane	May have limited vocabulary and speech disorders	Auditory learning dysfunction	May act inappropriately if directions are not heard well	Hearing aid, surgery
	Sensorineural loss			Acting out behavior	Favorable class setting, hearing aid, cochlear implant
	Tympanosclerosis			Poor self-concept	Lip reading instruction Speech therapy
<i>Moderate</i> 40–65 dB (ASA)	Chronic otitis media/middle ear effusions	Conversation must be loud to be understood.	Learning disability	Emotional and social problems	Special education resource or special class, surgery
	Middle ear anomaly	Defective speech	Difficulty with group learning or discussion	Behavioral reactions of childhood	Special help in speech-language development
	Sensorineural loss	Deficient language use and comprehension	Auditory processing dysfunction Limited vocabulary	Acting out Poor self-concept	Hearing aid and lip reading Speech therapy
<i>Severe</i> 65–95 dB (ASA)	Sensorineural loss	Loud voices may be heard 2 ft from ear.	Marked educational disability	Emotional and social problems that are associated with handicap	Full-time special education for deaf children, cochlear implant
	Severe middle ear disease	Defective speech and language No spontaneous speech development if loss present before 1 yr	Marked learning disability, limited vocabulary	Poor self-concept	Full-time special education for deaf children, hearing aid, lip reading, speech therapy, surgery, cochlear implant
<i>Profound</i> ≥95 dB (ASA)	Sensorineural or mixed loss	Relies on vision rather than hearing Defective speech and language Speech and language will not develop spontaneously if loss present before 1 yr.	Marked learning disability because of lack of understanding of speech	Congenital and prelingually deaf may show severe emotional problems.	Full-time special education for deaf children, hearing aid, lip reading, speech therapy, surgery, cochlear implant

ASA, Acoustical Society of America.

Modified and updated from Gottlieb MI. Otitis media. In: Levine MD, Carey WB, Crocker AC, et al., eds. *Developmental-Behavioral Pediatrics*. Philadelphia: WB Saunders; 1983.

other techniques are needed (ABR, behavior audiology) for young, neurologically immature or impaired, and behaviorally difficult children. The typical audiologic assessment includes pure-tone audiometry over a variety of sound frequencies (pitches), especially over the range of frequencies in which

most speech occurs. **Pneumatic otoscopic** examination and **tympanometry** are used to assess middle ear function and the tympanic membrane compliance for pathology in the middle ear, such as fluid, ossicular dysfunction, and eustachian tube dysfunction (see [Chapter 9](#)).

The treatment of conductive hearing loss (largely due to otitis media and middle ear effusions) is discussed in Chapter 105. Treatment of sensorineural hearing impairment may be medical or surgical. If amplification is indicated, hearing aids can be tuned preferentially to amplify the frequency ranges in which the patient has decreased acuity. Educational intervention typically includes speech-language therapy and teaching American Sign Language. Even with amplification, many hearing-impaired children show deficits in processing auditory information, requiring special educational services for helping to read and for other academic skills. **Cochlear implants** are surgically implantable devices that provide hearing sensation to individuals with severe to profound hearing loss. The implants are designed to substitute for the function of the middle ear, cochlear mechanical motion, and sensory cells, transforming sound energy into electrical energy that initiates impulses in the auditory nerve. Cochlear implants are indicated for children older than 12 months with profound bilateral sensorineural hearing loss who have limited benefit from hearing aids, have failed to progress in auditory skill development, and have no radiologic or medical contraindications. Implantation in children as young as possible gives them the most advantageous auditory environment for speech-language learning.

Speech-Language Impairment

Parents often bring the concern of speech delay to the physician's attention when they compare their young child with others of the same age (Table 10.9). The most common causes of the speech delay are ID, hearing impairment, social deprivation, autism, and oral-motor abnormalities. If a problem is suspected based on screening with tests such as Ages and Stages Questionnaires or the Parents' Evaluation of Developmental Status test (see Chapter 8) or other standard screening test (Early Language Milestone Scale), a referral to a specialized hearing and speech center is indicated. While awaiting the results of testing or initiation of speech-language therapy, parents should be advised to speak slowly and clearly to the child (and avoid *baby talk*). Parents and older siblings should read frequently to the speech-delayed child.

Speech disorders include **articulation, fluency, and resonance disorders**. Articulation disorders include difficulties producing sounds in syllables or saying words incorrectly to the point that other people cannot understand what is being said. Fluency disorders include problems such as **stuttering**, the condition in which the flow of speech is interrupted by abnormal stoppages, repetitions (*st-st-stuttering*), or prolonged sounds and syllables (*sssstuttering*). Resonance or voice disorders include problems with the pitch, volume, or quality of a child's voice that distract listeners from what is being said.

Language disorders can be either receptive or expressive. Receptive disorders refer to difficulties understanding or processing language. Expressive disorders include difficulty putting words together, limited vocabulary, or inability to use language in a socially appropriate way.

Speech-language pathologists (also called speech or oral-motor therapists) assess the speech, language, cognitive communication, and swallowing skills of children; determine what types of communication problems exist; and identify the best way to treat these challenges. Speech-language pathologists skilled at working with infants and young children are also vital in training parents and infants in other oral-motor skills, such as how to feed an infant born with a cleft lip and palate.

TABLE 10.9 Clues to When a Child with a Communication Disorder Needs Help

0–11 MONTHS
Before 6 months, the child does not startle, blink, or change immediate activity in response to sudden, loud sounds.
Before 6 months, the child does not attend to the human voice and is not soothed by mother's voice.
By 6 months, the child does not babble strings of consonant and vowel syllables or imitate gurgling or cooing sounds.
By 10 months, the child does not respond to own name.
At 10 months, the child's sound-making is limited to shrieks, grunts, or sustained vowel production.
12–23 MONTHS
At 12 months, the child's babbling or speech is limited to vowel sounds.
By 15 months, the child does not respond to "no," "bye-bye," or "bottle."
By 15 months, the child does not imitate sounds or words.
By 18 months, the child is not consistently using at least six words with appropriate meaning.
By 21 months, the child does not respond correctly to "Give me...", "Sit down," or "Come here" when spoken without gestural cues.
By 23 months, two-word phrases that are spoken as single units (e.g., "whatszit," "thankyou," "allgone") have not emerged.
24–36 MONTHS
By 24 months, at least 50% of the child's speech is not understood by familiar listeners.
By 24 months, the child does not point to body parts without gestural cues.
By 24 months, the child is not combining words into phrases (e.g., "go bye-bye," "go car," "want cookie").
By 30 months, the child does not show understanding of spatial concepts: on, in, under, front, and back.
By 30 months, the child is not using short sentences (e.g., "Daddy went bye-bye").
By 30 months, the child has not begun to ask questions (using <i>where, what, why</i>).
By 36 months, the child's speech is not understood by unfamiliar listeners.
ALL AGES
At any age, the child is consistently dysfluent with repetitions, hesitations; blocks or struggles to say words. Struggle may be accompanied by grimaces, eye blinks, or hand gestures.

Modified and updated from Weiss CE, Lillywhite HE. Communication Disorders: A Handbook for Prevention and Early Detection. St Louis: Mosby; 1976.

Speech-language therapy involves having a speech-language specialist work with a child on a one-on-one basis, in a small group, or directly in a classroom to overcome a specific disorder using a variety of therapeutic strategies. Language intervention activities involve having a speech-language specialist interact with a child by playing and talking to the child using pictures, books, objects, or ongoing events to stimulate language development. Articulation therapy involves having

TABLE 10.10 Risk Factors for Cerebral Palsy

the therapist model correct sounds and syllables for a child, often during play activities.

Children enrolled in therapy early (<3 years of age) tend to have better outcomes than children who begin therapy later. Older children can make progress in therapy, but progress may occur more slowly because these children often have learned patterns that need to be modified or changed. Parental involvement is crucial to the success of a child's progress in speech-language therapy.

Cerebral Palsy

Cerebral palsy (CP) refers to a group of non-progressive, but often changing, motor impairment syndromes secondary to anomalies or lesions of the brain arising before or after birth. The prevalence of CP at age 8 in the United States is 1.5–4 per 1,000; prevalence is much higher in premature and twin births. Prematurity and low birthweight infants (leading to perinatal asphyxia), congenital malformations, and kernicterus are causes of CP noted at birth. Ten percent of children with CP have acquired CP, developing at later ages. Meningitis

TABLE 10.11 Descriptions of Cerebral Palsy by Site of Involvement

Hemiparesis (hemiplegia): predominantly unilateral impairment of the arm and leg on the same (e.g., right or left) side
Diplegia: motor impairment primarily of the legs (often with some limited involvement of the arms; some authors challenge this specific type as not being different from quadriplegia)
Quadriplegia: all four limbs (whole body) are functionally compromised.

TABLE 10.12 Classification of Cerebral Palsy by Type of Motor Disorder

Spastic cerebral palsy: the most common form of cerebral palsy, it accounts for 70–80% of cases. It results from injury to the upper motor neurons of the pyramidal tract. It may occasionally be bilateral. It is characterized by at least two of the following: abnormal movement pattern, increased tone, or pathologic reflexes (e.g., Babinski response, hyperreflexia).

Dyskinetic cerebral palsy: occurs in 10–15% of cases. It is dominated by abnormal patterns of movement and involuntary, uncontrolled, recurring movements.

Ataxic cerebral palsy: accounts for <5% of cases. This form results from cerebellar injury and features abnormal posture or movement and loss of orderly muscle coordination or both.

Dystonic cerebral palsy: also uncommon. It is characterized by reduced activity and stiff movement (hypokinesia) and hypotonia.

Choreoathetotic cerebral palsy: rare now that excessive hyperbilirubinemia is aggressively prevented and treated. This form is dominated by increased and stormy movements (hyperkinesia) and hypotonia.

Mixed cerebral palsy: accounts for 10–15% of cases. This term is used when more than one type of motor pattern is present and when one pattern does not clearly dominate another. It typically is associated with more complications, including sensory deficits, seizures, and cognitive-perceptual impairments.

and head injury (accidental and nonaccidental) are the most common causes of acquired CP (Table 10.10). Nearly 50% of children with CP have no identifiable risk factors. As genomic medicine advances, many of these causes of idiopathic CP may be identified.

Most children with CP, except in its mildest forms, are diagnosed in the first 18 months of life when they fail to attain motor milestones or show abnormalities such as asymmetric gross motor function, hypertonia, or hypotonia. CP can be characterized further by the affected parts of the body (Table 10.11) and descriptions of the predominant type of motor disorder (Table 10.12). Co-morbidities in these children often include epilepsy, learning difficulties, behavioral challenges, and sensory impairments. Many of these children have an isolated motor defect. Some affected children may be intellectually gifted.

Treatment depends on the pattern of dysfunction. Physical and occupational therapy can facilitate optimal positioning and movement patterns, increasing function of the affected parts. Spasticity management also may include oral medications

(dantrolene, benzodiazepines, and baclofen), botulinum toxin injections, and implantation of intrathecal baclofen pumps. Management of seizures, spasticity, orthopedic impairments, and sensory impairments may help improve educational attainment. CP cannot be cured, but a host of interventions can improve functional abilities, participation in society, and quality of life. Like all children, an assessment and reinforcement of strengths are important, especially for intellectually intact or gifted children who have simple motor deficits.

PEARLS FOR PRACTITIONERS

See *Growth and Development: Pearls for Practitioners at the end of this section*.

PEARLS FOR PRACTITIONERS

CHAPTER 5

Normal Growth

- Standard growth charts are used; they are available free from the CDC.
 - 0–2 years, use the WHO growth charts and measure weight, recumbent length, and head circumference; plot these as well as the weight for length.
 - For >2 years, use the CDC growth charts and measure weight, standing height, and calculate BMI. All should be plotted.
- Rules of thumb
 - Double birthweight in 4–5 months
 - Triple birthweight by age 1 year
 - Double birth length by age 4 years

CHAPTER 6

Disorders of Growth

- The pattern of decreased growth may assist in the evaluation.
 - Weight decreases first, then length, then head circumference: caloric inadequacy
 - May be organic (e.g., increased work of breathing with congestive heart failure)
 - Often is nonorganic (neglected child, maternal depression)
 - All growth parameters less than the 5th percentile
 - Normal variants: familial short stature, constitutional delay
 - Endocrine disorders (especially with pituitary dysfunction)
- Declining percentiles but otherwise normal 6–18 months: “catch-down growth”

CHAPTER 7

Normal Development

- Selected age-appropriate issues
 - Neonatal reflexes assist in evaluation of the newborn: Moro, rooting, sucking, asymmetric tonic neck reflex.
 - Contractures of the joints at birth should be followed if the joint can be moved to the proper position; fixed deformities require pediatric orthopedic evaluation.
 - By no later than 1 year, examine for binocular vision with the light reflex and cover test.
 - Older children and adolescents who participate in sports need a careful cardiovascular and orthopedic risk assessment.
- Developmental milestones
 - Gross motor, fine motor, speech, and personal-social are the areas most used for comparison.
- Selected age-appropriate issues
 - Bonding and attachment in infancy are critical for optimal outcomes.
 - Developing autonomy in early childhood: child explores but needs quick access to the caregivers.
 - Stranger anxiety beginning at about 9 months: support the infant when the child is exploring and when others are present
 - “Terrible twos”: reinforce the desired behavior and try extinguishing the undesired behavior (by not responding to the behavior)
 - Value of early childhood education: increases educational attainment and is preferably started before age 3
 - School readiness should be assessed, not just assumed, to have optimal educational outcome.
 - Adolescent development divided into three phases
 - Early adolescent: “Am I normal?”

- Middle adolescent: risk behaviors and exploration of parental and cultural values
- Late adolescent: “been there, done that”; emerge from risk behaviors and planning for the future adult roles

CHAPTER 8

Disorders of Development

- Developmental surveillance at every office visit; more careful attention at health maintenance visits
- Developmental screening using validated tool
 - Done at 9, 18, and 30 months at a minimum
 - Most common tools are Ages and Stages and Parents’ Evaluation of Developmental Status
 - Abnormalities require definitive testing
- Autism screening using validated tool is done at 18 and 24 months.
 - Most common is the M-CHAT-R
 - Abnormalities require definitive testing
- Language development is critical in early childhood.
 - Highly correlates with cognitive development
 - Even with newborn hearing test, may need to re-test hearing at any age
 - Speech therapy is more effective the younger it is started.
- After age 6, school performance is assessed; if there are performance issues (academic or behavioral), there should be elaborate testing; testing should be done by psychologists, psychiatrists, developmental pediatricians, or educational experts.
- Context of behavioral problems
 - Parental factors: mismatch in temperament or expectations between parent and child, depression, other health issues
 - Adverse childhood experiences
 - Witnessed or experienced abuse and neglect, domestic violence, substance abuse, incarceration, and death of relative
- Social determinants of health
 - Stress, lack of parental support, perceived prejudice, and racism
 - Poverty: housing with environmental exposures, poor access to quality education, poor access to healthy nutrition (food deserts), toxic stress
- Adolescents are a special challenge; developing rapport and open communication is critical.
- Adolescents may usually consent for sexual health, mental health, and substance abuse services although local laws may vary.
 - As long as they are not homicidal, suicidal, or unable to give informed consent, adolescents should consent for above issues.
 - Confidentiality is critical unless there is information that would seem to allow harm to come to the individual or others.

CHAPTER 9

Evaluation of the Well Child

- Standardized by the American Academy of Pediatrics Bright Futures program; recommendations for Preventive Pediatric Health Care were updated in 2017

- Elements of the visits
 - Measurements: growth, blood pressure, sensory screening (vision and hearing)
 - Developmental/behavioral assessment
 - Depression screening should start at age 11; PHQ2 and PHQ9 are available in Bright Futures resources
 - Physical examination
 - Procedures
 - Newborn screening, screening for critical congenital heart disease
 - Hemoglobin, lead, TB testing at certain ages or if risks are present
 - Lipid screening once at age 9–11 and at 17–21, other ages if risk factors
 - STD/HIV risk assessment and screening between ages 16 and 18 (or if sexually active at earlier age)
 - Oral health: dental referral starting at age 1 year; fluoride varnish every 3–6 months between ages 6 months and 6 years
 - Anticipatory guidance that is age and developmentally appropriate
 - Bright Futures has age-appropriate one-page handouts for each health maintenance visit by age in the Tool and Resource Kit.
- Promoting optimal development
 - Discipline means to teach, not just to punish.
 - Reinforcing positive behaviors and activities is the most effective.
 - Time-out technique is optimal for altering undesired behaviors; corporal punishment teaches children it is okay to hit.
 - Setting limits that are agreed upon by all caregivers leads to optimal outcomes.

CHAPTER 10

Evaluation of the Child with Special Needs

- Children with special health care needs share broad experiences in school difficulties and family stress; 19% of U.S. children have a special health care need.
- Goal is to maximize potential by treating primary issue and helping the family and patient deal with the stresses and secondary impairments.
- Optimal care
 - Primary care pediatrician in a medical home—provides big picture oversight, evaluates the concern and provides diagnosis, provides preventive care, and facilitates
 - Pediatric subspecialists
 - Pediatric therapists—OT, PT, speech
 - Social work or health navigator may assist by finding needed community services (e.g., medically fragile child care).
 - Developmental assessments under age 3 are mandated to happen with no charge to the family or insurance through early intervention programs; over age 3, they are performed by school districts.
 - Psychology, education, and social environment assessments

- Selected special health care needs
 - Intellectual disability—myriad causes that should be investigated; children may often “outperform” their expected intelligence with excellent support
 - Vision impairment
 - Can be tested as early as newborn using visual evoked response
 - Diagnosed between 4 and 8 months; clues: the child does not respond to the parent’s smile, has wandering eye movements, or has motor delays in reaching for objects
 - Hearing impairment
 - Newborns have their hearing tested but may need additional testing later if there is a clinical suspicion.
 - A newborn should have a hearing screen by 1 month of age with follow-up testing for abnormal results by 3 months of age. If follow-up test is abnormal, interventions should be implemented by 6 months of age. (Test by 1 month, repeat by 3 months, intervene by 6 months.)
 - Hearing impairment can be conductive or sensorineural, each has different available treatment.
 - Speech disorders
 - For ages 2–4 years, a stranger should be able to understand a percentage of a child’s language that correlates with age in years divided by 4. (For age 2, $2/4 = 50\%$ of speech should be easily understood.)
- Many causes: ID, hearing impairment, deprivation and poor use of language with caregivers, autism, oral-motor abnormalities
- Immediate speech-language evaluation and hearing evaluation
- Commence speech therapy as soon as a true deficit is found; outcomes are better the earlier speech therapy is started
- Articulation, fluency, stuttering, and resonance disorders may be discovered and are amenable to speech-language therapy
- Cerebral palsy: non-progressive motor impairment syndrome
 - Myriad causes: 50% no cause identified
 - Congenital: prematurity, low birthweight, congenital malformations, kernicterus in the past
 - Acquired: meningitis/encephalitis, head injury (crashes or child abuse)
 - May be associated with other deficits depending on the causes, but this is a motor deficiency definition; some children are even intellectually gifted.
 - Team approach for optimal outcomes
 - Physicians provide antispasticity medications
 - Home health care and durable medical equipment
 - OT/PT/speech therapy as needed
 - Social work/health navigator

BEHAVIORAL DISORDERS

Caroline R. Paul | Colleen M. Wallace

CHAPTER 11

Crying and Colic

NORMAL DEVELOPMENT

Crying is best understood by the characteristics of timing, duration, frequency, intensity, and modifiability of the cry. Most infants cry little during the first 2 weeks of life. The duration of the cry gradually increases to a mean duration of crying that ranges from 117–133 minutes per day during the first 6 weeks of life. This decreases to 68 minutes per day by 10–12 weeks, although this can vary widely from infant to infant.

Cry **duration** differs by culture and infant care practices. Understanding patterns of crying may help the clinician determine the etiology of crying as well as how to guide the caregiver to cope with the infant's crying. Crying behavior in former premature infants also may be influenced by ongoing medical conditions. The duration of crying is often modifiable by caregiving strategies.

Frequency of crying is less variable than duration of crying. At 6 weeks of age, the mean frequency of combined crying and fussing is 10 episodes in 24 hours. Diurnal variation in crying is the norm, with crying concentrated in the late afternoon and evening.

The **intensity** of infant crying varies, ranging from fussing to screaming. An intense infant cry (pitch and loudness) is more likely to elicit concern or alarm from caregivers than an infant who frets more quietly. Pain cries of newborns are remarkably loud: 80 dB at a distance of 30.5 cm from the infant's mouth. Although pain cries have a higher frequency than hunger cries, when not attended to for a protracted period, hunger cries become acoustically similar to pain cries. Fortunately, most infant crying is of a lesser intensity, consistent with fussing.

COLIC

Infantile colic is defined as episodes of uncontrollable crying or fussing in an otherwise healthy infant. Colicky crying is often described as paroxysmal and may be characterized by facial grimacing, leg flexion, and passing flatus. It has been associated with shaken baby syndrome, postpartum depression, parental guilt, and multiple physician visits.

Varying diagnostic criteria for the actual medical definition for colic exist. **Wessel rule of threes** (crying for >3 hours per

day, at least 3 days per week, for >3 weeks) has been replaced by the 2016 ROME IV criteria, which include the following:

1. Age <5 months when the symptoms start and stop
2. Recurrent and prolonged periods of crying, fussing, or irritability that start and stop without obvious cause and cannot be prevented or resolved by caregivers
3. No evidence of poor weight gain, fever, or illness
4. Caregiver reports of crying/fussing for ≥ 3 hours per day on ≥ 3 days/week in a telephone or face-to-face interview
5. Total daily crying confirmed to be ≥ 3 hours when measured by at least one prospectively kept 24-hour diary

Epidemiology

Cumulative incidence rates of colic vary from 10–40%. It appears to peak at approximately 6 weeks of age. There is no known association with gender, gestational age, breast versus bottle feeding, season of year, or socioeconomic status. Concern about infant crying also varies by culture, and this may influence what is recorded as crying or fussing.

Etiology

Fewer than 5% of infants evaluated for excessive crying have an organic etiology. The etiology of colic is unknown and is likely multifactorial. Cow's milk protein intolerance, change in fecal flora, increase in serotonin secretion, poor feeding technique, and maternal smoking may be associated. Higher levels of fecal protectin, a marker of colonic inflammation, have been reported. Since it is a diagnosis of exclusion, a rigorous and thorough evaluation of infants with excessive crying is necessary to rule out other serious critical diagnoses.

Clinical Manifestations

A thorough history and physical examination to assess for underlying medical disorders and to determine the need for further testing is necessary, and serious diseases and injuries that can mimic the symptoms of colic must be ruled out. The **history** should include a description of the crying (i.e., onset, duration, frequency, diurnal pattern, intensity, periodicity, and relieving or exacerbating factors) as well as associated symptoms such as leg flexion, facial grimacing, vomiting, or back arching. The history should elicit any presence of fevers and any acute or subtle changes in the infant. A review of systems may identify or eliminate other serious conditions such as nonaccidental trauma. A birth history may identify perinatal

problems that could increase the likelihood of neurologic causes of crying. A detailed feeding history seeks feeding-related problems, including hunger, air swallowing (worsened by crying), gastroesophageal reflux, and food intolerance. The social history, the family's ability to handle the stress, and their knowledge of infant soothing strategies can assist in assessing risk for parental mental health comorbidities and developing an intervention plan suitable for the family.

The diagnosis of colic is made only when the **physical examination** reveals no organic cause for the infant's excessive crying. An infant who is not consolable is considered to be irritable and warrants further investigation. The examination includes vital signs, weight, length, and head circumference, looking for effects of systemic illness on growth trends, and the general examination of the infant. A thorough inspection may identify possible sources of pain, including skin lesions, **corneal abrasions, hair tourniquets**, or signs of nonaccidental trauma such as **bruising or fractures** (see [Chapters 22 and 198](#)). A neurologic examination may reveal previously undiagnosed neurologic conditions. Abdominal masses, hepatosplenomegaly, and possible signs of an acute abdomen (e.g., volvulus, tumors) should be ruled out. Observing the infant during a crying episode (or reviewing a recording of an episode) can be invaluable in assessing the infant's potential for calming and the parents' skills in soothing the infant.

Further evaluation, including potential laboratory and imaging studies, are warranted when the history or physical examination findings suggest an organic cause for excessive crying.

Differential Diagnosis

The differential diagnosis for colic is broad and includes any condition that can cause pain or discomfort in the infant as well as conditions associated with *nonpainful* distress, such as fatigue or sensory overload. It is important to evaluate for emergent conditions such as intracranial involvement, infectious disease, nonaccidental trauma, and the acute abdomen.

Cow's milk protein intolerance, gastroesophageal reflux disease (GERD), maternal substance use including nicotine, and anomalous left coronary artery all have been reported as causes of persistent crying. In addition, situations associated with poor infant regulation, including fatigue, hunger, parental anxiety, and chaotic and disruptive environmental conditions, may increase the risk of excessive crying.

Anticipatory Guidance and Management

The management of colic begins with education (including the natural history and features of colic), demystification, and a discussion of its natural course. Anticipatory guidance should also be provided regarding atypical crying that warrants further medical attention. Helping families develop caregiving strategies for the infant's fussy period is critical to overall outcomes. Techniques for calming infants include Dr. Harvey Karp's "5 Ss": swaddling, side or stomach holding, soothing noises (such as shushing, singing, or white noise), swinging or slow rhythmic movement (such as rocking, walking, or riding in a car), and sucking on a pacifier. Giving caregivers permission to allow the infant to rest or leave the infant alone in a safe place when soothing strategies are not working may alleviate overstimulation in some infants. It is important to encourage

parents to seek help and support from others when they are becoming overwhelmed and to advise against harmful methods to soothe an infant (such as placing the infant on a vibrating clothes dryer). Parents should be specifically educated about the dangers of shaking babies. A deliberate approach in management provides access to resources and follow-up of caregivers given the stressors and challenges that accompany colic. Educating parents regarding variable hunger cues, avoiding excessive caffeine and any use of alcohol in nursing mothers, ensuring adequate yet not excessive bottle nipple flow, and cautioning against overfeeding may be helpful.

Therapeutic modalities such as chiropractic manipulation and acupuncture have insufficient evidence to support their use. Similarly, while some herbal medications (such as chamomile, fennel, vervain, licorice, and balm-mint teas) have been suggested, there is no evidence of effectiveness, and they may result in side effects such as hyponatremia and anemia.

In most circumstances, **dietary changes** are not effective in reducing colic but should be considered in certain specific circumstances such as when there is concern for cow's milk protein allergy/intolerance or lactose deficiency.

Medications, including phenobarbital, diphenhydramine, alcohol, simethicone, dicyclomine, and lactase, have no benefit and may cause serious side effects. Some studies have suggested that probiotics may be useful. The use of probiotics such as *Lactobacillus reuteri* has been shown to decrease crying time in the infant with colic without adverse effects and can be considered after careful evaluation, certainty of diagnosis, and close follow-up.

Prognosis

There is no evidence that infants with colic have adverse long-term outcomes in health or temperament after the affected period. Similarly, infantile colic does not have untoward long-term effects on maternal mental health, as parental distress tends to resolve as colic subsides. The most serious complication of colic is nonaccidental trauma.

PEARLS FOR PRACTITIONERS

See *Behavioral Disorders: Pearls for Practitioners* at the end of this section.

CHAPTER 12

Temper Tantrums

Temper tantrums are a very common childhood behavioral condition, prompting presentation to care providers and referrals to behavioral consultants. Temper tantrums are brief episodes of extreme or unpleasant behavior that appear disproportionate to the situation, typically in response to frustration or anger. The median duration of a tantrum is 3 minutes. Behaviors vary and may include whining, crying, screaming, stomping, flailing, head banging, hitting, throwing objects, and biting. Tantrums can instigate breath-holding spells in some children (see [Chapter 134](#)), which can be particularly frightening for caretakers.

ETIOLOGY

Temper tantrums are a normal human developmental behavior. Children between 1 and 4 years old have an increasing desire for independence and are often unable to effectively communicate physical needs and emotions. Common triggers of temper tantrums include fatigue, hunger, discomfort, and frustration.

EPIDEMIOLOGY

Temper tantrums usually begin around the age of 12 to 18 months, worsen until 3 years of age, and taper off as children develop increased ability to control emotions, gain independence, and communicate wants and needs. In U.S. studies, up to 90% of 2- to 3-year-old children have regular tantrums, and 20% have them daily. Approximately 20% of 4-year-olds still have regular tantrums. They usually disappear by the age of 5 years. Tantrums can be more frequent, as well as more aggressive, in children with language delays or underlying conditions. Children with intellectual disability may exhibit tantrums when their developmental age is comparable to 3 to 4 years. There are no gender, race, or ethnicity differences in tantrum occurrence.

CLINICAL MANIFESTATIONS

The evaluation of a child with tantrums must include a comprehensive and detailed medical and developmental **history** to evaluate for other behavioral, psychologic, or physiologic conditions. Social history should include past or ongoing family stressors (including parental well-being, changes in living situation or school, financial difficulty, barriers to care, and recent additions or losses to the family), as these factors can exacerbate or prolong the normal developmental trajectory of tantrums. The coexistence of sleep disturbances, enuresis, aggression, or learning problems may suggest the possibility of underlying conditions such as attention-deficit/hyperactivity disorder (ADHD), autism spectrum disorder (ASD), anxiety, or depression.

It is important to differentiate between typical and atypical temper tantrums (Table 12.1); atypical tantrums may be indicative of more serious behavioral, mood, or other medical problems. About 5–7% of children 1–3 years old have temper tantrums that last more than 15 minutes. The history should include the circumstances surrounding tantrums, including triggers. Careful attention to the child's daily routines may reveal triggers such as hunger, fatigue, inadequate physical activity, or overstimulation. The tantrum history should also include parental response to tantrum episodes.

The **physical examination** should focus on identifying signs of underlying illness and include vision, hearing, and developmental exams to identify possible causes of increased frustration for the child. Behavioral observations can reveal a child's ability to follow instructions, play with age-appropriate toys, and interact with parents and the clinician; observation of attention may be especially helpful in evaluating for ASD. Dysmorphic features may reveal a genetic syndrome, and a full skin exam may reveal signs of anemia, neurocutaneous stigmata, or signs of nonaccidental trauma (see Chapter 22). Neurologic exam includes the general disposition of the child, a brief cognition assessment, and exploration for neurologic findings that could suggest brain tumors or other underlying conditions.

TABLE 12.1 Normal and Abnormal Tantrums

	NORMAL TEMPER TANTRUM	ABNORMAL TEMPER TANTRUM
Age	12 months up to age 4	Continuing past age 4
Behavior during tantrum	Crying, flailing arms or legs, falling to the floor, pushing, pulling, or biting	Injury to themselves or others during the tantrum
Duration	Up to 15 min	Lasting longer than 15 min
Frequency	Less than five times a day	More than five times a day
Mood	Should return to normal between tantrums	Persistent negative mood between tantrums

From Daniels E, Mandleco B, Luthy KE. Assessment, management, and prevention of childhood temper tantrums. *J Amer Acad Nurse Pract.* 2012;24(10):569–573 [Table 1].

Laboratory studies may include screening for iron-deficiency anemia and lead exposure as indicated. Additional laboratory and imaging studies should be reserved for situations where the history and physical examination suggest a possible underlying etiology.

DIFFERENTIAL DIAGNOSIS

Most children who have temper tantrums have no underlying medical problem. Children with atypical tantrums or with concerning signs or symptoms warrant referral for further workup. The differential diagnosis for atypical tantrums includes visual and hearing deficits, language or other developmental delays, sleep disturbances, psychosocial stressors, learning disabilities, neurologic disease or injury, genetic syndromes, and psychiatric conditions such as anxiety, depression, oppositional defiant disorder, conduct disorder, post-traumatic stress disorder, ADHD, and ASD.

ANTICIPATORY GUIDANCE AND MANAGEMENT

Management of typical temper tantrums focuses on parental education and reassurance regarding tantrums as a normal developmental phase. It is important to provide anticipatory guidance regarding tantrums at the 12-, 15-, 18-, and 24-month well child visits in order to guide expectations, provide strategies for assisting children with emotional regulation, and emphasize the importance of routines to minimize the negative impact of tantrums.

It is helpful to provide parents with strategies to help prevent tantrums, such as communicating clear, consistent, and developmentally appropriate expectations and consequences, providing appropriate positive reinforcements for good behavior, maintaining routine and structure in a child's environment, using distraction techniques when possible, and avoiding triggers (such as hunger, fatigue, loneliness, or hyperstimulation). Helping children learn to communicate desires, needs, and emotions (verbally or in alternate ways such as signing) can help decrease frustration and prevent tantrums. Another

helpful strategy is providing children with choices among acceptable alternatives and supporting autonomy when safe and appropriate (i.e., “picking your battles,” such as allowing a child to wear mismatched clothing). For children who struggle with transitions, providing a short warning prior to a change or undesired activity can be very helpful.

Resources for managing tantrums when they inevitably occur are useful. Parents should be encouraged to stay calm and meet physical and safety needs without complying with the child’s demands. Distraction and physically removing the child from the inciting environment can be an effective means of short-circuiting impending tantrums. Parents should be discouraged from punishing children for having tantrums. Further behavioral intervention therapy may be helpful for families for whom typical management is unsuccessful. During the initial stages of any behavioral intervention, tantrum behavior may increase. While parents are working to extinguish or decrease the tantrums, it is important that they provide positive reinforcement for good behavior.

PEARLS FOR PRACTITIONERS

See Behavioral Disorders: Pearls for Practitioners at the end of this section.

CHAPTER 13

Attention-Deficit/Hyperactivity Disorder

Attention-deficit/hyperactivity disorder (ADHD) is the most prevalent neurobehavioral disorder of childhood and one of the most common chronic conditions in school-age children. It is characterized by symptoms of age-inappropriate inattention, motor restlessness, hyperactivity, distractibility, poor impulse control, or a combination of these symptoms. It is typically diagnosed in childhood and impacts behavioral, emotional, cognitive, and social domains. Without optimal treatment, ADHD can have long-term implications, including decreased likelihood of high school and postsecondary graduation as well as poor peer relations.

ETIOLOGY

ADHD is multifactorial in origin with certain prenatal exposures, genetic, neural, and environmental contributions. Many studies suggest strong but variable degrees of genetic associations with ADHD. Twin and family studies demonstrate high heritability and greater risk of developing ADHD in first-degree relatives, especially those where ADHD persists into adolescence and adulthood. Two candidate genes have been primarily implicated regarding the development of ADHD: dopamine transporter gene (*DAT1*) and the dopamine 4 receptor gene (*DRD4*).

Neuroimaging studies have demonstrated structural differences, including smaller cortical volumes, small-volume reduction throughout the brain, and abnormalities of the cerebellum especially with the midline and vermian elements in

patients with ADHD. However, these findings overlap with findings of other conditions; therefore imaging is not useful in the general diagnosis of ADHD. Imaging studies have also identified functional differences in patients with ADHD, including overall delay in cortical maturation and dysregulation of the frontal subcortical circuits, suggesting that the pathophysiologic features include large-scale neuronal networks including frontal to parietal cortical connections.

Environmental links have been described with prenatal exposure to a variety of substances, including nicotine, alcohol, prescription medications, substances of abuse, lead, organophosphate pesticides, and polychlorinated biphenyls. Additionally, central nervous system injury from trauma or infection increases the risk of ADHD.

EPIDEMIOLOGY

Prevalence rates for ADHD vary depending on research methodologies used, the population studied, and changing diagnostic criteria. Worldwide ADHD prevalence in children is 7.2%. In the United States, 9.4% of children aged 2–17 years, including 2.4% of children aged 2–5 years, have had a diagnosis of ADHD. Symptoms consistent with motor restlessness and aggression are more commonly seen in preschool children, while symptoms of disorganization and inattention are more often noted in older children and adolescents. The male:female ratio is greater than 2:1. Girls with ADHD are more likely to be diagnosed with anxiety or depression, while boys tend to have comorbidities such as oppositional defiant disorder. Symptoms of ADHD, particularly impulsivity and inattention, frequently persist past childhood, with up to 80% of those affected having symptoms into adolescence and 40% into adulthood.

Clinical Symptoms

Many of the symptoms of ADHD mimic typical findings of normal development. Thus it is important to consider the child's symptoms in the context of typical, atypical, and abnormal development. The symptoms to meet the *Diagnostic and Statistical Manual of Mental Health Disorders*, Fifth Edition (DSM-5) criteria must be developmentally inappropriate, and the onset of these symptoms should be before the age of 12. Symptoms of inattention (e.g., failing to pay close attention to details, appearing to not listen when spoken to directly, executive functioning skills' concern), hyperactivity (e.g., being fidgety or restless, leaving a seat when expected to remain seated), or impulsivity (e.g., blurting out and interruption) may indicate a diagnosis of ADHD (Table 13.1).

Diagnosis and Evaluation

Universal screening for ADHD is not recommended. The DSM-5 led to an expanded window of the age of onset with broader-based criteria. ADHD is diagnosed in the clinical setting after a full evaluation with a history and a full physical exam. The **history** should rely on open-ended questions to explore specific behaviors and their impact on academic performance, family and peer relationships, safety, self-esteem, and daily activities. Ultimately, a diagnosis of ADHD requires that the symptoms be measured with valid rating scales to establish the diagnosis. These rating scales should

TABLE 13.1 Key Diagnostic Symptoms of Attention-Deficit/Hyperactivity Disorder

INATTENTIVE SYMPTOMS	
•	Does not give close attention to details or makes careless mistakes
•	Has difficulty sustaining attention on tasks or play activities
•	Does not seem to listen when directly spoken to
•	Does not follow through on instructions and does not finish schoolwork, chores, or duties in the workplace
•	Has trouble organizing tasks or activities
•	Avoids, dislikes, or is reluctant to do tasks that need sustained mental effort
•	Loses things needed for tasks or activities
•	Easily distracted
•	Forgetful in daily activities
HYPERACTIVITY OR IMPULSIVITY SYMPTOMS	
•	Fidgets with or taps hands or feet, or squirms in seat
•	Leaves seat in situations when staying seated is expected
•	Runs about or climbs when not appropriate (may present as feelings of restlessness in adolescents or adults)
•	Unable to play or undertake leisure activities quietly
•	“On the go,” acting as if “driven by a motor”
•	Talks excessively
•	Blurts out answers before a question has been finished
•	Has difficulty waiting to take turns
•	Interrupts or intrudes on others

From Thapar A, Cooper M. Attention deficit hyperactivity disorder. *Lancet*. 2016;387(10024):1240–1250.

reflect performance in at least two settings such as in school and in home.

Clinical guidelines emphasize the use of DSM-5 with specific criteria to diagnose ADHD (<http://www.cdc.gov/ncbddd/adhd/diagnosis.html>). Symptoms generally should be present prior to 12 years of age with evidence of significant impairment per rating scales in social, academic, or work settings; additionally, other mental health disorders must be excluded. Changes incorporated into the DSM-5 diagnostic criteria include the age prior to which symptoms must occur (to identify the subset of older children, mainly female, who exhibit predominantly inattentive symptoms, which may not be noted until adolescence), as well as the need for symptoms in at least two settings.

A **physical examination** is essential to identify medical (e.g., neurologic, genetic) or developmental problems (e.g., cognitive impairment, language disorder, learning disability, autism spectrum disorder) that may underlie, coexist, or provide an alternative explanation for the child's behaviors.

Pertinent laboratory tests to evaluate for other disorders should be considered based on the relevant history and clinical components. Consider thyroid function studies, blood lead levels, genetic studies, anemia screening, or other evaluation if indicated by medical history, environmental history, or physical examination.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis can be challenging. The diagnostic process should evaluate for other conditions such as sleep disorders, seizure disorders, substance use, thyroid abnormalities, lead intoxication, sensory processing conditions, and vision or auditory deficits—all of which can cause or exacerbate hyperactivity and distractibility. Migraine headaches, asthma, hematologic disorders, and malignancies can also affect attention and impact school performance. Inattention and hyperactivity may also be features of genetic disorders such as fragile X, 22q11.2 deletion syndrome, and neurofibromatosis type 1. Attention must be paid to any medications that could contribute to symptoms of ADHD. Finally, psychologic stress from bullying, abuse, or disruptive surroundings can also lead to symptoms of hyperactivity, impulsivity, and inattention and mimic ADHD. Children who have symptoms of ADHD in only one setting may be having problems due to cognitive disability, level of emotional maturity, or feelings of inadequate well-being in that setting. Overall, it is prudent to investigate and ensure overall well-being, including sleep and nutritional hygiene, before embarking on an extensive evaluation of ADHD.

Co-morbidities

Co-morbidities are often present in children with ADHD, including anxiety (20–25%), learning disabilities (15–25%), developmental language disorders (30–35%), and mood disorders (15–20%). Other co-morbidities and associated conditions include sleep disorders, decreased motor coordination skills, oppositional defiant disorder, conduct disorders, Tourette syndrome, and fragile X syndrome. Close surveillance for co-morbidities is necessary not only at the time of diagnosis but also in the longitudinal management of ADHD.

Treatment

Management begins with recognizing ADHD as a chronic condition and educating affected children and their parents about the diagnosis, treatment options, and prognosis. A management plan should focus on achievable outcomes (such as improved relationships, increased academic performance, or fewer classroom interruptions) jointly agreed upon by the parent, the school, and the child.

Treatment strategies vary with age. A majority of children have significant response to a multimodal-treatment approach that includes behavior and academic interventions and medications when appropriate. Anticipatory guidance provides proactive strategies to mediate adverse effects on learning, school functioning, social relationships, family life, and self-esteem. Formal parent training interventions and social skills training have been shown to have some impact on ADHD symptomatology. Management of co-morbidities (such as sleep disorders, anemia, mood disorders, and learning disabilities) is needed for the optimal management of ADHD. In addition, guidance should be given on general nutrition and the use of screen time.

Behavioral therapy is central to children of all ages with ADHD and is the core of overall treatment. **Behavioral management** includes establishment of structure, routine, consistency in adult responses to behaviors, and appropriate behavioral goals. Children also benefit when parents and clinicians work with teachers to address the child's needs. Regular

behavior report cards and other “check-in” aids may be helpful to the child in the respective environments within a classroom or for the overall school day. Behavioral management strategies such as organizational skills training for the older child can enhance executive function skills.

The pediatrician should advocate for **optimal educational settings** in the school. Children may qualify for individual education plans where school psychologists can establish organizational plans and charts for the individual child as part of a management plan. Social skills training or additional mental health interventions may assist some children with behavior change or preservation of self-esteem, particularly when they have coexisting developmental or mental health conditions also requiring treatment.

Medications

Medication-based treatments have been studied rigorously and have been shown to be effective in combination with developmental psychosocial interventions. Behavioral management alone is the standard of care for the preschool child age group. However, non-pharmacologic treatments alone, for the older child and young adult, are not as effective as previously thought.

The clinician should balance the benefits and risks of initiating treatment in the preschool child, especially in cases where evidence-based behavioral treatments are not available to the child and caregivers. Stimulants have been shown to provide some benefit to preschool-aged children in short-term studies, but the overall guiding principal must rest on behavioral management. Medications can be considered, especially if there is moderate to severe continued disturbance such as a history of injury to other children or caregivers, a strong family history of ADHD, other underlying or associated neurodevelopmental disorders, or if ADHD symptoms may be interfering with the other therapies that the child is receiving.

Stimulant medications (methylphenidate or amphetamine compounds) are the first-line agents for pharmacologic treatment of ADHD. Stimulants improve parent report of quality of life and are associated with improved academic performance and lower rates of co-morbidities such as mood disorders. Stimulant medications are associated with a significant clinical benefit in many areas including decision-making, handwriting, and schoolwork productivity. Stimulant use is also associated with improved reading and math scores, fewer injuries, and overall reduced morbidity and mortality involving motor vehicle accident. In adolescents, the use of extended-release stimulants has a positive impact on evening driving performance.

Stimulant medications are available in short-acting, intermediate-acting, and long-acting forms. Extended-release and long-acting forms are preferred and are considered as first-line therapy for most children and adolescents with ADHD outside of the preschool age group. Extended-release forms correlate with improved medication adherence. It is essential to determine the optimal dose in order to avoid significant side effects or lack of efficacy, both of which can result in poor adherence.

Nonstimulant medications, including atomoxetine (norepinephrine reuptake inhibitor), guanfacine, or clonidine (α -agonists), may be helpful in children and are considered as a second-line medication intervention. They have lower treatment response rates and effect size compared to that of stimulants but may be useful for patients in whom stimulants

are contraindicated, not well tolerated, are ineffective (or only partially effective), or who have a history of substance abuse. Guanfacine chloral hydrate XR has been shown to have some efficacy as a monotherapy regimen or adjunctively with a stimulant medication especially when treating for both ADHD and co-morbid oppositional symptoms in children and adolescents.

Overall, dosing should be based on the individual rather than on the severity of the presentation or the child’s age or size. Close monitoring is needed with surveillance for future dose adjustments. The effects of the initial dose should be followed closely within a few days, and then on a weekly basis during the first month of medication initiation.

Information on medication efficacy, associated adverse effects, and appropriateness for various ages continues to emerge. Current information on specific medications is available through the Centers for Disease Control and Prevention (CDC) and American Academy of Pediatrics (AAP).

Medication side effects, including insomnia, loss of appetite, weight loss, jitteriness, and rebound moodiness, are common and are often dose dependent. Medications may exacerbate existing tic conditions. Other potential side effects include dry mouth, dizziness, drowsiness, constipation, euphoria, dysphoria, irritability, agitation, anxiety, hallucinations, mania, social withdrawal, nightmares, headaches, abdominal pain, and medication rebound. Children who are taking medications must be regularly screened for side effects, including careful monitoring of the child’s growth. Providers should titrate medication dosages and timing to minimize side effects and optimize treatment response.

Stimulant drugs may be associated with adverse cardiovascular events such as sudden cardiac death in patients with an underlying disorder exacerbated by sympathomimetic agents. While episodes are rare, screening for cardiac disease by history, family history, and physical exam is critical prior to initiation of stimulant medication and with continued surveillance during the ongoing treatment with stimulants.

Complementary Alternative Medicine

Non-traditional interventions are frequently used by families despite a lack of evidence for their effectiveness in children. Practitioners should explicitly ask about the use of alternative medicines including herbal supplements, chiropractic interventions, and meditation/relaxation techniques.

PEARLS FOR PRACTITIONERS

See Behavioral Disorders: Pearls for Practitioners at the end of this section.

CHAPTER 14

Control of Elimination

NORMAL DEVELOPMENT OF ELIMINATION

Control of urination and defecation involves physical, developmental, and cognitive maturation and is influenced by cultural norms and practices within the United States and throughout the world. In the first half of the 20th century, toilet mastery

by 18 months of age was the norm in the United States. Brazelton's introduction of the *child-centered approach* and the invention of disposable diapers facilitated later toilet training. Social changes, including increased parental work outside of the home and group child care, have influenced the trend to later initiation of toilet training. Between 2 and 4 years of age, a typical-developing child is considered ready to begin toilet training. In general, the control of bowel movement passage is achieved before bladder control.

Prerequisites for achieving elimination in the toilet include the child's ability to recognize the urge for urination and defecation, to get to the toilet, to understand the sequence of tasks required, to avoid oppositional behavior, and to take pride in achievement. The entire process of toilet training can take several months.

ENURESIS

Enuresis is defined as urinary incontinence in a child who is adequately mature to have achieved continence. Enuresis is classified as **monosymptomatic** (intermittent nocturnal incontinence), which is the focus of this chapter, or **non-monosymptomatic** (associated with other urinary tract abnormalities such as frequency, urgency, hesitancy, straining, weak stream, intermittency, postvoid dribbling, dysuria, and daytime wetting; see Chapter 168). Nocturnal enuresis refers to discrete episodes of incontinence during sleep in children over the age of 5 years. Nighttime dryness is usually achieved months after daytime dryness. Nocturnal enuresis is classified as either **primary** (incontinence in a child who has never achieved a period of nighttime dryness) or **secondary** (incontinence in a child who has been dry for at least 6 months).

Etiology

Enuresis results from a child failing to wake before voiding and may be due to a variety of factors. A correlation with slower growth and motor delays suggests a maturational delay in the neurologic ability to recognize bladder fullness and suppress bladder contraction; such delays are likely due to normal variations in development. There is strong evidence of genetic predisposition with higher monozygotic (68%) than dizygotic (36%) twin concordance. A child's likelihood of being affected is strongly linked to parental history of nocturnal enuresis and rises from 15% (if neither parent was affected) to 50% (if one parent was affected) and 75% (if both parents were affected).

Anatomic or physiologic abnormalities may contribute to nocturnal enuresis, but there is no consistent evidence for any particular cause. Nocturnal polyuria, suggested by increased nighttime void volumes, may be a factor in some children and could be due to a decreased nocturnal vasopressin peak but could also be secondary to excessive fluid intake late in the day. Small bladder capacity is more likely functional than anatomic, as affected children were found to have similar bladder capacity as unaffected children under general anesthesia. In children with chronic constipation, a dilated colon can impinge on the bladder, resulting in reduced bladder capacity and higher likelihood of enuresis. A malfunction of the detrusor muscle with a tendency for involuntary contractions even when the bladder contains small amounts of urine is possible; however, an overactive detrusor muscle generally results in daytime wetting as well. Sleep physiology may play a role in

the etiology of nocturnal enuresis, with a high arousal threshold of some affected children, although there are conflicting results regarding deeper sleep as a potential cause of enuresis.

Psychologic or behavioral concerns may be associated with primary nocturnal enuresis, but they tend to improve after acquisition of bladder control, suggesting they are more likely a result than a cause. Stressful life events are more commonly associated with (and a contributing factor for) secondary nocturnal enuresis, which can also be caused by development of poor daily voiding habits and stool retention from constipation.

Epidemiology

Nocturnal enuresis is common with a prevalence of 15% at 5 years of age, gradually decreasing to 5% at 10 years. However, 1–2% of adolescents aged 15 and older are still affected (Fig. 14.1). The spontaneous remission rate is reported to be 15% per year. Nocturnal enuresis is twice as common in boys than in girls. Primary nocturnal enuresis accounts for 80% of cases.

Clinical Manifestations

The **history** focuses on elucidating daytime and nighttime voiding patterns, frequency, and timing; typical amount and timing of fluid intake; and determining whether enuresis is primary (having never achieved nighttime dryness) or secondary (following a ≥ 6 -month period of nighttime dryness). It is important to explore the expectations of the family and the impact that enuresis has on the child and family. Many families have already attempted interventions prior to seeking care; identifying such attempts and the effect they had on the child and family are essential in determining the impact of the problem and helping identify potential future interventions.

The history should differentiate between monosymptomatic (intermittent nocturnal incontinence) and non-monosymptomatic enuresis (associated with other abnormalities). The presence of daytime incontinence or any associated urinary tract symptoms (urgency, holding maneuvers, interrupted micturition, weak stream, straining to void, or continual dampness suggesting urine leak) or neurologic symptoms (such as abnormal gait or weakness) is concerning for an underlying urologic or neurologic disorder such as posterior urethral valves, ectopic ureter, or spinal dysraphism. Urinary tract infection (UTI), renal disease, diabetes, and primary/psychogenic polydipsia may be suggested by a history pertinent for symptoms such as dysuria, frequency, anorexia, vomiting, weakness, poor growth, weight loss, polydipsia, or polyuria. A sleep history can help identify obstructive sleep apnea (OSA) or other sleep disorders (see Chapter 15); the history should also elicit symptoms suggesting seizure activity. A stooling history is also essential, as chronic constipation can contribute to enuresis via bladder impingement. A family history frequently reveals other affected family members, and a developmental history is important in identifying comorbidities such as autism spectrum disorder or attention-deficit/hyperactivity disorder (ADHD). A social history must include recent stressful events or changes, which are often associated with secondary nocturnal enuresis.

A complete **physical examination** is usually normal in a child with monosymptomatic nocturnal enuresis. Poor

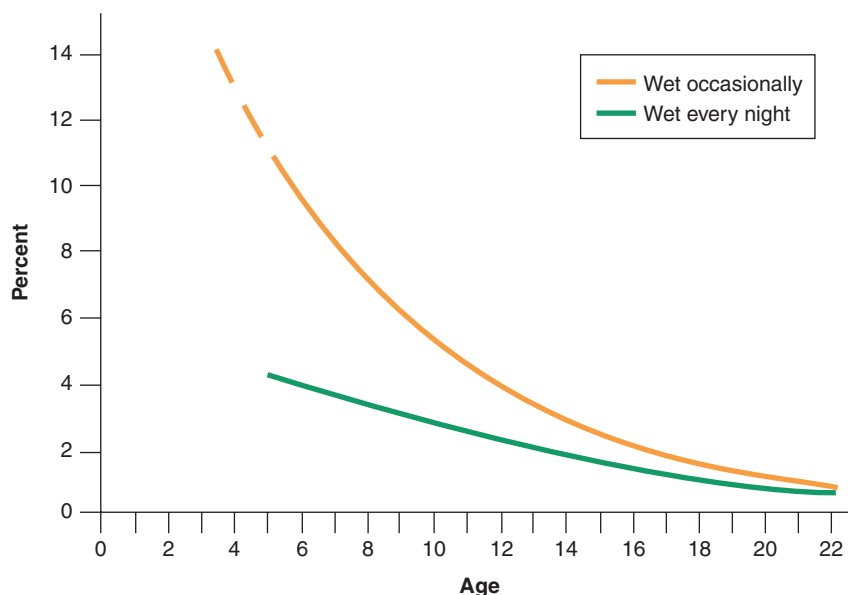

FIGURE 14.1 Epidemiology and prognosis of monosymptomatic enuresis. (From Neveus T, Eggert P, Evans J, et al. Evaluation of and treatment for monosymptomatic enuresis: a standardization document from the International Children's Continence Society. *J Urol.* 2010;183[2]:441–447.)

growth, hypertension, and edema may signify renal disease; HEENT exam may help identify findings consistent with OSA; and the abdominal and rectal exam may suggest chronic constipation. A careful neurologic exam is indicated to identify signs such as a sacral tuft or other neurocutaneous stigmata, asymmetric gluteal folds, or lower extremity weakness, which are concerning for an occult spinal cord abnormality. When possible, an observed void may help identify weak stream, intermittency, postvoid dribbling, or other signs that can signal urologic abnormalities such as posterior urethral valves, ectopic ureter, or vesicoureteral reflux.

For most children with enuresis, the only **laboratory** test recommended is a clean catch urinalysis with specific gravity to screen for UTI, renal disease, and diabetes mellitus. A first-morning void is particularly helpful to best evaluate for possible diabetes insipidus or water intoxication. Further testing, such as a urine culture, is based on the urinalysis. A renal ultrasound and/or voiding cystourethrogram (VCUG) is indicated in children with daytime symptoms, recurrent UTI, or concerns for underlying urologic abnormality, while neurologic findings warrant imaging such as MRI.

Differential Diagnosis

In most cases there is no identified underlying cause of enuresis, and it typically resolves by adolescence without treatment. Children with monosymptomatic primary nocturnal enuresis are most likely to have a family history, and those with secondary nocturnal enuresis are more likely to have a significant psychosocial stressor. Children with non-monosymptomatic or secondary nocturnal enuresis are more likely to have an identified organic etiology. The differential diagnosis includes constipation, psychiatric or developmental problems, renal disease, chronic or recurrent UTIs, diabetes mellitus, diabetes insipidus, primary polydipsia, posterior urethral valves, ectopic ureter, vesicoureteral reflux, sleep disturbance such as OSA, occult spinal dysraphism, or a mass impinging on

the urinary system. Referral to renal, endocrine, urologic, sleep, or neurosurgical specialists is recommended when such underlying anatomic or physiologic abnormality is suspected. Constipation may be successfully treated by the primary physician with referral to gastroenterology for refractory cases. Referral to a behavior or developmental pediatrician, psychologist, or other enuresis specialist is warranted for concerns of underlying developmental or psychiatric problems, children with refractory or nightly enuresis, and for situations where families have unreasonable expectations or blame the child for wetting.

Treatment

Treatment of monosymptomatic enuresis depends on the goals of the child and family (such as fewer wet nights overall or only for occasional sleep-overs) and the degree to which it causes distress to the child and family. Treatment success depends largely on the level of motivation for both the child and family, as it requires consistency and close follow-up in order to be successful. For many families, the only intervention needed is simple reassurance that enuresis is common and generally self-resolves. Parents should be educated that nocturnal enuresis is involuntary and should not be punished, which can result in poor self-esteem. Families may benefit from simple tips to help manage enuresis, such as the use of bed protection, room deodorizers, and emollients to protect skin. A plan for handling wet garments and linens in a nonhumiliating and hygienic manner is essential in order to protect the child's self-esteem. The child should take as much responsibility for cleaning soiled linens as possible, depending on age, development, and family culture.

Minor **behavioral interventions** may be helpful for some highly motivated children and should be considered prior to active therapy. These children may benefit from encouragement to void more frequently during the day and right before bed, as well as overnight if they awaken. Refraining from

drinks with sugar and caffeine in the evening can be helpful, but limiting the amount of evening fluid intake should only be done when sufficient fluid intake is ensured earlier in the day. Positive reinforcement should be provided for choices made (such as remembering to void before bed), not for remaining dry overnight. Older children are advised to not wear disposable undergarments to sleep (except for occasional use such as sleep-overs) because they may decrease motivation to get out of bed when they awaken with a need to void.

In situations where active treatment is desired, recommended first-line therapy consists of either enuresis alarm **conditioning therapy** or desmopressin **pharmacotherapy**. Enuresis alarms consist of a sensor in the undergarment or bed pad and an arousal device worn on the wrist or waist. The alarm should wake the child when the probe first senses moisture so that the child can arouse and complete the void in the bathroom. Desmopressin decreases urine production and is taken 1 hour before bed. Fluid intake must be limited prior to dosing and overnight in order to prevent hyponatremia, and the medication should be held during illness or times of potential fluid and electrolyte imbalance.

Results overall in terms of treatment success and relapse rates for both forms of treatment are conflicting. Alarm therapy is more time-intensive with high attrition rates and takes longer to work, but overall it has a superior response rate and a lower relapse rate and is especially helpful in situations where the patient and family are coping well and adhering to the routine required for success. Desmopressin may work more quickly, making it ideal for occasional use such as sleep-overs; it may also be indicated when a more rapid effect is needed due to poor coping or when families have difficulty adhering to the routine of an alarm. Desmopressin may be used nightly, in which case trials off the medication should be attempted every few months, and tapering may decrease relapse rate. Desmopressin is contraindicated for children with a history of hyponatremia.

Children with relapse after initial successful treatment often respond to re-initiation of the same treatment regimen. Poor response to either alarm or desmopressin therapy alone may benefit from a combination therapy of both. Some studies have shown that the addition of an anticholinergic medication to desmopressin may be more effective than desmopressin alone. Tricyclic antidepressants (most commonly imipramine) are reserved for refractory cases due to potential for serious toxicity (particularly cardiac and psychiatric) and should only be prescribed by a specialist. Various other interventions and therapies (including regular waking of the child, bladder training for increased capacity, electrical stimulation therapy, hypnosis, acupuncture, chiropractic, and herbal treatments) have not been studied enough to be considered safe and/or effective.

Complications

Children who experience enuresis often experience social consequences, such as an inability or fear of attending sleep-overs or overnight camps with peers. Additionally, the psychological impact of low self-esteem is a threat, particularly in situations where families misunderstand the cause of enuresis and punish the child, which occurs in up to a third of patients. Therefore it is essential to educate families about the etiology and natural course of enuresis regardless of the treatment plan.

FUNCTIONAL CONSTIPATION AND ENCOPRESIS

There are varying definitions of constipation and, indeed, diagnostic criteria can be relative to the age of a child. Parental perception of normal and abnormal bowel movements also interplays with the diagnosis of functional constipation. For instance, a young child may have bowel movements every 2 days. An infant who is breast-fed exclusively may have soft and seedy bowel movement every 4–5 days. These bowel movement patterns can be considered normal depending on the patient's age and developmental stage. An encompassing definition includes the presence of any of the following: infrequent bowel movements, passage of hard stools, difficult passage of large-diameter stool, and voluntary and involuntary fecal evacuation, also called soiling. When discussing the presence of hard stools with parents, Bristol stool charts (available online at <https://www.continence.org.au/bristol-stool-chart>) are very helpful in arriving at the diagnosis of constipation.

Epidemiology

About 30% of U.S. children are affected by constipation. Parental surveys indicate that 16–37% of toddlers have suffered from constipation. Constipation constitutes up to 5% of all outpatient general pediatric visits and accounts for approximately 25% of referrals to pediatric gastroenterology. The peak prevalence is in the preschool child age group.

More than 90% of constipation is considered functional. Functional constipation implies that there is no identifiable causative organic condition. Key features of functional constipation are occurrence after infancy, presence of stool-withholding behavior, absence of red flags, and the episodic passage of large-diameter stools. Red flags include poor growth, a loss of weight, failure to thrive, emesis, abdominal distention and bloating, perianal disease, blood in stool, abnormal urinary stream, and a history of delayed passage of meconium. Fifty to 90% of children with functional constipation are eventually cured.

Encopresis (soiling) is the intentional or involuntary passage of feces into clothing in children with a developmental age of 4 years of more. This condition should be also be considered in a 3-year-old who still is not potty-trained with respect to bowel movements. Children with encopresis often leak stool due to underlying constipation or a fecal impaction. Nonretentive encopresis refers to the passage of normal stools into underwear.

Etiology

There are three periods in child development during which children are particularly prone to developing functional constipation. These periods are after the introduction of solids in an infant's diet (>6 months of age), during toilet training (2–3 years of age), and during the start of school (3–5 years of age). In addition, adolescents can develop functional constipation, particularly if associated with eating disorders, school stressors, and ADHD.

The etiology of functional constipation and soiling includes diet, slow gastrointestinal transit time for neurologic or genetic reasons, and chronic withholding of bowel movements. Approximately 95% of children referred to a subspecialist for encopresis have no other underlying pathologic condition.

Diet

In the past, a low-fiber diet was strongly thought to contribute to functional constipation; however, data supporting this practice are now considered weak and conflicting. A well-balanced diet of fruits and vegetables with an age-appropriate amount of fiber is recommended for all children and may be useful in preventing or treating mild functional constipation. Currently there is little evidence that adding extra fiber is helpful to the child with significant constipation.

Evidence to support a strong link between cow's milk introduction and constipation is lacking. However, the emergence of constipation with the introduction with cow's milk in the toddler age group has been described anecdotally.

Withholding Behaviors

Withholding of bowel movements can be traced back to prior, painful defecation experiences due to constipation. The child may begin to delay defecation due to a history of pain. Stool then accumulates in the rectum and becomes harder or larger, causing even more pain when eventually passed. Thus it is critical that the underlying primary constipation is addressed to help resolve stool withholding behavior. Finally, parental attempts at early toilet training and coercion to potty train can lead to stool holding behavior with significant sequelae including constipation.

History

The history should include a complete review of systems for gastrointestinal, endocrine, and neurologic disorders and a developmental and psychosocial history excluding organic etiologies.

Clinical Manifestations

The presenting clinical symptom for encopresis is typically a complaint of uncontrolled defecation. Parents may report that the child has diarrhea because of soiling of liquid stool. Soiling may be frequent or continuous. Children younger than 3 years of age often present with painful defecation, impaction, and withholding.

Stool impaction can be felt on abdominal examination in about 50% of patients at presentation. Firm packed stool in the rectum is highly predictive of fecal impaction. A rectal examination allows assessment of sphincter tone and size of the rectal vault. Evaluation of anal placement and existence of anal fissures also is helpful in considering etiology and severity. A neurologic examination, including lower extremity reflexes, anal wink, and cremasteric reflexes, may reveal underlying spinal cord abnormalities. A complete exam of the lower back should be performed, including examination for any neurocutaneous stigmata.

Abdominal imaging is not required in the diagnosis of functional constipation. It may be helpful to demonstrate the degree of stool load to parents. Other imaging should be considered if an organic cause for the constipation is indicated by history or physical examination (see [Chapter 129](#)). Pediatric gastroenterology specialty care should be then sought for consideration of other etiologies such as Hirschsprung disease. Similarly, although endocrinologic conditions such as hypothyroidism can cause chronic constipation, routine, cursory laboratory studies are not indicated without the history or physical examination suggesting such a disorder.

Differential Diagnosis

The differential diagnosis for functional constipation and soiling includes organic causes of constipation (e.g., neurogenic, anatomic, endocrinologic, gastrointestinal, and pharmacologic). For instance, a child with chronic constipation with or without soiling who had delayed passage of meconium and has an empty rectum and tight sphincter may have Hirschsprung disease (see [Chapter 129](#)). Chronic constipation may be a presenting sign of spinal cord abnormalities, such as a spinal cord tumor or a tethered cord. Physical examination findings of altered lower extremity reflexes, absent anal wink, or a sacral hairy tuft or sacral sinus may be a clue to these anomalies. Hypothyroidism can present with chronic constipation and typically is accompanied by poor linear growth. Anal stenosis may lead to chronic constipation, as can the use of opiates, phenothiazine, antidepressants, and anticholinergics. Developmental problems, including cognitive impairment and developmental delays, may be associated with chronic constipation.

Treatment

Treatment begins first with education and demystification for the child and family about functional constipation, as well as encopresis. Education should emphasize the chronic nature of this condition, the good prognosis with optimal management, and the time that it can take for full resolution. Explaining the physiologic and behavioral component to the child and the family alleviates blame, enlists cooperation, and avoids the use of inappropriate, negative-reinforcement behavioral interventions. Education may improve adherence to the long-term treatment plan. Treatment plans need to be created for the individual patient given the physical and developmental status, parental expectations, and close surveillance for the appropriate use of medications. More proactive and early approaches to the diagnosis of functional constipation and a keen surveillance of encopresis make the treatment management program more effective and shorter in duration. Treatment involves a combination of behavioral training and use of stool-softening therapy, with the possible addition of laxative therapy ([Fig. 14.2](#)).

The next step of treatment is to ensure an effective process for adequate colonic cleanout or disimpaction. Cleanout methods often include higher doses of polyethylene glycol within short windows of administration along with the use of laxatives such as Ex-Lax. It is important that an evidence-based behavioral and medicinal approach is used during both the cleanout and the maintenance phase of functional constipation and encopresis. Choice of disimpaction method depends on the age of the child, family choice, and the clinician's experience with a particular method. The approach for treatment for children with constipation can be seen in [Fig. 14.3](#). The child and family should be included in the process of choosing the cleanout method. It is important to educate the parents and child in a developmentally appropriate manner about the need for the cleanout and that the overall goal is to lessen the frequency of cleanouts. Allowing choice and control for the child and praising all signs of cooperation are critical to the overall management plan.

Behavioral training is essential to the treatment of chronic constipation and soiling both in the acute phases of cleanouts and in the maintenance phase of treatment. There are many types of behavioral trainings plans available for

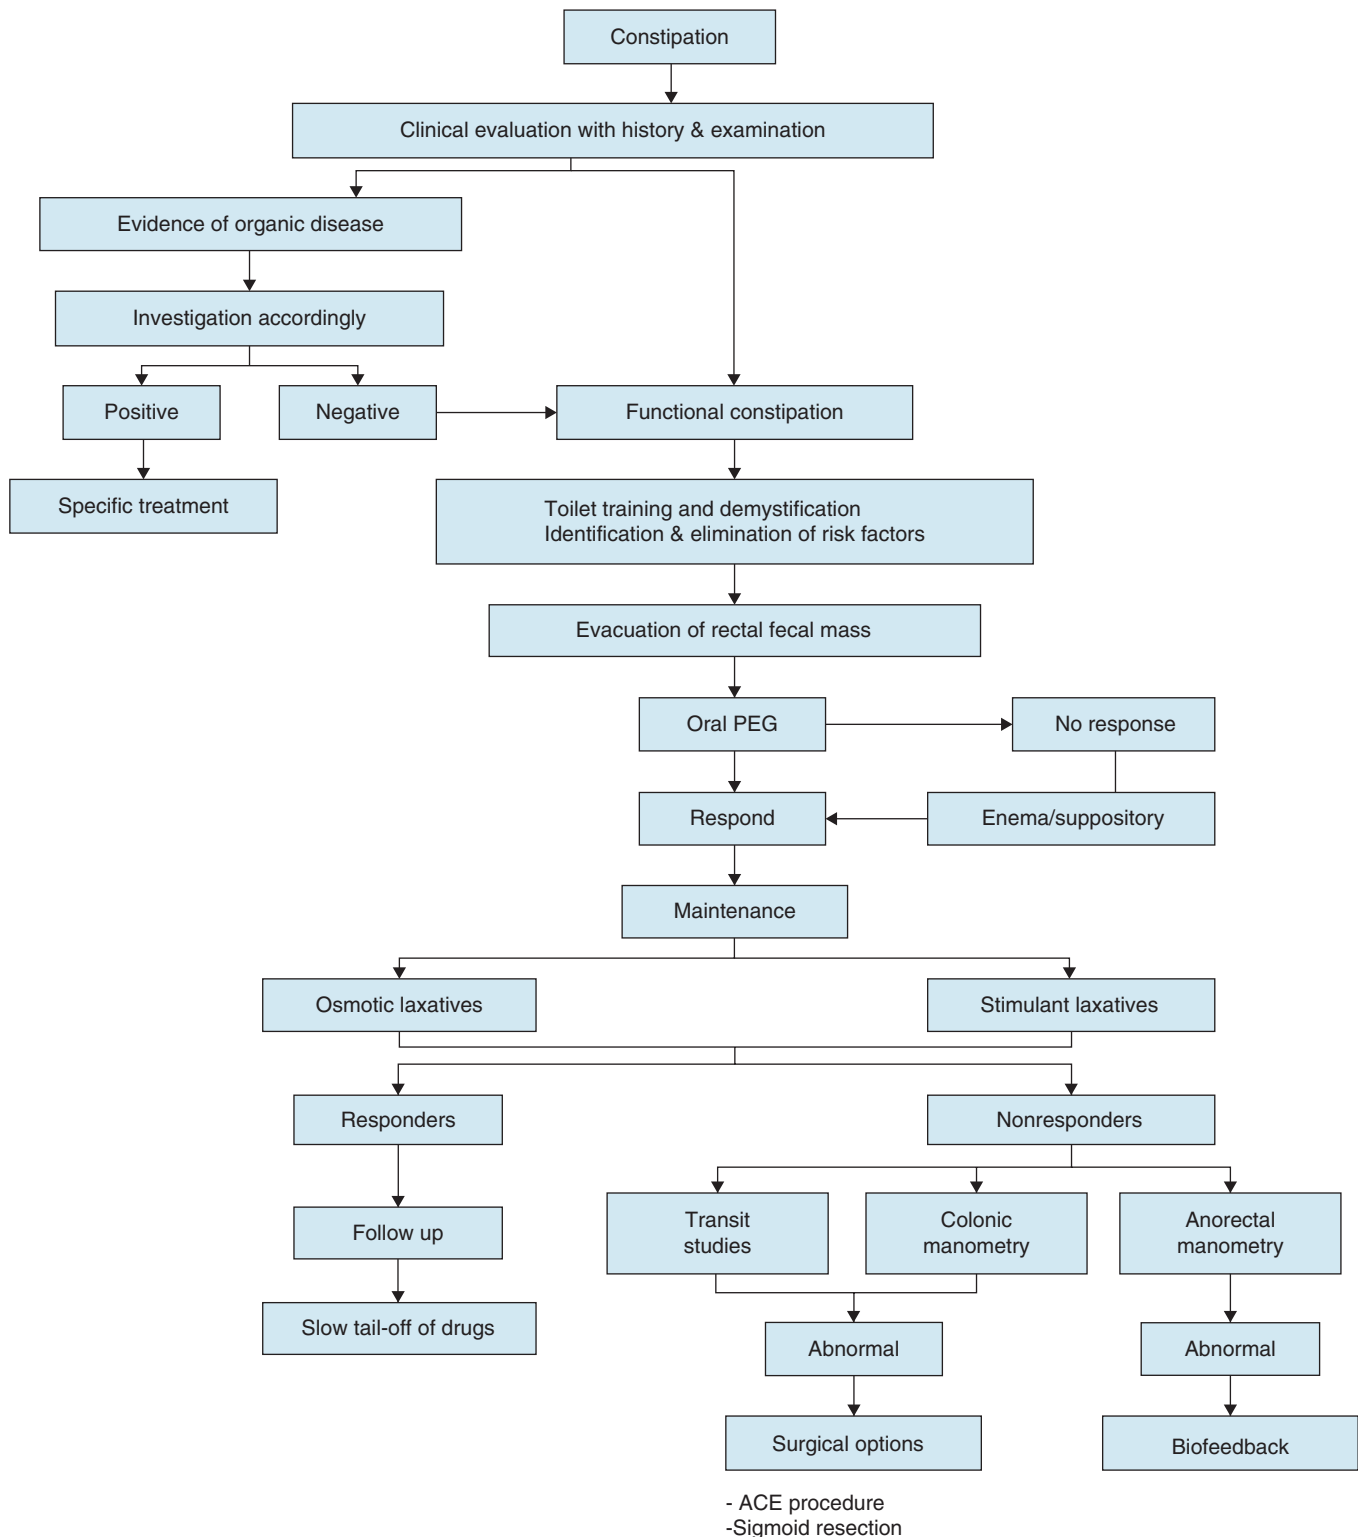

FIGURE 14.3 Algorithm of management of childhood constipation. ACE, Antegrade colonic enema; PEG, polyethylene glycol. (From Rajindrajith S, Devanarayana NM. Constipation in children: novel insight into epidemiology, pathophysiology and management. *J Neurogastroenterol Motil.* 2011;17[1]:35–47.)

families (e.g., see <https://pedsinreview.aappublications.org/content/36/9/392#sec-14>). A log that monitors and documents the frequency of stool passage and type of stool can be helpful. Most behavioral plans emphasize timed toilet-sitting sessions at scheduled frequencies. It is critical to recognize

that often a stepwise, staggered approach is needed to optimize engagement. Every step in the behavioral management plan should feature praise and positive reinforcement for continued behavioral engagement, while punishment and embarrassment must be avoided.

TABLE 14.1 Maintenance Therapies for Children with Constipation		
THERAPY	DOSAGE	ADVERSE EFFECTS
OSMOTICS		
Polyethylene glycol 3350 (Miralax) ^{†,†}	0.5–0.8 g/kg up to 17 g/day	Anaphylaxis, flatulence
Lactulose [†]	1 mL/kg/day once or twice per day, single dose or in two divided doses	Abdominal cramps, flatulence
Magnesium hydroxide	<2 yr: 0.5 mL/kg/day	Infants are susceptible to magnesium overdose (hypermagnesemia, hyperphosphatemia, hypocalcemia)
	2–5 yr: 5–15 mL/day	
	6–11 yr: 15–30 mL/day	
	≥12 yr: 30–60 mL/day	
	Medication may be given at bedtime or in divided doses	
Sorbitol (e.g., prune juice) [†]	1–3 mL/kg once or twice per day in infants	Similar to lactulose
STIMULANTS		
Senna (Senokot) [†]	1 month–2 yr: 1.25–2.5 mL (2.2–4.4 mg) at bedtime (<5 mL/day); 8.8 mg/day	Idiosyncratic hepatitis, melanosis coli, hypertrophic osteoarthropathy, analgesic nephropathy
	2–6 yr: 2.5–3.75 mL (4.4–6.6 mg) or ½ tablet (4.3 mg) at bedtime (<7.5 mL/day or 1 tablet/day)	
	6–12 yr: 5–7.5 mL (8.8–13.2 mg) or 1 tablet (8.6 mg) at bedtime (<15 mL/day or 2 tablets/day)	
	>12 yr: 10–15 mL (26.4 mg) or 2 tablets (17.2 mg) at bedtime (<30 mL/day or 4 tablets/day)	
Bisacodyl (Dulcolax)	>2 yr: 5–15 mg (1–3 tablets) once per day	Abdominal cramps, diarrhea, hypokalemia, abnormal rectal mucosa, proctitis (rare), urolithiasis (case reports)
LUBRICANTS		
Mineral oil	Children: 5–15 mL/day	Lipoid pneumonia if aspirated, theoretical interference with absorption of fat-soluble substances, foreign body reaction in intestine
	Adolescents: 15–45 mL/day	

*First-line therapy.

†May be used in infants <1 yr.

Evaluation and treatment of constipation in infants and children. *Am Fam Physician*. 2006;73(3):469–477.

When successful cleanout has been achieved, the child begins the maintenance phase of treatment. This phase promotes regular stool production and prevents re-impaction. It involves attention to diet, medications to promote soft stool regularity, and behavioral training. Attention to any dietary factors that may help the child is particularly helpful in this phase. The use of sorbitol-based juices, including prune, pear, and apple juice, increases the water content of bowel movements. Maintenance medications, including side effects, are listed in Table 14.1. Studies have shown polyethylene glycol powder to be superior to older medications such as lactulose, both in terms of efficacy and compliance. It is well tolerated because the taste and texture are palatable. Treatment failures are often due to problems with adherence, poor recognition

of inadequate treatment resulting in re-impaction, or a lack of caregiver understanding of the underlying factors of functional constipation. Referral to pediatric gastroenterology specialty care may be considered for continued persistent or intermittent functional constipation and encopresis.

Prevention

Anticipatory guidance for parents should begin in early infancy regarding typical bowel movements for the different ages and stages of their child. This helps in the early detection of constipation and also establishes appropriate parental expectations and behavior approaches to their child's elimination habits. It is very important that complete stool histories

are obtained at the regular well child visits, as well as in detail when a child presents with complaints of other concerns such as UTI, poor appetite, or abdominal pain. Such surveillance is needed for the early detection of functional constipation. Early diagnosis with prompt treatment plans given to families has been shown to decrease the duration and the severity of constipation and help prevent sequelae such as encopresis.

PEARLS FOR PRACTITIONERS

See Behavioral Disorders: Pearls for Practitioners at the end of this section.

CHAPTER 15

Normal Sleep and Pediatric Sleep Disorders

Sleep is a universal phenomenon that is critical to child health, development, and daily functioning. Expectations and habits surrounding sleep vary greatly and must be interpreted in the context of each family and culture. Sleep is broadly categorized by polysomnographic patterns into rapid eye movement (REM) sleep and non-REM (NREM) sleep. REM sleep is characterized by an active, awakelike electroencephalography (EEG) pattern and muscle atonia. NREM sleep is further divided into three stages. Stage 1 (N1) is the lightest sleep stage and consists of low-amplitude, high-frequency EEG activity. Stage 2 (N2) is similar to Stage 1, although eye movements stop. Brain waves become slower with occasional bursts of rapid waves (called *sleep spindles* or *K complexes*). Stage 3 (N3), also known as *deep* or *slow-wave* sleep, is characterized by low-frequency, high-amplitude delta waves. REM and NREM sleep alternate in cycles throughout the night. Sleep architecture changes from fetal life through infancy and childhood and parallels physical maturation and development. Newborns require the most sleep and have the most disrupted sleep patterns; newborn sleep cycles last approximately 60 minutes and gradually lengthen to 90 minutes in children and adults. Neonates typically begin their sleep cycle in REM sleep, whereas older children and adults begin sleep in NREM sleep. REM sleep comprises up to 50% of total sleep time in newborns and gradually decreases to 25–30% by adolescence. Slow-wave sleep is not seen before 3–6 months of age. Starting at 6–12 months and continuing through adulthood, the amount of REM sleep shifts toward the last third of the night, while NREM sleep predominates during the first third of the night. Infants are capable of sleeping through the night without feeds at around 6 months of age; this age varies with many factors including gestational age, type of feeding (e.g., breast-fed infants tend to awaken more frequently than formula-fed infants), familial factors, and general cultural contexts.

The timing and duration of sleep also change with age. Sleep duration gradually decreases with age (0–12 years), while longest sleep period increases (0–2 years); number of night awakenings decreases in the first 2 years of life; number of daytime naps decreases (up to age 2). Sleep patterns also become more diurnal. Full-term infants sleep on average 16–18 hours per day in fragmented intervals throughout the day and night, and

1- to 3-year-old children sleep on average 10–16 hours. Naps begin to decrease from two naps to one starting around 15–18 months of age. The biologic need for napping diminishes after age 2; significant consistent napping after age 2 has been associated with later sleep onset and reduced sleep quality and duration. However, 50% of 3-year-olds still nap. Napping in the older child and adolescent suggests insufficient sleep or a sleep disorder.

ADOLESCENT SLEEP

Adolescents also develop a physiologically based shift toward later sleep onset and wake times relative to those in middle childhood. While experts recommend that adolescents sleep at least 9 hours each night, only about 20% of U.S. adolescents achieve this goal. The average amount of adolescent sleep is 7.5 hours per day; up to 25% of adolescents achieve only 6 hours of sleep a night. Insufficient sleep in adolescents has been associated with morning tiredness, day sleepiness, and negative effects on cognitive function, moods, and motivation. Early school start times have been associated with negative sleep profiles in adolescence. Furthermore, sleep onset latency (the time it takes to fall asleep) in adolescents has been associated with fatigue, mood disorders, and anxiety. Adolescents should be advised to limit or reduce screen time exposure prior to bedtime in order to optimize sleep hygiene.

SLEEP DISORDERS

Sleep disorders are a common complaint in pediatrics and can be categorized into organic disorders, parasomnias, behavioral and environmental causes, and circadian rhythm disorders (Table 15.1).

Epidemiology

Sleep disorders occur in up to 80% of children at some point during childhood. Children with co-morbid medical conditions, particularly neurodevelopmental and psychiatric disorders, are at higher risk than other children. Behavioral sleep disorders are most prevalent from infancy through preschool age, though they can occur at any age. Overall, behavioral insomnias affect up to 30% of children, with bedtime resistance occurring in 10–15% of toddlers and difficulty falling and/or staying asleep in 20–30% of school-age children and 10% of adolescents. Parasomnias are also common in children. Several studies have shown a genetic predisposition to parasomnias; they are also more common in children with other sleep disorders that may increase arousal from sleep, such as obstructive sleep apnea (OSA) and restless legs syndrome (RLS). Sleepwalking affects about 15% of children, peaks between 8 and 12 years of age, has a familial association, and is more common in males. Confusional arousals and sleep terrors (or night terrors) have a prevalence of about 35% and occur most often in young children, typically resolving spontaneously by adolescence. Circadian rhythm disorders occur in up to 16% of adolescents. OSA is reported in up to 5% of children; risk factors include obesity, craniofacial abnormalities, hypotonia, trisomy 21, and second-hand smoke exposure (see Chapter 134). RLS occurs in about 2% of children and up to 4% of adolescents. Narcolepsy is rarely found in children.

TABLE 15.1 Sleep Disorders

	CAUSE	CLINICAL SYMPTOMS	DIAGNOSIS	TREATMENT	SPECIAL CONSIDERATIONS
ORGANIC					
Obstructive sleep apnea (OSA)	Adenotonsillar hypertrophy Overweight/obesity Allergic rhinitis Craniofacial abnormalities Neuromuscular diseases	Frequent snoring, unusual sleep positions, enlarged tonsils and adenoids, gasps/snorts, mouth breathing, episodes of apnea, labored breathing, daytime sleepiness, attention and/or learning and/or behavioral problems	PSG	Adenotonsillectomy Weight loss Noninvasive positive pressure support (CPAP/BiPAP)	Detailed history is often needed to detect early symptoms of OSA
Illness	Any chronically irritating disorder (e.g., AOM, atopic dermatitis, URI, GERD, asthma) Triggers can be chronic or acute	Disrupted sleep, variant sleep patterns due to discomfort and pain	Hx and PE	Treat primary illness	Consider when an otherwise normal child presents with acute disruption in sleep Atypical sleep patterns may linger after resolution of instigating illness; behavioral interventions may be needed to restore to normal sleep patterns
Neurodevelopment and CNS disorders	Variable; may need to rule out seizures, OSA	Variable sleep disruptions	Hx and PE May need PSG, EEG, and imaging	Evaluate environment Sleep hygiene Depending on disorder, medications may be helpful	Consider use of sleep medicine or neurology specialist, especially when considering medication
Restless legs syndrome	Not fully defined but associated with genetics and iron deficiency	Unpleasant sensation in legs, urge to move legs often starting in the evening or during the night, difficulty falling asleep, lack of focus/hyperactivity, fatigue during the day	Hx, family Hx, PSG, ferritin level	If ferritin is <50 µg, treat with iron replacement and recheck in 3 mo No other standard medications for children Consider referral to sleep medicine	Diagnosis can be a challenge
PARASOMNIAS					
Sleepwalking, sleep terrors	Stage N3 (deep) sleep instability Genetic predisposition	Awakening 1–3 hr after falling asleep with characteristic behaviors	Hx	Reassurance Protective environment	—
Confusional arousals	Irregular sleep patterns (e.g., nightshift work); stress	Awakening in first 1/3 of night with confused thinking, slow speech	Hx, PSG	Sleep hygiene; treat other sleep disorders	—
BEHAVIORAL AND ENVIRONMENTAL					
Insomnia of childhood (can have overlap of subtypes) • Sleep-onset association subtype • Limit setting subtype	10–30% prevalence Inability/unwillingness to fall asleep or return to sleep in absence of a specific conditions such as parental rocking Parental anxiety, unwillingness/inability to enforce bedtime rules and limits such as allowing child to sleep in parents' room	Frequent or prolonged night awakenings requiring intervention Bedtime resistance/refusal Excessive expression of "needs" by child	Hx	Prevention and education Put child to bed drowsy but awake; allow to fall asleep independently Minimize nocturnal parental response Modify parental behavior to improve limit setting (provide rewards/positive reinforcement, appropriate consequences)	Careful attention to detailed history and recognition of familial and cultural expectations is needed to negotiate an optimal sleep management plan with caregivers Recognize there are cultural norms for family sleep behavior

Continued

TABLE 15.1 Sleep Disorders—cont'd					
	CAUSE	CLINICAL SYMPTOMS	DIAGNOSIS	TREATMENT	SPECIAL CONSIDERATIONS
Social disruptions	Family stressors	Night waking Refusal to sleep	Hx	Regularize routines Family counseling Family education regarding development and sleep needs of child	Respect family dynamics and refrain from blaming when providing guidance
Nighttime anxiety/fears	Anxiety, stress, traumatic events, disruption in social surrounding such as change in house, bed type, although no specific trigger may be identified	Bedtime resistance Crying, clinging, seeking parental reassurance	Hx	Reassurance of safety Teach coping skills Nightlights, security objects Avoiding “drama” during the night awakening Avoid denial of fears; rather acknowledge and equip child with coping skills	Pay attention to any changes in child’s environment and recognize normal development fears
CIRCADIAN RHYTHM DISORDERS					
Irregular sleep-wake pattern	No defined sleep schedule	Variable waking and sleeping	Hx	Regularize schedule	
Delayed sleep phase disorder	A shift in sleep-wake schedule with resetting of circadian rhythm Prevalence is 7–16% in adolescents due to longer circadian rhythm combined with increased social activity (delayed sleep onset)	Not sleepy at bedtime Sleep onset at a consistently late time Morning/daytime sleepiness	Hx	Depends on the trigger that is causing the discrepancy Good sleep hygiene Avoid bright light before bedtime Remove light-emitting devices in bedroom Melatonin	Detailed history and family education is helpful for optimal treatment response Sleep diary is helpful

AOM, Acute otitis media; BiPAP, bilevel positive airway pressure; CNS, central nervous system; CPAP, continuous positive airway pressure; EEG, electroencephalography; GERD, gastroesophageal reflux disease; Hx, history; PE, physical examination; PSG, polysomnography; URI, upper respiratory infection.

Clinical Manifestations and Evaluation

Sleep disorders may manifest in a variety of ways and are often unrecognized. Some children present with daytime behavioral problems, including inattentiveness, hyperactivity, or irritability rather than overt sleepiness. Screening for sleep disorders is recommended as part of primary care health supervision visits. Clinicians should inquire about problems such as excessive daytime sleepiness, awakenings during the night, and presence of snoring or sleep-disordered breathing. The assessment of sleep complaints begins with a **history** of sleep habits, including typical bedtime, sleep onset and wake times, and schedule variation from day to day. A detailed description of the sleep environment can result in a dynamic understanding of the challenges to and resources for achieving normal sleep; such details include typical bedtime routine, type of bed, household members sharing the bed or room, ambient light, noise, and temperature. Dietary practices (timing of meals, caffeine intake) and household routines (parental work patterns, evening activities) may influence the timing and ease of sleep. A detailed history assessing for symptoms of OSA (snoring, gasping, open-mouth breathing, breathing pauses, etc.) should be obtained in all children who snore regularly. Complaints of unpleasant

sensations in the legs or frequent urges to move the legs at night may suggest RLS. New-onset sleep disorders may be associated with a psychologic trauma. When the history does not initially reveal the cause of the sleep disorder, a sleep diary can be helpful, especially for adolescents, and should include bedtime routines, timing of food and caffeine intake, electronics use, light or noise in the room, and timing of sleep onset and waking.

A complete **physical examination** is important to rule out organic causes of sleep disturbance. HEENT exam may help identify findings consistent with OSA. A careful exam may reveal signs of acute or chronic disorders (such as otitis media or eczema) that cause pain or pruritus, which can disrupt sleep. A neurologic exam may reveal signs of central nervous system disorders.

Work-up is generally not warranted for children with primary insomnia (difficulty initiating or maintaining sleep), uncomplicated parasomnias, behaviorally based sleep problems, or circadian rhythm disorders. A polysomnogram, consisting of an overnight observation and recording in a sleep laboratory, can detect OSA, excessive limb movements, seizure disorder, and other sleep disorders. Low ferritin levels (<50 µg/L) have been associated with RLS, so obtaining ferritin levels is helpful in the diagnosis of RLS.

Differential Diagnosis

Behavioral insomnia of childhood is divided into two subtypes. *Sleep-onset association subtype* manifests as frequent or prolonged nighttime awakenings that occur in infants or young children. During periods of normal brief arousal with each sleep cycle, the child awakens under conditions different from those experienced as they fell asleep, and they are unable to return to sleep independently. *Limit-setting subtype* is most common in preschool-age and older children and is characterized by bedtime resistance or refusal that stems from a caregiver's unwillingness or inability to enforce bedtime rules and expectations. Nighttime fears are also common causes of bedtime refusal.

Parasomnias include sleepwalking, sleep terrors, and confusional arousals. These occur during NREM sleep and are more likely during the first third of the night. They are most common in preschool children and are likely to resolve with time and developmental maturation. Parasomnias are commonly caused by triggers such as sleep deprivation and fever. Sleepwalking is common and usually benign but is sometimes associated with agitation or dangerous behaviors. Sleep terrors consist of an abrupt awakening with a loud scream or agitation that is unresponsive to caregivers' attempts to console. Sleep terrors are differentiated from nightmares, which occur later in the night and result from arousal in REM or dreaming sleep. Children typically remember their nightmares but have no recollection of sleep terrors. Confusional arousals are similar to sleep terrors but tend to be less dramatic and last longer.

Circadian rhythm disorders are most common during adolescence but can occur at any age. They consist of an exaggerated delayed sleep phase, leading to difficulty arousing in the mornings and failure to meet sleep requirements. The resulting sleep deprivation can lead to problems with cognition and emotional regulation. Many adolescents attempt to recoup lost sleep on the weekends, which has not been found to be effective in preventing the long-term health consequences of sleep deprivation.

Primary organic sleep disorders include OSA and RLS. OSA in childhood is commonly caused by tonsillar and adenoidal hypertrophy. OSA is often associated with poor growth in toddlers and can be associated with neurocognitive, developmental, and behavioral problems in older children. These sequelae can be mitigated by adenotonsillectomy. Primary sleep disorders must be differentiated from sleep disorders associated with psychiatric disorders including anxiety, depression, psychosis, autism spectrum disorder (ASD), attention-deficit/hyperactivity disorder (ADHD), post-traumatic stress disorder, and substance use. The clinician should also consider medication side effects and other medical problems such as sleep-related epilepsy, neurologic and developmental disorders, and other illnesses that disrupt sleep (such as painful or pruritic conditions) as causes of sleep disorders.

Complications

The most common sequela of suboptimal sleep is daytime sleepiness. Other sequelae include irritability, behavioral problems, learning difficulties, and motor vehicle accidents in adolescents. Clear links between sleep-disordered breathing and academic performance in the school-age child have been firmly established. Children may present with concerns for behavior or emotional lability, which after a careful history is found to be associated with insufficient quantity or quality of sleep.

TABLE 15.2 Prevention of Pediatric Behavioral Sleep Disorders

Consistent and appropriate bedtime and wake-up time
Consistent bedtime routine (~30 min) to cue sleep
Consistent ambient noise, light, temperature in bedroom
Adequate food, hydration, socialization, and physical activity during the day
No television, other electronics, electronic media, light emission products (e.g., chargers) in bedroom
Avoidance of naps (unless developmentally appropriate)
Caffeine avoidance
Child feels safe and protected
Child allowed to develop self-soothing strategies
Parents are comfortable setting limits/boundaries

Prevention and Treatment

Establishing a baseline of healthy sleep habits is essential to both prevention and treatment of sleep disorders at all ages. Recommendations include a consistent and appropriate bedtime and bedtime routine, as well as close attention to sleep hygiene (Table 15.2). A bedtime routine should last no more than 30 minutes and consist of three or four soothing activities that help calm the child and signal that it is time for sleep; activities may include bathing, brushing teeth, reading a story, or singing a song. In older children for whom safe sleep does not require an empty bed, a transitional object such as a blanket or stuffed animal can be used to promote positive sleep associations and encourage self-soothing behaviors. Older children and adolescents also benefit from a consistent pre-bed routine, including use of relaxation techniques. The bedtime should be set early enough to allow for sufficient nighttime sleep, and both bedtime and morning wake time should be consistent, including on weekends. Televisions and other electronic devices should be removed from the bedroom because they can lead to delayed sleep onset and maladaptive sleep associations. Children should also restrict the use of the bed for sleeping (not studying, using electronics, etc.), in order to associate the bed with sleep.

Sleep-onset association disorder in infancy usually can be prevented by parental understanding of infant sleep physiology, developmentally appropriate expectations, and planning the infant sleep environment to coincide with family needs. It is important to recognize and respect cultural and other familial contexts when providing guidance. There is varying guidance regarding "sleep training" itself. Overall, it is recommended that starting around 6 months of age, after feeding, diapering, and comforting measures, infants be put in bed drowsy, but still awake. Some toleration of infant crying is required for the infant to achieve self-regulation of sleep. A safe sleep environment is essential. It is important for parents to understand that it is normal for their infant to wake frequently for the first 6 weeks before settling into a routine of waking every 3–4 hours for feeding. Infants typically do not sleep through the night before 6 months of age, and some do not sleep through the night before 12–18 months of age. Despite co-sleeping (infant sleeping with parent) being common and desired by many

families for the purposes of convenience and closeness, it is contraindicated due to the increased risk of unexpected death from sudden infant death syndrome or accidental suffocation.

In addition to meticulous attention to sleep hygiene and bedtime practices, **behavioral interventions** comprise the mainstay of treatment for behavioral sleep disorders and circadian rhythm disorders. *Systematic ignoring* consists of not responding to a child's demands for parental attention at bedtime and consists of either *unmodified extinction* ("cry it out"), which involves putting the child to bed and then ignoring the child's demands until the next morning, or *graduated extinction*, which involves waiting successively longer periods of time before briefly checking on the child. Both methods, when consistently applied, are effective in decreasing bedtime resistance and enabling young children to fall asleep independently. *Strategic napping* involves planning the timing and duration of naps to not interfere with bedtime since too much sleep during the day or napping too late in the day can make falling asleep at bedtime difficult. *Positive reinforcement* strategies such as sticker charts can also be used in preschool-age and older children. Rewards should be given for meeting a bedtime goal (such as staying in bed) and should be provided first thing in the morning to increase effectiveness and better link the reward with the positive behavior. Children with nighttime fears may benefit from behavioral therapy aimed at reinforcing feelings of safety. *Bedtime fading* involves gradual resetting of the biologic clock and can assist with circadian rhythm disorders. Bedtime fading involves allowing children or adolescents to go to bed at the time they naturally feel tired and then gradually advancing the bedtime forward over the course of several weeks.

Infrequent or nonintrusive parasomnias do not need treatment beyond education, reassurance, and ensuring a safe environment. Sleep terrors are best managed by minimal intervention because conversation with the child is impossible during the episode, and attempts at calming are unlikely to be successful. Anticipatory brief awakening of the child shortly before the typical occurrence of a parasomnia may be effective in aborting the event. Children with frequent or prolonged parasomnias may need a sleep study to evaluate for possible coexisting sleep disorders or nocturnal seizures. Medications that suppress slow-wave sleep may be indicated in severe cases.

Rarely, children with insomnia are treated **pharmacologically**. There are no U.S. Food and Drug Administration–approved medications for treating insomnia in children, and clinical evidence is lacking for most medications with off-label use. *Melatonin* has soporific properties useful in treating delayed sleep phase syndrome and has been found to be effective in both children with normal development and those with developmental delays, as well as in children with ADHD and ASD. Melatonin should only be used after a full evaluation and with close medical surveillance. Optimal dosing is challenging, particularly since melatonin is not a regulated substance and

can vary by manufacturer. Non-prescription *antihistamines* such as diphenhydramine may be used in children with atopic disease and can also be useful for their sedative properties in short-term situations such as illness or travel. They can lead to tolerance and should not be used chronically. Other medications such as clonidine have been used in some situations, but generally should only be used in consultation with a sleep specialist.

PEARLS FOR PRACTITIONERS

CHAPTER 11

Crying and Colic

- Infantile colic is defined as episodes of extreme crying or fussiness in an otherwise healthy infant.
- It has been associated with shaken baby syndrome, postpartum depression, parental guilt, and multiple physician visits.
- Colic is a diagnosis of exclusion; it is critical to fully evaluate for other conditions.
- Management of colic includes parental education regarding its natural, self-limited course, advocacy of parental coping mechanisms, and safe maneuvers to soothe baby.
- Symptoms of colic can overlap with the symptoms of gastroesophageal disease and milk protein intolerance.
- Complementary alternative medicine, including herbal therapies, neonatal chiropractor care, and medications, has not been shown to be effective and safe.

CHAPTER 12

Temper Tantrums

- Temper tantrums are part of normal human development during early childhood and are characterized by episodes of extreme frustration and anger, manifesting as a wide range of behaviors that appear disproportionate to the situation.
- Evaluation should include a thorough history and physical examination to rule out other etiologies and underlying conditions.
- Atypical tantrums, particularly those that are destructive or injurious, may be indicative of a more serious underlying condition and warrant referral for further work-up.
- Anticipatory guidance for parents should include tips for acute management of temper tantrums (e.g., staying calm, using distraction, cool-down techniques, not giving into the child's demands, and ignoring inappropriate behavior).
- Anticipatory guidance should include strategies to mitigate future tantrums (e.g., avoiding triggers, setting and consistently enforcing clear limits, providing routine and structure, teaching communication skills, offering choices, role-modeling, and using positive reinforcement).

CHAPTER 13

Attention-Deficit/Hyperactivity Disorder

- Attention-deficit/hyperactivity disorder (ADHD) is the most prevalent neurobehavioral disorder in children.
- ADHD is multifactorial in origin with genetic, neural, and environmental contributions.

- The use of valid screening tools from at least two domains that reflect a child's daily life are needed to establish a diagnosis.
- Coexisting conditions and problems, especially learning disorders, anxiety and depression, and oppositional behaviors and conduct disturbance must be considered in the initial evaluation and in the continued longitudinal management of ADHD.
- Males often present with hyperactivity. Females more often present with inattentive symptoms and are more likely to be underdiagnosed or to receive later diagnoses.
- Treatment is outcome based; it should address functional disability and not focus on a decrease in the constellation of symptoms.
- Management plans should include the child, parents, other relevant caregivers, and school personnel.
- Stimulant medications reduce the symptoms of ADHD without necessarily improving corresponding functional limitations.
- Behavior management alone, outside of the preschool group, is not as effective as behavior management with medication in reducing core symptoms.

CHAPTER 14

Control of Elimination

- Prerequisites for achieving elimination in the toilet include the child's ability to recognize the urge for urination and defecation, to get to the toilet, to understand the sequence of tasks required, and to take pride in achievement.
- Daytime dryness usually precedes nighttime dryness by at least several months, and often several years.
- Enuresis is classified as non-monosymptomatic (associated with daytime wetting or other urinary tract abnormalities) or monosymptomatic (intermittent nocturnal incontinence), which is further classified as either primary (having never achieved nighttime dryness) or secondary (nocturnal incontinence after having achieved dryness).
- Primary monosymptomatic nocturnal enuresis has a prevalence of 15% at 5 years of age, 5% at 10 years of age, and 1% at 15 years of age.
- A complete history and physical exam are necessary to rule out underlying causes of enuresis, and non-monosymptomatic enuresis warrants referral for work-up and management.
- The most commonly used treatment options for primary enuresis are enuresis alarm conditioning therapy and desmopressin pharmacotherapy.
- Encopresis is the regular, voluntary, or involuntary passage of feces into a place other than the toilet after 4 years of age.
- Encopresis without constipation is uncommon.
- Approximately 95% of children referred to a subspecialist for encopresis have no other underlying pathologic condition.

- Treatment of constipation/encopresis involves a combination of behavioral training and the use of stool softener therapy.

CHAPTER 15

Normal Sleep and Pediatric Sleep Disorders

- Sleep architecture, timing, and duration change from fetal life through infancy and childhood and parallel physical maturation and development.
- Establishing a baseline of healthy sleep habits is essential to both prevention and treatment of sleep disorders at all ages.
- Sleep disorders include organic disorders (such as OSA and RLS), parasomnias (such as sleepwalking and night terrors), behavioral and environmental causes, and circadian rhythm disorders.
- Evaluation should include a careful history, including a sleep diary, as well as a complete physical examination to rule out underlying causes of sleep disorders.
- Adolescents develop a physiologically based shift toward later sleep-onset and wake times relative to those in middle childhood. Insufficient sleep in adolescents is very common and has been associated with negative effects on cognitive function, moods, and motivation.

PSYCHIATRIC DISORDERS

Gray M. Buchanan

CHAPTER 16

Somatoform Disorders, Factitious Disorders, and Malingering

Somatic symptom and related disorders (SSRDs) make up a relatively new category in the most recent version of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). While DSM-4 emphasized medically unexplained symptoms, DSM-5 allows for unexplained symptoms and those that may accompany diagnosed medical disorders. SSRDs involve physical symptoms (pain or loss of function), may occur in the context of a physical illness, and are identified by symptoms that go beyond the expected pathophysiology, affecting the child's school, home life, and peer relationships. SSRDs are often associated with psychosocial stress that persists beyond the acute stressor, leading to the belief by the child and family that the correct medical diagnosis has not yet been found.

The prevalence of SSRDs in children is not clearly known. Adolescent girls tend to report nearly twice as many functional somatic symptoms as adolescent boys, whereas prior to puberty the ratio is equal. Affected children are more likely to have difficulty expressing emotional distress, come from families with a history of marital conflict, child maltreatment (including emotional, sexual, physical abuse), or history of physical illness. In early childhood, symptoms often include recurrent abdominal pain (RAP). Later, headaches, neurologic symptoms, insomnia, and fatigue are more common.

Explainable medical conditions and an SSRD (e.g., seizures and pseudoseizures) can coexist in up to 50% of patients and present difficult diagnostic dilemmas. The most common systemic medical disorders presenting with unexplained physical symptoms include chronic fatigue syndrome (CFS), multiple sclerosis, myasthenia gravis, endocrine disorders, chronic systemic infections, vocal cord dysfunction, periodic paralysis, acute intermittent porphyria, fibromyalgia, polymyositis, and other myopathies.

Depression, anxiety, and panic are common co-morbidities and frequently precede the somatic symptoms. Disorders in the SSRD group include **somatic symptom disorder (SSD)**, **illness anxiety disorder**, **conversion disorder**, **factitious disorder**, and **psychologic factors affecting other medical conditions**. The diagnostic criteria for SSRDs are well established for adults and need additional study in pediatric populations.

SSD typically involves one or more somatic symptoms that are distressing or result in significant disruption in daily

life. The criteria used to diagnose this disorder are listed in [Table 16.1](#). The majority of those previously diagnosed with somatization disorder and hypochondriasis meet the criteria for SSD. Key symptoms of the disorder often involve excessive thoughts, feelings, or behaviors regarding the somatic complaint (e.g., excessive fatigue or pain). Prevalence estimates for SSD in children are highly variable; however, between 5% and 7% of adults may be identified with SSD, with a greater proportion being female.

Illness anxiety disorder ([Table 16.2](#)) involves children who have a preoccupation with having or acquiring a serious illness. An elevated rate of medical utilization is fairly common. Typically, somatic symptoms are not present, and there is a high level of anxiety about health status. These children commonly seek reassurance from family, friends, and medical staff regarding their health, but may be alarmed by illness in others and seldom respond to reassurance regarding their health. Approximately 25% of those previously diagnosed with hypochondriasis meet criteria for this disorder and can be distinguished from those with SSD by their high anxiety and absence of somatic symptoms. Prevalence estimates in children are not clearly known, but many estimate the rate between 0.1% and 0.75%. There appears to be similar prevalence rates in boys and girls, and the condition appears to worsen in adolescence.

Conversion disorder involves symptoms affecting voluntary motor or sensory function and is suggestive of a neurologic illness in the absence of a disease process ([Table 16.3](#)). A physical condition and a conversion disorder (e.g., epileptic and nonepileptic seizures) may coexist in the same patient. Adjustment difficulties, recent family stress, unresolved grief reactions, and family psychopathology commonly co-occur with conversion disorder. There are multiple subtypes of conversion disorder based upon the symptoms present including difficulties with primarily motor, sensory, neurologic, or mixed symptoms.

Presenting symptoms follow the psychologic stressor by hours to weeks and may cause more distress for others than for the patient. This seeming lack of concern regarding potentially serious symptoms is referred to as *la belle indifférence*. Symptoms are often self-limited but may be associated with chronic sequelae, such as contractures or iatrogenic injury.

Psychologic factors affecting other medical conditions are marked by psychologic or behavioral factors that adversely impact a medical condition by increasing the risk for suffering, death, or disability ([Table 16.4](#)). The factors interfere with the treatment of a medical condition (e.g., anxiety exacerbating asthma, poor medication adherence). This diagnosis is more common in young children and may require corroborative

TABLE 16.1 Criteria for Diagnosis of Somatic Symptom Disorder	
A.	One or more somatic symptoms that are distressing or result in significant disruption of daily life.
B.	Excessive thoughts, feelings, behaviors related to the somatic symptoms or associated health concerns as manifested by at least one of the following: <ol style="list-style-type: none"> 1. Disproportionate and persistent thoughts about the seriousness of one's symptoms. 2. Persistently high level of anxiety about health or symptoms. 3. Excessive time and energy devoted to these symptoms or health concerns.
C.	Although any one somatic symptom may not be continuously present, the state of being symptomatic is persistent (>6 mo).
Specify if:	
<i>With predominant pain (previously pain disorder):</i> This specifier is for individuals whose somatic symptoms predominantly involve pain.	
<i>Persistent:</i> A persistent course is characterized by severe symptoms, marked impairment, and long duration (>6 mo).	
Specify current severity:	
Mild: Only one of the symptoms specified in Criterion B is fulfilled.	
Moderate: Two or more of the symptoms specified in Criterion B are fulfilled.	
Severe: Two or more of the symptoms specified in Criterion B are fulfilled, plus there are multiple somatic complaints (or one very severe somatic symptom).	

TABLE 16.2 Criteria for Diagnosis of Illness Anxiety Disorder	
A.	Preoccupation with the idea that one has or will get a serious illness.
B.	Somatic symptoms are not present or, if present, are only mild in intensity. If another medical condition is present or there is a high risk for developing a medical condition (e.g., strong family history is present), the preoccupation is clearly excessive or disproportionate.
C.	There is a high level of anxiety about health, and the individual is easily alarmed about personal health status.
D.	The individual performs excessive health-related behaviors (e.g., repeatedly checks body for signs of illness) or exhibits maladaptive avoidance (e.g., avoids doctor appointments and hospitals).
E.	Illness preoccupation has been present for at least 6 months, but the specific illness that is feared may change over that period of time.
F.	The illness-related preoccupation is not better explained by another mental disorder, such as somatic symptom disorder, panic disorder, generalized anxiety disorder, body dysmorphic disorder, obsessive-compulsive disorder, or delusional disorder, somatic type.
Specify whether:	
Care-seeking type: Medical care, including physician visits or undergoing tests and procedures, is frequently used.	
Care-avoidant type: Medical care is rarely used.	

TABLE 16.3 Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5) Diagnostic Criteria for Conversion Disorder or Functional Neurologic Symptom Disorder	
A.	One or more symptoms of altered voluntary motor or sensory function.
B.	Clinical findings provide evidence of incompatibility between the symptom and recognized neurologic or medical conditions.
C.	The symptom or deficit is not better explained by another medical or mental disorder.
D.	The symptom or deficit causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or warrants medical evaluation.
Specify symptom type: weakness or paralysis, abnormal movements, swallowing symptoms, speech symptom, attacks/seizures, or anesthesia/sensory loss, special sensory symptom (visual, olfactory, or hearing), or mixed symptoms

TABLE 16.4 Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5) Diagnostic Criteria for Psychologic Factors Affecting Other Medical Conditions	
A.	A medical symptom or condition (other than a mental disorder) is present.
B.	Psychologic or behavioral factors adversely affect the medical condition in one of the following ways: <ol style="list-style-type: none"> 1. The factors have influenced the course of the medical condition as shown by a close temporal association between the psychologic factors and the development or exacerbation of, or delayed recovery from, the medical condition. 2. The factors interfere with the treatment of the medical condition (e.g., poor adherence). 3. The factors constitute additional well-established health risks for the individual. 4. The factors influence the underlying pathophysiology, precipitating or exacerbating symptoms or necessitating medical attention.
C.	The psychologic and behavioral factors in Criterion B are not better explained by another mental disorder (e.g., panic disorder, major depressive disorder, post-traumatic stress disorder).

history from parents and the child's school. Prevalence of this condition is unclear due to its wide breadth; however, data suggest that this disorder is more prevalent than SSDs.

Factitious disorder is a condition in which physical or psychologic symptoms are produced intentionally and often with the intent to assume a sick role (Table 16.5). This diagnosis is made either by direct observation or by eliminating other possible causes. This falsification of physical and psychologic symptoms may also present as imposing illness or injury on another person (i.e., factitious disorder imposed on another

TABLE 16.5 *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5) Diagnostic Criteria for Factitious Disorders*

FACTITIOUS DISORDER IMPOSED ON SELF

- A. Falsification of physical or psychological signs or symptoms, or induction of injury or disease, associated with identified deception.
- B. The individual presents self to others as ill, impaired, or injured.
- C. The deceptive behavior is evident even in the absence of obvious external rewards.
- D. The behavior is not better explained by another mental disorder, such as delusional disorder or another psychotic disorder.

FACTITIOUS DISORDER IMPOSED ON ANOTHER (PREVIOUSLY FACTITIOUS DISORDER BY PROXY)

- A. Falsification of physical or psychological signs or symptoms, or induction of injury or disease, in another, associated with identified deception.
- B. The individual presents another individual (victim) to others as ill, impaired, or injured.
- C. The deceptive behavior is evident even in the absence of obvious external rewards.
- D. The behavior is not better explained by another mental disorder, such as delusional disorder or another psychotic disorder.

Note: The perpetrator, not the victim, receives this diagnosis.

Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, 5th ed. (Copyright 2013). American Psychiatric Association. 2013:324. All rights reserved.

[FDIA]; formerly Munchausen by proxy). FDIA most commonly occurs following hospitalization of the child or another family member. Many patients demonstrate improvement when confronted with their behavior or acknowledge the factitious nature of their symptoms. Approximate answers (e.g., the patient provides 16 as the answer for 20 – 3) reported during a mental status examination are commonly found in factitious disorders. The prevalence of factitious disorder in children is unknown. Approximately 1% of individuals in hospital settings present with such a condition. FDIA is considered a type of child abuse and most commonly occurs in neonates and preschoolers.

Screening tools for SSRDs are being developed. Previous tools for somatoform disorders include the Children's Somatization Inventory (child and parent versions) and the Illness Attitude Scales and Soma Assessment Interview (parental interview questionnaires). The functional disability inventory assesses the severity of symptoms. Many also employ an adapted version of the Patient Health Questionnaire–15 (PHQ-15).

Treatment for SSRDs should employ an integrated medical and psychiatric approach. The goals are to identify concurrent psychiatric disorders, rule out concurrent physical disorders, improve overall functioning, and minimize unnecessary invasive tests and doctor shopping. This is most successful when mental health consultation is presented as part of a comprehensive evaluation, thereby minimizing stigma and distrust.

Antidepressant medications may be of benefit in the treatment of some conditions such as unexplained headaches,

fibromyalgia, body dysmorphic disorder, pain disorder, irritable bowel syndrome, and functional gastrointestinal disorders. Tricyclic antidepressants (e.g., clomipramine) should be avoided in youth with functional abdominal pain (FAP), because it has little proven efficacy in either pain management or mood disorders and is very dangerous in overdose. In CFS with co-morbid depression and anxiety, a more activating antidepressant, such as bupropion, may be useful. Stimulants may also be helpful in CFS.

Cognitive behavioral therapies, which reward health-promoting behaviors and discourage disability and illness behaviors, have been shown to help in the treatment of recurrent pain, CFS, fibromyalgia, and FAP. Additionally, self-management strategies such as self-monitoring, relaxation, hypnosis, and biofeedback provide some symptomatic relief and encourage more active coping strategies. Family therapy and family-based interventions may also be useful. Home schooling should be avoided. School attendance and performance should be emphasized as important indicators of appropriate functioning. In dealing with pain symptoms (e.g., headaches, stomachaches), parents should limit attention/reinforcement for pain behavior; strongly encourage normal routines/appropriate schedules (e.g., going to school), help the child identify stress at home and school, provide attention and special activities on days when the child does not have symptoms, and limit activities and interactions on sick days. Attempts to educate parents and personnel working with the child about limiting discussions about excessive discomfort or illness should occur. Caregivers and the child should also be taught methods of controlling their physiologic and cognitive responses to discomfort via practicing relaxation techniques and mindfulness techniques.

Malingering is considered a V code in the DSM-5 and involves the purposeful falsification or exaggeration of physical and/or psychologic symptoms for external gain (e.g., money, avoidance of school, work, jail). The key feature of malingering is the seeking of an external reward. Symptoms may not lessen when the reward is attained. Unless the patient is directly observed or confesses to such falsification, malingering is difficult to prove.

PEARLS FOR PRACTITIONERS

See *Psychiatric Disorders: Pearls for Practitioners at the end of this section.*

CHAPTER 17

Anxiety and Phobias

Anxiety disorders are characterized by uneasiness, excessive rumination, and apprehension about the future. The conditions tend to be chronic, recurring, and vary in intensity over time. They affect 5–10% of children and adolescents (Table 17.1) and have a lifetime prevalence of approximately 30%. Some conditions (i.e., obsessive-compulsive disorder [OCD] and post-traumatic stress disorder [PTSD]) are not included in the section on anxiety in the current version of the DSM; however, these disorders continue to share a close relationship with anxiety disorders.

FEATURE	PANIC DISORDER	GENERALIZED ANXIETY DISORDER	SEPARATION ANXIETY DISORDER	SPECIFIC PHOBIA
Epidemiology	Prevalence is 0.2–10%. Eight times more common and of early onset in family members of affected individuals than general population.	Prevalence is 2–4%. Sex ratio equal before puberty but higher in female following puberty. Genetic factors play only a modest role in the etiology.	Prevalence is 3–4% of children and adolescents. The sex ratio is almost equal. Heritability of SAD is greater for girls than for boys.	Prevalence is 5% in children and approximately 16% in adolescence. Sex ratio is 2:1 females:males. Increased risk of specific phobias in first-degree relatives of patients with specific phobias.
Onset	Average age at onset is 20–24 yr; <0.4% onset before 14 years of age.	The average age at onset is 10 yr.	The average age at onset is 7 yr.	Varies
Differential diagnosis	Anxiety disorder due to a general medical condition. Substance-related anxiety disorder due to caffeine or other stimulants.	Other anxiety disorders, OCD, PTSD, and depressive, bipolar, and psychotic disorders. Substance-related (caffeine and sedative-hypnotic withdrawal).	Other anxiety disorders and conduct, impulse-control, and disruptive behavior disorders.	Agoraphobia, panic disorder, OCD, and PTSD.
Co-morbidities	Separation anxiety disorder (common). Agoraphobia, substance use, major depression, OCD, and other anxiety disorders. Asthma patients have a high incidence of panic attacks.	Unipolar depression and other anxiety disorders.	GAD and specific phobia.	Depression and other anxiety disorders.
Prognosis	Frequently chronic with a relative high rate of suicide attempts and completions.	One study showed that 65% of children cease to have the diagnosis in 2 yr.	Variable. The majority of children are not diagnosed with significant anxiety disorders as adults.	Social phobia in childhood may become associated with alcohol abuse in adolescence.

GAD, Generalized anxiety disorder; OCD, obsessive-compulsive disorder; PTSD, post-traumatic stress disorder; SAD, separation anxiety disorder.

Panic disorder is the presence of recurrent, unexpected panic attacks. A **panic attack** is a sudden unexpected onset of intense fear associated with a feeling of impending doom in the absence of real danger and may occur in the context of any anxiety disorder. The individual must experience four or more symptoms (e.g., sweating, palpitations, feeling of choking, chest pain, trembling/shaking, chills, paresthesias, fear of dying, fear of losing control, derealization, dizziness, nausea, or shortness of breath) during the attack. At least 1 month of persistent worrying about having another panic attack and/or a significant behavioral change following an attack (e.g., attempting to avoid another attack, avoidance of triggers such as exercise) is required to make the diagnosis.

Panic disorder often begins in adolescence or early adulthood. Symptom severity varies greatly. In children, the most commonly experienced symptoms include shortness of breath, palpitations, chest pain, a choking sensation, and a fear of losing control. Symptoms may be brief or may last for prolonged periods of time; however, they typically last less than 15 minutes. Patients may believe that they are experiencing an acute medical condition (e.g., a heart attack).

Agoraphobia is a disorder marked by fear of situations where escape is difficult or would draw unwanted attention to the person. The condition involves two or more of five specific situations: fear/anxiety about the use of public transportation, being in open spaces, being in enclosed spaces, standing in line or being in a crowd, or being outside of the home alone. Agoraphobia is often chronic and can leave people

homebound. While agoraphobia does commonly occur with panic disorder, a substantial number of individuals experience agoraphobia without panic symptoms. First onset of agoraphobia commonly presents in adolescence, with females being twice as likely to experience the disorder. In children, being outside of the home alone and worries regarding becoming lost are common complaints.

Generalized anxiety disorder (GAD) is characterized by 6 or more months of persistent, excessive worry and anxiety about a variety of situations or activities. The worries should be multiple, not paroxysmal, not focused on a single theme, and should cause significant impairment. The anxiety must be accompanied by at least one of the following symptoms: restlessness, fatigue, concentration difficulties, irritability, muscle tension, or sleep disturbance. Physiologic signs of anxiety are often present, including shakiness, trembling, and myalgias. Gastrointestinal symptoms (nausea, vomiting, diarrhea) and autonomic symptoms (tachycardia, shortness of breath) are also common. In children and adolescents, symptoms of autonomic arousal are less prominent. Children commonly present as perfectionistic, report symptoms related to school performance or sports, and exhibit concerns about punctuality. Children with GAD are often exceedingly self-conscious, have low self-esteem, and have more sleep disturbance than patients with other anxiety disorders. Care must be taken to elicit internalizing symptoms of negative cognitions about the self (hopelessness, helplessness, worthlessness, suicidal ideation), as well as those concerning relationships (embarrassment,

TABLE 17.2 *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5) Diagnostic Criteria for Separation Anxiety Disorder*

A.	Developmentally inappropriate and excessive fear or anxiety concerning separation from those to whom the individual is attached, as evidenced by at least three of the following:
1.	Recurrent, excessive distress when anticipating or experiencing separation from home or from major attachment figures.
2.	Persistent and excessive worry about losing major attachment figures or about possible harm to them, such as illness, injury, disasters, or death.
3.	Persistent and excessive worry about experiencing an untoward event (e.g., getting lost, being kidnapped, having an accident, becoming ill) that causes separation from a major attachment figure.
4.	Persistent reluctance or refusal to go out, away from home, to school, to work, or elsewhere because of fear of separation.
5.	Persistent and excessive fear of or reluctance about being alone or without major attachment figures at home or in other settings.
6.	Persistent reluctance or refusal to sleep away from home or to go to sleep without being near a major attachment figure.
7.	Repeated nightmares involving the theme of separation.
8.	Repeated complaints of physical symptoms (e.g., headaches, stomachaches, nausea, vomiting) when separation from major attachment figures occurs or is anticipated.
B.	The fear, anxiety, or avoidance is persistent, lasting at least 4 weeks in children and adolescents and typically 6 months or more in adults.
C.	The disturbance causes clinically significant distress or impairment in social, academic, occupational, or other important areas of functioning.
D.	The disturbance is not better explained by another mental disorder, such as refusing to leave home because of excessive resistance to change in autism spectrum disorder, delusions or hallucinations concerning separation in psychotic disorders, refusal to go outside without a trusted companion in agoraphobia, worries about ill health or other harm befalling significant others in generalized anxiety disorder, or concerns about having an illness in illness anxiety disorder.

Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, 5th ed. (Copyright 2013). American Psychiatric Association. 2013:190–191. All rights reserved.

self-consciousness) and associated with anxieties. Inquiry about appetite, weight, energy, and interests should also be performed to eliminate a mood disorder. GAD is more predominant in males prior to puberty, but by adolescence, females outnumber males.

Unspecified anxiety disorder is a common condition in clinical practice. This diagnosis is used when there is impairing anxiety or phobic symptoms that do not meet full criteria for another anxiety disorder.

Separation anxiety disorder (SAD) is marked by excessive distress or concern when separating from a major attachment figure (Table 17.2). Children and adolescents often express vague somatic symptoms (e.g., headaches, abdominal pain,

fatigue) in an attempt to avoid going to school or leaving their home. Patients may present with a valid or an irrational concern about a parent or have had an unpleasant experience in school, and the prospect of returning to school provokes extreme anxiety and escalating symptoms. Children may refuse to go to school or leave their home. Children with SAD may seek frequent attention and often struggle with separation at bedtime. SAD is a significant (78%) risk factor for developing problems in adulthood, such as panic disorder, agoraphobia, and depression. SAD is highly heritable with community samples estimating such genetic rates as high as 73%.

Selective mutism is present in up to 1% of children who consistently fail to speak in one or more social settings despite adequate receptive and expressive language skills. Symptoms are present for at least 1 month and interfere with educational or occupational achievement or social communication. Children with selective mutism will often speak at home in the presence of first-degree relatives but may refuse to speak to extended family or others in their environment. Between 25% and 50% of children with selective mutism exhibit some history of speech delay or speech disorder; however, diagnosis does not typically occur until kindergarten or first grade when there is an increased demand on speech and social interaction. Children of immigrants (who are non-English speaking) and a parental history of reticence and/or social anxiety are often found in children with selective mutism.

Specific phobias are marked, persistent fears of specific things/objects or situations that often lead to avoidance behaviors. The anxiety is almost always felt immediately when the person is confronted with the feared object or situation, and many patients have had actual fearful experiences with the object or situation (traumatic event). The closer the proximity or the more difficult it is to escape, the higher the anxiety. The response to the fear can range from limited symptoms of anxiety to full panic attacks. Children may not recognize that their fears are out of proportion to the circumstances, unlike adolescents and adults, and express their anxiety as crying, tantrums, freezing, or clinging. Many fears are normal in childhood; therefore only fears lasting greater than 6 months in duration should be considered diagnostically for children. Specific fears may be related to animals/insects, natural events (storms, flooding), blood-related events (injections, needles, medical procedures), situational events (elevator, airplane), or other circumstances/events (loud sounds, clowns).

Social anxiety disorder is a common (~7% prevalence; girls predominate over boys) type of anxiety characterized by a marked and persistent fear of social or performance situations in which embarrassment might occur (Table 17.3). In children, this apprehension must be present with peers and not just in the presence of adults. The vast majority of individuals with this disorder are identified prior to 15 years of age. Children appear to have a lower rate of negative cognitions (e.g., embarrassment, overconcern, self-consciousness) than adults. Left untreated or poorly treated, social anxiety disorder can become immobilizing and result in significant functional impairments; however, approximately a third of individuals experience remission of symptoms within 1 year if untreated.

In the **management of anxiety disorders**, likely medical conditions should be carefully excluded, including hyperthyroidism, medication side effects, and substance abuse. Additionally, screening for co-morbid psychiatric disorders

TABLE 17.3 *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5) Diagnostic Criteria for Social Anxiety Disorder (Social Phobia)*

A.	Marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny by others. Examples include social interactions (e.g., having a conversation, meeting unfamiliar people), being observed (e.g., eating or drinking), and performing in front of others (e.g., giving a speech).
	Note: In children, the anxiety must occur in peer settings and not just during interactions with adults.
B.	The individual fears that they will act in a way or show anxiety symptoms that will be negatively evaluated (i.e., will be humiliating or embarrassing; will lead to rejection or offend others).
C.	The social situations almost always provoke fear or anxiety.
	Note: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, clinging, shrinking, or failing to speak in social situations.
D.	The social situations are avoided or endured with intense fear or anxiety.
E.	The fear or anxiety is out of proportion to the actual threat posed by the social situation and to the sociocultural context.
F.	The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
G.	The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
H.	The fear, anxiety, or avoidance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
I.	The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder, such as panic disorder, body dysmorphic disorder, or autism spectrum disorder.
J.	If another medical condition (e.g., Parkinson disease, obesity, disfigurement from burns or injury) is present, the anxiety or avoidance is clearly unrelated or is excessive.
	Specify if:
	Performance only: If the fear is restricted to speaking or performing in public.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, 5th ed. (Copyright 2013)*. American Psychiatric Association. 2013:202–203. All rights reserved.

such as mood disorders, eating disorders, tic disorders, and behavioral disorders should occur. A collaborative history from multiple sources is important, as the child may be unable to effectively communicate symptoms. Screening with validated measures of anxiety can often be helpful.

Pharmacotherapy is a common approach to helping those with anxiety. In general, for mild to moderate anxiety, evidence-based psychotherapies and psychoeducation should be used first. Combined therapy demonstrates better efficacy than psychotherapy and psychopharmacology alone. Cognitive and behavioral therapy (e.g., systematic desensitization, exposure techniques, operant conditioning, modeling, and cognitive restructuring) can be beneficial in a variety of anxiety disorders. Children with anxiety disorders are often less tolerant of medication side effects. Supportive therapy may help maintain treatment regimens and increase compliance rates.

Care coordination with a patient's school is often necessary. Reassurance that the patient does not have a life-threatening illness is important. Other psychosocial treatments that have demonstrated efficacy include stress management, supportive therapies, and biofeedback.

Selective serotonin reuptake inhibitors (SSRIs) are the medications of choice, and the U.S. Food and Drug Administration has approved fluoxetine, sertraline, and fluvoxamine for use in children. SSRIs can initially exacerbate anxiety or even panic symptoms, and tricyclic antidepressants have also shown efficacy. Benzodiazepines (alprazolam and clonazepam) may cause disinhibition in children. α_{2a} agonists (guanfacine and clonidine) may be useful if autonomic symptoms are present. Anticonvulsant agents (gabapentin, topiramate, and oxcarbazepine) are used when other agents are ineffective, and β blockers help with performance anxiety.

Co-occurrence of the inattentive type of attention-deficit/hyperactivity disorder and an anxiety disorder is common. When using a stimulant, it is advisable to start at a low dose, increasing slowly to minimize the risk of increasing anxiety. Additionally, careful monitoring of sleep and appetite is important.

PEARLS FOR PRACTITIONERS

See *Psychiatric Disorders: Pearls for Practitioners* at the end of this section.

CHAPTER 18

Depression and Bipolar Disorders

Depressive disorders and bipolar and related disorders were reorganized in DSM-5; several new diagnoses were added to aid with diagnostic clarity and assist in limiting overdiagnosis of some conditions, such as bipolar disorder in children.

Major depressive disorder (MDD) requires a minimum of 2 weeks of symptoms including either depressed mood or loss of interest or pleasure in nearly all activities. Four additional symptoms must also be present (Table 18.1). In children and adolescents, a new onset of irritability and/or restlessness may be present instead of depressed mood. Many children/adolescents also complain of pervasive boredom. A change in appetite (usually decreased but can be increased), with or without accompanying weight changes, and sleep disturbance along with somatic complaints (fatigue, vague aches and pains) may also be present. Furthermore, a key indicator in children may be declining performance in school. Psychotic symptoms, seen in severe cases of MDD, are generally mood congruent (e.g., derogatory auditory hallucinations, guilt-associated delusional thinking). Suicidal thoughts and attempts are common, and a prior history of such thoughts/attempts and prominent feelings of hopelessness are risk factors that should be closely monitored.

Historically, a bereavement exclusion existed in making a diagnosis of MDD. Recent evidence suggests that although most people experience bereavement following a significant loss (e.g., loss of a loved one, financial ruin) without developing depression, many do, in fact, experience depressive symptoms. As such, evidence suggests that treatments for MDD and

TABLE 18.1 Diagnostic and Statistical Manual of Mental Disorders-5 Diagnostic Criteria for Bipolar I Disorder

For a diagnosis of bipolar I disorder, it is necessary to meet the following criteria for a manic episode. The manic episode may have been preceded by and may be followed by hypomanic or major depressive episodes.

MANIC EPISODE

- A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 wk and present most of the day, nearly every day (or any duration if hospitalization is necessary).
- B. During the period of mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) are present to a significant degree and represent a noticeable change from usual behavior:
 - 1. Inflated self-esteem or grandiosity.
 - 2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep).
 - 3. More talkative than usual or pressure to keep talking.
 - 4. Flight of ideas or subjective experience that thoughts are racing.
 - 5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
 - 6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (i.e., purposeless non-goal-directed activity).
 - 7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).
- C. The mood disturbance is sufficiently severe to cause marked impairment in social or occupational functioning or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
- D. The episode is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication, other treatment) or to another medical condition.

Note: A full manic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiologic effect of that treatment is sufficient evidence for a manic episode and therefore a bipolar I diagnosis.

Note: Criteria A–D constitute a manic episode. At least one lifetime manic episode is required for the diagnosis of bipolar I disorder.

HYPOMANIC EPISODE

- A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased activity or energy, lasting at least 4 consecutive days and present most of the day, nearly every day.
- B. During the period of mood disturbance and increased energy and activity, three (or more) of the following symptoms (four if the mood is only irritable) have persisted, represent a noticeable change from usual behavior, and have been present to a significant degree:
 - 1. Inflated self-esteem or grandiosity.
 - 2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep).
 - 3. More talkative than usual or pressure to keep talking.
 - 4. Flight of ideas or subjective experience that thoughts are racing.
 - 5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
 - 6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation.
 - 7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).
- C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the individual when not symptomatic.
- D. The disturbance in mood and the change in functioning are observable by others.
- E. The episode is not severe enough to cause marked impairment in social or occupational functioning or to necessitate hospitalization. If there are psychotic features, the episode is, by definition, manic.
- F. The episode is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication, other treatment).

Note: A full hypomanic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiologic effect of that treatment is sufficient evidence for a hypomanic episode diagnosis. However, caution is indicated so that one or two symptoms (particularly increased irritability, edginess, or agitation following antidepressant use) are not taken as sufficient for diagnosis of a hypomanic episode, nor necessarily indicative of a bipolar diathesis.

Note: Criteria A–F constitute a hypomanic episode. Hypomanic episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.

MAJOR DEPRESSIVE EPISODE

- A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly attributable to another medical condition.

 - 1. Depressed most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, hopeless) or observation made by others (e.g., appears tearful). (**Note:** In children and adolescents, can be irritable mood.)
 - 2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation).
 - 3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. (**Note:** In children, consider failure to make expected weight gain.)
 - 4. Insomnia or hypersomnia nearly every day.
 - 5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
 - 6. Fatigue or loss of energy nearly every day.
 - 7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
 - 8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
 - 9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

(Continued)

TABLE 18.1 Diagnostic and Statistical Manual of Mental Disorders-5 Diagnostic Criteria for Bipolar I Disorder—con'd

- B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
 C. The episode is not attributable to the physiologic effects of a substance or to another medical condition.

Note: Criteria A–C constitute a major depressive episode. Major depressive episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.

Note: Responses to a significant loss (e.g., bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in Criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be carefully considered. The decision inevitably requires the exercise of clinical judgement based on the individual's history and the cultural norms for the expression of distress in the context of loss.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, 5th ed.* (Copyright 2013). American Psychiatric Association; 2013:123–126. All rights reserved.

MDD with bereavement are often likely to help with the remittance of symptoms.

The prevalence of MDD in prepubertal children is approximately 2% with a 1:1 female:male ratio. In adolescence the prevalence is approximately 5% with a female:male ratio of 2:1 (similar to adults). If untreated, major depression can become chronic in 10% of patients.

Genetic predisposition for MDD is present with twin studies showing 40–65% heritability. Additionally, family studies show a two- to fourfold increased risk for depression in offspring of depressed parents. Dysregulation of central serotonergic and/or noradrenergic systems, hypothalamic-pituitary-adrenal axis dysfunction, and the influence of pubertal sex hormones have been shown to be potential responsible factors for depression. Stressful life events such as abuse and neglect have also been found to precipitate MDD, especially in young children.

Anxiety-related disorders (up to 80% prevalence), substance-related disorders (up to 30% prevalence), and conduct/disruptive disorders (up to 20% prevalence) frequently present as co-morbid with MDD. Onset of MDD in childhood is also more likely to be related to bipolar symptoms versus adult-onset bipolar disorder. This is especially true when a family history of bipolar disorder is present.

Differential diagnoses for MDD are diverse. It is always prudent to rule out mood disorder due to another medical condition or substance-related mood disorder before considering MDD. Dysphoria and concentration concerns related to untreated attention-deficit/hyperactivity disorder (ADHD) may also be misdiagnosed as depression. Medically, conditions such as hypothyroidism, anemia, diabetes, and folate and B₁₂ vitamin deficiencies need to be ruled out.

Persistent depressive disorder (formerly dysthymia and chronic MDD) (prevalence rate 0.5–2.0%) is a chronic form of depression characterized by a depressed or irritable mood present for at least 1 year. Two of the following symptoms are also required: changes in appetite, sleep difficulty, fatigue, low self-esteem, poor concentration or difficulty making decisions, and feelings of hopelessness. Approximately 70% of children and adolescents with persistent depressive disorder eventually develop major depression.

Disruptive mood dysregulation disorder (DMDD) includes children ages 6–18 years who present with a chronic (≥12 months) pattern of severe irritability and behavioral dysregulation. The prevalence rate of DMDD is not fully known; however, estimates based upon the core feature of chronic

irritability suggest a rate between 2% and 9% (up to 31% in community mental health center samples). DMDD typically first presents in school-age children and is more common among males. In distinguishing bipolar disorder in children from DMDD, particular attention should be given to the course of symptoms (DMDD being chronic/persistent and bipolar disorder presenting with episodic mood changes). Co-morbidities with DMDD are common, and conditions such as conduct, impulse control, and disruptive behavior disorders should be assessed. Furthermore, children and adolescents with DMDD may also present with other mood concerns, anxiety, and/or autism spectrum disorder symptoms and diagnoses.

Premenstrual dysphoric disorder (PDD) is marked by repeated irritability, anxiety, and mood lability that presents during the premenstrual cycle and remits near the onset of menses. Approximately 3–8% of adult women are thought to experience PDD with adolescent rates thought to be at a similar level. At least five physical (e.g., sleep disturbance, breast tenderness, joint/muscle pain, fatigue, appetite changes) and/or behavioral symptoms (e.g., affective lability, irritability, depressed mood, anxiety) must be present. Symptoms typically peak near the onset of menses. PDD differs from premenstrual syndrome in the number of symptoms present and in regard to the affective symptoms that are present. MDD is the most commonly presenting co-morbidity. Past traumatic events, pre-existing anxiety disorder, cigarette smoking, obesity/body mass index (BMI), and genetic history (gene that codes for serotonergic 5-HT_{1A} receptor and allelic variants of the estrogen receptor alpha gene [*ESR1*]) are risk factors for PDD.

Unspecified depressive disorder is a diagnosis used when patients have functionally impairing depressive symptoms that do not meet criteria for another condition.

Numerous **specifiers for depressive disorders** may also be identified. These include methods of noting additional struggles with anxious distress, mixed features (including elevated mood/hypomanic symptoms), melancholic features (loss of pleasure/lack of reactivity to pleasurable stimuli), psychotic features, and seasonal patterns (symptoms occur in the late fall and early winter when the hours of daylight are shortening).

Treatment of depression involves psychopharmacologic approaches and/or psychotherapy. Regardless of the treatment approach chosen, a thorough diagnostic interview and screening measures should be completed. There are a variety of screening tools such as Kovacs Children's Depression

Inventory (CDI) that may be helpful. First-line pharmacologic treatment involves selective serotonin reuptake inhibitors (SSRIs) that have demonstrated response rates of 50–70% despite high-placebo response rates. Fluoxetine is the only medication approved by the U.S. Food and Drug Administration (FDA) for treatment in youth 8 years and older, and escitalopram is approved for youth 12 and older. However, many other off-label medications such as citalopram, paroxetine, and venlafaxine have positive clinical trial results as well. An antidepressant should be given an adequate trial (6 weeks at therapeutic doses) before switching or discontinuing unless there are serious side effects. For a first episode of depression in children and adolescents, treatment for 6–9 months after remission of symptoms is recommended. Patients with recurrent or persistent depression may need to take antidepressants for extended periods (years or even a lifetime). If a patient does not respond to adequate trials of two or more antidepressants, a child psychiatrist should be consulted. Following a thorough evaluation, the psychiatrist may use augmentation strategies that include other medications such as lithium, thyroid hormone, lamotrigine, or bupropion.

For acute depression, more frequent office visits and monitoring (e.g., telephone calls) are indicated, and the risks of medication (including suicidal and self-destructive behaviors) should always be discussed with the caregiver and patient. Psychoeducation about the illness and a discussion about calling if new symptoms occur should be held with the family. Notable side effects are thoughts of suicide, increased agitation, or restlessness. Other side effects include headache, dizziness, gastrointestinal symptoms, sleep cycle disturbance, sexual dysfunction, akathisia, serotonin syndrome, and risk of increased bruising (due to platelet inhibition).

In 2004, the FDA issued warnings regarding the potential for increased suicidal thoughts and/or behaviors when using an antidepressant. The data suggest that antidepressants pose a 4% risk, versus a 2% risk in placebo. An increase in suicides in children and adolescents since that year has many experts believing that it might be related to lowered prescription rates of antidepressants and resultant untreated depression. Substance use, concomitant conduct problems, and impulsivity increase the risk of suicide.

Psychotherapy has good efficacy in mild to moderate depression. In moderate to severe depression, combined treatment with psychotherapy and medication has the greatest rate of response, although in severe cases the efficacy was equivalent to medication alone. Cognitive-behavioral therapy (CBT) and interpersonal therapies have received the most empirical support. CBT involves a variety of behavioral techniques and skills-building to mitigate cognitive distortions and maladaptive processing. Interpersonal therapy focuses on collaborative decisions between the therapist and patient and is based on the exploration and recognition of precipitants of depression. Family therapy is often used as an adjunct to other treatments for depression. Light therapy is beneficial for seasonal variants of MDD. Electroconvulsive therapy (ECT) is also used in refractory and life-threatening depression.

Suicide is a fatal complication of MDD. It has high prevalence among high school students; 20% contemplate suicide and 8% attempt suicide each year. While the risk of suicide during an MDD episode is high, it can be paradoxically higher during start of treatment, as energy and motivation improve with cognitive recovery from depression.

Treatment is targeted toward decreasing morbidity and suicide. Along with treatments mentioned previously, modalities such as hospitalization, partial hospitalization, therapeutic after-school programs, or group therapies may be needed.

BIPOLAR AND RELATED DISORDERS

Bipolar I disorder (BD) consists of distinct periods of mania (elevated, expansive, or irritable moods and distractibility) and persistent goal-directed activity or energy (Table 18.1) that may alternate with periods of severe depression (Table 18.2).

To diagnose mania associated with BD, euphoria (elevated or expansive mood) with three additional symptoms or irritable mood with four additional symptoms is required. Children and adolescents with euphoric mood often present as bubbly, giggly, and “over-the-top” happy, to a degree that is

TABLE 18.2 *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5) Diagnostic Criteria for a Major Depressive Episode*

- A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly attributable to another medical condition.

1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, or hopeless) or observation made by others (e.g., appears tearful). Note: In children and adolescents, can be irritable mood.
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation).
3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. Note: In children, consider failure to make expected weight gain.
4. Insomnia or hypersomnia nearly every day.
5. Psychomotor agitation or retardation nearly every day (observable by others; not merely subjective feelings of restlessness or being slowed down).
6. Fatigue or loss of energy nearly every day.
7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
8. Diminished ability to think or concentrate, or indecisiveness, early every day (either by subjective account or as observed by others).
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

- B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

- C. The episode is not attributable to the physiological effects of a substance or another medical condition.

socially unacceptable to others. Grandiosity in children is often dramatic, and they may believe they are superior to others in activities, sports, or academics even when it is obvious that it is not true. Racing thoughts and concentration difficulties are common in BD, and speech can be loud and pressured. Periods of extreme rage may also present. Children with BD often present with rapid shifts in mood or lability over brief time frames (e.g., shifting between euphoria and dysphoria or irritability).

A decreased need for sleep without fatigue is a hallmark of mania. There are no other diagnoses where a child has a greatly decreased amount of total sleep (compared with age-appropriate norms) and is not fatigued. Sleep deprivation, substance abuse, and antidepressants may trigger mania. BD onset often begins with an episode of depression. Mania rarely occurs prior to adolescence. It is estimated that 33% of youth will develop BD within 5 years of a depressive episode and 20% of all patients with BD will experience their first manic episode during adolescence. *Hypomania* is used to describe a period of more than 4 but fewer than 7 days of manic symptoms. It also is used, less specifically, to describe less intense mania. The prevalence of psychosis in adolescents with BD (most often auditory hallucinations) is 16–60%. Although high, it is still less than its prevalence in adult BD.

Bipolar II disorder includes at least one current or past full major depressive episode and at least one period of current or past hypomania. **Unspecified bipolar and related disorder** is used to describe prominent symptoms of BD that do not meet full diagnostic criteria or when historical information is unclear or insufficient to make a specific diagnosis.

Cyclothymic disorder is a chronic (>1 year) mood disorder characterized by several periods of hypomanic symptoms and depressive symptoms (which do not have to meet the full diagnostic criteria for hypomania or a depressive episode, respectively). The lifetime prevalence rate for cyclothymic disorder is around 1%. Childhood rates are not clearly established. The male:female ratio for the disorder is fairly equal, and in children, the mean age of onset is 6.5 years. ADHD, sleep disorders, and substance-related disorders also show high co-morbidity with cyclothymic disorder.

Numerous **specifiers for bipolar disorders** may also be identified. These include methods of noting additional struggles with anxious distress, mixed features (including elevated mood/hypomanic symptoms), melancholic features (loss of pleasure/lack of reactivity to pleasurable stimuli), psychotic features, seasonal patterns, and rapid cycling (four or more mood episodes during a 12-month period).

It is estimated that 1% of children and adolescents meet diagnostic criteria for BD. Retrospective studies show that 60% of BD onset occurs before 20 years of age, although it is often not until adulthood that BD is diagnosed. Although BD in adults tends to be gender neutral, it is estimated that prepubertal BD is almost four times more frequently diagnosed in boys.

A family history of mental illness, including MDD, BD, schizophrenia, or ADHD, is common in BD. A first-degree relative with BD leads to a 10-fold increase in a child's chance of developing BD. An earlier onset of BD in a parent increases the risk of early-onset BD in offspring with a more chronic and debilitating course that may be less responsive to treatment.

Patients with BD often have concurrent conditions that warrant treatment. ADHD occurs in approximately 60–90% of children with BD. Anxiety disorders also commonly occur with BD and do not respond to antimanic agents. Substance

abuse can precipitate and perpetuate mania and depression. The alteration between highs and lows related to some types of substance abuse often mimics BD. Patients with BD may also self-medicate in attempts to alleviate symptoms (with up to 50% of BD patients presenting with alcohol use disorder). It may be necessary to evaluate a patient in a substance-free state to make an accurate diagnosis of BD. Many patients with BD may meet criteria for conduct disorder (CD) due to aggression and impulsivity. In distinguishing BD from CD, patients with BD generally exhibit reactive aggression, whereas those with CD are more likely to preplan acts/crimes.

No laboratory or imaging studies can diagnose BD. Physical examination, careful history, review of systems, and laboratory testing may be performed to rule out suspected medical etiologies, including neurologic and substance-related disorders.

Treatment of BD often initially targets acute symptoms. If suicidal ideation and/or risk-taking behaviors are present, hospitalization may be necessary. Treatment typically involves a variety of approaches depending upon the developmental level of the child/adolescent. Multiple FDA-approved medications including lithium, divalproex sodium, carbamazepine, olanzapine, risperidone, quetiapine, ziprasidone, lurasidone, and aripiprazole are available for patients with BD. Lithium is the oldest proven treatment for mania and has been used in acute episodes and as a maintenance treatment in children and adolescents. Common side effects of lithium include hypothyroidism, polyuria, and acne. Anticonvulsants are also a first-line agent (preferable for mixed or rapid cycling cases) for adults. They have also been used effectively in youth, but are not FDA approved in children for BD. Monitoring of blood levels for select medications (lithium and divalproex sodium) can help ensure both treatment safety and an appropriate therapeutic dose of the medication. Neuroleptics (e.g., risperidone, olanzapine, quetiapine, aripiprazole, and ziprasidone) have had positive results in youth with BD. The increased risk of tardive dyskinesia should be considered in using such agents. Benzodiazepines may also be helpful for alleviating insomnia and agitation during acute mania.

Treating co-morbid psychiatric disorders must be done carefully. Stimulants may be used to treat ADHD once the patient has been stabilized on a mood stabilizer. In general, antidepressants should be avoided; if the youth is depressed or has significant anxiety and is not responsive to other pharmacotherapy, cautious use of antidepressants may be necessary. Careful monitoring for manic reactivation, cycling, and suicidality is needed.

CBT is aimed at initially improving adherence to medication treatments and ameliorating anxiety and depressive symptoms. Psychoeducation and family therapy may also be needed to stabilize the patient's environment and improve prognosis. There should be ongoing safety assessment. Additionally, patients may display struggles with coping skills, impaired social/interpersonal relationships, and developmental deficits due to poor learning while symptomatic; therefore additional skills training and collaboration with the child's school regarding behavior management, special education needs, and an appropriate individualized education plan may also be needed.

When compared with depression, the rates of suicide and suicidal ideation are higher in BD. Forty percent of children and 50% of adolescents with BD attempt suicide with approximately 10–15% completing attempts. High levels of irritability, impulsivity, and poor ability to consider consequences (e.g., substance abuse) increase the risk of completed suicide. Attempters are

more likely to be older, have mixed episodes and psychotic features, have co-morbidities (e.g., substance use, panic disorder), and have a history of physical or sexual abuse. They also commonly have a history of nonsuicidal self-injurious behaviors, a family history of suicide attempts, and a history of hospitalizations. Legal problems in adolescence is also a strong predictor of suicide attempts, with approximately a fourth of those attempting suicide having experienced legal concerns in the preceding 12 months. Ensuring safety should always be the first goal of treatment. Hospitalization, partial hospitalization, intensive outpatient treatment, and intensive in-home services are used as needed for stabilization and safety.

PEARLS FOR PRACTITIONERS

See Psychiatric Disorders: Pearls for Practitioners at the end of this section.

CHAPTER 19

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is characterized by obsessions, compulsions, or both in the absence of another psychiatric disorder that better explains the symptoms (Table 19.1). Obsessions involve recurrent intrusive thoughts, images, or impulses. Compulsions are repetitive, non-gratifying behaviors that a person feels driven to perform in order to reduce or prevent distress or anxiety. In children, rituals or compulsive symptoms often predominate over worries or obsessions, and the child may attempt to neutralize an obsessive thought by performing compulsions. Symptoms may or may not be recognized as being excessive or unreasonable. The most common obsessions in children involve fears of contamination, fears of dirt/germs, repeated doubts, orderliness or precision, and aggressive thoughts. Common compulsions include grooming rituals (e.g., handwashing, showering), ordering, checking, requesting reassurance, praying, counting, repeating words silently, and touching rituals.

Prevalence of OCD in children ranges from 1–4%, increasing with age. Boys typically have an earlier age of onset with approximately one quarter of boys being diagnosed prior to 10 years of age. It is most commonly diagnosed between the ages of 7 and 12 years. Symptoms typically have a gradual onset. Twin studies suggest that obsessive-compulsive symptoms are moderately heritable, with genetic factors accounting for 45–65% of variance.

Up to 50% of youth with OCD have at least one other psychiatric illness. Some of the most common co-morbidities include mood and anxiety disorders (up to 75%), behavioral disorders (attention-deficit/hyperactivity disorder [ADHD] and oppositional defiant disorder) (up to 50%), tic disorders (20–30%), hoarding disorder, developmental disorders, body dysmorphic disorder, hypochondriasis, and obsessive-compulsive personality disorder (OCPD).

Streptococcal infection causing inflammation in the basal ganglia may account for 10% of childhood-onset OCD and is part of a condition referred to as *pediatric autoimmune neuropsychiatric disorders associated with streptococcal* (PANDAS) infection. PANDAS is a subtype of *pediatric acute-onset*

TABLE 19.1 *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5) Criteria for Diagnosis of Obsessive-Compulsive Disorder*

A. Presence of either obsessions or compulsions, or both.

Obsessions are defined by (1) and (2).

1. Recurrent and persistent thoughts, urges, or images that are experienced at some time during the disturbance as intrusive and unwanted, and that in most individuals cause marked anxiety or distress.
2. The individual attempts to ignore or suppress such thoughts, urges, or images or to neutralize them with some other thought or action (i.e., by performing a compulsion).

Compulsions are defined by (1) and (2).

1. Repetitive behaviors (e.g., handwashing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) that the individual feels driven to perform in response to an obsession or according to rules that must be applied rigidly.
2. The behaviors or mental acts are aimed at preventing or reducing anxiety or distress or preventing some dreaded event or situation; however, these behaviors or mental acts are not connected in a realistic way with what they are designed to neutralize or prevent or are clearly excessive.

Note: Young children may not be able to articulate the aims of these behaviors or mental acts.

- B. The obsessions or compulsions are time-consuming (taking >1 hour a day); or cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The obsessive-compulsive symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.
- D. The disturbance is not better explained by the symptoms of another mental disorder (e.g., excessive worries, as in generalized anxiety disorder; preoccupation with appearance, as in body dysmorphic disorder; difficulty discarding or parting with possessions, as in hoarding disorder; hair pulling, as in trichotillomania; skin picking, as in excoriation; stereotypies, as in stereotypical movement disorder; ritualized eating behavior, as in eating disorders; preoccupation with substances or gambling, as in substance-related and addictive disorders; preoccupation with having an illness, as in illness anxiety disorder; sexual urges or fantasies, as in paraphilic disorders; impulses, as in disruptive, impulse-control, and conduct disorders; guilty ruminations, as in major depressive disorder; thought insertion or delusional preoccupations, as in schizophrenia spectrum and other psychotic disorders; or repetitive patterns of behavior, as in autism spectrum disorder).

Specify if:

With good or fair insight: The individual recognizes that obsessive-compulsive disorder beliefs are definitely or probably not true or that they may or may not be true.

With poor insight: The individual thinks obsessive-compulsive disorder beliefs are probably true.

With absent insight/delusional beliefs: The individual is completely convinced that obsessive-compulsive disorder beliefs are true.

Specify if:

Tic related: The individual has a current or past history of a tic disorder.

neuropsychiatric syndrome (PANS), which can, in part, be distinguished by an abrupt onset of moderate to severe OCD symptoms. Antistreptolysin O, antistreptococcal DNAase B titers, and a throat culture assist in diagnosing a group A β -hemolytic streptococcal infection. Early antibiotic therapy may help treat these cases.

OCD has been linked to a disruption in the brain's serotonin, glutamate, and dopamine systems. Overactivity in neural pathways involving the orbital frontal cortex and caudate nucleus has also been implicated in OCD.

The differential diagnosis for OCD includes depression, other obsessive-compulsive and related disorders (e.g., hoarding, trichotillomania), psychotic disorders, tic disorders, anxiety disorders, and OCPD. Although some children with OCD may have poor insight, they typically present with clear obsessions/compulsions that distinguish them from delusions. They lack hallucinations, which help to distinguish them from schizophrenia spectrum disorders. This may be at times difficult to discern. For instance, a delusional fixation on appearance in body dysmorphic disorder and impulsive hair pulling to relieve anxiety or tension in trichotillomania can be confused with OCD. OCPD is a character style involving preoccupation with orderliness, perfectionism, and control. It can be distinguished from OCD in that no true obsessions or compulsions are present in OCPD. However, if symptoms of both conditions are present, they can be co-morbid, although this is rare.

Physical examination may reveal rough, cracked skin as evidence of excessive handwashing. Many children also express concerns of persistent fear of illness, concerns regarding the health of family members, and the fear that something bad will happen to someone.

There are numerous diagnostic questionnaires available to assist in making an accurate diagnosis of OCD. The Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) is regarded as the gold standard measure of obsessive-compulsive symptom severity. Although somewhat lengthy, it can be helpful in the clinical setting.

Cognitive-behavioral therapy (CBT) is considered the treatment of choice in mild to moderate cases. CBT provides durability of symptom relief and avoidance of potential pharmacotherapy-associated side effects. As with anxiety disorders, CBT is at least as good, if not better, than medications. The combination of medications and CBT has shown the best response. CBT typically involves gradually exposing the children to their fear/obsession paired with strategies that target preventing them from performing the unwanted ritual/compulsion. Over time with repeated exposure and response prevention, the urge to repeat the compulsion(s) dissipates.

Selective serotonin reuptake inhibitors (SSRIs) are recommended for higher severity of symptoms and complications with co-morbidities or when cognitive or emotional ability are insufficient to demonstrate success in CBT. Additionally, if quality CBT is not available, treatment with medications alone while psychotherapy referral is pursued is a reasonable choice.

SSRI (e.g., paroxetine, fluoxetine, fluvoxamine, sertraline, citalopram, and escitalopram) treatment is generally thought to show a favorable risk:benefit ratio in OCD. Side effects such as activation, akathisia, disinhibition, impulsivity, and hyperactivity may be seen. Monitoring of height may be advisable due to possible growth suppression associated with the SSRIs.

Common protocols suggest up to three trials of an SSRI and, if unsuccessful, clomipramine can be attempted. Careful monitoring of potential anticholinergic side effects, lowering of blood pressure, and ECG monitoring is necessary. Combination therapy using an SSRI with an antipsychotic medication (risperidone or another atypical antipsychotic) may also be considered, especially with specific co-morbidities (e.g., tic disorders). Antipsychotics may also be useful when the intrusive thoughts associated with OCD become nearly delusional in nature. The risk of increasing obsessional symptoms and tics may occur with using psychostimulants with co-morbid ADHD, but have shown some benefit. Suicidal ideation in children is not uncommon and should be closely monitored, especially with increasing symptom severity and depressive co-morbidities.

Most *responders* exhibit partial response only, and as many as one-third of young people with OCD are refractory to treatment. Poor prognostic factors include co-morbid psychiatric illness and a poor initial treatment response.

Deep brain stimulation of the basal ganglia, through surgically implanted electrodes and surgical interventions (anterior capsulotomy, anterior cingulotomy, subcaudate tractotomy, and limbic leucotomy), are reserved for very severe cases or highly refractory cases.

PEARLS FOR PRACTITIONERS

See *Psychiatric Disorders: Pearls for Practitioners at the end of this section.*

CHAPTER 20

Pervasive Developmental Disorders and Psychoses

Autism spectrum disorder (ASD; Table 20.1) involves persistent difficulties with social communication and restricted, repetitive patterns of behavior (RRPB). Specifiers of symptom severity in regard to core deficits in the domains of social communication impairments and RRPB are also provided. A diagnosis of **social (pragmatic) communication disorder (SCD)** may be made in the absence of RRPBs.

Onset of ASD is in infancy and preschool years. Intellectual disability is common (~33% according to Centers for Disease Control and Prevention [CDC] estimates); although approximately 42% demonstrate average to high intelligence scores, they often show uneven abilities. ASD is seen in approximately 1% of the population with fairly equal prevalence rates among all racial and ethnic groups. Boys are diagnosed much more frequently than girls (4.3:1 ratio); however, girls with the disorder tend to be more severely affected regarding intellectual abilities and symptom severity.

ASD is often characterized by lifelong impairment in social interaction and social communication in addition to RRPBs. Approximately 20% of parents report relatively normal development until 1–2 years of age, followed by a steady or sudden decline. Many infants with ASD display delayed or absent social smiling. Young children may spend extended time in solitary play and be socially withdrawn with limited

TABLE 20.1 *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5) Diagnostic Criteria for Autism Spectrum Disorder*

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history:
1. Deficits in social-emotional reciprocity.
2. Deficits in nonverbal communicative behaviors used for social interaction.
3. Deficits in developing, maintaining, and understanding relationships.
B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history:
1. Stereotyped or repetitive motor movements, use of objects, or speech.
2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior.
3. Highly restricted, fixated interests that are abnormal in intensity or focus.
4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment.
C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities or may be masked by learned strategies in later life).
D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.
E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and spectrum disorder frequently co-occur; to make co-morbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.
Note: Individuals with a well-established Diagnostic and Statistical Manual of Mental Disorders-IV diagnosis of autistic disorder, Asperger disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder. Individuals who have marked deficits in social communication but whose symptoms do not otherwise meet criteria for autism spectrum disorder should be evaluated for social (pragmatic) communication disorder.
Specify if:
With or without accompanying intellectual impairment
With or without accompanying language impairment
Associated with a known medical or genetic condition or environmental factor
Associated with another neurodevelopmental, mental, or behavioral disorder
With catatonia (refer to the criteria for catatonia associated with another mental disorder)

Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, 5th ed. (Copyright 2013). American Psychiatric Association, 2013:50–51. All rights reserved.

responsiveness to attempts at communication. Patients with ASD often struggle to understand nonverbal communication (e.g., eye contact, facial expressions) and do not interact with people as significantly different from objects. Communication and speech are often delayed and, when present, may be marked by echolalia (repetition of language of others), perseveration (prolonged repetition of words or behaviors of others), pronoun reversal, nonsense rhyming, and other abnormalities. Intense interests, ritualistic behavior, and compulsive routines are characteristic, and their disruption may invoke behavioral dysregulation. Self-injurious behaviors (head banging, biting), repetitive motor mannerisms (rocking, lining up objects, simple motor stereotypies), and hyperreactivity/hyporeactivity to their environment (diminished response to pain, adverse reactions to sounds/textures, or unusual visual inspection of objects) are common.

Although the full etiology of ASD is unknown, it is largely considered a genetic disorder. There is an increased risk of ASD in siblings compared to the general population. Twin studies have revealed high concordance rates (36–95%) for identical twins. Family studies reveal prevalence rates of between 2% and 18% in siblings, and when absent, there may be increased risk for other language, learning, and social development difficulties.

It has been proposed that brain connectivity is adversely affected. Abnormalities in the limbic system, temporal, and

frontal lobes have been examined. Some postmortem studies reveal abnormalities in the brain microarchitecture, size, and neuronal packing. Functional magnetic resonance imaging (fMRI) studies show that hypoactivity of the fusiform gyrus of the amygdala, a location involved in face processing tasks and facial expression recognition involved in social and affective judgments, may be impacted in ASD.

There are no definitive laboratory studies for ASD, but they can help rule out other diagnoses. A hearing test (may account for the language deficits), chromosomal testing (to identify fragile X syndrome, tuberous sclerosis, and genetic polymorphisms), congenital viral infections, and metabolic disorders (phenylketonuria) should be performed. Electroencephalography abnormalities may be seen in 20–25% of children with ASD, but they are not diagnostic.

The American Academy of Pediatrics (AAP) recommends screening for autism at 18 and 24 months of age. There are numerous screening measures that may be employed (e.g., Childhood Autism Rating Scale, 2nd Edition [CARS2], Modified Checklist for Autism in Toddlers–Revised [M-CHAT-R], Gilliam Autism Rating Scale, 3rd Edition [GARS3], and Screening Tool for Autism in Toddlers and Young Children [STAT]) to assist with appropriate referral for diagnostic evaluation. Gold standard psychological measures such as the Autism Diagnostic Observation Schedule–2nd

Edition (ADOS-2) and Autism Diagnostic Interview–Revised (ADI-R) are commonly recommended to confirm a diagnosis. Additionally, measures of language, adaptive skills, and intelligence are commonly administered if ASD is suspected. Neurocognitive tests in children with ASD often show relative strengths in nonverbal tasks (e.g., puzzles) and weaknesses in verbal abilities. Speech pathology consultation can be helpful in evaluating the communication difficulties.

Common psychiatric co-morbidities include intellectual disability, language disorders, anxiety disorders, attention-deficit/hyperactivity disorder, developmental coordination disorder, and depressive disorders. Other medical complexities commonly seen in children with ASD include seizure disorder, sleep disorders, and gastrointestinal disorders (constipation, food selectivity). Early studies of autism suggested a relatively poor prognosis, with only a small number of individuals (1–2%) being able to function independently as adults. Recent research reveals major gains, but not a cure, with early diagnosis and treatment. Cognitive abilities and language abilities are the strongest predictors of improved long-term prognosis.

SCD involves struggles with using communication for social purposes (e.g., greeting others, sharing information, conversational rules, inferences, and pragmatic skills). SCD is marked by many of the same communication deficits seen in children with ASD with the absence of RRPBs. SCD is believed to be rare in children prior to 4 years of age. Prevalence rates are largely unclear because of its recent addition to the DSM-5; however, the estimated prevalence is thought to be around 0.5%. Typically, speech and language therapy and social skills training are employed to treat SCD.

Treatment of ASD is multimodal. There are no pharmacologic treatments for the core symptoms of ASDs. Antipsychotics (risperidone, olanzapine, quetiapine, aripiprazole, ziprasidone, paliperidone, haloperidol, thioridazine) are used for aggression, agitation, irritability, and self-injurious behavior. Anti-convulsants have also been used for aggression. Naltrexone has been used to decrease self-injurious behavior, presumably by blocking endogenous opioids. Selective serotonin reuptake inhibitors are given for anxiety, perseveration, compulsions, depression, and social isolation. Stimulants target hyperactivity and inattention; however, there are reports of worsening of irritability and aggression in some patients treated with stimulants. α_2 agonists (guanfacine, clonidine) are used for hyperactivity, aggression, and sleep dysregulation, although melatonin is first-line medication for sleep dysregulation.

Most treatments for ASD are nonpharmacologic. The most effective interventions have largely fallen under the classification of behavioral training. Models have typically employed therapies individually tailored for children with ASD and their families/caregivers. Evidence suggests that useful therapies have included techniques from applied behavior analysis (ABA), discrete trial training (DTT), functional behavioral analysis (FBA), and structured teaching (TEACCH model). Behavioral management training for parents has also demonstrated efficacy in helping with unwanted behaviors. Special education services should be individualized for the child and should be aimed at maximizing functioning. Occupational, speech, and physical therapy are often required. Referral for disability services, family support groups, and individual supportive counseling for parents are useful. The prognosis for ASD varies greatly from child to child. There are no known methods of primary prevention.

SCHIZOPHRENIA SPECTRUM DISORDERS

Schizophrenia generally presents in adolescence or early adulthood. The same diagnostic criteria are applied as in adults but must be interpreted in terms of the developmental level of the child (Table 20.2). Schizophrenia requires two or more of the core features of a psychotic disorder (delusion, hallucinations, disorganized speech, disorganized/catatonic behavior, negative symptoms) to be present, with at least one of the first three “positive symptoms” also being present. Historically, subtypes of schizophrenia (e.g., paranoid, catatonic, undifferentiated) were classified; however, currently a more dimensional approach to schizophrenia spectrum disorders uses severity ratings for the core symptoms.

Schizophrenia in childhood is rare (<1 in 10,000 children) and usually indicates a more severe form of the disorder. The frequency increases between 13 and 18 years of age, typically with psychotic features presenting initially. The incidence in boys is slightly greater than in girls, and the age of onset tends to be later for girls. The etiology of schizophrenia is not clearly known, but numerous studies have demonstrated a substantial genetic predisposition for the disorder. Family studies consistently show a higher risk in monozygotic twins compared with dizygotic twins and siblings. First-degree relatives of patients with schizophrenia have a 10-fold higher risk.

TABLE 20.2 *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5) Diagnostic Criteria for Brief Psychotic Disorder*

A. Presence of one (or more) of the following symptoms. At least one of these must be (1), (2), or (3):

1. Delusions
2. Hallucinations
3. Disorganized speech (e.g., frequent derailment or incoherence)
4. Grossly disorganized or catatonic behavior

Note: Do not include a symptom if it is a culturally sanctioned response.

B. Duration of an episode of the disturbance is at least one day but less than 1 month, with eventual full return to premorbid level of functioning.

C. The disturbance is not better explained by major depressive or bipolar disorder with psychotic features or another psychotic disorder such as schizophrenia or catatonia, and is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

Specify if:

With marked stressor(s) (brief reactive psychosis): If symptoms occur in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the individual's culture.

Without marked stressor(s): If the symptoms do not occur in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the individual's culture.

With postpartum onset: If onset is during pregnancy or within 4 weeks postpartum.

The symptoms of schizophrenia typically fall into four broad categories:

- **Positive symptoms** include hallucinations and delusions. Hallucinations are auditory or visual misperceptions that occur without external stimuli. Delusions are fixed false beliefs and can be bizarre or non-bizarre depending on cultural norms.
- **Negative symptoms** include a lack of motivation, poor social interactions, and flat affect. Negative symptoms are more common in early childhood and later adolescence. Children with high intelligence often show more positive and fewer negative symptoms than children with low intelligence.
- Disorganization of thoughts and behavior can cause significant impairment.
- Cognitive impairment is common and is perhaps the most disabling feature of schizophrenia, causing marked social and functional impairment.

To meet criteria for schizophrenia, clinical symptoms should be present for at least 6 months. If symptoms are present for less than 1 month, the condition is called a **brief psychotic disorder**. If symptoms are present for more than 1 month but less than 6 months, a diagnosis of **schizophreniform disorder** is made. Psychotic symptoms that do not meet full diagnostic criteria for schizophrenia but are clinically significant are diagnosed as an **unspecified schizophrenia spectrum or other psychotic disorder**. The differential diagnosis of a schizophrenia spectrum disorder commonly includes ASD, neurocognitive disorders, substance-induced psychosis, bipolar disorders, and organic brain disorders.

There are several disorders that also fall within the spectrum of schizophrenia and other psychotic disorders that should be distinguished from schizophrenia. These include the following:

Schizoaffective disorder is diagnosed when a person has clear symptoms of schizophrenia lasting at least 2 weeks and experiences a major mood episode (major depression/mania) during an uninterrupted period of the illness. These affective episodes occur at other times, even when psychotic symptoms are present. This condition is very rare in children and has a lifetime prevalence that is much lower than schizophrenia (0.3% lifetime prevalence).

Psychotic disorder due to another medical condition describes psychotic symptoms that are judged to be the direct result of a general medical condition. There are a variety of potential underlying medical etiologies seen in children with epilepsy, metabolic disorders, and autoimmune disorders being the most common.

Substance/medication-induced psychotic disorders involve psychotic symptoms related to substance intoxication/withdrawal or follow exposure to a medication. While prevalence is not clearly known, estimates suggest that between 7% and 25% of first episodes of psychoses are related to substances.

No medical tests or imaging studies are diagnostic for schizophrenia. It is a clinical diagnosis of exclusion. Obtaining a family history with attention to mental illness is critical. Identifying schizophrenia should include a physical and neurologic examination, MRI, substance/drug screening, electroencephalography (to rule out epilepsy, especially temporal lobe epilepsy), and metabolic screening for endocrinopathies. Evaluation to rule out Wilson disease and delirium is also indicated. Psychotic symptoms in younger children must be differentiated from

manifestations of normal vivid fantasy life or abuse-related symptoms. Youth with post-traumatic stress disorder often have vivid recollections and nightmares related to abuse but, sometimes, are less specific and can include nightmares with other negative topics. Psychologic testing can also be helpful in identifying psychotic thought processes. The poorest prognosis is seen if the onset is at an age younger than 13 years, with poor premorbid function, when marked negative symptoms are present, and when a family history of schizophrenia exists.

Treatment is multimodal and frequently includes the use of antipsychotic medications. First-line drugs are atypical antipsychotics (e.g., risperidone, olanzapine, quetiapine, aripiprazole, ziprasidone, and paliperidone). Second-line medications are typical antipsychotics (e.g., haloperidol, thiothixene, chlorpromazine, trifluoperazine, loxapine, and molindone). It is likely that the newer antipsychotics approved for adults will also work in youth; however, all are not yet approved by the U.S. Food and Drug Administration for use in children. Antipsychotics can be augmented with lithium or another mood stabilizer. Clozapine is generally reserved for resistant cases. Neuroleptic medications carry the risk of tardive dyskinesia and should be employed cautiously in children. Evidence suggests that prepubertal children are less responsive to antipsychotics and that adolescents, while demonstrating efficacy with the medications, do not reach the level of full efficacy seen in adults.

Psychosocial treatments, including skills training, supportive psychotherapy, behavior modification, and cognitive-behavioral therapy, are all appropriate and should be considered as needed for individual patients. Attention should be paid to psychoeducation for parents and the child about the disease and its treatments. School interventions are needed to ensure that any special learning needs are addressed. Schizophrenia spectrum disorders also carry a high risk for suicidality, and ideation should be reevaluated throughout treatment. Co-morbid depressive symptoms increase the risk for suicide.

PEARLS FOR PRACTITIONERS

CHAPTER 16

Somatoform Disorders, Factitious Disorders, and Malingering

- Involve physical symptoms (pain, fatigue, or loss of function) that may be medically unexplained or that may accompany diagnosed medical disorders.
- Elevated rates of medical utilization are common. Patients repeatedly seek reassurance from family, friends, and medical staff regarding their health.
- In early childhood, symptoms often include recurrent abdominal pain (RAP). Later headaches, neurologic symptoms, insomnia, and fatigue are common.
- Screening tools for somatic symptom and related disorders (SSRDs) include the Children's Somatization Inventory, Illness Attitude Scales, Soma Assessment Interview, an adapted version of the Patient Health Questionnaire-15 (PHQ-15), and the Functional Disability Inventory.
- Selective serotonin reuptake inhibitors (SSRIs) benefit SSRDs involving unexplained headaches, fibromyalgia, body dysmorphic disorder, pain disorder, irritable bowel syndrome, and functional gastrointestinal disorders.
- Tricyclic antidepressants should be avoided in youth with functional abdominal pain (FAP); they have little proven efficacy and are very dangerous in overdose.
- Stimulants may also be helpful in chronic fatigue syndrome (CFS).
- Therapy, such as cognitive-behavioral therapy (CBT), has demonstrated efficacy in treating recurrent pain, CFS, fibromyalgia, and FAP. Self-management strategies (self-monitoring, relaxation, hypnosis, and biofeedback) have also demonstrated efficacy.
- Home schooling should be avoided; school attendance and performance should be emphasized; parents should limit attention/reinforcement for pain behavior; and normal routines/appropriate schedules (e.g., going to school) should be emphasized.

CHAPTER 17

Anxiety and Phobias

- Characterized by uneasiness, excessive rumination, and apprehension about the future.
- Tend to be chronic, recurring, and vary in intensity over time.
- Medical conditions (e.g., hyperthyroidism, medication side effects, and substance abuse) should be ruled out.
- First-line treatment for mild to moderate anxiety includes evidence-based psychotherapies and psychoeducation. CBT (e.g., systematic desensitization, exposure techniques, operant conditioning, modeling, and cognitive restructuring) can be beneficial in anxiety disorders.

- SSRIs are the medication of choice, and FDA-approved SSRIs for children are fluoxetine, sertraline, and fluvoxamine. They can initially exacerbate anxiety or even panic symptoms. Tricyclic antidepressants have also shown efficacy.
- Benzodiazepines (e.g., clonazepam) include a risk of causing disinhibition in children.
- α_{2a} agonists (guanfacine and clonidine) may be useful with autonomic symptoms.
- Anticonvulsant agents (e.g., gabapentin) are used when other agents are ineffective.
- β blockers help with performance anxiety.

CHAPTER 18

Depression and Bipolar Disorders

Depressive Disorders

- Depressive disorders involve the presence of sad/irritable mood along with physical and cognitive impacts on the child's daily functioning.
- In children, depressed mood often presents as irritability and/or restlessness. Furthermore, many children/adolescents complain of pervasive boredom in major depressive disorder (MDD).
- Many depressive disorders demonstrate genetic predispositions. Anxiety disorders, substance disorders, and conduct/disruptive disorders frequently present as co-morbid with MDD.
- Screening tools such as Kovacs Children's Depression Inventory (CDI) may be helpful.
- SSRIs are first-line pharmacologic treatments. Fluoxetine is the only medication approved by the FDA for treatment in youth 8 years and older, and escitalopram is approved for youth 12 and older. Off-label medications such as citalopram, paroxetine, and venlafaxine have positive clinical trial results as well.
- An antidepressant should be given an adequate trial (6 weeks at therapeutic doses) before switching or discontinuing unless there are serious side effects. For a first episode of depression, treatment for 6–9 months after remission of symptoms is recommended.
- Psychotherapy has good efficacy in mild to moderate depression. In moderate to severe depression, combined treatment with psychotherapy and medication has the greatest rate of response, and CBT and interpersonal therapies have received the most empirical support.
- Suicidal ideation and attempts at suicide are high in depressive disorders. Regular assessment of suicidal ideation should occur.

Bipolar Disorders (BD)

- Consist of distinct periods of mania (elevated, expansive, or irritable mood) and persistent goal-directed activity or energy that may alternate with periods of severe depression.

- Often present with rapid shifts in mood or lability over brief time frames (e.g., shifting between euphoria and dysphoria or irritability). A decreased need for sleep is also common.
- Commonly used medications include lithium, divalproex sodium, carbamazepine, olanzapine, risperidone, quetiapine, ziprasidone, lurasidone, and aripiprazole. Lithium is often used in acute episodes and as a maintenance treatment in children and adolescents but requires periodic monitoring of blood levels.
- Anticonvulsants are used for mixed or rapid cycling cases in adults. They have also been used effectively in youth, but they are not FDA approved in children for BD.
- Neuroleptics have had positive results in youth with BD; however, the increased risk of tardive dyskinesia should be considered in using such agents.

CHAPTER 19

Obsessive-Compulsive Disorder

- Obsessions (e.g., fears of contamination, fears of dirt/germs, repeated doubts, aggressive thoughts, and orderliness/precision) involve recurrent intrusive thoughts, images, or impulses.
- Compulsions (e.g., grooming rituals, ordering, checking, requesting reassurance, praying, counting, repeating words silently, and touching rituals) are repetitive non-gratifying behaviors that a person feels driven to perform to reduce or prevent distress or anxiety.
- The Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) is regarded as the gold standard measure of obsessive-compulsive symptom severity.
- CBT involving exposure and response prevention is considered the treatment of choice in mild to moderate cases.
- SSRIs have demonstrated a favorable risk:benefit ratio in obsessive-compulsive disorder (OCD) and are recommended in higher severities of OCD.

CHAPTER 20

Pervasive Developmental Disorders and Psychoses

Autism Spectrum Disorder (ASD)

- Onset is in infancy and preschool years. Core symptoms reflect communication and restricted, repetitive patterns of behavior.
- Intellectual disability is common, and the male:female ratio is 4.3:1.

- Children with ASD commonly prefer solitary play, are socially withdrawn, struggle to understand nonverbal communication (e.g., eye contact, facial expressions), and do not interact with people as significantly different from objects.
- Communication and speech often are delayed. Intense absorbing interests, ritualistic behavior, and compulsive routines are characteristic.
- Self-injurious behaviors, repetitive motor mannerisms, and hyperreactivity/hyporeactivity to their environment may be noted.
- Screening at 18 and 24 months (e.g., CARS2, M-CHAT-R, GARS3, and STAT) and gold standard psychologic measures (i.e., Autism Diagnostic Observation Schedule [ADOS-2] and Autism Diagnostic Interview [ADI-R]) are recommended to confirm ASD.
- Nonpharmacologic interventions are first line. Therapies have included techniques from applied behavior analysis (ABA), discrete trial training (DTT), functional behavioral analysis (FBA), and structured teaching (TEACCH model).
- Occupational, speech, and physical therapy are often required.
- There are no pharmacologic treatments for the core symptoms of ASDs. Antipsychotics, anticonvulsants, SSRIs, stimulants, and α_2 agonists are commonly used to assist with ameliorating secondary and co-morbid symptoms.

Schizophrenia Spectrum Disorders

- Childhood-onset schizophrenia is rare and involves both positive (hallucinations, delusions) and negative (poor motivation/social interactions, flat affect) symptoms.
- No diagnostic tests or imaging studies are specific for schizophrenia. It is a clinical diagnosis of exclusion.
- Work-up for schizophrenia should include a physical and neurologic examination, MRI, electroencephalography (to exclude epilepsy), drug screening, and metabolic screening for endocrinopathies. Evaluation to exclude Wilson disease and delirium is also indicated.
- First-line pharmacologic treatment includes atypical antipsychotics. Second-line medications are typical antipsychotics. Antipsychotics can be augmented with lithium or another mood stabilizer. Neuroleptic medications also carry the risk of tardive dyskinesia and should be employed cautiously in children.
- Prepubertal children are less responsive to antipsychotics and adolescents, while demonstrating efficacy, do not reach the level of full efficacy seen in adults.
- Psychosocial treatments (e.g., skills training, supportive psychotherapy, behavior modification, and CBT) are all appropriate and should be considered as needed.

PSYCHOSOCIAL ISSUES

Kristine Fortin | Alison H. Downes

CHAPTER 21

Failure to Thrive

Failure to thrive (FTT) is a descriptive term used when growth is inadequate compared to expected standards. The terms *malnutrition* and *undernutrition* have also been used. To date, there is no universally accepted definition. Different anthropometric criteria and cut points have been used to define FTT. Commonly used criteria include weight below the 3rd or 5th percentile for age; weight decreasing, crossing two major percentile lines on the growth chart over time; or weight less than 80% of the median weight for the height of the child. Caveats to these definitions exist. According to growth chart standards, 3% of the population naturally falls below the 3rd percentile. Children who have constitutional delay of growth usually are proportional (normal weight for height). Additionally, in the first few years of life, fluctuations in percentile position can occur in normal children. For example, children with familial short stature who are born large or appropriate for gestational age can experience catch-down growth. *z* scores are another way to express anthropometric measures, reflecting the number of standard deviations above or below the population median. A commonly used cut point for undernutrition is a *z* score below -2 . *z* scores can provide more detailed information than percentiles, especially when following growth over time. Given the limitations of anthropometric measurements alone to define FTT, clinical diagnosis tools such as the Subjective Global Nutritional Assessment (SGNA) and the Semi-Objective Failure to Thrive (SOFTT) have been studied.

ETIOLOGY

There are multiple possible causes of growth failure (Table 21.1). In the past, etiologies of FTT were sometimes categorized as organic (underlying medical condition diagnosed) and nonorganic (no underlying medical cause). This dichotomous classification can be problematic because, in many cases, the cause of FTT is multifactorial with interaction between multiple biologic and psychosocial factors. FTT can be caused by inadequate nutritional intake (e.g., neurologic condition impeding feeding, improper mixing of formula, food insecurity), malabsorption (e.g., celiac disease, milk protein allergy), and/or increased metabolic demands (e.g., cardiac disease, chronic infection). Studies suggest that clinically unsuspected major organic diseases are detected in a minority of patients worked

up for FTT. Recent studies have found that approximately half of children hospitalized for FTT have known complex chronic conditions, a reflection of the overall increasing prevalence of children with complex care conditions.

DIAGNOSIS AND CLINICAL MANIFESTATIONS

A careful history and physical examination are the cornerstone of FTT evaluations. A medical history should include prenatal history, gestational age and perinatal history, birth size (weight, length, and head circumference), family, and travel history. Indicators of medical diseases, such as vomiting, diarrhea, fever, respiratory symptoms, and fatigue, should be noted. A careful diet history is essential. Lactation problems in breast-fed infants and improper formula preparation are frequent causes of growth failure early in infancy. It is crucial to evaluate intake of solid foods and liquids for older infants and children. Some parental dietary beliefs lead to inappropriately restricted diets; drinking excessive amounts of fruit juice may result in malabsorption or anorexia. The child's daily meal schedule (timing, frequency, location) should be noted. Mealtime practices, especially distractions that interfere with completing meals, can influence growth. A complete psychosocial assessment of the child and family is required. Child factors (temperament, development), parental factors (depression, domestic violence, social isolation, cognitive deficits, substance abuse), and environmental and societal factors (poverty, unemployment, illiteracy, lead toxicity) all may contribute to growth failure.

A complete physical examination should be completed starting with vital signs and growth parameters. Growth charts provide important information. Changes in weight should be assessed in relation to height (length) and head circumference. Allowances must be made for prematurity; weight corrections are needed until 24 months of age, height corrections until 40 months of age, and head circumference corrections until 18 months of age. There are specific growth charts for genetic conditions such as Down syndrome and Turner syndrome that should be used when assessing growth for children with these conditions. Although some growth variants can be difficult to distinguish from FTT, growth velocity and height-for-weight determinations can be useful in distinguishing the cause. In children with FTT, malnutrition initially results in wasting (deficiency in weight gain). Stunting (deficiency in linear growth) generally occurs after months of malnutrition, and head circumference is spared except with chronic, severe malnutrition. FTT that is symmetric (proportional weight,

TABLE 21.1 Examples of Causes of Failure to Thrive

INADEQUATE INTAKE
• Improper formula preparation
• Neglect
• Food insecurity
• Poor feeding techniques
• Parental depression
• Breastfeeding difficulties
• Lack of knowledge of dietary needs
• Behavioral issues in toddlers
• Neurologic condition impeding feeding
• Congenital condition such as cleft lip or palate impeding feeding
• Upper airway obstruction
• Gastroesophageal reflux
• Malrotation, volvulus
MALABSORPTION/INCREASED NUTRIENT LOSSES
• Protein allergy
• Protein-losing enteropathy
• Inborn errors of metabolism
• Biliary atresia
• Short bowel syndrome
• Celiac disease
• Cystic fibrosis and other causes of pancreatic insufficiency
• Other malabsorption syndromes
INCREASED METABOLIC DEMAND
• Congenital heart disease
• Infections (HIV, tuberculosis, urinary tract infection, chronic sinusitis, parasitic infection, TORCH)
• Chronic lung disease
• Thyroid disease
• Adrenal or pituitary disease
• Sickle cell disease
• Renal disease (chronic renal failure, renal tubular acidosis)

TORCH, toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus.

height/length, and head circumference) suggests long-standing malnutrition, chromosomal abnormalities, congenital infection, or teratogenic exposures. Short stature with preserved weight suggests an endocrine etiology. Physical examination should also assess for signs of inflicted injury; oral or dental problems; indicators of pulmonary, cardiac, or gastrointestinal disease; and dysmorphic features that may suggest a genetic or teratogenic cause for growth failure. A complete neurologic examination may reveal spasticity or hypotonia, which can have untoward effects on feeding and growth. Physical findings related to malnutrition include decreased subcutaneous fat, decreased muscle mass, dermatitis, hepatomegaly, cheilosis, or

edema (see Chapter 30). Additionally, children with FTT have more otitis media, respiratory, and gastrointestinal infections than age-matched controls; severely malnourished children are at risk for a variety of serious infections. Observation during feeding and home visitation, if possible, is of great diagnostic value in assessing feeding problems, food preferences, meal-time distractions, unusual or disruptive parent-child interactions, and the home environment. Feeding evaluation by a speech therapist could also be helpful.

The history and physical examination findings should guide the laboratory evaluation. Routine extensive laboratory and radiology studies are not indicated, but rather tests should be ordered based on findings from the clinical evaluation. Simple screening tests could be used to identify common illnesses that cause growth failure and to search for medical problems resulting from malnutrition. Initial tests may include a complete blood count; screening for iron-deficiency anemia and lead toxicity; urinalysis, urine culture, and serum electrolytes to assess renal infection or dysfunction. A review of the child's newborn screen may also be warranted. Additional testing can be ordered as needed, based on the child's signs and symptoms. For example, a stool sample for culture and ova and parasites may be indicated in children with diarrhea, abdominal pain, or malodorous stools.

TREATMENT

Identified biopsychosocial etiologies will inform the treatment plan. Most children with FTT can be treated in the outpatient setting. Children with severe malnutrition, underlying diagnoses that require hospitalization for evaluation or treatment, or whose safety is in jeopardy because of maltreatment, require hospitalization. Admitting children to the hospital to induce and document weight gain is not recommended unless intensive outpatient evaluation and intervention has failed or the social circumstances are a contraindication for attempting outpatient management. Potential multidisciplinary treatment team members include pediatricians, nutritionists, developmental specialists, nurses, and social workers.

Nutritional management is the cornerstone of treatment. Children with FTT who are anorexic or picky eaters may have difficulty consuming the amount of calories and protein needed for catch-up growth, and require calorie dense foods. For formula-fed infants, the concentration of formula can be adjusted appropriately. For healthy term infants, formulas are prepared to provide 20 kcal/oz. Powder and liquid concentrates can be mixed with less water to provide a higher caloric density if needed. Final concentrations are reached by adding formula to the specific amount of water needed to reach the desired caloric density. Breast milk can also be fortified if needed. For toddlers, dietary changes should include increasing the caloric density of favorite foods. High-calorie oral supplements (30 cal/oz) are often well tolerated by toddlers. In some cases, specific carbohydrate, fat, or protein additives are used to boost calories by increasing calories without increasing volume requirements. Nasogastric tube feedings are used when children cannot take adequate calories safely by mouth. Vitamin and mineral supplementation can be required, especially during catch-up growth. In general, the simplest and least costly approach to dietary change is warranted.

Treatment must also address the psychosocial needs of the family. Families may need concrete resources. Parents of malnourished children may feel personally responsible and threatened by the diagnosis. Parents may be so depressed they cannot focus on their child's needs; they may not recognize the psychosocial and family contributors to malnutrition. These issues can have a profound effect on the success of treatment and need to be addressed.

COMPLICATIONS

Malnutrition causes defects in host defenses. Children with FTT may suffer from a **malnutrition-infection cycle**, in which recurrent infections exacerbate malnutrition, leading to greater susceptibility to infection.

During starvation, the body slows metabolic processes and growth to minimize the need for nutrients and uses its stores of glycogen, fat, and protein to maintain normal metabolic requirements. The body also generally maintains homeostasis and normal serum concentrations of electrolytes. With the rapid reinstatement of feeding after starvation, fluid and electrolyte homeostasis may be lost. Changes in serum electrolyte concentrations and the associated complications are collectively termed the **re-feeding syndrome**. These changes typically affect phosphorus, potassium, calcium, and magnesium and can result in life-threatening cardiac, pulmonary, or neurologic problems. Infants and children with marasmus, kwashiorkor, and anorexia nervosa and those who experience prolonged fasting are at risk for re-feeding syndrome. Re-feeding syndrome can be avoided by slow institution of nutrition, close monitoring of serum electrolytes during the initial days of feeding, and prompt replacement of depleted electrolytes.

There is concern that FTT could be associated with negative metabolic and neurodevelopmental outcomes in some cases.

PSYCHOSOCIAL SHORT STATURE

Occasionally, children who live in psychologic deprivation develop short stature with or without concomitant FTT or delayed puberty, a syndrome called **psychosocial short stature**. The signs and symptoms include polyphagia, polydipsia, hoarding and stealing of food, gorging and vomiting, and other notable behaviors. Affected children are typically depressed and socially withdrawn. Endocrine dysfunction including decreased growth hormone and muted response to exogenous growth hormone is often identified in affected children. Removal of the child from the adverse environment typically results in rapid improvement in endocrine function and subsequent rapid somatic and pubertal growth of the child. The prognosis for children with psychosocial short stature depends on the age at diagnosis and the degree of psychologic trauma. Early identification and removal from the environment portends a healthy prognosis. Those diagnosed in later childhood or adolescence may not reach their genetic potential for growth and have a poorer psychosocial prognosis.

PEARLS FOR PRACTITIONERS

See *Psychosocial Issues: Pearls for Practitioners* at the end of this section.

CHAPTER 22

Child Abuse and Neglect

Child maltreatment is a significant public health concern given its prevalence and potential impact on health not only during childhood but also later in life. Each year in the United States, approximately 3 million reports are made to child welfare agencies. These reports represent only a small proportion of the children who suffer from child maltreatment; surveys of adults about their childhood experiences indicate that many cases never come to the attention of authorities. Abusive head trauma rates increased during and after the Great Recession suggesting that macroeconomic factors impact the incidence of child maltreatment. Child maltreatment can cause short-term physical, mental, and developmental health problems, and in extreme cases can be fatal. Research, including the Adverse Childhood Experiences Study, has shown an association between childhood maltreatment and negative adult health outcomes, including physical health problems such as cardiovascular disease and obesity, as well as psychosocial health problems such as depression and substance abuse. A growing body of research demonstrates how toxic stressors in childhood can influence brain development and epigenetics.

Child maltreatment is an act or failure to act by a parent or caretaker that results in death, sexual abuse, harm, or imminent risk of harm. States define child abuse and neglect in civil and criminal statutes. In every state, physicians are mandated by law to report all cases of *suspected* child abuse and neglect. Child abuse and neglect result from a complex interaction of individual, family, and societal risk factors. Risk factors for maltreatment, such as parental substance abuse, parental depression, and domestic violence in the household, can alert physicians to potential risk and guide development of child maltreatment prevention strategies. However, risk factors should not be used to determine whether a specific patient is a victim of abuse. Child abuse and neglect are often considered in broad categories that include physical abuse, sexual abuse, emotional abuse, and neglect.

NEGLECT

Neglect is the most common form of child maltreatment and is broadly defined as omissions that prevent a child's basic needs from being met. Basic needs include adequate nutrition, shelter, education, emotional needs, adequate supervision, as well as medical and dental care. Different types of neglect have been described including dental, emotional, medical, physical, and supervisory neglect. Neglect can impact a child's physical, mental, developmental, and behavioral health. Potential physical health consequences include abnormal growth, poor dentition, injuries, or ingestions resulting from lack of supervision or environmental hazards, as well as poorly controlled health problems. Child neglect can contribute to developmental delays, risk-taking behaviors or other behavioral problems, school difficulties, emotional problems, as well as attachment problems. Health care providers play an important role in the multidisciplinary response to neglect. Medical interventions could include treating physical health

problems such as growth disturbance or injury, simplifying and clarifying treatment plans for chronic conditions, making referrals to community agencies that can assist with concrete needs such as food or transportation, providing developmental assessments and referrals, as well as referring patients to mental and behavioral health specialists. The approach to neglect involves identification of both contributing factors and strengths and protective factors. Health care providers can play a role in preventing neglect by screening for potential precipitating factors such as parental depression as well as by providing anticipatory guidance on topics such as supervision and injury prevention tailored to the child's developmental level.

PHYSICAL ABUSE

Physical abuse is second to neglect as the reason for child protective services reports and child maltreatment related fatality. Physical abuse affects children of all ages. If the child has obvious external abusive injuries or is capable of providing a history of the abuse, the diagnosis of physical abuse can be made easily. In many cases, the diagnosis is not obvious. Abusive injuries are sometimes occult, and children can present with nonspecific symptoms. The history provided by the parent is often inaccurate because the parent is unwilling to provide the correct history or is a nonoffending parent unaware of the abuse. The child may be too young or ill to provide a history of the assault. An older child may be too scared to do so or may have a strong sense of loyalty to the perpetrator. History that seems incongruent with the clinical presentation of the child raises concern for physical abuse (Table 22.1).

Although injury to any organ system can occur from physical abuse, some injuries are more common. Bruises are common findings in healthy ambulatory children but also are among the most common injury identified in abused children. Bruising location, pattern, and the child's age/developmental level are important considerations when evaluating bruising. Bruises suggestive of abuse include those that are patterned, such as a slap mark on the face or looped extension cord marks on the body (Fig. 22.1). Bruises in healthy children generally are distributed over bony prominences; bruises that occur in an unusual distribution, such as isolated to the torso, ears, or neck, should raise concern. Bruises in nonambulatory infants are unusual, occurring in less than 2% of healthy infants seen for routine medical care. TEN-4-FACESp is a bruising clinical decision rule validated in children <4 years of age to identify need for further evaluation for potential physical abuse. *TEN* refers to bruising to the torso, ear, or neck; *4* refers to bruising on an infant <4.99 months of age; *FACES* refers to bruising on the frenulum, angle of the jaw, cheek (fleshy part of face cheek), eyelid, and subconjunctivae; and *p* refers to bruising with a pattern. Occasionally, a subtle bruise may be the only external clue to abuse and can be associated with significant internal injury. Previous sentinel injuries, such as bruising, are common among infants presenting with severe physical abuse. Appropriate evaluation and intervention when non-mobile infants present with unexplained bruising could prevent escalating abuse.

Burns are common pediatric injuries and usually represent preventable unintentional trauma (see Chapter 44).

TABLE 22.1 Clues to the Diagnosis of Physical Abuse

A child presents for medical care with significant injuries and a history of trauma is denied, especially if the child is an infant or toddler.
The history provided by the caregiver does not explain the injuries identified.
The history of the injury changes significantly over time.
A history of self-inflicted trauma does not correlate with the child's developmental abilities.
There is an unexpected or unexplained delay in seeking medical care.
Multiple organ systems are injured, including injuries of various ages.
The injuries have a high specificity for child abuse.

FIGURE 22.1 Multiple looped cord marks on a 2-year-old abused child who presented to the hospital with multiple untreated burns to the back, arms, and feet.

Approximately 10% of children hospitalized with burns are victims of abuse. Thermal burns are the most common type of burn and can result from scalding injuries (Fig. 22.2) or contact with hot objects (e.g., irons, radiators, or cigarettes). Features of scald burns that are concerning for inflicted trauma include clear lines of demarcation, uniformity of burn depth, and characteristic pattern. Abusive contact burns tend to have distinct margins (branding of the hot object), while accidental contact burns tend to have less distinctive edges.

Inflicted fractures occur more commonly in infants and young children. Although diaphyseal fractures are most common in abuse, they are nonspecific for inflicted injury. Fractures that should raise suspicion for abuse include fractures that are

unexplained especially in young, nonambulatory children and/or involve multiple bones. Certain fractures have a high specificity for abuse, such as rib, classic metaphyseal, scapular, vertebral, or other unusual fractures (Fig. 22.3). Classic metaphyseal lesions (CML) are fractures through the immature metaphysis. They are sometimes referred to as corner fractures or bucket handle fractures given their appearance on radiographs. Some metabolic diseases can be confused with abuse and should be considered in the differential diagnosis when appropriate.

Abusive head trauma is the leading cause of mortality and morbidity from physical abuse. Most victims are young; infants predominate. Shaking and/or blunt impact trauma cause injuries. Caregiver intolerance of infant crying is a

common precipitator, and many prevention programs provide education on developmentally normal crying as well as coping techniques. Symptoms at the time of presentation to medical care can range from occult head trauma with no neurologic symptoms to irritability, lethargy, vomiting, seizures, apnea, and coma. Unsuspecting physicians misdiagnose approximately one third of infants initially; of these, more than 25% are reinjured before diagnosis. Subdural hemorrhage is a common intracranial injury in children with abusive head trauma (Fig. 22.4). Secondary brain injury can be due to factors such as cerebral edema, hypoxic-ischemic injury, and hypoperfusion. Retinal hemorrhages are seen in many but not all victims. Skeletal trauma, including rib and classic metaphyseal fractures, is sometimes present as well. Victims may present with bruising, but often there are no external signs of injury. Survivors are at high risk for permanent neurologic sequelae.

While abdominal injury is not as common as other forms of child physical abuse, it is associated with a high mortality rate. Abdominal trauma is therefore the second leading cause of death from child physical abuse after head injury. Blunt trauma to the abdomen is the primary mechanism of injury; infants and toddlers are the most common victims. Injuries to solid organs such as the liver or pancreas predominate, and hollow viscus injury occurs more commonly with inflicted trauma than accidental. Even in severe cases of trauma, there may be no bruising to the abdominal wall. The lack of external trauma, along with an inaccurate history, can cause delay in diagnosis. CT scan is the imaging modality of choice in most settings when abusive abdominal trauma is suspected.

The medical evaluation for physical abuse includes taking a detailed history of the events leading up to presentation, presence and timeline of abnormal symptoms, personal and family medical history including birth history and diet for young children, and child development. The physical exam should include a head-to-toe skin examination. Skin injuries to the neck and ears could be missed if these areas are not carefully examined. Attention should be paid to the frenula during the oral exam of young children.

FIGURE 22.2 A 1-year-old child brought to the hospital with a history that she sat on a hot radiator. Suspicious injuries such as this require a full medical and social investigation, including a skeletal survey to look for occult skeletal injuries and a child welfare evaluation.

FIGURE 22.3 (A) Metaphyseal fracture of the distal tibia in a 3-month-old infant admitted to the hospital with severe head injury. There also is periosteal new bone formation of that tibia, perhaps from a previous injury. (B) Follow-up radiograph 2 weeks later showed multiple healing rib fractures. This pattern of fracture is highly specific for child abuse.

FIGURE 22.4 Acute subdural hemorrhage in the posterior interhemispheric fissure in an abused infant.

Work-up for physical abuse includes evaluation for occult injury as well as medical conditions that can mimic physical abuse. Children younger than 2 years with suspected physical abuse should undergo a skeletal survey looking for occult or healing fractures. Infants presenting with extracranial injuries may have occult head trauma, and therefore neuroimaging may be indicated. Laboratory tests including aminotransferase and aspartate aminotransferase can be used to screen for occult abdominal injury. The extensive **differential diagnosis** of physical abuse depends on the type of injury (Table 22.2). For children who present with different types of specific injuries to multiple organ systems, an exhaustive search for medical diagnoses is unwarranted. Some medical conditions can be mistaken for abuse, emphasizing the need for careful, objective evaluation of all children. There is also an evidence base for medical evaluation of household contacts of physically abused children, including skeletal survey in contacts younger than 2 years as well as physical examination.

MEDICAL CHILD ABUSE

Also referred to as Munchausen syndrome by proxy, factitious disorder by proxy, and caregiver-fabricated illness in a child, this form of child maltreatment involves a child receiving unnecessary and harmful or potentially harmful medical care at the instigation of a caregiver. The newer terms proposed to replace Munchausen syndrome by proxy shift focus away from the offender to the abuse experienced by the

From Christian CW. Child abuse physical. In: Schwartz MW, ed. The 5-Minute Pediatric Consult. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2003.

child. Exaggeration, fabrication, and induction of symptoms can lead to unnecessary medical care. The former refers to a pattern of exaggerating the intensity and/or frequency of a child's symptoms. Fabrication refers to reporting illness that never occurred (e.g., providing a history of seizure symptoms in a child without these symptoms). Induction involves producing signs and symptoms (e.g., by administering medicine that was not prescribed or indicated to produce symptoms or intentionally contaminating a central line to produce infection).

Medical child abuse does not present in a singular way; presenting symptoms can involve any body system. Concerns for medical child abuse may arise when there is a pattern of symptoms only observed or reported by one caregiver, objective findings discordant from reported symptoms, and/or unusual symptoms with an unexpected clinical course. Steps in evaluating for medical child abuse include review of medical records from the different locations care has been sought, noting patterns of misreporting diagnoses or recommendations across care settings, and patterns of inappropriate utilization of care resulting in unnecessary tests and treatments. Discussion with the specialists and primary care providers involved in the child's care is another source of information. Physicians are mandated to report suspected abuse; in addition, harm and risk of harm to the child are important elements to communicate with child welfare professionals. Medical providers can collaborate to deescalate unnecessary care.

SEXUAL ABUSE

Child sexual abuse is the involvement of children in sexual activities that they cannot understand, for which they are developmentally unprepared, and thus cannot give consent. Sexual abuse can, but does not always, involve physical contact. Examples of abuse not involving physical contact are indecent exposure and deliberately exposing a child to pornography. Sexual abuse can be a single event but is often chronic. Most perpetrators are known to the child through relationships such as family member, neighbor, or member of the community. Most sexual abuse involves manipulation and coercion. Sexual abuse is more common in girls than boys, although sexual abuse of boys is underrecognized and underreported.

Children generally come to attention after they have made a disclosure of abuse, often to a nonoffending parent, sibling, relative, friend, teacher, counselor, or other professional. Children commonly delay disclosure for many weeks, months, or years. Children may also present to care with sexual behaviors that raise concern for sexual abuse. Distinguishing between developmentally normal behaviors and sexual behavior problems is a first step in the evaluation. Behaviors that involve children with an age gap (≥ 4 years), physical or emotional pain, coercion, explicit imitation of intercourse, as well as behaviors that persist despite attempts to redirect are of concern. Hypersexual behaviors are concerning but not pathognomonic for sexual abuse. Alternative considerations include exposure to sexual content or other forms of maltreatment such as neglect. Sexual abuse occasionally is recognized by the discovery of an unexplained vaginal, penile, or anal injury or by the discovery of a sexually transmitted infection. Medical providers may be asked to determine the urgency of medical evaluations. Factors that prompt emergent evaluation include ongoing contact with the alleged perpetrator as well as active physical or psychologic symptoms such as bleeding or suicidal ideation. Timing of the last possible incident of abuse is an important consideration, as there are time windows for collecting forensic evidence and administering sexually transmitted infection prophylaxis, HIV post-exposure prophylaxis, and emergency contraception.

In most cases, the diagnosis of sexual abuse is made by the history obtained from the child. In cases in which the sexual abuse has been reported to Child Protective Services (CPS) or the police (or both), and the child has been interviewed before the medical visit, a complete forensic interview at the physician's office is not needed. Many communities have systems in place including Children's Advocacy Centers to ensure quality investigative interviews of sexually abused children. However, children may make spontaneous disclosures to the physician, or physicians may evaluate patients prior to investigative interviews and require information for medical decision making. In these circumstances, open-ended and nonleading questions should be used and carefully documented in the medical record. Information about the medical review of systems, including physical symptoms (e.g., genital discharge, pain) and behavioral/emotional health (e.g., suicidal ideation, depression, sleep problems), should also be obtained from the patient and/or the caregiver, as appropriate for the child's developmental level.

The **physical examination** should be complete, with careful external inspection of the genitals and anus. Most sexually abused children have a normal genital examination at the time of the medical evaluation; injuries are diagnosed in only approximately 5% of sexually abused children. Many types of sexual abuse (fondling, vulvar coitus, oral genital contact, exhibitionism) do not injure genital tissue or do not even involve contact with the genital tissue. Genital mucosa heals so rapidly and completely that injuries often heal by the time of the medical examination. For children who present within 72 hours of the most recent assault, special attention should be given to identifying acute injury. Guidelines based on research and expert consensus can assist clinicians in differentiating normal variants or nonspecific findings from findings caused by trauma. Examples of the latter include acute, unexplained lacerations or ecchymosis of the hymen, and complete transection of the hymen. Injuries to other parts of the body such as the oral mucosa, breasts, or thighs should not be overlooked. Forensic evidence collection is also a consideration when children present acutely. Policies vary by jurisdiction. Forensic evidence collection within 72 hours of an assault that could involve transfer of forensic evidence is recommended in many states, although the time frame is longer in some states. Research showing that forensic evidence is rarely recovered from swabs collected from the bodies of prepubertal children 24 hours after assault may also influence local practice.

The **laboratory evaluation** of a sexually abused child is dictated by the child's age, history, and symptoms. Universal screening for sexually transmitted infections for prepubertal children is unnecessary because the risk of infection is low in asymptomatic young children. The type of assault, identity and known medical history of the perpetrator, and the epidemiology of sexually transmitted infections in the community also are considered. Testing methods for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* have evolved with the advent of nucleic acid amplification tests (NAAT) and the declining use of culture, with many labs no longer offering testing by culture. Local experts, such as specialists in infectious diseases and laboratory medicine, can inform protocols for confirmation of positive NAATs. The diagnosis of most sexually transmitted infections in young children requires an investigation for sexual abuse (see Chapter 116).

Commercial Sexual Exploitation of Children (CSEC)

CSEC refers to abuse or exploitation of a child for financial benefit or in exchange for something of value and includes sex trafficking as well as pornography. CSEC could lead to medical consultation for chief complaints such as injuries, sexual assault, sexually transmitted infections, pregnancy, and treatment of chronic medical conditions. It can be difficult to identify potential victims, but possible indicators include changing demographic information, a child not allowed to speak for oneself, a child accompanied by an unrelated adult, history of multiple sexually transmitted infections, tattoos concerning for branding, and signs of inflicted injury. The American Academy of Pediatrics clinical report related to CSEC provides

guidance on questions providers could ask when concerned, including “Has anyone ever asked you to have sex in exchange for something you wanted or needed?” and “Has anyone ever taken sexual pictures of you or posted such pictures on the Internet?” Health providers are mandated reporters who should comply with local reporting laws. In addition to local resources for assistance in determining procedures and resources, there is a National Human Trafficking Resource Center.

MANAGEMENT

The management of child abuse includes medical treatment for injuries and infections, and careful medical documentation of verbal statements and findings. Photographic documentation of physical examination findings can be helpful when possible. Physicians are mandated to report *suspected* child maltreatment to the appropriate authorities (Fig. 22.5). Parents should be informed of the concerns and the need to report to CPS, focusing on the need to ensure the safety and well-being of the child. Crimes that are committed against children are also investigated by law enforcement, so the police become involved in some, but not all, cases of suspected abuse. Physicians should be aware of the potential long-term impacts of maltreatment on child health. Trauma-focused cognitive-behavioral therapy has been shown to improve mental health and behavioral difficulties among children who have experienced trauma. Physicians occasionally are called to testify in court hearings regarding civil issues, such as dependency and custody, or criminal issues. Careful review of the medical records and preparation for court are needed to provide an educated, unbiased account of the child's medical condition and diagnoses.

Medical providers play a role in preventing child abuse and its consequences through interventions and referrals that strengthen and educate families, recognition of abuse and mandated reporting, as well as through trauma-informed management of children who have experienced child maltreatment. Abusive head trauma prevention programs consisting of education about the dangers of shaking and strategies to cope with crying are mandated to occur during birth hospital admissions in some states. Programs to address psychosocial factors through provider training and caregiver screening with response to identified needs have shown a reduction in child maltreatment concerns in urban primary care settings. Visiting home nursing programs that begin during pregnancy and continue through early childhood can reduce the risk of abuse and neglect.

Physicians can advocate for individual patients and families, as well as for community prevention programs. Ultimately, physicians need to remain cognizant of the diagnosis, aware of their professional mandates, and willing to advocate on behalf of these vulnerable patients.

PEARLS FOR PRACTITIONERS

See *Psychosocial Issues: Pearls for Practitioners* at the end of this section.

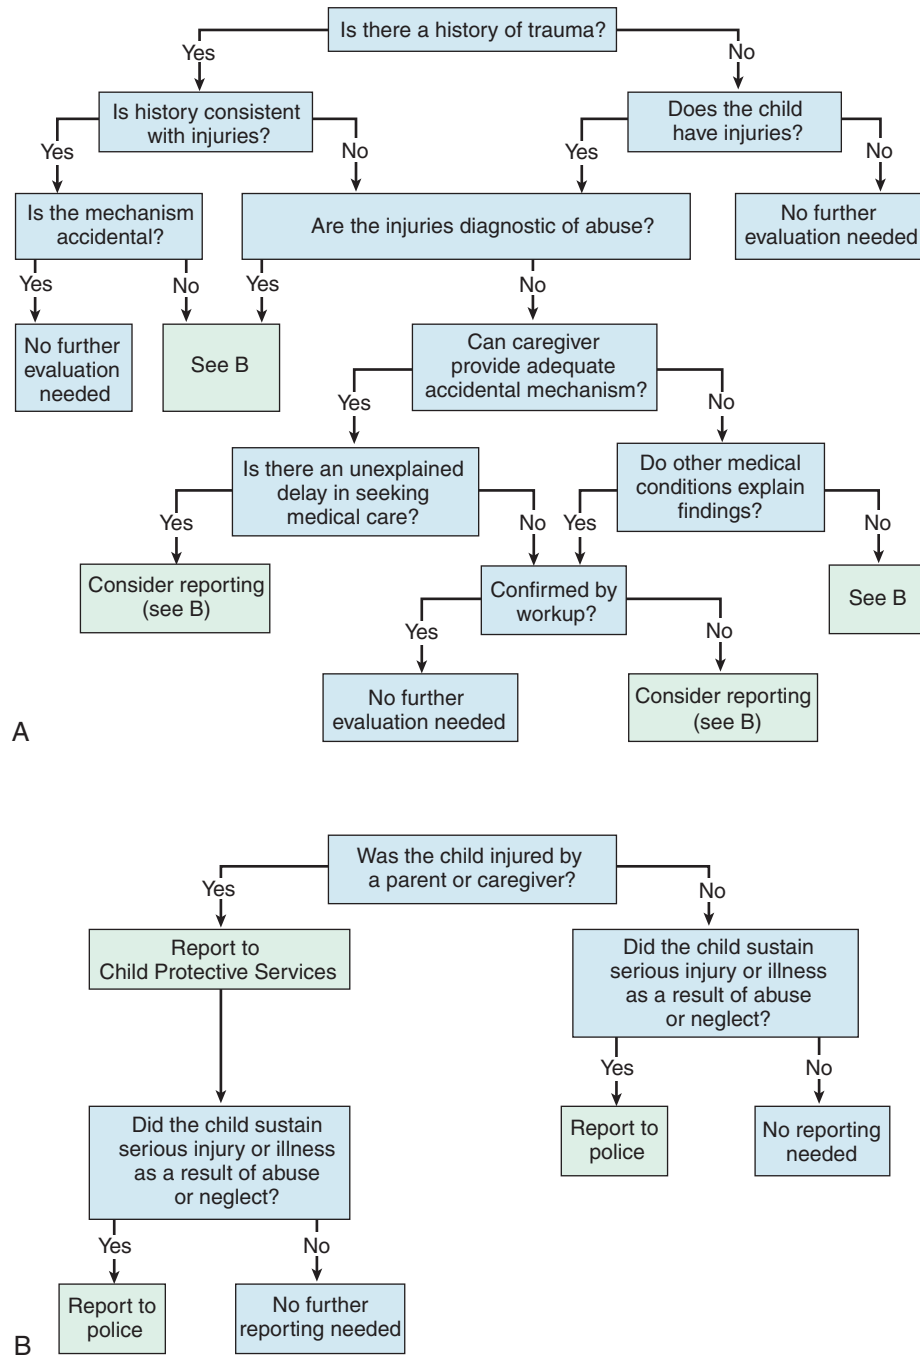

FIGURE 22.5 (A) Approach to initiating the civil and criminal investigation of suspected abuse. (B) Reporting to Child Protective Services (CPS), law enforcement, or both in child abuse cases. CPS reports are required when a child is injured by a parent, by an adult acting as a parent, or by a caregiver of the child. The police investigate crimes against children committed by any person, including parents or other caregivers. (From Christian CW. Child abuse. In: Schwartz MW, ed. *Clinical Handbook of Pediatrics*. 3rd ed. Baltimore: Lippincott Williams & Wilkins; 2003:192–193.)

CHAPTER 23

Sexuality and Gender Identity

The development of sexuality occurs throughout a child's life. Sexuality includes the interplay of gender roles, gender identity, sexual orientation, and sexual behaviors. It is influenced

by biologic and social factors, as well as individual experience. Pediatricians are likely to be consulted if parents have a concern about their child's sexual development or behavior. A pediatrician who provides an open and nonjudgmental environment will also be a valuable resource for an adolescent with questions about sexual behaviors, sexual orientation, and/or gender identity ([Table 23.1](#)).

TABLE 23.1 Gender Terminology

Gender identity
Internal sense of one's self as male, female, some of both, or neither
Cisgender
An individual whose gender identity and expression aligns with the sex assigned at birth
Transgender
An individual whose gender identity and expression is not consistent with the sex assigned at birth
Gender expansive
Individuals whose gender identity and expression extend beyond the binary gender system including those who identify as nonbinary, agender, and genderfluid
Gender expression
Behaviors and appearance used to communicate one's gender identity

DEVELOPMENT OF SEXUALITY

Sexual development begins early on in childhood. Often, parents express concern when their male infant has an erection or when their child touches the genitals during diaper changes or bathing. During the preschool period, masturbation occurs in both sexes. Reassurance is critical as these behaviors are part of typical child development and represent normal exploration of the body and should not be treated punitively. However, it is important for children by age 3 years to learn the proper anatomic names for their body parts and that genitals and sexual behaviors are private. Although it is common for pre-elementary age children to touch their genitals in public, show their genitals to others, or “play doctor,” it would be highly unusual for a child at that age to imitate intercourse or other adult sexual behaviors. If this behavior is occurring, the child should be evaluated for exposure to inappropriate sexual material and possible sexual abuse (see [Chapter 22](#)).

Children in elementary school are typically intrigued by the topics of pregnancy, birth and gender roles, and often will begin to preferentially play with children of the same gender. Their curiosity and inquiries should be met with accurate information and limited judgment so that future questions will be directed to reliable resources and not answered by peers and the media.

The biologic, social, and cognitive changes that occur during adolescence place a focus on sexuality. Puberty can be both scary and exciting. One of the principal developmental tasks of this period is to become comfortable with one's own sexuality, and this is often achieved through questioning and experimentation. Some teenagers may try out different sexual practices, including those with members of the same sex, as they explore their own emerging sexuality; almost half of high school students report ever having had sexual intercourse. The nature of these experiences does not necessarily predict sexual orientation, and similarly, stereotypical masculine and feminine traits do not predict sexual orientation either.

SEXUAL ORIENTATION

Sexual orientation, the pattern of physical and emotional arousal toward another person, is not always the same as sexual behavior. Typically, an individual's sexual orientation emerges before or early in adolescence. Although many adolescents have sexual experiences with a same-sex partner (10–25%, more often reported by males than females), fewer will affirm LGBTQ (lesbian, gay, bisexual, transgender, queer) orientation by late adolescence. By 18 years of age, most individuals endorse certainty around their sexual orientation.

There is no reliable way to predict an individual's sexual orientation. Identical twins (even twins raised in separate families) show a higher concordance rate for sexual orientation than would be expected by chance alone, but nowhere near 100%, as would be expected if genetics were the sole determinant. Attempts to correlate brain imaging or levels of androgens and estrogens with sexual orientation have thus far been inconsistent. Although it is well established that parents tend to treat boys and girls differently, there is no evidence that parental behavior alters the developmental trajectory toward sexual orientation.

Classic definitions of heterosexuality, homosexuality, and bisexuality do not account for the complex interplay of sexual identity, behaviors, and attraction. It is important that pediatricians use gender-neutral terms to promote an environment of inclusivity and to appropriately counsel based on sexual behaviors and not solely on sexual orientation. LGBTQ children and adolescents face stigmatization derived from homophobia and heterosexism, ostracism, and family rejection. A persistent negative societal attitude toward LGBTQ individuals is reflected in higher rates of social isolation, verbal harassment, and physical assault experienced by sexual minority youth. Additionally, educational and unbiased LGBTQ information is often not available in school and community settings where homophobic jokes, teasing, and violence are common. Not surprisingly, sexual minority youth are at high risk for having negative self-esteem, mental health issues, substance abuse, and sexual risk-taking behaviors. Sexual minority youth were more than twice as likely to report considering suicide than their heterosexual peers, and rates of legal and illegal substance abuse are significantly higher.

There are also significant health disparities for sexual minority youth related to sexual health outcomes. Although sexual behaviors, not sexual orientation, determine risk of sexually transmitted infections (STI), sexual minority youth are more likely to have intercourse at a younger age, less likely to use contraception, and report a greater number of sexual partners compared to heterosexual peers. Rates of STI in the minority group of men who have sex with men (MSM) have not declined along with the downward trend of STI in adolescents overall, including rates of HIV. Although education about safe sexual practices should be part of all adolescent well-child visits, the Centers for Disease Control and Prevention (CDC) guidelines recommend asking about the gender of all sex partners as part of STI risk assessment. Health care providers should be aware of specific STI screening recommendations for MSM related to anal intercourse (see [Chapter 116](#)). Many adolescents who identify as women who have sex with women (WSW) have also had sex with men and require cervical cancer screening per guidelines. Immunization for human papillomavirus per CDC guidelines is recommended for adolescents regardless of gender or sexual behavior. Additionally,

discussions around highly effective birth control methods are prudent with both heterosexual and sexual minority youth.

Acknowledging that one is LGBTQ and disclosing it to one's parents is often extremely stressful. Although many parents are supportive of their child's sexual orientation, some parents, particularly those who view this behavior as immoral, may reject their child. Adolescents should be counseled that even parents whose initial reaction is one of shock, fear, or grief can come to accept their child's sexuality. LGBTQ youth are at a high risk for homelessness following parental rejection. Interventions designed to change sexual orientation are strongly opposed and are not only unsuccessful but can be detrimental to the mental health of the child or adolescent. Health care providers should provide reassurance to parents feeling guilt or shame by affirming that sexual minority youth are normal and sexual orientation is not related to parenting practices. Evidence supports improved health outcomes for sexual minority youth who experience family connectedness and receive encouragement and positive support for their sexual orientation from their parents. For medical and psychosocial reasons, health care providers need to provide an environment in which adolescents feel comfortable discussing their sexual orientation and families can find the support and resources they need (Table 23.2).

TABLE 23.2 Providing Supportive Health Care Environments for Sexual Minority Youth

Offices should be welcoming to all, regardless of sexual orientation and behavior.

Ensure that office staff and information-gathering forms do not presume heterosexuality of patients or parents (i.e., use gender-neutral language).

All adolescents should have a confidential adolescent psychosocial history including screening and referral for depression, suicidality, other mood disorders, substance abuse, and eating disorders.

Adolescents should have sexual behaviors and risks assessed, with particular attention to sexually transmitted infections testing guidelines affecting sexual minority youths. This should include contraceptive counseling.

Target behavioral interventions to maximize the individual's strengths and resources and minimize risk-taking behaviors.

Be available to answer questions, correct misinformation, and reinforce that minority sexual orientations are normal.

Support and affirm transgender youth and refer as appropriate.

Support parents in working through adjustment issues related to having a child with a minority sexual orientation and encouraging the commitment to a loving and supportive family environment.

Support gay-straight alliances at schools and zero-tolerance policies for bullying and violence.

Provide information about support groups and resources for sexual minority youth and their families.

If a health care provider does not feel competent to provide appropriate care for sexual minority youth, this person has the responsibility to evaluate and refer families for medically appropriate care.

Data from Levine DA. Committee on adolescence. Office-based care for lesbian, gay, bisexual, transgender, and questioning youth. *Pediatrics*. 2013;132(1):198–203.

DEVELOPMENT OF GENDER IDENTITY

Developing an awareness and appreciation for one's gender identity is an important milestone in psychosocial development. Typically, a child can identify oneself as a boy or a girl by 3 years of age and begins to demonstrate initial expressions of gender identity. Gender atypical behavior is common in young children and may be part of typical development. However, gender constancy, the understanding that one is always a male or always a female, is typically achieved by age 6 years.

Most elementary school-age children show a strong and consistent **gender identity**, and their behaviors (**gender roles**) reflect this. If a child this age is demonstrating gender role confusion such as engaging in cross gender role behaviors or playing with toys that are stereotypically associated with the opposite gender, parents may be concerned about teasing/bullying or about the child's eventual sexual orientation. In assessing parental concerns, the type of behavior exhibited and its consistency and persistence over time should be considered. Reassurance is appropriate when gender non-conformity is part of a flexible repertoire of male and female gender roles or in response to a stressor, such as the birth of an infant of the opposite sex or divorce of the parents. In contrast, stating the desire to be, or asserting that one is, of the opposite gender, and demanding clothing, hairstyles, privileges, and/or to be called a name classically used for the opposite gender, is uncommon. A referral for evaluation for **gender dysphoria** is appropriate when a nearly exclusive preference for cross-gender roles in play, playmates, and games/activities stereotypically associated with the opposite gender combines with a dislike of one's sexual anatomy and a desire to be of the other gender, have matching physical sex characteristics, is distressing, impedes functioning, and persists beyond a period of 6 months.

GENDER DYSPHORIA

Gender dysphoria (GD) is defined as marked distress related to the inconsistency between the way an individual may feel and think of oneself (experienced/expressed gender) and the individual's physical or assigned gender. GD represents a revision of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) diagnosis of gender identity disorder and embodies an effort to remove the stigmatizing impact of the term *disorder* while maintaining a diagnosis in DSM-V to ensure insurance coverage for medical interventions. According to DSM-V, in children, GD is 2–4.5 times more common among natal boys than among natal girls. By adolescence, the male:female ratio is closer to even. There are some associations between gender atypical behavior in young children and the ultimate development of same-sex attraction; many children with GD grow up to be adults who identify as LGBTQ.

In contrast, the term *transgender* refers to an individual that does not conform to the culturally derived gender role for the sex assigned at birth. A person can have gender dysphoria, a medical diagnosis, without being considered transgender. The majority of children with GD will not identify as transgender during adolescence and adulthood. There are data to support that children with GD who demonstrate more insistence in affirming their gender identity, use more declarative language, and are more significantly distressed by their body may be more likely to identify as transgender in adolescence or adulthood.

Transgender youth are often faced with rejection from their community and family, leading to rates of depression, anxiety, and suicidality that greatly exceed those in the general population. Allowing social transitions for prepubescent transgender children may be linked to improved mental health outcomes. This involves family acceptance and allows the child to present in all aspects as the gender role that aligns with the child's gender identity and not the gender assigned at birth. In 2018, the American Academy of Pediatrics confirmed a commitment to gender-affirmative care comprising developmentally appropriate support for the child's gender experience. The Endocrine Society issued an update to its Clinical Practice Guideline in 2017 recommending treatment of gender-dysphoric/gender-incongruent adolescents who have entered puberty at Tanner stage G2/B2 by suppression with gonadotropin-releasing hormone agonists following a comprehensive evaluation to confirm the diagnosis and capacity for informed consent. Specialty centers with multidisciplinary teams now exist across the country to address the many needs of transgender children and their families.

PEARLS FOR PRACTITIONERS

See Psychosocial Issues: Pearls for Practitioners at the end of this section.

CHAPTER 24

Family Structure and Function

A family is a dynamic system of interactions among biologically, socially, or legally related individuals. As such, families have a unique power to influence health and development. When a family functions well, interactions support the physical and emotional needs of all members and the family can serve as a valuable resource for any individual member in need. Alternatively, the problems of an individual member or the negative interactions between members may interfere with the ability of the family system to satisfy the physical and emotional needs of members, and, ultimately, lead to physical and/or emotional harm. The consequence of a social practice or behavior pattern that undermines the stability of a family unit is referred to as **family dysfunction**.

FAMILY FUNCTIONS

The functions that families carry out in support of their children can be considered within the broad categories of physical needs, emotional support, education, and socialization (Table 24.1). Within these groupings, all families have strengths and weaknesses. The amount of support that an individual child needs in each domain varies with the child's developmental level, personality, temperament, health status, experiences, and stressors. In a healthy family, parents can be counted on to provide consistent and appropriate support for their children. Either too much or too little support can interfere with optimal child health and development. In the case of child neglect, the family underfunctions, providing inappropriate or inadequate support for the child's basic needs. Further, the violation

of basic boundaries of appropriate behavior and infringement on safety is considered child abuse. In contrast, a family that overfunctions may limit a child's opportunity for growth and development of independence skills, creating feelings of helplessness and inadequacy. Parental anxiety and perfectionism create intense pressure on children around achievement and sets them up to become anxious and fearful themselves.

Most families have periods of time where functioning is compromised by stressful circumstances (e.g., serious illness, financial difficulties). Healthy families tend to resume normal functioning once the crisis resolves.

FAMILY STRUCTURE

The traditional "nuclear" family consists of a pair of adults (typically married) and their biological and/or adoptive children. The diversity in the structure of the family in the United States has increased dramatically since 1965; today only one third of Americans live in this type of family. Children may live with unmarried parents, single parents of any gender, a parent and a stepparent, grandparents, parents living as an LGBTQ (lesbian, gay, bisexual, transgender, queer) couple, or foster care families. There is little evidence that family structure alone is a significant predictor of child health or development. Regardless of family structure, the best predictor of secure child health and development is the presence of a loving adult or adults serving in a parental role committed to fulfilling a child's basic needs. Stressful life experiences can test a family's ability to promote optimal developmental outcomes, and different family structures face different challenges.

Single-Parent Families

At any one time, approximately a third of children in the United States are living with an unmarried parent; more than 40% of

children are born to unmarried mothers. In some instances, a child is born to a single mother by choice, but often the child is the result of an unplanned pregnancy. Children may also live in single-parent families as the result of divorce or the death of a parent (see Chapter 26). The majority of children in single-parent households are raised by mothers (81%), although the number of solo father households is steadily increasing.

Single parents may have limited financial resources and social supports. For single-mother households, the median income is only 40% of the income in two-parent families; for single-father households, it is only 60% of the income of two-parent families. Thus the frequency of children living in poverty is three to five times higher in single-parent families. These parents must also rely to a greater extent on other adults for child care. Although these adults may be sources of support for the single parent, they also may criticize the parent, decreasing confidence in parenting skills. Fatigue associated with working and raising a child independently contributes to parenting difficulties. Single parents are likely to have less time for a social life or other activities, intensifying feelings of isolation and negatively impacting mental health. When the increased burdens of single parenting are associated with exhaustion, isolation, and depression, the evolution of developmental and behavioral problems in the child is more likely.

In the case of a teenage mother in the role of single parent, challenges associated with parenting may be even more impactful (see Section 12). Being a teenage parent is associated with lower educational attainment, lower paying jobs without much opportunity for autonomy or advancement, and lower self-esteem. Teenage mothers are even less likely than adult single mothers to receive any support from the child's father. Children of adolescent mothers are at high risk for cognitive delays, behavioral problems, and difficulties in school. Referral to early intervention services or Head Start programs is imperative in these situations.

When a single parent has adequate social supports, is able to collaborate well with other care providers, and has sufficient financial resources, this parent is likely to be successful in raising a child. Pediatricians can improve parental self-esteem through education about child development and behavior, validation of good parenting strategies, positive feedback for compliance, and demonstrating confidence in them as parents. Demonstrating empathy and acknowledging difficulties faced by single parents can have a healing effect or help a parent feel comfortable to share concerns suggesting the need for a referral to other professionals.

Children Living with LGBTQ Parents

Children living with LGBTQ parents may encompass many possible family structures. Many children with an LGBTQ parent were conceived in the context of a heterosexual relationship. Additionally, single LGBTQ parents, as well as LGBTQ couples, become parents through adoption, donor insemination, or surrogacy. There are an estimated 2–4 million children living in LGBTQ families in the United States.

LGBTQ parents and their children face unique challenges. Many states do not afford joint parenting rights to the non-biological, non-adoptive parent. This can impact employer benefits, medical decision-making, tax filing, and the right to custody in the event of death of the legally recognized parent. Same-sex parents may worry about how to explain family

makeup and relationship status to the child, child's friends, teachers, and medical providers. Children of LGBTQ parents may experience bullying and discrimination in school and peer groups. They may also refrain from telling their parents to "protect" them from pain.

Evidence suggests that having an LGBTQ parent does not cause increased problems in the parent-child relationship or impair the child's social-emotional development. Gender and gender role behaviors are typical for the child's age. In 2013, the American Academy of Pediatrics issued a revised policy statement on marriage equality that concluded "children's well-being is affected much more by their relationships with their parents, their parents' sense of competence and security, and the presence of social and economic support for the family than by the gender or the sexual orientation of their parents."

Adoption

Adoption is a legal and social process that provides full family membership to a child not born to the adoptive parents. According to the U.S. Department of Health and Human Services, more than 61,000 children and youth were adopted in 2018. A large proportion of legal and informal adoptions are by stepparents or relatives of the child. Most adoptions in the United States involve U.S. parents adopting U.S. children, but shifting cultural trends have increased the diversity in the ways in which adoptions occur (e.g., international adoptions, single-parent adoptions, privately arranged adoptions, and the use of a surrogate parent). These types of adoption each raise unique issues for families and health care providers. *Open adoptions* in which the biological parents and birth parents agree to interact are increasing in frequency and create new issues for the adoption triad (biological parent, adoptive parent, and child).

Pediatricians are in an ideal position to help adoptive parents obtain and evaluate medical information, consider the unique medical needs of the adopted child, and provide a source of advice and counseling from the preadoption period through the issues that may arise when the child is an adolescent. A *preadoption visit* may allow discussion of medical information that prospective parents have received about the child and identify important missing information such as the medical history of the biological family and the educational and social history of the biological parents. The preadoption period is the time that families are most likely to be able to obtain this information. Depending on the preadoption history, there may be risks of infections, in utero substance exposure, poor nutrition, or inadequate infant care that should be discussed with adoptive parents.

When the adopted child is first seen, screening for medical disorders beyond the typical age-appropriate screening tests should be considered. If the child has not had the standard newborn screening tests, the pediatrician may need to obtain these tests. Documented immunizations should be reviewed and, if needed, a plan developed to complete the needed immunizations (see Chapter 94). Children may be at high risk for infection based on the biological mother's social history or the country from which the child was adopted, including infection with human immunodeficiency virus, hepatitis B, cytomegalovirus, tuberculosis, syphilis, and parasites. A complete blood count may be needed to screen for iron deficiency.

A knowledgeable pediatrician can be a valuable source of support and advice about psychosocial issues. The pediatrician should help the adoptive parents think about how they will raise the child while helping the child understand the facts of being adopted. Neither denial of nor intense focus on the adoption is healthy. Parents should use the term *adoption* around their children during the toddler years and explain the simplest facts first. Children's questions should be answered honestly. Parents should expect the same or similar questions repeatedly, and that the preschool child's cognitive limitations make it likely the child will not fully understand the meaning of adoption. As children get older, they may have fantasies of being reunited with their biological parents, and there may be new challenges as the child begins to interact more with individuals outside of the family. Families may want advice about difficulties created by school assignments such as creating a genealogical chart or teasing by peers. During the teenage years, the child may have questions about self-identity and a desire to find the biological parents. Adoptive parents may need reassurance that these desires do not represent rejection of the adoptive family but the child's desire to understand more about one's life. In general, adopted adolescents should be supported in efforts to learn about their past, but most experts recommend encouraging children to wait until late adolescence before deciding to search actively for the biological parents.

Although adopted children have a higher rate of school, learning, and behavioral problems, much of this increase is likely to be related to biologic and social influences before the adoption. The pediatrician can play an important role in helping families distinguish developmental and behavioral variations from problems that may require recommendations for early intervention, counseling, or other services.

Foster Care

Foster care is a means of providing protection for children who require out-of-home placement, most commonly because of homelessness, parental inability to care for the child, parental substance abuse, or child abuse or neglect. From the late 1990s through 2005, over half a million children were in foster care, but between 2005 and 2010, the number of children living in foster care decreased by about 20%. These decreases were associated with changes in federal and state policies that have emphasized shortened stays in foster care, promoted more rapid adoptions, and expanded efforts to support troubled families. In 2018, 56% of the children who left foster care were reunited with their families or placed in kinship care (living with a relative); 25% were adopted.

Children and youth in foster care are at extremely high risk for medical, nutritional, developmental, behavioral, and mental health problems. At the time of placement in foster care, most of these children have received incomplete medical care and have had multiple adverse childhood experiences. Comprehensive assessments at the time of placement reveal many untreated acute medical problems, and nearly half of the children have a chronic illness. Developmental delays and serious behavioral or emotional disorders are common.

Ideally foster care provides a healing service for these children and families, leading to reunification or adoption. Too often children experience multiple changes in placement

within the foster care system, further exacerbating the problems foster children may have in forming a secure relationship with adult caregivers. Children may manifest this difficulty by resisting foster parents' attempts to develop a close relationship. This detachment may be difficult for the foster parent to endure, which may perpetuate a cycle of placement failures. The trauma or neglect experienced that led to the need for foster care in combination with instability of placements causes enduring long-term difficulties. Foster care alumni report rates of anxiety disorders, depression, substance abuse, and post-traumatic stress disorder that are two to six times higher than in the general population. Furthermore, although the *protections* of the foster care system often end at 18 years of age, these adolescents rarely have the skills and maturity needed to allow them to be successful living independently. The Fostering Connections to Success and Increasing Adoptions Act of 2008 mandates that effective transition to adulthood planning be done with youth in foster care. However, approximately 25% of the almost 18,000 youths aging out of foster care in 2018 did not have a high school diploma or GED.

The challenges for the foster care system are significant. However, when children are placed with competent and nurturing foster parents and provided coordinated care from skilled professionals, significant improvements in a child's health status, development, and academic achievement usually occur.

FAMILY DYSFUNCTION: PHYSICAL NEEDS

Failure to meet a child's physical needs for protection or nutrition results in some of the most severe forms of family dysfunction (see [Chapters 21 and 22](#)). There are many other ways in which parental behaviors can interfere with a child having a healthy and safe environment, such as prenatal and postnatal substance abuse. Prenatal use of alcohol can damage the fetus resulting in **fetal alcohol spectrum disorders (FASD)**. At the most severe end of the spectrum, this teratogen causes **fetal alcohol syndrome (FAS)**, characterized by in utero and postnatal growth retardation, microcephaly, intellectual disability, and a characteristic dysmorphic facial appearance. Other manifestations of FASD include birth defects and problems with coordination, attention, hyperactivity, impulsivity, learning, or behavior. Children with these difficulties may be diagnosed with *alcohol-related neurodevelopmental disorder*, *alcohol-related birth defects*, or *partial FAS*.

Other substances also may affect the fetus, but investigation of these effects is complicated by the fact that often more than one substance is used and nutrition and prenatal care are not optimal. Cigarette smoking during pregnancy is associated with lower birthweight and increased child behavioral problems. Use of cocaine in the perinatal period has been associated with prematurity, intracranial hemorrhages, and abruptio placentae. Exposure to opiates in utero can result in prematurity and neonatal withdrawal syndrome. Investigations of the effects of cocaine and opiates on cognitive development have produced mixed results.

Parental substance abuse after the child's birth is associated with increased family conflict, decreased organization, increased isolation, and increased family stress related to marital and work problems. Family violence may be more frequent. Despite the fact that these parents often have difficulty providing discipline and structure, they may expect their

children to be competent at a variety of tasks at a younger age than non-substance-abusing parents. This sets the children up for failure and contributes to increased rates of depression, anxiety, and low self-esteem. The parents' more accepting attitude toward alcohol and drugs seems to increase the chance that their children will use substances during adolescence.

Parents also may expose children directly to the harmful effects of other substances, such as exposure to *second-hand cigarette smoke*, which is consistently associated with increased rates of childhood respiratory illnesses, otitis media, and sudden infant death syndrome. Despite these effects, only a few parents restrict smoking in their homes. Failing to immunize children, to childproof the home adequately, and to provide adequate supervision are other examples of the many ways in which parents may not physically protect their children.

Parents' attempts to provide too much protection for their child also can cause problems. One example of this is the **vulnerable child syndrome**, in which a child who is ill early in life continues to be viewed as vulnerable by the parents despite the child's full recovery. Behavioral difficulties may result if parents are overindulgent and fail to set limits. Parental reluctance to leave the child may contribute to the child's separation anxiety. Parents may be particularly attentive to minor variations in bodily functions, leading them to seek excess medical care. If the physician does not recognize this situation, the child may be exposed to unnecessary medical procedures.

FAMILY DYSFUNCTION: EMOTIONAL SUPPORT, EDUCATION, AND SOCIALIZATION

Failure to meet a child's emotional or educational needs can have a severe and enduring negative impact on child development and behavior. Infants need a consistent adult who learns to understand their signals and meets the infant's needs for attention as well as food. As the adult caregiver learns these signals, the caregiver responds more rapidly and appropriately to the infant's attempts at communication. Through this process, often referred to as **attachment**, the special relationship between parent and child develops. When affectionate and responsive adults are not consistently available, infants often are less willing to explore the environment and may become unusually clingy, angry, or difficult to comfort.

Appropriate stimulation is vital for a child's cognitive development. Children whose parents do not read to them and do not play developmentally appropriate games with them have lower scores on intelligence tests and more school problems. In these situations, early intervention has been shown to be particularly effective in improving skill development and subsequent school performance. At the other extreme, there are increasing concerns that some parents may provide too much stimulation and scheduling of the child's day. There may be such emphasis on achievement that children come to feel that parental love is contingent on achievement. There are concerns that this narrow definition of success may contribute to problems with anxiety and self-esteem for some children.

PEARLS FOR PRACTITIONERS

See *Psychosocial Issues: Pearls for Practitioners* at the end of this section.

CHAPTER 25

Violence

The National Survey of Children's Exposure to Violence found that close to two thirds of children experienced at least one self- or parent-reported direct exposure to violence in the preceding year. Violence is an important individual and public health concern given its prevalence and impact on well-being. The landmark Adverse Childhood Experiences (ACE) study conducted in the 1990s demonstrated a graded relationship between ACE and negative health outcomes later in life. Child abuse (see [Chapter 22](#)) and witnessing domestic violence were among the forms of violence included in the original ACE study. Subsequent research on ACE demonstrated an association between negative adult health outcomes and additional forms of violence such as witnessing violence, unsafe neighborhoods, and bullying. Importantly, research has also shown that positive childhood experiences can mitigate health outcomes associated with ACE. A Benevolent Childhood Experiences (BCE) scale was developed to assess positive childhood experiences and includes having a safe caregiver, a good friend, positive school experiences, a supportive adult, and routines at home. Therefore it is important to prevent violence, provide timely identification and treatment for violence-related problems, and promote factors associated with resiliency. Physical and sexual abuse were discussed in [Chapter 22](#), and additional types of violence are reviewed in this chapter. Perpetration of violence by youth is also addressed.

INTIMATE PARTNER VIOLENCE AND CHILDREN

Intimate partner violence (IPV) is abuse occurring in a relationship with a current or former intimate partner and can involve physical violence, sexual violence, threats, stalking, and/or psychologic abuse including humiliation, controlling, social isolation, and deprivation. Although IPV often occurs between male perpetrators and female victims in heterosexual relationships, males can also experience IPV. It also occurs in LGBTQ relationships.

Violence may escalate during the perinatal period. IPV in parent relationships affects children. Youth can also experience teen dating violence.

Regarding IPV in caregiver relationships, children experience IPV by seeing or hearing the violence and its aftermath. Children may be injured during violent outbursts, sometimes while attempting to intervene. Children may also be victims of abuse themselves. It is estimated that there is at least a 50% concurrence rate between IPV and child abuse. Exposure to IPV can also impact child development, emotional health, and behavior. Children may have symptoms of **post-traumatic stress disorder**, depression, anxiety, aggression, or hypervigilance. Older children may have conduct disorders, poor school performance, low self-esteem, or other nonspecific behaviors. Infants and young toddlers are at risk for disrupted attachment and routines around eating and sleeping. Preschoolers may show signs of regression, irritable behavior, or temper tantrums. School-age children may show both externalizing (aggressive or disruptive) and internalizing (withdrawn and passive) behaviors. Because of family isolation, some children

have no opportunity to participate in extracurricular activities at school and do not form friendships. Adolescents in homes where IPV is present have higher rates of school failure, substance abuse, and risky sexual behaviors. These adolescents are more likely than their peers to enter into a violent dating relationship.

The American Academy of Pediatrics endorses screening for IPV in the pediatric setting. While less than a quarter of women who reported injuries from IPV sought medical care for themselves, almost all sought well care for their children. Without standardized screening, pediatricians may underestimate the IPV prevalence in their practices. Parents should not be screened together. Questions about family violence should be direct, nonjudgmental, and done in the context of child safety and anticipatory guidance. Standardized IPV screening tools include Hurt, Insult, Threaten and Scream (HITS), Woman Abuse Screening Tool (WAST), and the Partner Violence Screen.

When caregivers disclose IPV, interventions can include showing support and providing available community resources. It is important to assess the safety of the victim and the children. In some states, physicians are mandated to report IPV. In addition to local resources, the National Domestic Violence Hotline can be reached by phone (1-800-799-7233), web (www.thehotline.org), or text (22522).

DATING VIOLENCE AND DATE RAPE

Teen dating violence includes physical violence, sexual violence, stalking, and/or psychological abuse (such as name calling, shaming, controlling). Violence can also occur online (e.g., if the perpetrator posts intimate photos, messages constantly to check up, and/or asks for passwords as a way to monitor and control communications). The 2013 National Youth Risk Behavior Survey found that 21% of female and 10% of male students who dated experienced some form of dating violence. Risk factors for dating violence include initiating dating and sexual activity at an early age, prior sexual abuse or victimization, and belief that dating violence is acceptable. Risk factors for perpetrating dating violence include witnessing or experiencing violence in the home, early initiation of sexual activity, and depression or anxiety. Substance use is also a risk factor for harming a partner; alcohol, marijuana, and cocaine may contribute. Flunitrazepam (Rohypnol) and γ -hydroxybutyrate are two commonly implicated drugs that cause sedation and amnesia, especially when used in conjunction with alcohol. Mental health impacts of dating violence can include depression, anxiety, and suicidality. Dating violence can increase the likelihood of unhealthy behaviors such as smoking and substance abuse. It can also have a negative impact on educational outcomes. Experiencing intimate partner violence as a teen can increase risk for victimization later in life.

Medical management for acute sexual assault is detailed in [Chapter 22](#). However, relatively few victims of date rape report the assault to law enforcement, and this can decrease the likelihood of timely medical care. It is likely that many sexually assaulted adolescents do not receive medical attention, putting them at risk for physical and mental health consequences. Health care providers can also intervene by screening for adolescent dating violence, counseling about risk factors such as substance abuse, providing routine sexually transmitted infection evaluation, and identifying counseling resources for

teens who are victims or perpetrators of dating violence (see [Chapter 116](#)). [Loveisrespect.org](http://loveisrespect.org) is a project of the National Domestic Violence Hotline focused on preventing and ending abusive relationships among young people; their services include 24/7 support for youth experiencing violence or persons concerned about youth via phone (1-866-331-9474), text, or chat (www.loveisrespect.org). Another resource for teen dating violence prevention is the Centers for Disease Control and Prevention (CDC) Dating Matters, an evidenced-based curriculum for 11- to 14-year-olds to promote healthy relationship skills and decrease risky behaviors.

BULLYING

The CDC defines bullying as repeated unwanted aggressive behavior by another youth or group of youths with a power imbalance (observed or perceived). Bullying can be verbal (name calling, threats), social (spreading rumors, excluding on purpose), or physical (damaging belongings, hitting, pushing, tripping, spitting). Bullying can also occur digitally over social media, games, texts, or apps; this is referred to as cyberbullying. Bullying is common; the 2017 Youth Risk Behavior Surveillance System indicates that 19% of students experienced bullying on school property and 15% experienced cyberbullying within the preceding 12 months. Bullying peaks in middle school. Bullied youth may experience negative physical, emotional-social, and educational outcomes such as depression, anxiety, decreased school participation, decreased academic achievement, and physical injuries. Prevention strategies include talking to children about bullying, as well as educating children and families on how they can stand up to it and how to get help. Health care providers can screen for bullying and address it by providing anticipatory guidance, helping to identify school contacts who can help, sharing knowledge of local policies, and providing community referrals. Strategies at the school level include policies and rules, education, and bullying reporting systems. National resources include stopbullying.gov.

ASSAULT

The National Survey of Children's Exposure to Violence found that a third of youth experienced a physical assault within the past year. Peers and siblings were the most common perpetrators of physical assault on youth. Other perpetrators of physical violence on youth include adults as well as groups or gangs. Assaults sometimes involve a weapon. Assaults can result in significant physical injury. Homicide is one of the leading causes of death among adolescents. Physical assaults can also have psychosocial consequences.

Bias attack refers to assault of a child because of the child's race, religion, disability, or sexual orientation. Among 14- to 17-year-olds surveyed as part of the National Survey of Children's Exposure to Violence, the lifetime prevalence of experiencing a bias attack was 5%. Bullying, discussed in the previous section, can also occur on the basis of race or gender orientation. Feeling discrimination, defined as being treated badly or unfairly because of race or ethnicity, has been included in studies aimed at expanding the ACE included in the original CDC study. Potential health consequences of discrimination include anxiety, depression, impact on educational performance, and post-traumatic stress disorder. The American Academy of Pediatrics and the National Child

Traumatic Stress Network have resources detailing the health impacts of racism and avenues for intervention.

COMMUNITY VIOLENCE

Community violence is defined as direct or indirect exposure to intentional violence in public areas. Examples include witnessing shootings, robberies, terrorist attacks, and fights. The National Survey of Children's Exposure to Violence found that 58% of youth aged 14–17 witnessed a community assault, and 13% witnessed a shooting in their lifetime. Community violence can affect psychologic, developmental, and physical health; anxiety, sleep disturbance, somatic pain, and asthma exacerbations are some health issues that could occur after witnessing violence. An example screening question for community violence is, "Has anything violent or frightening happened at school or in the neighborhood?" Anticipatory guidance for families after community violence can include encouraging parental reassurance and finding strategies to get through the crisis period, such as keeping the lights on. Pediatricians can also provide referrals to trauma-informed community resources as needed.

VIOLENCE AND TECHNOLOGY

Technology use among youths is prevalent and evolving with the development of new applications and devices. Medical providers, educators, parents, and youth should be aware of the risks for violence through technology. Cyberbullying is discussed earlier. Children can be exposed to violence on television, the Internet including social media, and videogames. Online sexual solicitation involves requests to engage in sexual activities or talk. In some cases, the solicitor attempts to contact the victim offline as well. Negative outcomes of electronic victimization include emotional distress, school absenteeism, and increased risk for in-person victimization. Anticipatory guidance for technology violence prevention includes setting rules for technology use to regulate content, location of use (i.e., common areas of the home), and amount of time spent with technology. Adults should educate children on steps to take if they are victimized, including informing a trusted adult. Children should be advised not to give out personal information online, friend strangers on social media, or meet someone known from the Internet in person without parental supervision.

YOUTH VIOLENCE, THE JUVENILE JUSTICE SYSTEM, AND HEALTH

Most violent youth begin to exhibit their delinquent behaviors during early adolescence. The prevalence of delinquent behaviors decreases in the late teens into early adulthood, and most adolescent violence ends by young adulthood. Most violent youth are only intermittently violent. A small proportion of delinquent youth commit frequent, serious crimes; these offenders are more likely to have initiated delinquent activity before puberty. Serious youth violence is not an isolated problem but usually coexists with other adolescent risk-taking behaviors, such as drug use, truancy, school dropout, and early sexual activity as well as with mental health concerns. Gang membership is an important community level factor. Often, these risk factors exist in clusters and tend to be additive. Although understanding risk factors for violence is crucial

for developing prevention strategies, the risk factors do not predict whether a particular individual will become violent. It is also important to identify protective factors, which include school connectedness as well as support of nonviolent family members and close friends.

Comparison of data from the juvenile justice system and surveys of self-reported behavior highlights that many juveniles commit chargeable offenses and are never arrested. The majority of confined youth are detained for non-violent offenses including status offenses (offenses that are illegal for minors but not adults such as truancy, runaway, or drinking), violations of probation, or drug possession. Violent crime index offenses are homicide, aggravated assault, robbery, and sexual assault. After peaking in the 1990s, the annual number of arrests of youth younger than 18 years in the United States was an estimated 728,280 in 2018. There are racial disparities including overrepresentation of black youth. Health care providers can play a role in preventing youth violence and in addressing the health care needs of youth involved in the juvenile justice system.

Youth in the juvenile justice system have high rates of unmet health needs. Physical health needs can include dental, injuries, vision, reproductive health, as well as chronic illness that went unrecognized or undertreated. There is also an increased prevalence of unmet mental health needs such as untreated substance use disorders, depression, and post-traumatic stress disorder. Pediatric health care providers can also play a role in promoting successful reentry for youth after release. Pediatricians can request prior medical records to ensure continuity of care and treatment of ongoing health needs. Pediatricians can also support academic and social needs. Finally, pediatric health care providers can play a role in preventing juvenile justice involvement by screening for and addressing risk behaviors such as substance use. Offering parenting support and community referrals is another avenue for prevention. Providers can also support protective factors; educational attainment is a key protective factor.

TRAUMA-INFORMED CARE

Providing trauma-informed medical care includes realizing the prevalence and impact of trauma, recognizing signs and symptoms of trauma, as well as responding to the medical needs of traumatized patients. Examples of trauma-related symptoms include sleep difficulties, abnormal eating patterns (e.g., hoarding food, loss of appetite), hypervigilance, anxiety, detachment, and decline in school functioning. Anticipatory guidance for caregivers of children with trauma symptoms includes explaining the relationship between symptoms and the trauma experience and reminding the caregiver not to take the behaviors personally. Examples of anticipatory guidance for specific trauma-related symptoms include developing routines for bedtime and eating, remaining calm when children act out, teaching children calming skills such as breathing exercises, as well as helping children verbalize emotions. Health care providers can also make referrals to trauma-informed mental health providers. Trauma-focused cognitive behavioral therapy has been shown to benefit children who have experienced trauma.

PEARLS FOR PRACTITIONERS

See *Psychosocial Issues: Pearls for Practitioners* at the end of this section.

CHAPTER 26

Divorce, Separation, and Bereavement

Each year more than 1 million American children experience separation from a parent due to divorce, death, and deployment. Although the context, sequence, length of separation, and advance knowledge vary across these situations, disruption of the family structure in this way may influence child development, cause stress, and contribute to long-term adverse consequences. The child's adaptation to stress is affected by the reasons for the separation and the child's age, temperament, and available support systems. Stable, responsive relationships are the predominant defense against stress-related adverse outcomes.

DIVORCE

Few events in childhood are as dramatic and challenging for the child as divorce. The most recent data suggest that just under 40% of marriages end in divorce. About half of these divorces occur in the first 10 years of marriage, so there are often young children in the family when divorce occurs. At least 25% of children experience the divorce or separation of their parents.

Divorce and the resultant family structure transition are associated with behavioral and emotional adjustments. In the immediate post-divorce period, many children exhibit anger, noncompliance, anxiety, and depression. Children from divorced families require psychologic help two to three times more frequently than children with married parents. Long-term studies suggest that, in the absence of ongoing stressors, most children demonstrate good adjustment a few years after the divorce, but some have enduring difficulties.

Divorce is not a single event, but a process that occurs over time. In most cases, marital conflict begins long before the physical or legal separation; the divorce results in permanent changes to the family structure. Divorce is often accompanied by changes in living arrangements, reductions in economic resources, and decreases in parental time and attention available to the child. These consequences further contribute to child stress and conflict.

The child's relationship with each parent is changed by divorce. In the short term, the parent is likely to experience new burdens and feelings of guilt, anger, or sadness that may disrupt parenting skills and family routines. Contact with the noncustodial parent may decline greatly. Parents may be perceived by their children as being unaware of the child's distress around the time of the divorce. Pediatricians can help parents understand how to reassure the child. Maintaining contact with both parents, seeing where the noncustodial parent is living, and, in particular, maintaining familiar routines are comforting to the child in the midst of the turmoil of a separation and divorce. The child should attend school and continue to have opportunities to interact with friends. Assistance from the extended family can be helpful, but these family members may not offer to help for fear of "interfering." Pediatricians should look for maladaptive adult coping responses and encourage parents to ask for assistance. Some parents may

respond to their increased burdens and distress by treating their children as friends with whom they share their distress. Alternatively, they may place excessive responsibilities on the child or leave the child unsupervised for long periods of time. These responses increase the chance that the child will develop behavioral or emotional problems.

Reaction to Divorce at Different Ages

The child's reaction to the divorce is influenced by the child's age and developmental level. Although infants do not react directly to the divorce, they require special considerations in relation to custody and visitation to sustain a stable daily routine and regular contact with a primary caregiver to develop secure attachment. Separations from a primary caregiver should be brief. Consequences of stress in infants and toddlers can include irritability and disturbance in sleep and feeding patterns. **Preschool children** may have magical beliefs about cause and effects and an egocentric view of the world. They may believe that something they did caused the divorce, leading them to be particularly upset. They may engage in unusual behaviors that they believe will bring the parents back together again. At this age, parents need to deliver a clear message that the divorce was related to disagreements between the parents, that nothing the child did caused the divorce, and that nothing the child could do would bring the parents back together again. Preschool children may reason that if the parents left each other they also might leave the child. To counteract this fear of abandonment, children may need to be reassured that although parents separated, they will not abandon the child and that the child's relationship with both parents will endure.

School-age children have a concrete understanding of cause and effect; if something bad happened, they understand that something caused it to happen. They are not likely to understand fully the subtleties of parental conflict or the idea that multiple factors contribute to a conflict. Children at this age may still worry that something they did caused the divorce. They may express more anger than younger children and often feel rejected. Many young school-age children worry about what will happen to one or both parents. School performance often deteriorates. Older elementary school-age children may believe that one parent was wronged by the other. This belief, in conjunction with their concrete understanding of cause and effect, allows children to be easily co-opted by one parent to take sides against the other. Parents need to understand this vulnerability and resist the temptation to support their child in taking sides.

Adolescents may respond to the divorce by acting out, developing anxiety and/or depression, or by experiencing somatic symptoms. Adolescents are developing a sense of autonomy, a sense of morality, and the capacity for intimacy, and divorce may lead them to question previously held beliefs. They may be concerned about what the divorce means for their future and whether they, too, will experience marital failure. Questioning of previous beliefs in conjunction with decreased supervision may set the stage for risk-taking behaviors, such as truancy, sexual behaviors, and alcohol or drug use.

Outcome of Divorce

One of the best predictors of children's adaptation to divorce is whether the physical separation is associated with a decrease

in the child's exposure to parental discord. In most cases, divorced parents still must interact with each other around the child's schedule, child custody and support, and other parenting issues. These types of issues create the potential for the child to have ongoing exposure to significant discord between the parents. For example, if one parent tends to keep the child up much later than the bedtime at the other parent's house, sleep problems may develop. When children feel caught in the middle of ongoing conflicts between their divorced parents, behavior or emotional problems are much more likely. Regardless of how angry parents are with each other, the parents should be counseled that they must shield their child from this animosity. Clear rules about schedules, discipline, and other parenting roles is ideal, but in cases of conflict it can also be helpful to help parents accept that they can only control their own actions and decisions related to the child. When parents have trouble resolving these issues, mediation may be helpful. Pediatricians need to be wary of parents' attempts to recruit them into custody battles to substantiate claims of poor parenting, unless the pediatrician has first-hand knowledge that the concerns are valid.

Although the primary physical residence for most children is still with the mother, the court's bias toward preferring mothers in custody decisions has decreased, and there is more emphasis on including both parents in the child's life. In the early 1980s, 50% of children had no contact with their fathers 2 or 3 years after a divorce, whereas today only 20% to 25% of children have no contact with their father. Most states now allow joint physical or legal custody. In joint physical custody, the child spends a significant amount of time with each parent, and in joint legal custody, parents share authority in decision making. Although joint custody arrangements may promote the involvement of both parents in the child's life, they also can be a vehicle through which parents continue to express their anger at each other. When parents have severe difficulty working together, joint custody is an inappropriate arrangement and has been associated with deterioration in the child's psychologic and social adjustment.

Divorce often creates financial difficulties. Family income usually declines in the first year after the divorce. Only about half of mothers who have child support awards receive the full amount, and a fourth receive no money at all. These financial changes may have multiple adverse effects on the child. A move to a new house may require the child to attend a new school, disrupting peer relationships and other potential supports. The child may spend more time in child care if one or both parents have to increase work hours.

Role of the Pediatrician

Pediatricians may be confronted with issues related to marital discord before the divorce, may be consulted around the time of the divorce, or may be involved in helping the family manage issues in the years after the divorce. The pediatrician can be an important voice in helping the parents understand and meet the child's needs (Table 26.1). Before the divorce, parents may wonder what they should tell their children. Children should be told of the parents' decision before the physical separation. The separation should be presented as a rational step in managing marital conflict and should prepare the child for the changes that will occur. Parents should be prepared to answer children's questions, and they should expect that the

TABLE 26.1 General Recommendations for Pediatricians to Help Children During Separation, Divorce, or Death of a Close Relative

Acknowledge and provide support for grief that the parent/caregiver is experiencing.
Help parent/caregiver consider child's needs and validate feelings.
Encourage parent/caregiver to maintain routines familiar to the child.
Encourage continued contact between child and friends.
If primary residence changes, the child should take transitional objects, familiar toys, and other important objects to the new residence.
Minimize frequent changes in caregivers, and for infants, keep brief the times spent away from primary caregiver.
Have parent/caregiver reassure the child about continued care.
Have parent/caregiver reassure the child that the child did not cause the separation, divorce, or death (especially important in preschool children).
Encourage parent/caregiver to create times or rituals that allow the child to discuss questions and feelings if the child wishes.
Encourage parental self-care. Ensuring that parents are addressing their own mental health needs will have a positive impact on the child's emotional well-being.

questions will be repeated over the next months. Once parents have told children of the separation, it may be confusing to the child if the parents continue to appear to live together and may raise false hopes that the parents will not divorce.

Many parents report not feeling like their life had stabilized until 2 to 3 years or more after the divorce, and for some the divorce remains a painful issue 10 years later. The child's emotional adjustment to divorce is closely predicted by the parents' adjustment, so parents should be encouraged to get help for themselves if they are struggling emotionally after a divorce. Although most children ultimately show good adjustment, some have significant acting-out behaviors or depression that requires referral to a mental health professional. Some parents need the assistance of a mediator or family therapist to help them stay focused on their child's needs. In the most contentious situations, a guardian ad litem may need to be appointed by the court. This individual is usually a lawyer or mental health professional with the power to investigate the child and family's background and relationships to make a recommendation to the court as to what would be in the best interests of the child.

SEPARATIONS FROM PARENTS

Children experience separations from their primary caregiver for a variety of reasons. Brief separations, such as those to attend school, camp, or other activities, are nearly a universal experience. Many children experience longer separations for a variety of reasons, including parental business trips, military service, or hospitalization. Child adjustment to separation is affected by child factors, such as the age of the child and the child's temperament; factors related to the separation, such as the length of and reason for the separation, whether the separation was planned or unplanned; and factors related to the caregiving environment during the separation, such as how

familiar the child is with the caregiver and whether the child has access to friends and familiar toys and routines.

Children between 6 months and 3–4 years of age often have the most difficulty adjusting to a separation from their primary caregiver. Older children have cognitive and emotional skills that help them adjust. They may be better able to understand the reason for the separation, communicate their feelings, and comprehend the passage of time, allowing them to anticipate the parent's return. For older children, the period immediately before a planned separation may be particularly difficult. In the case of military service, stress tends to be most concentrated at times of deployment and reintegration.

If parents anticipate a separation, they should explain the reason for the separation and, to the extent possible, give concrete information about when they will be in contact with the child and when they will return home. If the child can remain at home with a familiar and responsive caregiver, this is likely to help adjustment. If children cannot remain at home, they should be encouraged to take transitional objects with them, such as a favorite blanket or stuffed animal, familiar toys, and important objects such as a picture of the parent. Maintenance of familiar family routines and relationships with friends should be encouraged.

DEATH OF A PARENT OR FAMILY MEMBER AND BEREAVEMENT

Death of a close family member is a sad and difficult experience. When a child loses a parent, the situation is devastating. This experience is not rare. By 15 years of age, 4% of children in the United States experience the death of a parent. This experience is likely to alter forever the child's view of the world as a secure and safe place. Similar to the other separations, a child's cognitive development and temperament along with the available support systems affect the child's adjustment after the death of a parent. Many of the recommendations in Table 26.1 are helpful. The death of a parent or close family member also brings up some unique issues.

Explaining Death to a Child

Children's understanding of death changes with their cognitive development and experiences (see Chapter 4). Preschool children often do not view death as permanent and may have magical beliefs about what caused death. As children become older, they understand death as permanent and inevitable, but the concept that death represents the cessation of all bodily functions and has a biologic cause may not be fully appreciated until adolescence.

Death should not be hidden from the child. It should be explained in simple and honest terms that are consistent with the family's beliefs. The explanation should help the child to understand that the dead person's body stopped functioning and that the deceased person will not return. Preschool children should be reassured that nothing they did caused the individual to die. One should be prepared to answer questions about where the body is and let the child's questions help determine what information the child is prepared to hear. False or misleading information should be avoided. Comparisons of death to sleep may contribute to sleep problems in the child.

There are many possible reactions of children to the death of a parent or close relative. Sadness and a yearning to be with the

dead relative are common. Sometimes a child might express a wish to die and so visit the dead relative, but a plan or desire to commit suicide is uncommon and would need immediate evaluation. A decrease in academic functioning, lack of enjoyment with activities, and changes in appetite and sleep can occur. About half of children have their most severe symptoms about 1 month after the death, but for many the most severe symptoms in reaction to the death do not occur until 6 to 12 months after.

Should the Child Attend the Funeral?

Children often find it helpful to attend the funeral. It may help the child to understand that the death occurred and provide an opportunity to say good-bye. Seeing others express their grief and sadness may help the child to express these feelings. Going to the funeral helps prevent the child from having fears or fantasies about what happened at the funeral. If attending the funeral, the child should be informed of what will happen. If a preschool-age child expresses a desire not to attend the funeral, the child should not be encouraged to attend. For older children, it may be appropriate to encourage attendance, but a child who feels strongly about not wanting to go to the funeral should not be required to attend.

PEARLS FOR PRACTITIONERS

CHAPTER 21

Failure to Thrive

- There is no single, universally accepted anthropometric criterion for failure to thrive. Commonly used criteria include weight below the 3rd or 5th percentile for age; weight decreasing, crossing two major percentile lines on the growth chart over time; a z score below -2 ; or weight less than 80% of the median weight for the height of the child.
- Failure to thrive can be caused by inadequate intake, malabsorption, or increased metabolic demands.
- History and physical examinations to assess for biologic and psychosocial etiologies are the cornerstone of failure to thrive evaluations.

CHAPTER 22

Child Abuse and Neglect

- In every state, physicians are mandated by law to report child abuse and neglect.
- Neglect is the most common form of child maltreatment and can impact physical, mental, developmental, and behavioral health in both the short and long term.
- Bruising characteristics that raise concern for inflicted injury include patterned bruising (e.g., loop mark, slap mark), unusual location (such as ears, neck, or genitals), and bruising in nonmobile infants.
- Children with significant internal abdominal injuries may present without any external bruising.
- Abusive head trauma is the leading cause of mortality and morbidity from child physical abuse. Prevention programs often emphasize coping with crying techniques and education.
- Factors to consider when determining the urgency of medical evaluations for sexual abuse include timing of last abuse within window for forensic evidence collection per local practices; need for emergency contraception, HIV prophylaxis, and sexually transmitted infection prophylaxis; physical symptoms (bleeding, pain), psychologic symptoms (suicidal ideation); and safety concerns.

CHAPTER 23

Sexuality and Gender Identity

- There is no reliable way to predict an individual's sexual orientation and no evidence that parental behavior alters the developmental trajectory toward a particular sexual orientation.
- There are significant health disparities for sexual minority youth related to sexual health outcomes. Education about safe sexual practices should be part of all adolescent well-child visits, including asking about the gender of all sex partners as part of STI risk assessment.
- Transgender youth have rates of depression, anxiety, self-destructive choices, and suicide that greatly exceed those in the general population. Connecting with a specialty center with a multidisciplinary team to address the needs of transgender children and their families is vital.

CHAPTER 24

Family Structure and Function

- Most families have periods of time where functioning is compromised by stressful circumstances (e.g., serious illness, financial difficulties). Healthy families tend to resume normal functioning once the crisis resolves.
- Regardless of family structure and parent gender or sexual orientation, the best predictors of secure child health and psychologic development are the quality of the parent-child relationship, the quality of the relationship between adult caregivers, and the availability of social and economic resources.
- Pediatricians can improve parental self-esteem through education about child development and behavior, validation of good parenting strategies, positive feedback for compliance, and demonstrating confidence in them as parents.
- Children and adolescents in foster care are at extremely high risk for medical, nutritional, developmental, behavioral, and mental health problems.

CHAPTER 25

Violence

- Direct and/or indirect exposure to violence is prevalent among youth. Traumatic experiences impact health outcomes not only in childhood, but also into adulthood. Trauma-informed care includes recognizing and responding to signs/symptoms of trauma including hypervigilance, anxiety, sleep problems, and decline in school functioning.
- Violence through technology such as online solicitation, cyberbullying, or exposure to violent materials is a growing concern. Anticipatory guidance could include setting rules for technology use (e.g., location of use, amount of time of allowable use, social media–related rules), advising children not to give out personal information or meet someone

known from the Internet in person, and educating children on steps to take if they are bullied.

CHAPTER 26

Divorce, Separation, and Bereavement

- A child's reaction to divorce, separation from a parent, or the death of a loved one is influenced by the child's age, cognitive development, and previous experiences.
- In times of family disruption, it is important that children are assured of continued safety and care, their feelings are validated, any concerns of personal responsibility are nullified, consistency of routine is maintained, and time is appropriated for questions and open communication without punitive judgment.

PEDIATRIC NUTRITION AND NUTRITIONAL DISORDERS

April O. Buchanan | Maria L. Marquez

CHAPTER 27

Diet of the Normal Infant

Proper nutrition in infancy is essential for normal growth, resistance to infections, long-term adult health, and optimal neurologic and cognitive development. Healthy nutrition is especially important during the first 6 months, a period of exceptionally accelerated growth and high nutrient requirements relative to body weight. Infancy and early childhood may also be crucial periods for metabolic programming that may have associations with subsequent obesity or metabolic syndrome in childhood. Breast-feeding is associated with a reduced risk of many diseases in infants, children, and mothers (for more details visit <http://www.nutrition.gov>).

BREAST-FEEDING

Human milk and breast-feeding are the ideal and normative standards for infant feeding and nutrition. Human milk is recognized as the optimal feeding for all infants because of its proven health benefits to infants and their mothers. The World Health Organization (WHO), the American Academy of Pediatrics (AAP), the American College of Obstetricians and Gynecologists (ACOG), and the U.S. Preventive Services Task Force all recommend exclusive breast-feeding for the first 6 months of life. The AAP recommends human milk as the sole source of nutrition for the first 6 months of life with continued intake for the first year and as long as desired thereafter. Breast-feeding has short- and long-term advantages for infant neurodevelopment and is linked to reduced risks for many illnesses in children and mothers. Breast-feeding rates have increased in the United States, reaching the targeted initiation rate of 82% set by the goals for *Healthy People 2020*, but they remain below the target of maintaining any (target 61%) or exclusive (target 26%) breast-feeding rates at 6 months. The first 2 days of breast-feeding, and perhaps the first hours of life, may determine the success of breast-feeding.

Pediatric health care providers should approach breast-feeding at multiple levels (individual, community, social, and political) in order to increase breast-feeding initiation and maintenance. Strategies such as peer support, education, longer maternity leaves, and breast-feeding support in the hospital, workplace, and community may help more women breast-feed exclusively and for longer times. Especially important are identifying and addressing those issues that impede initiation of breast-feeding and the reasons for early

termination. A combination of prenatal and postnatal educational and support programs should provide parents with accurate information to help them make an informed decision. Early termination of breast-feeding may be associated with difficulties in breast-feeding, maternal perception that breast-feeding is not meeting the needs of the infant, and concerns that the infant had difficulty in breast-feeding or was not satisfied. In addition to mother's lack of confidence to breast-feed, other factors associated with early discontinuation of breast-feeding include return to work and maternal depression. Educational resources including a designated health educator may provide information about the benefits and possible hardships, education on manual expression of breast milk, and information and counseling about breast-feeding to supplement the clinician's role. The health insurance plan must cover the cost of a breast pump (either rental or purchase). Clinicians also play a key role in prenatal education. Measures to ensure a breast-feeding-friendly pediatric office environment include counseling and encouragement of sustained breast-feeding during postnatal visits, not distributing infant formula in the office, linking with breast-feeding support resources in the community, and monitoring breast-feeding rates in the practice. Antepartum programs are recommended as the primary educational tool. Clinicians should also evaluate the contraindications and precautions. There are only a few true contraindications to breast-feeding. [Table 27.1](#) contains the contraindications.

Comprehensive hospital practices and policies that support breast-feeding reduce medically unnecessary formula supplementation and reduce disparities in breast-feeding. In 2018, a survey of 2,045 hospitals identified early postpartum care practices, feeding practices, education and support of mothers and caregivers, staff and provider responsibilities and training, and hospital policies and procedures. Six main areas of care, called *subdomains*, are scored and comprise each state's total Maternity Practices in Infant Nutrition and Care (mPINC) score ([Fig. 27.1](#)). Data can be used to monitor and improve evidence-based maternity care practices and policies.

One important **Baby-Friendly Hospital Initiative (BFHI)** is a global initiative that assists hospitals in giving mothers the information, confidence, and skills necessary to successfully initiate and continue breast-feeding. In cases where breast-feeding is contraindicated or an informed decision to use formula was made, the safe preparation and feeding of formula is provided to mothers.

Breast-feeding offers infants, mothers, and society compelling advantages in both industrialized and developing

TABLE 27.1 Maternal Contraindications and Recommendations for Breast-Feeding	
MATERNAL CONTRAINDICATIONS	RECOMMENDATIONS FOR MOTHER
Tuberculosis (active)	Should not breast-feed; expressed milk may be provided to child.
Varicella	Should not breast-feed; expressed milk may be provided to child.
H1N1 influenza	Should not breast-feed; expressed milk may be provided to child. Alternately provide prophylaxis to infant and continue nursing.
Herpes simplex infection of the breast	Should not breast-feed; expressed milk may be provided to child.
HIV	Mothers in industrialized countries should not breast-feed. Women in developing countries should combine breast-feeding with antiretroviral therapy for 6 months.
Use of phencyclidine (PCP), cocaine, or amphetamines	Mothers should stop use of drugs while breast-feeding. Mothers enrolled in supervised methadone programs are encouraged to breast-feed.
Alcohol	Limit ingestion to <0.5 mg alcohol per kg of body weight.
Radiopharmaceutic agents	Express milk before exposure to feed infant. Express milk and discard during therapies.
Antineoplastic and immunosuppressive agents	Substitute formula.

Modified from Eidelman AI, Schanler RJ. American Academy of Pediatrics section on breastfeeding. Breastfeeding and the use of human milk. Pediatrics. 2012;129(3):827–841.

countries (Figs. 27.2 and 27.3). Human milk feeding decreases the incidence and severity of diarrhea, respiratory illness, otitis media, bacteremia, bacterial meningitis, and necrotizing enterocolitis. Infants who are breast-fed may have reduced risks of asthma, obesity, type 2 diabetes, ear and respiratory infections, and sudden infant death syndrome (SIDS).

Mothers who breast-feed have a decreased risk of postpartum hemorrhage, more rapid uterine involution, longer period of amenorrhea, and decreased postpartum depression. A cumulative lactation of all pregnancies of 12–23 months reduces hypertension, hyperlipidemia, cardiovascular disease, and type 2 diabetes and is correlated with reduced risk of ovarian and breast cancer.

Feeding *preterm* infants human milk has beneficial effects on their long-term neurodevelopment (IQ). Preterm breast-fed infants also have a lower readmission rate in the first year of life.

Adequacy of milk intake can be assessed by voiding and stooling patterns of the infant. A well-hydrated infant voids 6–8 times a day. Each void should soak a diaper, and urine should be colorless. By 5–7 days, loose yellow stools should be passed approximately four times a day. Rate of weight gain provides the most objective indicator of adequate milk intake. Total weight loss after birth should not exceed 7%, and birth-weight should be regained by 10 days. The mean feeding frequency during the early weeks postpartum is 8–12 times per day. An infant may be adequately hydrated while not receiving enough milk to achieve adequate energy and nutrient intake. Telephone follow-up is valuable during the interim between discharge and the first doctor visit to monitor the progress of lactation. A follow-up visit should be scheduled by 3–5 days of age and again by 2 weeks of age.

In the newborn period, elevated concentrations of serum bilirubin are present more often in breast-fed infants than in formula-fed infants (see Chapter 62). Feeding frequency during the first 3 days of life of breast-fed infants is inversely

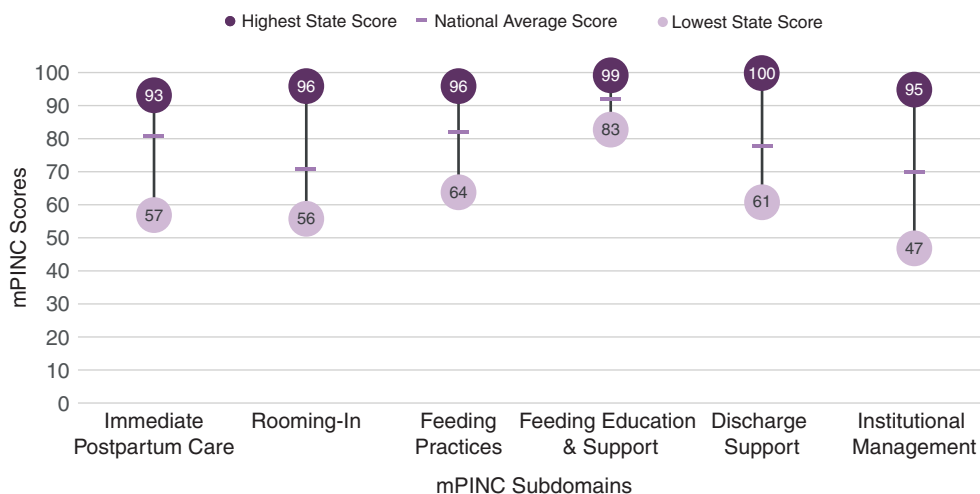

FIGURE 27.1 National score and state score ranges for Maternity Practices in Infant Nutrition and Care (mPINC) subdomains. Data sources for the Breastfeeding Report Card Indicators—2020: National Immunization Survey (NIS). Breast-feeding rates for infants born in 2017 come from the NIS 2018 and 2019. The NIS provides current national, state, and selected urban-area estimates of vaccination coverage rates for U.S. children. Because breast-feeding data are obtained by maternal recall when children are between 19 and 35 months of age, breast-feeding rates are analyzed by birth cohort rather than survey year. (From Centers for Disease Control and Prevention. Breast feeding report card; 2020. <https://www.cdc.gov/breastfeeding/data/reportcard.htm>. Accessed November 30, 2020.)

FIGURE 27.2 Mothers need support throughout their breast-feeding journey. (From Centers for Disease Control and Prevention. CDC's work to support & promote breastfeeding in hospitals, worksites, & communities; 2020. <https://www.cdc.gov/breastfeeding/pdf/breastfeeding-cdcs-work-508.pdf>. Accessed November 30, 2020.)

FIGURE 27.3 Breast-feeding is an investment in health, not just a lifestyle decision. (From Centers for Disease Control and Prevention. CDC's work to support & promote breastfeeding in hospitals, worksites, & communities; 2020. <https://www.cdc.gov/breastfeeding/pdf/breastfeeding-cdcs-work-508.pdf>. Accessed November 30, 2020.)

related to the serum level of bilirubin; frequent feedings stimulate meconium passage and excretion of bilirubin in the stool. Infants who have insufficient milk intake and poor weight gain in the first week of life may have an increase in unconjugated bilirubin secondary to an exaggerated enterohepatic circulation of bilirubin. This is known as **breast-feeding jaundice**. Attention should be directed toward improved milk production and intake. The use of water supplements in breast-fed infants has no effect on bilirubin levels and is not recommended. After the first week of life in a breast-fed infant, prolonged elevated serum unconjugated bilirubin may be due to the presence of an unknown factor in milk that enhances intestinal absorption of bilirubin. This is termed **breast milk jaundice**, a diagnosis of exclusion made only if an infant is otherwise thriving, with normal growth and no evidence of hemolysis, infection, biliary atresia, or metabolic disease (see Chapter 62). Breast milk jaundice usually lasts no more than 1–2 weeks.

The AAP recommends vitamin D supplementation (400 IU/day starting soon after birth) for breast-fed infants.

Common Breast-Feeding Problems

Breast tenderness, engorgement, and cracked nipples are the most common problems encountered by breast-feeding mothers. Engorgement, one of the most common causes of lactation failure, should receive prompt attention because milk supply can decrease quickly if the breasts are not adequately emptied. Applying warm or cold compresses to the breasts before nursing and hand expression or pumping of some milk can provide relief to the mother and make the areola easier to grasp by the infant. Nipple tenderness requires attention to proper latch-on and positioning of the infant. Supportive measures include nursing for shorter periods, beginning feedings on the less sore side, air-drying the nipples well after nursing, and applying lanolin cream after each nursing session. Severe nipple pain and cracking usually indicate improper latch-on. Temporary pumping, which is well tolerated, may be needed. Meeting with a lactation consultant may help minimize these problems and allow the successful continuation of breast-feeding.

If a lactating woman reports fever, chills, and malaise, **mastitis** should be considered. Treatment includes frequent and complete emptying of the breast and antibiotics. Breast-feeding usually should not be stopped because mastitis commonly has no adverse effects on the infant. Untreated mastitis may rarely progress to a **breast abscess**. If an abscess is diagnosed, treatment includes incision and drainage, antibiotics, and regular emptying of the breast. Nursing from the contralateral breast can be continued with a healthy infant. If maternal comfort allows, nursing can continue on the affected side.

Contraindications (see Table 27.1)

Maternal infection with HIV is considered a contraindication for breast-feeding in developed countries. When the mother has active tuberculosis, syphilis, or varicella, restarting breast-feeding may be considered after therapy is initiated. If a woman has herpetic lesions on her breast, nursing and contact with the infant on that breast should be avoided. Women with genital herpes can breast-feed. Proper handwashing procedures should be stressed.

It is unknown whether mothers with COVID-19 can transmit the virus via breast milk, but the limited data available suggest this is not likely to be a source of transmission. Mothers should perform hand hygiene before and wear a mask during breast-feeding.

There are limited numbers of medical contraindications for breast-feeding, including pediatric metabolic disorders such as galactosemia and infants with phenylketonuria, although infants with the latter may alternate breast-feeding with special protein-free or modified formulas.

Maternal Drug Use

Any medication prescribed therapeutically to newborns usually can be consumed via breast milk without ill effect. The factors that determine the effects of maternal medication therapy on the nursing infant include the route of administration, dosage, molecular weight, pH, and protein binding. Few therapeutic drugs are absolutely contraindicated; these include radioactive compounds, antimetabolites, lithium, and certain antithyroid drugs. The mother should be advised against the use of unprescribed drugs, including alcohol, nicotine, caffeine, or “street drugs.”

Maternal use of illicit or recreational drugs is a contraindication to breast-feeding. Breast-fed infants of mothers taking methadone (but no alcohol or other drugs) as part of a treatment program generally have not experienced ill effects. Maternal cannabis use may have effects on the infant’s neurodevelopment.

FORMULA FEEDING

The vast majority of commercial formulas are cow’s milk based. Most have added iron; parents should use only iron-fortified formula unless advised otherwise by the primary health care provider. Infant formula manufacturers have begun to examine the benefits of adding a variety of nutrients and biologic factors to infant formula to mimic the composition and quality of breast milk. These include long-chain polyunsaturated fatty acids, nucleotides, prebiotics, and probiotics. Soy-based formulas, which sometimes have added iron, may be used for newborns who may be allergic to cow’s milk. However, some

newborns allergic to cow’s milk are also allergic to the protein in soy formulas. There are hypoallergenic formulas for infants who cannot tolerate the common formulas. The proteins in these hypoallergenic formulas are broken down to their basic components and are therefore easier to digest (Table 27.2). Specialized formulas are designed for premature, low birth-weight babies. The carbohydrate in standard formulas is generally lactose, although lactose-free cow’s milk-based formulas are available. The caloric density of formulas is 20 kcal/oz (0.67 kcal/mL), similar to that of human milk. A relatively high-fat and calorically dense diet (human milk or formula) is needed to deliver adequate calories. Formula-fed infants are at higher risk for obesity later in childhood; this may be related to better caloric self-regulation by the newborns and infants who are breast-fed.

COMPLEMENTARY FOODS

By approximately 6 months, complementary feeding of semi-solid pureed food is suggested. By this age, an exclusively breast-fed infant requires additional sources of several nutrients, including protein, iron, and zinc. Single-grain iron-fortified cereals (rice, oatmeal, or barley) are commonly introduced around 6 months of age. Cereals are usually introduced first; however, there is no medical evidence that a particular order is better than others for infants. Starting with single-grain cereals can help identify allergies or food intolerances that may arise especially when new foods and solids are added to the infant diet. Then, it is recommended to introduce cooked pureed vegetables to the mix of solid foods and avoid potential allergens; keep in mind preparation should be developmentally appropriate, avoid choking hazards, and offer healthy food as well. It is important for the infant to get used to the process of eating (sitting up, taking food from a spoon, resting between bites, and stopping when full). The early experiences will help the child learn good eating habits. This includes starting family meals from the first feeding, if possible. Having dinner together on a regular basis has positive effects on development. Offering a good variety of healthy nutrient-rich foods, watching for cues that the infant is satiated, and avoiding over-feeding are also important. Snacks are a very important part of the infant nutrition, so providing vegetables and fruits as snacks every day helps avoid increasing non-nutritive finger and snack foods. Infants have an innate ability to self-regulate their food, so responsive feeding helps self-regulation at early ages. Responsive feeding involves parents responding to the infant’s cues, as well as their own desire to feed their baby. Inadequate feeding practices can happen more frequently with bottle feeding of infant formula, especially the use of bottle feeding as a method to soothe infants—contributing to over-feeding. Inattention to a child’s hunger and satiety cues has been associated with overfeeding. Introduction of solids prior to 4 months of age is associated with increased weight gain and adiposity, both in infancy and early childhood. Formula-fed infants are at risk for early introduction of solids; many families introduce solids early especially if they perceive the infant is fussy. It is important to expose children to a wide variety of flavors and textures.

Infants do not need juices, but if juice is given, it should be started only after 12 months of age, given in a cup (as opposed to a bottle), and limited to 4 oz of 100% natural unsweetened juice (for toddlers age 1–3 yr) daily; juices should also be

TABLE 27.2 Composition of Breast Milk, Breast Milk After Freezing and Pasteurization, and Representative Infant Formulas

COMPONENT	BREAST MILK	BREAST MILK AFTER FREEZING AND PASTEURIZING	STANDARD FORMULA	SOY FORMULA	HYPOALLERGENIC FORMULA
Protein	1.1/dL	Reduced	1.5/dL	1.7/dL	1.9/dL
Fat	4.0/dL	4.0/dL	3.6/dL	3.6/dL	3.8–3.3/dL
Carbohydrate	7.2/dL	7.2/dL	6.9–7.2/dL	6.8/dL	6.9–7.3/dL
Calcium	290mg/L	290mg/L	420–550mg/L	700mg/L	635–777 mg/L
Phosphorus	140mg/L	140mg/L	280–390mg/L	500mg/L	420–500mg/L
Sodium	8.0mg/L	8.0mg/L	6.5–8.3mg/L	13mg/L	14mg/L

Ig, Immunoglobulin; SIg, secretory immunoglobulin.

offered only with meals or snacks. Excess juices may reduce appetite for other more nutritious foods and cause diaper rash, diarrhea, and weight gain. An infant should never be put to sleep with a bottle or sippy cup filled with milk, formula, or juice because this can result in **early childhood caries (ECCs)**, formerly known as infant bottle tooth decay (see Chapter 127). Healthy infants do not need extra water; breast milk and formula provide all the fluids needed. However, with the introduction of solid foods, water can be added to the infant's diet. If the family lives in an area with fluoridated water, the recommendation is to provide infants the fluoridated water for preventing future tooth decay. For the first 2 months, it is also important to set the stage for making a distinction between sleeping and feeding time. For infants 4–6 months of age, actively separating mealtime from bedtime is recommended.

After 6 months of age, other foods may be introduced as the infant shows signs of readiness for solid feedings. Solid

cereals are usually introduced first. Infants should start with foods that are of low allergy risk: for example, infant cereal, vegetables, and fruits. Once the infant learns to eat them, parents gradually introduce one food at a time, and should wait 2–3 days before introducing a new one and watch for signs of an allergic reaction such as diarrhea, rash, or vomiting. In general, meats and vegetables have more nutrients per serving than fruits and cereals. Green vegetables bring nutrients, vitamins, minerals, and micronutrients. If there is not a special reason to be concerned about food allergy risk after the first few foods introduced have been tolerated, parents can start to introduce the potentially allergenic foods (e.g., fish, tree nuts, peanuts, dairy products, and egg); *early introduction may actually help to prevent food allergies*. **Children with eczema may be at a higher risk of developing peanut allergy.** These infants should be introduced to peanut-containing products around 4–6 months of age in order to prevent peanut allergies in the future. If the infant has **mild eczema**, peanuts can be

introduced at home (after other complementary foods). If the patient has **severe eczema**, allergy testing prior to providing peanuts is indicated as is the start of feeding with peanut products in the office for the first time. Infants without eczema or other food allergies, who are not at increased risk for developing an allergy, may start having peanut-containing products and other highly allergenic foods freely after a few solid foods have already been introduced and tolerated without signs of allergy.

Cow's milk is not recommended before 12 months of age; parents may provide processed dairy products such as cheese and yogurt before 1 year of age.

Once the child can sit and bring the hands or other objects to the mouth, parents may provide finger food to help the infant learn to self-feed. To avoid choking, make sure that anything given to the infant is easy to swallow, soft, and cut in very small pieces. Initially, the infant should be eating approximately 4–6 oz of solids at each daily meal. If the food fed to the infant is prepared by the adult, it should be made without preservatives or high salt. All foods with the potential to obstruct the young infant's main airway should be avoided in general until 4 years of age or older. Honey (risk of infant botulism) should not be given before 1 year of age. If the introduction of solid foods is delayed, nutritional deficiencies can develop, and oral sensory issues (texture and oral aversion) may occur. General signs of readiness include the ability to hold the head up, adequate growth (around double the birth-weight), opening the mouth wide showing eager anticipation of eating food and interest in foods, sitting unassisted, bringing objects to the mouth, the ability to track a spoon and take food from the spoon, and stopping when full. The choice of foods to meet micronutrient needs may be less critical for formula-fed infants because formulas are fortified with those nutrients. With the introduction of solid foods, the infants' stools may have appropriate changes; they become more solid and/or have a stronger odor as new and more sugars may be added.

All infants and children should take a minimum of 400 IU of **vitamin D** per day beginning soon after birth. Vitamin D supplementation should continue until the infant is consuming cow's milk/formula of at least 1 qt (1 L, 32 oz). All formulas in the United States have at least 400 IU/L of vitamin D.

Iron Supplements

Full-term healthy infants receive enough iron from their mothers in the third trimester of pregnancy to last for the first 4 months of life. Human milk contains little iron, so infants who are exclusively breast-fed are at increased risk of iron deficiency after 4 months. The AAP recommends giving breast-fed infants 1 mg/kg/day of liquid iron supplement until iron-containing foods are introduced at about 6 months of age. If the infant is on formula, iron-fortified formula should be used from birth through the entire first year of life. Premature infants have less iron stores; additional iron is recommended.

Arsenic occurs naturally in our environment; inorganic arsenic is toxic and carcinogenic. The greatest health risks from exposure to inorganic arsenic occurs during pregnancy, infancy, and early childhood. The Food and Drug Administration recommends that infants, children, and pregnant women eat a variety of foods, including a variety of

TABLE 27.3 Approach to Reducing Infant Arsenic Exposure

Breast-feeding	Breast-feed solely for ~6 months, begin solid foods but continue breast-feeding until at least 12 months.
Provide a well-balanced diet for toddlers with a variety of grains	Rice cereal fortified with iron. Other sources of cereals are oat, barley, and multigrain.
Limit fruit juices	Eat fruits instead of juices and limit amount of juices (see text).
Avoid brown rice syrup	Arsenic may be concentrated in rice syrups.
Rice milk is not appropriate dairy substitute	Can have high levels of arsenic.

grains, avoiding those with highest arsenic concentrations. Helpful tips for parents are noted in [Table 27.3](#).

PEARLS FOR PRACTITIONERS

See *Pediatric Nutrition and Nutritional Disorders: Pearls for Practitioners* at the end of this section.

CHAPTER 28

Diet of the Normal Child and Adolescent

For a discussion of nutrient needs for children and adolescents, see <https://www.usda.gov> and <https://medlineplus.gov/childnutrition.html>.

NUTRITION ISSUES FOR TODDLERS AND OLDER CHILDREN

Learning healthy eating behaviors at an early age is an important preventive measure because of the association of diet with several chronic diseases, such as obesity, diabetes, and cardiovascular disease, which account for approximately 63% of all deaths worldwide. These diseases share risk factors that can be modified by lifestyle changes. Diets high in fruits and vegetables together with increased physical activity reduce metabolic risk factors. The first 1,000 days of life are an important time to engage in healthy nutrition behaviors that will promote well-being, including teaching healthy feeding behaviors. Excessively accelerated postnatal growth in infants and young children is an important risk factor for obesity.

MILK

Cow's milk is ideally not introduced until approximately 1 year of age. Low-fat (2%) or whole milk is recommended until 2 years of age, after which fat-free or 1% milk is recommended. Excessive milk intake (>24 oz/day) should be avoided in toddlers because larger intakes may reduce the intake of a good

variety of nutritionally important solid foods and result in iron-deficiency anemia; large intakes also may contribute to excessive caloric intake.

JUICES

Juice intake for toddlers and young children should be limited to 4 oz; juice intake for children 7–18 years of age should be limited to 6–8 oz/day. If juices are provided to children, they should be only natural fruit juices with no added sugar (sugar, fructose, and honey). Children younger than 2 years should not have any added sugars. Young people between the ages of 2 and 18 years should get no more than 25 g of added sugar each day. This is the equivalent of six white sugar packets or 6 teaspoons of serving sugar. The typical American child consumes approximately triple the recommended amount of added sugars. Starting in July 2018, food products sold in the United States were required to list the amount of added sugars on the Nutrition Facts Panel. Water and milk are the recommended drinks during the day.

GENERAL RECOMMENDATIONS

Many people in the United States don't eat a healthy diet. *Healthy People 2030* focuses on helping people get the recommended amounts of healthy foods (e.g., fruits, vegetables, whole grains) and key nutrients (e.g., calcium, potassium) to reduce risk for chronic diseases and improve their health. A diet high in unhealthy foods such as saturated fat and added sugars increases risk for obesity, heart disease, type 2 diabetes, and other health problems. Choosing healthy foods can help reduce risk of chronic diseases and improve overall health. Lack of information needed to choose healthy foods, lack of access to healthy foods, or inability to purchase enough healthy food are key issues. Public health interventions that focus on helping everyone get healthy foods are key to reducing food insecurity and hunger and improving health.

"ChooseMyPlate" by the U.S. Department of Agriculture provides parents with general guidelines for the types of foods and the volume to be offered on a regular basis. A child should eat three meals a day and two healthy snacks. A general rule is to offer a child 1 tbs per year of age for each food provided per meal, with more given if the child requests. As a rule of thumb, children should not be eating more than the size of an adult palm per serving. By 1 year of age, infants should be eating meals with the family, have a regular schedule of meals and snacks, and be encouraged to self-feed with appropriate finger foods. The "plate" image is divided into five sections: fruits, grains, vegetables, protein, and dairy (Fig. 28.1). Half of the "plate" should be vegetables and fruits and the other half grains and proteins, with dairy on the side. A weekly recommendation for vegetable intake is also provided (Table 28.1). Other suggestions include the following: provide low-fat 2% milk starting at 12 months of age, and switch to fat-free or low-fat (1%) milk after age 2 years; make at least half of the grains whole instead of refined grains; avoid oversized portions; compare sodium (salt) in foods such as soup, bread, and frozen meals; choose foods with lower sodium content; and drink water (fluoridated as possible) instead of sugary drinks. After 2 years, it is recommended that the fat intake gradually be reduced to approximately 30% and not less than 20% of

FIGURE 28.1 "ChooseMyPlate" guidelines. (From U.S. Department of Agriculture. MyPlate. www.ChooseMyPlate.gov.)

TABLE 28.1 Recommended Weekly Vegetable Intake (in Cups)					
AGE (YR)	GREEN	ORANGE	STARCH	DRY BEANS/PEAS	OTHER*
2–3	1	½	1½	½	4
4–8	1½	1	2½	5½	4½
>9 Girls	2	1½	2½	2½	5½
>9 Boys	3	2	3	3	6½

*Including cabbage, cauliflower, green beans, lettuce, and zucchini. From U.S. Department of Agriculture. MyPlate. www.ChooseMyPlate.gov.

calories. Replace proteins from red meat with a mix of fish, chicken, nuts, and legumes.

Power struggles over eating are common between parents and toddlers. The parent's role is to decide the what, when, and where of the meals. The child's role is to decide if, what, and how much to eat.

Recommendations of a nutritious diet for a child are based on the following nutrient-dense foods:

Protein. Provide seafood and fish, lean meat and poultry, eggs, beans, peas, soy products, and unsalted nuts and seeds.

Fruits. Fruits are recommended as essential and help prevent obesity and many other chronic diseases. Using more than one strategy to promote healthy diet (nutrition counseling, school- and workplace-based programs, school healthy nutrition policies) can help people eat more fruits. Current fruit consumption is ~0.51 cup equivalents of fruits per 1,000 calories as the mean daily intake by persons age 2 years and older. The target is to increase the consumption to 0.56 cup equivalents of fruit per 1,000 calories by 2030.

Vegetables. One of the *Healthy People 2030* goals is to increase vegetable consumption from a baseline of 0.76 cup equivalents of total vegetables per 1,000 calories as the mean daily

intake by persons age 2 years and older to a target in 2030 of 0.84 cup equivalents of vegetable per 1,000 calories. Also, *Healthy People 2030* targets an increase in consumption of dark green vegetables, red and orange vegetables, and beans and peas by age 2 years and older. At baseline, the mean daily intake by persons 2 years and older was 0.31 cup equivalents of dark green vegetables, red and orange vegetables, and beans and peas per 1,000 calories with a target of 0.33 cup equivalents of dark green vegetables, red and orange vegetables, and beans and peas per 1,000 calories by 2030.

Grains. Choose whole grains, such as whole-wheat bread, oatmeal, popcorn, quinoa, or brown or wild rice. Limit refined grains.

Dairy. Encourage the child to eat and drink fat-free or low-fat dairy products such as milk, yogurt, or cheese.

Milk recommended intake:

- 1-year-old maximum of 24 oz
- 2- to 20-year-old maximum of 16 oz

Aim to limit the child's calories from:

Added sugar. Added sugars in food and drinks can make it hard for people to get the nutrients they need without getting too many calories. People who eat too much added sugar may be at higher risk for tooth decay and obesity. Pricing strategies and education intervention in schools may help people limit foods and drinks with added sugars. Use of the Nutrition Facts label can help people track their consumption. Examples of added sugars include serving sugar, brown sugar, corn sweetener, corn syrup, honey, and others.

Saturated and trans-fats. Saturated fat is a type of fat that has fatty acid chains with all or predominantly single bonds and no double bonds between carbons. People who replace saturated fat in their diet with unsaturated fat are likely to have lower cholesterol, which may reduce the risk of chronic heart disease. Many people in the United States eat too much saturated fat. Nutrition counseling and behavioral interventions can help people eat less saturated fat, while use of the Nutrition Facts label can also help them track their consumption of saturated fat. *Healthy People 2030* recommends reduction in saturated fat intake from the baseline of 11.4% as the mean percentage of calories consumed by persons age 2 years and older to a target of 8.4%. Recommendations are to limit saturated fats, which are those that come from animal sources of food such as red meat, poultry, and full-fat dairy products (Table 28.2). Healthier fats are also naturally present in olives, nuts, avocados, and seafood. Limit trans-fats by avoiding foods that contain partially hydrogenated oil.

SALT INTAKE

Recommended salt intake for children varies from 1,900–2,300 mg a day, depending on age. Nearly 90% of children in the United States consume more than the recommended amount of salt for their age. About one in nine children has raised blood pressure, a major risk factor for heart disease and stroke. Sodium-heavy breads, pizza, cold cuts, sandwiches, ethnic-based dishes, processed snacks (chips, pretzels, popcorn, crackers), and soups are among the major high salt

TABLE 28.2 Key Elements of Dietary Guidelines for Americans

Consume a healthy eating pattern that accounts for all foods and beverages within an appropriate calorie level.

A healthy eating pattern includes:

- A variety of vegetables from all subgroups: dark green, red, and orange, legumes (beans and peas), starchy, and many others
- Fruits, especially fresh and whole fruits
- Grains, especially at least half of which are whole grains
- Fat-free or low-fat dairy, including milk, yogurt, cheese, and/or fortified soy beverages
- A variety of protein foods, including seafood, lean meats and poultry, eggs, legumes (beans and peas), nuts, seeds, and soy products
- Oils, especially unsaturated fat content oils

A healthy eating pattern limits:

- Saturated fats and trans fats, added sugars, and sodium

Key recommendations that are quantitative are provided for several components of the diet that should be limited. These components are of particular public health concern in the United States, and the specified limits can help individuals achieve healthy eating pattern within calorie limits.

Americans of all ages (children, adolescents, adults, and older adults) should meet *The Physical Activity Guidelines for Americans* to help health and reduce the risk of chronic disease. Americans should aim to achieve and maintain a healthy body weight. The relationship between diet and physical activity contributed to calorie balance and managing body weight.

From U.S. Department of Agriculture. *Food patterns: healthy US style eating patterns*. USDA Food Patterns; 2016.

products. *Healthy People 2030* recommends lowering sodium consumption from baseline of 3,406 mg of sodium from foods and beverages to a target of 2,725 mg.

IRON INTAKE

Iron intake may be inadequate in some children between 1 and 3 years of age in the United States. Toddlers with excessive milk intakes (>24 oz/day) and/or those who consume little meat, iron-rich green vegetables, or grains are at risk for iron deficiency. Iron-deficient children are at higher risk for developmental problems. Iron-rich foods and adding iron to more foods in general can help reduce iron deficiency. Supplemental iron is recommended if the child is iron deficient.

NUTRITION ISSUES FOR ADOLESCENTS

Teen nutrition can be a challenge. Ads for junk food and images of incredibly thin adolescents provide conflicting and unhealthy ideas about what they should eat. Females age 14–18 need anywhere from 1,800–2,400 calories per day, depending on their activity level and stage of development. Males of the same age group need 2,000–3,200 calories daily. Poor eating habits may develop during adolescence. Skipped meals (especially breakfast), binge eating with friends or alone, dieting, and consumption of nutrient-poor, calorically dense foods are common problems. Excessive consumption of sugar from soda, fruit drinks, and specialty coffee and tea drinks may

contribute to excess weight gain, as well as tooth decay, and it may displace other needed nutrients. Bones increase in size and mass during periods of growth in childhood and adolescence; peak bone mass is reached around age 30. The greater the peak bone mass, the longer one can delay serious bone loss with aging. Poor calcium intake during adolescence may predispose the adult to future osteoporotic hip fracture. Only 1 of 10 teenage females and 1 of 4 teenage males get enough calcium every day. Adolescents age 9–18 years need 1,300 mg of calcium daily. Good sources include milk, yogurt, fortified orange juice, cheese, soybeans, and tofu.

Inadequate iron intake may result in symptoms of fatigue and iron-deficiency anemia. Iron needs increase during growth spurts, which is why teens are more likely to suffer from iron-deficiency anemia. Teenage females are especially prone to anemia from menstrual blood loss. Student athletes are also vulnerable to inadequate iron intakes, severely restrictive eating patterns, and use of inappropriate nutritional and vitamin supplements. Adolescents should be counseled on specific and healthy dietary choices (see [Chapter 70](#)).

PEARLS FOR PRACTITIONERS

See Pediatric Nutrition and Nutritional Disorders: Pearls for Practitioners at the end of this section.

CHAPTER 29

Obesity

DEFINITIONS

Obesity is one of the most important public health concerns in the United States and many other resource-rich countries and transitional economies. As the prevalence of obesity has increased, so has the prevalence of the co-morbidities associated with obesity. More than one third of adults are obese in the United States. Severe obesity among children age 2–19 years has increased from 2.6% in 1994 to 6% in children with body mass index (BMI) >120% of the 95th percentile.

Child and adolescent obesity is defined as a BMI at or above the gender-specific 95th percentile on the Centers for Disease Control and Prevention (CDC) BMI-for-age growth charts. **Childhood extreme obesity** is defined as a BMI \geq 120% of the gender-specific 95th percentile on the CDC BMI-for-age growth chart. **Child and adolescent overweight** is defined as a BMI between the 85th and 95th percentile on the CDC BMI-for-age growth charts (Table 29.1). Overweight and obese children are more likely to stay obese into adulthood and to develop noncommunicable diseases (NCDs) such as diabetes and cardiovascular diseases (CVDs) at a younger age.

EPIDEMIOLOGY

Approximately one third of U.S. children are overweight or obese (Table 29.2). The risk of remaining obese into adulthood increases with age of onset and degree of obesity. Obesity may run in families; having one obese parent

TABLE 29.1 Body Mass Index (BMI) Interpretation

BMI/AGE PERCENTILE	INTERPRETATION
<5th	Underweight
5th–85th	Normal
85th–95th	Overweight
>95th	Obese

From Centers for Disease Control and Prevention. Healthy weight, nutrition, and physical activity. www.cdc.gov/healthyweight.

TABLE 29.2 Increasing Incidence of Overweight/Obesity with Age

	PRESCHOOL CHILDREN 2–5 YR (%)	SCHOOL-AGE CHILDREN 6–11 YR (%)	ADOLESCENTS 12–19 YR (%)
Overweight or obese BMI >85%	26	34.1	40
Obese BMI >95%	13.7	18.7	20.6
Severe obese BMI >120%/ BMI 35kg/m ²	1.8	5.2	7% girls 9.7% boys

increases the risk of obesity by 2- to 3-fold, and up to 15-fold if both parents are obese. The main causes of excess weight in youth include individual behaviors and rarely include genetics or endocrine disorders (Table 29.3). Behavior causes may include dietary patterns, physical inactivity, medication use, and other exposures. Childhood obesity is more common among American Indians, blacks, and Hispanics than non-Hispanic whites. Individuals with lower income and/or education levels are disproportionately more likely to be obese. It is hard for children to make the healthy decision when they are exposed to an environment in their home, child care, school, or community that is influenced by factors such as advertising, variation in licensure regulations among child-care centers, lack of a safe and appealing place to play, limited access to healthy affordable foods, greater availability of high-energy–dense foods and sugar-sweetened beverages, increased portion sizes, and lack of breast-feeding support. One early major risk factor is maternal obesity during pregnancy. Children born to mothers after bariatric surgery are at lower risk for obesity than the children born before the surgery. Women who gain more weight than recommended during pregnancy have children who have a higher BMI than normal in adolescence. Small for gestational age (SGA) newborns have higher risks for abnormal postnatal weight gain and diabetes; they may have long-lasting implications for health, which is possibly because of nutritional effects during the fetal life.

Preventive strategies include approaching all the risk factors that can be modified by lifestyle changes and policy

TABLE 29.3 Endocrine and Genetic Causes of Obesity		
DISEASE	SYMPTOMS	LABORATORY
ENDOCRINE		
Cushing syndrome	Central obesity, hirsutism, moon face, hypertension	Dexamethasone suppression test
GH deficiency	Short stature, slow linear growth	Evoked GH response, IGF-1
Hyperinsulinism	Nesidioblastosis, pancreatic adenoma, hypoglycemia, Mauriac syndrome	Insulin level
Hypothyroidism	Short stature, weight gain, fatigue, constipation, cold intolerance, myxedema	TSH, FT ₄
Pseudohypoparathyroidism	Short metacarpals, subcutaneous calcifications, dysmorphic facies, intellectual disability, short stature, hypocalcemia, hyperphosphatemia	Urine cAMP after synthetic PTH infusion
GENETIC		
Alstrom syndrome	Intellectual disability, retinitis pigmentosa, diabetes mellitus, hearing loss, hypogonadism, retinal degeneration	<i>ALMS1</i> gene
Bardet-Biedl syndrome	Retinitis pigmentosa, renal abnormalities, polydactyly, hypogonadism	<i>BBS1</i> gene
Biemond syndrome	Intellectual disability, iris coloboma, hypogonadism, polydactyly	
Carpenter syndrome	Polydactyly, syndactyly, cranial synostosis, intellectual disability	Mutations in the <i>RAB23</i> gene, located on chromosome 6 in humans
Cohen syndrome	Mid-childhood-onset obesity, short stature, prominent maxillary incisors, hypotonia, intellectual disability, microcephaly, decreased visual activity	Mutations in the <i>VPS13B</i> gene (often called the <i>COH1</i> gene) at locus 8q22
Deletion 9q34	Early-onset obesity, intellectual disability, brachycephaly, synophrys, prognathism, behavior and sleep disturbances	Deletion 9q34
Down syndrome	Short stature, dysmorphic facies, intellectual disability	Trisomy 21
<i>ENPP1</i> gene mutations	Insulin resistance, childhood obesity	Gene mutation on chromosome 6q
Fröhlich syndrome	Hypothalamic tumor	—
<i>FTO</i> gene polymorphism	Dysregulation of orexigenic hormone acyl-ghrelin, poor postprandial appetite suppression	Homozygous for <i>FTO</i> AA allele
Leptin or leptin receptor gene deficiency	Early-onset severe obesity, infertility (hypogonadotropic hypogonadism)	Leptin
Melanocortin 4 receptor gene mutation	Early-onset severe obesity, increased linear growth, hyperphagia, hyperinsulinemia Most common known genetic cause of obesity Homozygous worse than heterozygous	<i>MC4R</i> mutation
Prader-Willi syndrome	Neonatal hypotonia, slow infant growth, small hands and feet, intellectual disability, hypogonadism, hyperphagia leading to severe obesity, paradoxically elevated ghrelin	Partial deletion of chromosome 15 or loss of paternally expressed genes
Proopiomelanocortin deficiency	Obesity, red hair, adrenal insufficiency, hyperproinsulinemia	Loss-of-function mutations of the <i>POMC</i> gene
Rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation	Often confused with congenital central hypoventilation syndrome, presentation ≥ 1.5 years with weight gain, hyperphagia, hypoventilation, cardiac arrest, central diabetes insipidus, hypothyroidism, growth hormone deficiency, pain insensitivity, hypothermia, precocious puberty, neural crest tumors	Unknown genes May be a paraneoplastic disorder
Turner syndrome	Ovarian dysgenesis, lymphedema, web neck, short stature, intellectual disability	XO chromosome

cAMP, Cyclic adenosine monophosphate; FT₄, free thyroxine; GH, growth hormone; IGF, insulin-like growth factor; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone.

From Gahagan S. Overweight and obesity. In Kliegman RM, St. Geme JW, eds. Nelson Textbook of Pediatrics. 21st ed. Philadelphia: Elsevier; 2020 [Table 60.1].

TABLE 29.4 Eating and Activity Habits for Overweight/Obesity Prevention

ACTIVITIES FOR OVERWEIGHT/OBESITY PREVENTION	
INDIVIDUAL	<ol style="list-style-type: none"> 1. Be physically active >1 hr/day 2. Limit screen time (television, computer games/Internet, videogames) to <1–2hr/day (no television for child <2yr of age) 3. Consume five or more servings of fruits and vegetables per day 4. Minimize consumption of sugar-sweetened beverages 5. Consume a healthy breakfast every day
FAMILY	<ol style="list-style-type: none"> 1. Eat at table, as a family, at least five to six times per week 2. Prepare more meals at home rather than purchasing restaurant food 3. Allow child to self-regulate own meals and avoid overly restrictive feeding behaviors 4. Do not reward children with food or drinks 5. Have only healthy foods available for snacking 6. Encourage outdoor activity
COMMUNITY	<p>Schools</p> <ol style="list-style-type: none"> 1. Serve healthy foods 2. Limit what is available in vending machines 3. Have physical activity daily 4. Have outdoor recess daily 5. Teach healthy eating <p>Health Care Providers</p> <ol style="list-style-type: none"> 1. Take a nutrition history 2. Speak to patients about healthy weight and good nutrition 3. Advise exercise
GOVERNMENT	<ol style="list-style-type: none"> 1. Increase access to healthy food and eliminate food deserts 2. Regulate food ads or serving sizes 3. Add more sidewalks and parks 4. Emphasize safety

making (see Table 29.3; Tables 29.4 and 29.5), such as eating less processed food, increasing consumption of fruit and vegetables, and increasing physical activity. High BMI increases the risk of metabolic and CVDs and some cancers; it is the most important modifiable risk factor for diabetes.

ETIOLOGY

Etiologic factors such as sugar-sweetened beverages, television and screen time, sleep, medications, among others contribute to obesity in children. Environmental factors such as increasing trends of the glycemic index of foods, sugar-containing beverages, portion sizes for prepared foods, and fast-food services; diminished family presence at meals; decreasing structured physical activity; increasing computer, electronic, or digital oriented play activity; and school meal nutrition content are possible causes of obesity. In particular, the relation of the consumption of sugar-containing beverages or low physical activity is associated with obesity and metabolic abnormalities. During the COVID-19 pandemic of 2020, many of these factors may be exacerbated, such as

decreasing physical activity, locked-down and stay-at-home recommendations, food insecurity and availability of balanced nutrients, social isolation, and many other possible factors that may increase obesity in children. Television viewing is perhaps the best-established environmental influence on the development of obesity during childhood. The amount of time watching television or the presence of a television in the child's bedroom are directly related to the prevalence of obesity in children and adolescents. Children younger than 2 years should avoid digital media other than video chatting. Children ages 2–5 years should not watch more than 1 hour of high-quality children's programming per day. Video games that require interactive physical activity by the player, called "exergames," may increase energy expenditure. There is an association between shortened sleep duration or irregular sleep schedule and obesity. Sleep fragmentation and intermittent hypoxemia are associated with decreased insulin sensitivity, independent of adiposity. Similarly, short sleep duration is associated with markers of cardiometabolic risk factors, including abdominal obesity, increased blood pressure, and abnormal lipid profile. Some medications can also cause weight gain, including psychoactive drugs, antiepileptic drugs, and glucocorticoids.

CLINICAL MANIFESTATIONS

Complications of obesity in children and adolescents can affect every major organ system (Table 29.6). A substantial component of adolescent obesity is established before 5 years of age. Therefore interventions in early life may prevent and treat obesity.

High BMI increases the risk of metabolic and CVDs and some cancers; it is also the most important modifiable risk factor for hyperglycemia and diabetes. Children who are obese are at higher risk for (1) high blood pressure and high cholesterol, which are risk factors for CVD; (2) impaired glucose intolerance, insulin resistance, type 2 diabetes; (3) respiratory problems such as sleep apnea and asthma; (4) joint problems and musculoskeletal discomfort; (5) fatty liver disease, gallstones, and gastroesophageal reflux; (6) psychologic stress such as depression, behavioral problems, and bullying issues at school; (7) low self-esteem and low self-reported quality of life; and (8) impaired social, physical, and emotional functioning. The history and physical examination should screen for many potential complications noted among obese patients (see Table 29.6) in addition to specific diseases associated with obesity (see Table 29.3). Medical complications usually are related to the degree of obesity and usually decrease in severity or resolve with weight reduction.

BMI is a convenient screening tool that correlates fairly strongly with body fatness in children and adults. BMI age-specific and gender-specific percentile curves (for 2- to 20-year-olds) allow an assessment of BMI percentile (available online at <http://www.cdc.gov/growthcharts>). Table 29.1 provides BMI interpretation guidelines. For children younger than 2 years of age, weight-for-length measurements greater than the 95th percentile may indicate overweight and warrant further assessment. A BMI for age and gender above the 95th percentile is defined as obesity and is strongly associated with excessive body fat and co-morbidities. Extreme obesity is defined as a BMI $\geq 120\%$ of the gender-specific 95th percentile on the CDC BMI-for-age growth chart.

TABLE 29.5 Setting Explicit Goals to Prevent or Treat Obesity

FIGHT OBESITY EFFECTIVELY	AMBIGUOUS GOALS	SPECIFIC GOALS
Keep it simple	Walk or bike more	Walk or bike to school 2 days/wk
Countable goals/unambiguous	Watch less TV	Watch no TV on school days
Two short-term goals/time	—	—
Be able to count	Decrease size of serving	Small bowls (parent palm)
Aim to change behaviors	—	Avoid eating from the box
Do not focus on consumption of carbohydrates, fat, protein	Decrease to 20g of fat	Eat fish once a week
Focus on specific categories	Decrease sugars	Avoid sweetened foods
Focus on healthier preparation methods	—	Avoid frying
Focus on eating patterns	—	Avoid double dinner
Focus on portion size	—	Portion parent's palm size
Eating fast food	Eat less junk food	Limit trips to fast food restaurants to 1/wk
Sweetened beverages	Avoid soda/juices	No soda or juices
Healthy beverages	—	Drink only milk or water
Fruits	Buy fewer juices	Have no juices in the refrigerator
	Increase eating fruits	Keep a bowl of fruits in the kitchen
Vegetables	Increase eating veggies	Have a bowl of veggies in the refrigerator
		Cooperation, competition, and social interaction such as building a house of veggies
Physical activities	Walk more	Family hikes every Sunday Specific activity time for activities and sedentary behavior
	Increase walking from school	Parents picking up from school 2 days/wk

ASSESSMENT

Early recognition of excessive rates of weight gain, overweight, or obesity in children is essential because the earlier the interventions, the more likely they are to be successful.

Routine evaluation at well child visits should include the following:

- 1. Anthropometric data**, including weight, height, and calculation of BMI. Data should be plotted on age-appropriate and gender-appropriate growth charts and assessed for BMI trends (see Table 29.1).
- 2. Dietary and physical activity history** (see Table 29.4). Assess patterns and potential targets for behavioral change.
- 3. Physical examination.** Assess blood pressure, adiposity distribution (central vs generalized), markers of co-morbidities (acanthosis nigricans, hirsutism, hepatomegaly, orthopedic abnormalities), and physical stigmata of a genetic syndrome (explains <5% of cases).
- 4. Laboratory studies.** These are generally reserved for children who are obese (BMI >95th percentile), who have evidence of co-morbidities, or both. All 9- to 11-year-olds should be screened for high cholesterol levels. Other useful laboratory tests may include hemoglobin A_{1c}, fasting lipid

profile, fasting glucose levels, liver function tests, and thyroid function tests (if there is a faster increase in weight than height).

PREVENTION

Behavioral and lifestyle modifications are the primary tools for reducing obesity (see Table 29.5). However, if the environment contributes to the unhealthy eating practices and sedentary lifestyle, strategies and interventions relying only on individual “self-control” will not be very effective. There are three levels of prevention in dealing with childhood obesity: (1) primordial prevention deals with keeping a healthy weight and a normal BMI through childhood and into teens; (2) primary prevention aims to prevent *overweight* children from becoming *obese*; and (3) secondary prevention directed toward the treatment of obesity so as to reduce the co-morbidities and reverse overweight and obesity, if possible. The approach to therapy and aggressiveness of treatment should be based on risk factors including age, severity of overweight and obesity, co-morbidities, and family history and support. The primary goal for all children with

TABLE 29.6 Complications of Obesity

COMPLICATION	EFFECTS
Psychosocial	Peer discrimination, teasing, reduced college acceptance, isolation, depression, eating disorders (binge eating), reduced job promotion*
Growth	Advanced bone age, increased height, early menarche
Central nervous system	Idiopathic intracranial hypertension
Respiratory	Obstructive sleep apnea
Cardiovascular	Hypertension, cardiac hypertrophy, arrhythmias, ischemic heart disease,* sudden death*
Orthopedic	Slipped capital femoral epiphysis, Blount disease
Metabolic	Insulin resistance, type 2 diabetes mellitus, hypertriglyceridemia, hypercholesterolemia, gout,* hepatic steatosis, polycystic ovary disease, cholelithiasis
Cutaneous	Striae, acanthosis nigricans, intertriginous dermatitis

*Complications unusual until adulthood.

uncomplicated obesity and fast-rising weight-for-height is to achieve a healthy balance of energy consumption as a caloric intake, **healthy eating, with the number of calories used aligned with activities and activity patterns.** The United States has advocated for improving nutrition quality of children, including consumption of a diverse, nutrient-dense diet, and emphasizing vegetables, fruits, and whole grains; quality protein sources and low-fat or non-fat milk and dairy; limited intake of sugar-sweetened beverages; modest fat consumption; and moderate portion sizes (MyPlate.gov). For children with a secondary complication, improvement of the complication is an important goal. Access to sugar-sweetened beverages in school should be discouraged, including soft drinks and beverages marketed for rehydration during sports. Childhood and adolescent obesity treatment programs can lead to sustained weight loss and decreases in BMI when treatment focuses on behavioral changes and is family centered. Concurrent changes in dietary and physical activity patterns are most likely to provide success (see Table 29.5). In the **perinatal** period, this includes adequate prenatal nutrition with optimal maternal weight gain, good maternal blood sugar control in diabetes, and postpartum weight loss with healthy nutrition and exercises. During **infancy**, early initiation of breast-feeding, exclusive breast-feeding for 6 months followed by inclusion of solid foods, providing a balanced diet with avoidance of unhealthy calorie-rich snacks, and close monitoring of weight gain should be emphasized. The transition to complementary and table foods and the importance of regularly scheduled meals and snacks, versus grazing behavior, should be emphasized. During the **preschool** age period, putting these strategies into practice includes providing nutritional education and guidance to parents and children so as to develop healthy eating practices, offering healthy food preferences by giving early

experiences of different food and flavors, and closely following the rate of weight gain to prevent early adiposity rebound. In school-aged children, this includes monitoring both weight and height, preventing excessive prepubertal adiposity, providing nutritional counseling, and emphasizing daily physical activity. In **adolescence**, preventing the increase in weight after a growth spurt, maintaining healthy eating behavior, and reinforcing the need for daily exercise are most important.

Calorie intake is fundamental to achieving and maintaining calorie balance. The best way to determine whether an eating pattern is at an appropriate number of calories is to monitor body weight and adjust calorie intake and expenditure in physical activity based on changes in weight over time.

Physical activity is the key component for prevention and management of obesity. Preschool children require unstructured activities and thus benefit from outdoor play and games. School children and adolescents require at least 60 minutes of daily physical activities. Recommending a feasible increase in activity, such as walking or biking to school 2 or more days a week, is more effective than overly aggressive plans. Behavioral risk factors need to be identified and addressed.

Age-appropriate **portion sizes** for meals and snacks should be encouraged. Children should be taught to recognize hunger and satiety cues. Children should never be forced to eat when they are not willing, and overemphasis on food as a reward should be avoided. ChooseMyPlate.gov by the U.S. Department of Agriculture can provide parents with general guidelines.

TREATMENT

Treatment for Children Who Are Overweight

Children older than 2 years and adolescents whose weight falls in the overweight category should be put on a weight-maintenance program to slow the progress of weight gain. This strategy allows the child to add inches in height but not pounds, causing the BMI to drop over time into a healthier range.

Treatment for Children Who Are Obese

Obese children, ages 6–11 years, might be encouraged to modify their eating habits for gradual weight loss of no more than 1 lb (or ~0.5 kg) a month. Older children and adolescents who are obese or severely obese might be encouraged to modify their eating habits to aim for weight loss of up to 2 lb (or ~1 kg) a week.

More aggressive therapies are considered only for those who have not responded to other interventions. The initial interventions include a systematic approach that promotes multidisciplinary brief, office-based interventions for obese children and promotes reducing weight. Before enrolling any patient in a weight-loss program, the clinician must have a clear idea of that individual's expectations. Patients with unrealistic expectations should not be enrolled until these are changed to realistic and attainable goals.

Medications

Medication might be prescribed for some adolescents as part of an overall weight-loss plan. The risks of taking prescription

medication over the long term are unknown, and medications' effects on weight loss and weight maintenance for adolescents is still in question. Pediatric experiences with drugs are limited. Anorectic drugs are not recommended for routine use, and the efficiency and safety of these drugs have to be established by controlled clinical trial. Orlistat may be a safe and effective adjunct to dietary and behavioral modifications in the treatment of obesity for patients older than 8 years. Approved for use in children older than 12 years by the Food and Drug Administration in 2003, orlistat, 120 mg three times daily, is a reversible gastric and pancreatic lipase inhibitor that limits the gastrointestinal absorption of dietary cholesterol by approximately 30%. The resulting decrease in caloric intake is proposed to alter energy balance, thereby causing a beneficial effect on weight management. Because this agent reduces plasma fat-soluble vitamin levels, it may also complicate adolescent growth and development; concomitant administration of a daily multivitamin is recommended. Close provider follow-up is warranted until additional longer-term studies confirm the safety of orlistat in this population.

Metformin is a biguanide derivative used for the treatment of type 2 diabetes mellitus in adults and children at least 10 years of age. It is not approved for treatment of obesity.

Weight-Loss Surgery

Surgical treatment may be advocated as a preferred and cost-effective solution for severely obese adolescents who have been unable to lose weight through life changes. Bariatric surgery in severely obese adolescents results in significant weight loss and improvements in co-morbidities and quality of life.

Compared to lifestyle intervention, it may improve CVD morbidity and mortality as a function of the substantially greater weight loss that follows surgery, although neuroendocrine factors following gastrointestinal modification may also contribute. Postoperative complications (both physical and psychologic), compliance, and follow-up may be more problematic in adolescents than adults, and long-term data on safety, effectiveness, and cost remain largely unavailable.

PEARLS FOR PRACTITIONERS

See *Pediatric Nutrition and Nutritional Disorders: Pearls for Practitioners* at the end of this section.

CHAPTER 30

Pediatric Undernutrition

Pediatric undernutrition is usually the result of inadequate food supply, access (food insecurity), or utilization; poor access to health and sanitation; chronic health conditions; and/or inappropriate feeding, behavioral issues, or child-care practices. The greatest risk of undernutrition occurs when the child is in utero through age 2 years. Various guidelines can be used to classify pediatric malnutrition (Table 30.1). International references are established that allow normalization of anthropometric measures in terms of *z* scores. Measurements include height and weight for age, weight for

TABLE 30.1 Definitions of Malnutrition

CLASSIFICATION	DEFINITION	GRADING	
Gomez	Weight below % median WFA	Mild (grade 1)	75–90% WFA
		Moderate (grade 2)	60–74% WFA
		Severe (grade 3)	<60% WFA
Waterlow	<i>z</i> scores (SD) below median WFH	Mild	80–90% WFH
		Moderate	70–80% WFH
		Severe	<70% WFH
WHO (wasting)	<i>z</i> scores (SD) below median WFH	Moderate	$-3 \leq z \text{ score} < -2$
		Severe	$z \text{ score} < -3$
WHO (stunting)	<i>z</i> scores (SD) below median HFA	Moderate	$-3 \leq z \text{-score} < -2$
		Severe	$z \text{ score} < -3$
Kanawati	MUAC divided by occipitofrontal head circumference	Mild	<0.31
		Moderate	<0.28
		Severe	<0.25
Cole	<i>z</i> scores of BMI for age	Grade 1	BMI for age $z \text{ score} < -1$
		Grade 2	BMI for age $z \text{ score} < -2$
		Grade 3	BMI for age $z \text{ score} < -3$

BMI, Body mass index; HFA, height for age; MUAC, mid-upper arm circumference; NCHS, U.S. National Center for Health Statistics; SD, standard deviation; WFA, weight for age; WFH, weight for height; WHO, World Health Organization.

TABLE 30.2 Comprehensive Malnutrition Indicators

INDICATORS*	SEVERE MALNUTRITION	MODERATE MALNUTRITION	MILD MALNUTRITION
Weight-for-length z score	≥−3 z score or worse	−2.0 to 2.99 z score	−1.0 to −1.99 z score [†]
BMI-for-age z score	≥−3 z score or worse	−2.0 to 2.99 z score	−1.0 to −1.99 z score [†]
Weight-for-length/height z score	≥−3 z score or worse	No data available	No data available
Mid-upper arm circumference (<5yr of age)	≥−3 z score or worse	−2.0 to 2.99 z score	−1.0 to −1.99 z score
Weight gain velocity (≤2yr of age)	≤25% of norm	26–50% of norm	51–75% of the norm
Weight loss (2–20yr of age)	>10% of UBW	>7.5% UBW	>5% UBW
Deceleration in weight-for-length/height or BMI-for-age	Deceleration across 3 z score lines	Deceleration across 2 z score lines	Deceleration across 1 z score line
Inadequate nutrient intake	≤25% of estimated energy-protein need	26–50% of estimated energy-protein need	51–75% of estimated energy-protein need

BMI, Body mass index; UBW, usual body weight.

Use clinical judgment when applying these diagnostic criteria.

[†]It is recommended that when a child meets more than one malnutrition acuity level, the provider should document the severity of the malnutrition at the highest acuity level to ensure that an appropriate treatment plan and appropriate intervention, monitoring, and evaluation are provided.

[‡]Needs additional positive diagnostic criteria to make a malnutrition diagnosis.

Adapted from Becker PJ, Carney LN, Corkins MR, et al. Consensus statement of the Academy of Nutrition and Dietetics/American Society for Parenteral and Enteral Nutrition: indicators recommended for the identification and documentation of pediatric malnutrition (undernutrition). *J Acad Nutr Diet.* 2014;114(12):1988–2000.

height, body mass index (BMI), and mid-upper arm circumference (MUAC) as well as assessment for pitting edema. The 2006 World Health Organization (WHO) charts are recommended for children up to 2 years of age who are measured supine for length. The Centers for Disease Control and Prevention (CDC) 2000 growth charts are recommended for children and adolescents (age 2–20 years) when measured with a standing height. Plotting the z score (standard deviation [SD] from the mean) for each of these anthropometric values can be used to determine severity of malnutrition: mild, moderate, or severe (Table 30.2).

Protein-energy malnutrition (PEM) is a spectrum of conditions caused by varying levels of protein and calorie deficiencies. Primary PEM is caused by social or economic factors that result in a lack of adequate intake. Secondary PEM occurs in children with various conditions associated with increased caloric requirements (infection, trauma, cancer) (Fig. 30.1), increased caloric loss (malabsorption), reduced caloric intake (anorexia, cancer, oral intake restriction, social factors), or a combination of these three variables. Resulting nutrient deficiencies may be evident on physical examination (Table 30.3). Given the complex interplay of chronicity, etiology, and severity, a parenteral and enteral nutrition (ASPEN) working group developed a proposed classification scheme for malnutrition for hospitalized children (Fig. 30.2).

FAILURE TO THRIVE

Pediatric **undernutrition** in the United States is often termed **failure to thrive** and describes circumstances in which a child fails to gain weight appropriately or, in more severe cases, experiences failure in linear growth or head circumference. The terms *organic* and *nonorganic* failure to thrive have lost favor in recognition of the frequent interplay between underlying medical conditions that may cause maladaptive behaviors.

FIGURE 30.1 Increased energy needs with stress. (Modified from Wilmore D. *The Metabolic Management of the Critically Ill*. New York: Plenum Publishing; 1977. Revised in Walker W, Watkins J, eds. *Nutrition in Pediatrics: Basic Science and Clinical Application*. Boston: Little, Brown; 1985.)

Similarly, social and behavioral factors that initially may have been associated with feeding problems (see Chapter 21) and poor growth may also be associated with medical problems, including frequent minor acute illnesses.

TABLE 30.3 Physical Signs of Nutritional Deficiency Disorders

SYSTEM	SIGN	DEFICIENCY	SYSTEM	SIGN	DEFICIENCY
General appearance	Reduced weight for height	Calories	Face, mouth, and neck – cont'd	Atrophic papillae	Riboflavin, iron, niacin, folate, vitamin B ₁₂
Skin and hair	Pallor	Anemias (iron, vitamin B ₁₂ , vitamin E, folate, and copper)		Smooth tongue	Iron
	Edema	Protein, thiamine		Red tongue (glossitis)	Vitamins B ₆ , B ₁₂ , niacin, riboflavin, folate
	Nasolabial seborrhea	Calories, protein, vitamin B ₆ , niacin, riboflavin		Parotid swelling	Protein
	Dermatitis	Riboflavin, essential fatty acids, biotin		Caries	Fluoride
	Photosensitivity dermatitis	Niacin		Anosmia	Vitamins A, B ₁₂ , zinc
	Acrodermatitis	Zinc		Hypogeusia	Vitamin A, zinc
	Follicular hyperkeratosis (sandpaper-like)	Vitamin A		Goiter	Iodine
	Depigmented skin	Calories, protein	Cardiovascular	Heart failure	Thiamine, selenium, nutritional anemias
	Purpura	Vitamins C, K	Genital	Hypogonadism	Zinc
	Scrotal, vulval dermatitis	Riboflavin	Skeletal	Costochondral beading	Vitamins D, C
Alopecia	Zinc, biotin, protein	Subperiosteal hemorrhage		Vitamin C, copper	
Depigmented, dull hair, easily pluckable	Protein, calories, copper	Cranial bossing		Vitamin D	
Subcutaneous tissue	Decreased	Calories		Wide fontanel	Vitamin D
	Eye (vision)	Adaptation to dark		Vitamins A, E, zinc	Epiphyseal enlargement
Color discrimination		Vitamin A		Craniotabes	Vitamin D, calcium
Bitot spots, xerophthalmia, keratomalacia		Vitamin A		Tender bones	Vitamin C
Conjunctival pallor		Nutritional anemias		Tender calves	Thiamine, selenium, vitamin C
Fundal capillary microaneurysms		Vitamin C	Spoon-shaped nails (koilonychia)	Iron	
Face, mouth, and neck	Moon facies	Kwashiorkor	Transverse nail line	Protein	
	Simian facies	Marasmus	Neurologic	Sensory, motor neuropathy	Thiamine, biotin, vitamins E, B ₆ , B ₁₂
	Angular stomatitis	Riboflavin, iron		Ataxia, areflexia	Vitamin E
	Cheilosis	Vitamins B ₆ , niacin, riboflavin		Ophthalmoplegia	Vitamin E, thiamine
	Bleeding gums	Vitamins C, K		Tetany	Vitamin D, Ca ²⁺ , Mg ²⁺
		Intellectual disability		Iodine, niacin	
		Dementia, delirium	Vitamin E, niacin, thiamine		
		Poor position sense, ataxia	Thiamine, vitamin B ₁₂		

MARASMUS

Marasmus results from the body's physiologic response to inadequate calories and nutrients. Loss of muscle mass and subcutaneous fat stores can be confirmed by inspection or palpation and quantified by anthropometric measurements. The head may appear large but generally is proportional to the body length. Edema usually is absent. The skin is dry and thin, and the hair may be thin, sparse, and easily pulled out. Marasmic children may be apathetic and weak and may be irritable when touched. Bradycardia and hypothermia signify severe and life-threatening malnutrition. Inappropriate or inadequate weaning practices and chronic diarrhea are common findings in developing countries.

Stunting (impaired *linear* growth) results from a combination of malnutrition, especially micronutrients, and recurrent infections.

KWASHIORKOR

Kwashiorkor results from inadequate protein intake in the presence of fair to good caloric intake. The hypoalbuminemic state results in pitting edema that starts in the lower extremities and ascends with increasing severity. Other factors, such as acute infection, toxins, and possibly specific micronutrient or amino acid imbalances, are likely to contribute to the etiology. The major **clinical manifestation** of kwashiorkor

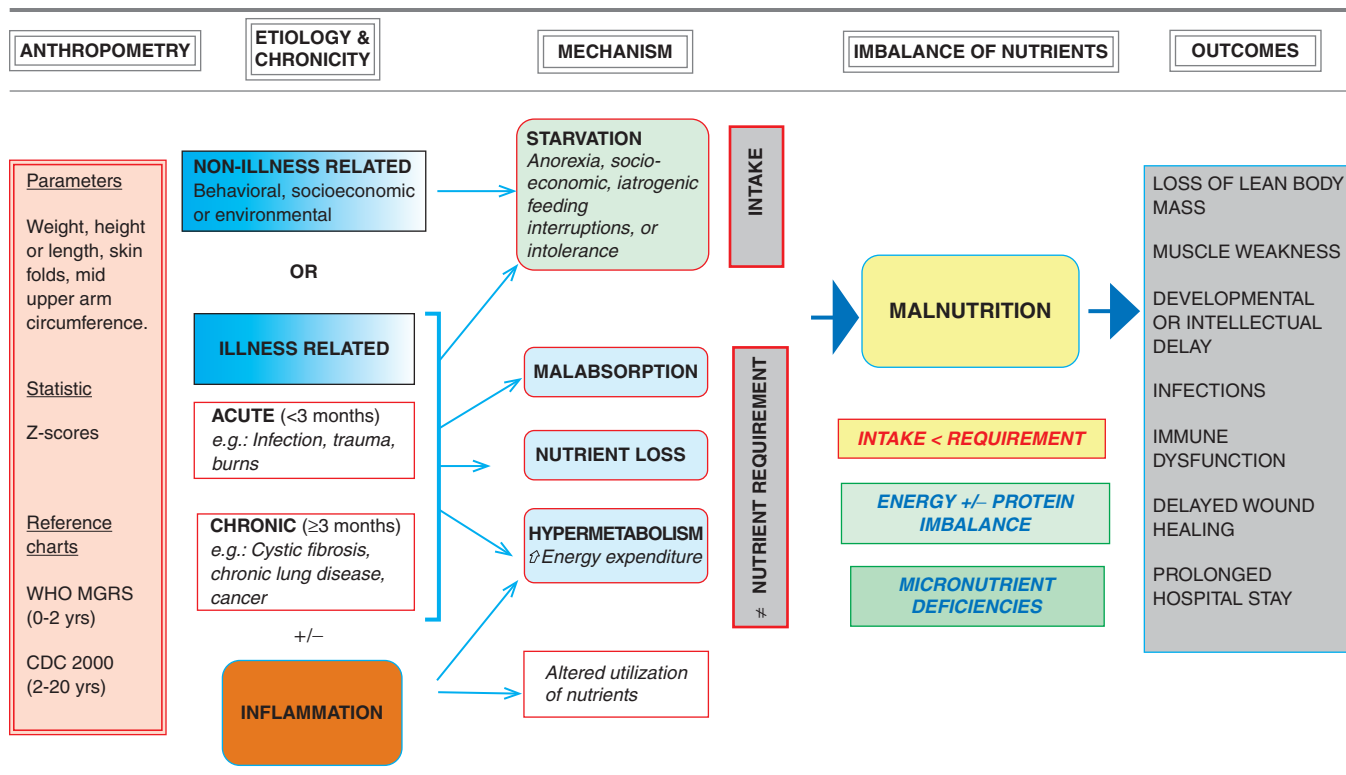

FIGURE 30.2 Defining malnutrition in hospitalized children (A.S.P.E.N.). CDC, Centers for Disease Control and Prevention; MGRS, Multicenter Growth Reference Study; WHO, World Health Organization. (From Mehta NM, Corkins MR, Lyman B, et al. Defining pediatric malnutrition: a paradigm shift toward etiology-related definitions. *JPEN*. 2013;37[4]:460–481.)

is that the body weight is near normal for age; weight alone does not accurately reflect the nutritional status because of edema. **Physical examination** reveals a relative maintenance of subcutaneous adipose tissue and a marked atrophy of muscle mass. Edema varies from a minor pitting of the dorsum of the foot to generalized edema with involvement of the eyelids and scrotum. The hair is sparse, easily plucked, and appears dull brown, red, or yellow-white. Nutritional repletion restores hair color, leaving a band of hair with altered pigmentation followed by a band with normal pigmentation (flag sign). Skin changes are common and range from hyperpigmented hyperkeratosis to an erythematous macular rash (pellagroid) on the trunk and extremities. In the most severe form of kwashiorkor, a superficial desquamation occurs over pressure surfaces (“flaky paint” rash). Angular cheilosis, atrophy of the filiform papillae of the tongue, and monilial stomatitis are common. Enlarged parotid glands and facial edema result in moon facies; apathy and disinterest in eating are typical of kwashiorkor. Examination of the abdomen may reveal an enlarged, soft liver with an indefinite edge. Lymph node and tonsils are commonly atrophic. Chest examination may reveal basilar rales. The abdomen is distended, and bowel sounds tend to be hypoactive.

MIXED MARASMUS-KWASHIORKOR

These children often have concurrent wasting and edema in addition to stunting. These children exhibit features of dermatitis, neurologic abnormalities, and fatty liver.

TREATMENT OF MALNUTRITION

The basal metabolic rate and immediate nutrient needs decrease in cases of malnutrition. When nutrients are provided, the metabolic rate increases, stimulating anabolism and increasing nutrient requirements. The body of the malnourished child may have compensated for micronutrient deficiencies with lower metabolic and growth rates, and refeeding may unmask these deficiencies. Nutritional rehabilitation should be initiated and advanced *slowly* to minimize these complications. The initial approach involves correction of dehydration and antimicrobial (bacteria, parasites) therapy if indicated. Oral rehydration is recommended over intravenous fluid to avoid excessive fluid and solute load and resultant heart or renal failure.

When nutritional rehabilitation is initiated, calories can be safely started at 20% above the child’s recent intake. If no estimate of the caloric intake is available, 50–75% of the normal energy requirement is safe. High-calorie oral solutions or ready-to-use therapeutic foods (a mixture of powdered milk, peanuts, sugar, vitamins, and minerals) are frequently used in developing countries. Nutritional rehabilitation can be complicated by **refeeding syndrome**, which is characterized by fluid retention, hypophosphatemia, hypomagnesemia, and hypokalemia. Careful monitoring of laboratory values and clinical status with severe malnutrition is essential.

When nutritional rehabilitation has begun, caloric intake can be increased 10–20% per day, monitoring for electrolyte imbalances, poor cardiac function, edema, or feeding intolerance. If any of these occurs, further caloric increases are

not made until the child's status stabilizes. Caloric intake is increased until appropriate regrowth or catch-up growth is initiated. Catch-up growth refers to gaining weight at greater than 50th percentile for age and may require 150% or more of the recommended calories for an age-matched, well-nourished child. A general rule of thumb for infants and children up to 3 years of age is to provide 100–120 kcal/kg based on *ideal* weight for height. Protein needs also are increased as anabolism begins and are provided in proportion to the caloric intake. Vitamin and mineral intake in excess of the daily recommended intake is provided to account for the increased requirements; this is frequently accomplished by giving an age-appropriate daily multiple vitamin with other individual micronutrient supplements as warranted by history, physical examination, or laboratory studies. Iron supplements are not recommended during the *acute* rehabilitation phase, especially for children with kwashiorkor, for whom ferritin levels are often high. Additional iron may pose an oxidative stress; iron supplementation at this time is associated with higher morbidity and mortality.

In most cases, cow's milk-based formulas are tolerated and provide an appropriate mix of nutrients. Other easily digested foods, appropriate for the age, also may be introduced slowly. If feeding intolerance occurs, lactose-free or semi-elemental formulas should be considered.

COMPLICATIONS OF MALNUTRITION

Malnourished children are more susceptible to **infection**, especially sepsis, pneumonia, and gastroenteritis. Hypoglycemia is common after periods of severe fasting but may also be a sign of sepsis. Hypothermia may signify infection or, with bradycardia, may signify a decreased metabolic rate to conserve energy. Bradycardia and poor cardiac output predispose the malnourished child to heart failure, which is exacerbated by acute fluid or solute loads. **Micronutrient deficiencies** also can complicate malnutrition. Vitamin A and zinc deficiencies are common in the developing world and are an important cause of altered immune response and increased morbidity and mortality. Depending on the age at onset and the duration of the malnutrition, malnourished children may have permanent growth stunting (from malnutrition in utero, infancy, or adolescence) and delayed development (from malnutrition in infancy or adolescence). Environmental (social) deprivation may interact with the effects of the malnutrition to impair further development and cognitive function.

PEARLS FOR PRACTITIONERS

See *Pediatric Nutrition and Nutritional Disorders: Pearls for Practitioners* at the end of this section.

TABLE 31.1 Etiology of Vitamin and Nutrient Deficiency States

ETIOLOGY	DEFICIENCY
DIET	
Vegans (strict)	Protein, vitamins B ₁₂ , D, riboflavin, iron
Breast-fed infant	Vitamins K, D
Cow's milk-fed infant	Iron
Bulimia, anorexia nervosa	Electrolytes, other deficiencies
Parenteral alimentation	Essential fatty acids, trace elements
Alcoholism	Calories, vitamin B ₁ , B ₆ , folate
MEDICAL PROBLEMS	
Malabsorption syndromes	Vitamins A, D, E, K, zinc, essential fatty acids
Cholestasis	Vitamins E, D, K, A, zinc, essential fatty acids
MEDICATIONS	
Sulfonamides	Folate
Phenytoin, phenobarbital	Vitamins D, K, folate
Mineral oil	Vitamins A, D, E, K
Antibiotics	Vitamin K
Isoniazid	Vitamin B ₆
Antacids	Iron, phosphate, calcium
Digitalis	Magnesium, calcium
Penicillamine	Vitamin B ₆
SPECIFIC MECHANISMS	
Transcobalamin II or intrinsic factor deficiency	Vitamin B ₁₂
Other digestive enzymes	Carbohydrate, fat, protein deficiencies
Menkes kinky hair syndrome	Copper
Acrodermatitis enteropathica	Zinc
Reduced exposure to direct sunlight	Vitamin D

CHAPTER 31

Vitamin and Mineral Deficiencies

Micronutrients include vitamins and trace elements. In industrialized societies, frank clinical deficiencies are unusual in healthy children, but they can and do occur in certain high-risk circumstances. Risk factors include diets that are consistently

limited in variety (especially with the exclusion of entire food groups), malabsorption syndromes, and conditions causing high physiologic requirements. Various common etiologies of vitamin and nutrient deficiency states are highlighted in Table 31.1, and characteristics of vitamin deficiencies are outlined in Table 31.2. Treatment is noted in Table 31.3.

WATER-SOLUBLE VITAMINS

Water-soluble vitamins are not stored in the body except for vitamin B₁₂; intake therefore alters tissue levels. Absorption from the diet is usually high, and the compounds exchange

TABLE 31.2 Characteristics of Vitamin Deficiencies

VITAMIN	PURPOSE	DEFICIENCY	COMMENTS	SOURCE
WATER SOLUBLE				
Thiamine (B ₁)	Coenzyme in ketoacid decarboxylation (e.g., pyruvate→acetyl-CoA transketolase reaction)	<i>Beriberi</i> : polyneuropathy, calf tenderness, heart failure, edema, ophthalmoplegia	Inborn errors of lactate metabolism; boiling milk destroys B ₁	Liver, meat, milk, cereals, nuts, legumes
Riboflavin (B ₂)	FAD coenzyme in oxidation-reduction reactions	Anorexia, mucositis, anemia, cheilosis, nasolabial seborrhea	Photosensitizer	Milk, cheese, liver, meat, eggs, whole grains, green leafy vegetables
Niacin (B ₃)	NAD coenzyme in oxidation-reduction reactions	<i>Pellagra</i> : photosensitivity, dermatitis, dementia, diarrhea, death	Tryptophan is a precursor	Meat, fish, liver, whole grains, green leafy vegetables
Pyridoxine (B ₆)	Cofactor in amino acid metabolism	Seizures, hyperacusis, microcytic anemia, nasolabial seborrhea, neuropathy	Dependency state: deficiency secondary to drugs	Meat, liver, whole grains, peanuts, soybeans
Pantothenic acid	CoA in Krebs cycle	None reported	—	Meat, vegetables
Biotin	Cofactor in carboxylase reactions of amino acids	Alopecia, dermatitis, hypotonia, death	Bowel resection, inborn error of metabolism,* and ingestion of raw eggs	Yeast, meats; made by intestinal flora
B ₁₂	Coenzyme for 5-methyltetrahydrofolate formation; DNA synthesis	Megaloblastic anemia, peripheral neuropathy, posterior lateral spinal column disease, vitiligo	Vegans; fish tapeworm; short gut syndrome; transcobalamin or intrinsic factor deficiencies	Meat, fish, cheese, eggs
Folate	DNA synthesis	Megaloblastic anemia; neural tube defects	Goat milk deficient; drug antagonists; heat inactivates	Liver, greens, vegetables, cereals, cheese
Ascorbic acid (C)	Reducing agent; collagen metabolism	<i>Scurvy</i> : irritability, purpura, bleeding gums, periosteal hemorrhage, aching bones	May improve tyrosine metabolism in preterm infants	Citrus fruits, green vegetables; cooking destroys it
FAT SOLUBLE				
A	Epithelial cell integrity; vision	Night blindness, xerophthalmia, Bitot spots, follicular hyperkeratosis; immune defects	Common with protein-calorie malnutrition; malabsorption	Liver, milk, eggs, green and yellow vegetables, fruits
D	Maintain serum calcium, phosphorus levels	<i>Rickets</i> : reduced bone mineralization	Prohormone of 25- and 1,25-vitamin D	Fortified milk, cheese, liver; sunlight
E	Antioxidant	Hemolysis in preterm infants; areflexia, ataxia, ophthalmoplegia	May benefit patients with G6PD deficiency	Seeds, vegetables, germ oils, grains
K	Post-translation carboxylation of clotting factors II, VII, IX, X and proteins C, S	Prolonged prothrombin time; hemorrhage; elevated protein induced in vitamin K absence (PIVKA)	Malabsorption; breast-fed infants	Liver, green vegetables; made by intestinal flora

*Biotinidase deficiency.

CoA, Coenzyme A; FAD, flavin adenine dinucleotide; G6PD, glucose-6-phosphate dehydrogenase; NAD, nicotinamide adenine dinucleotide.

readily between intracellular and extracellular fluids; excretion is via the urine. Water-soluble vitamins typically function as coenzymes in energy, protein, amino acid, and nucleic acid metabolism; as co-substrates in enzymatic reactions; and as structural components.

Ascorbic Acid

The principal forms of vitamin C are ascorbic acid and the oxidized form, dehydroascorbic acid. Ascorbic acid accelerates hydroxylation reactions in many biosynthetic reactions,

including hydroxylation of proline in the formation of collagen. The needs of full-term infants for ascorbic acid and dehydroascorbic acid are calculated by estimating the availability in human milk.

A deficiency of ascorbic acid results in the clinical manifestation of **scurvy**. Infantile scurvy is manifested by irritability, bone tenderness with swelling, and pseudoparalysis of the legs. The disease may occur if infants are fed unsupplemented cow's milk in the first year of life or if the diet is devoid of fruits and vegetables. Subperiosteal hemorrhage, bleeding gums and petechiae, hyperkeratosis of hair follicles, and a succession

TABLE 31.3 Treatment of Vitamin Deficiencies		
	CLINICAL FEATURES	SUGGESTED DOSES
Vitamin A	Severe deficiency with xerophthalmia	Infants: 7,500–15,000 U/day IM, followed by oral 5,000–10,000 U/day for 10 days. Children 1–8yr of age: oral 5,000–10,000 U/kg/day for 5 days or until recovery. Children >8yr of age and adults: oral 500,000 U/day for 3 days; then 50,000 U/day for 14 days; then 10,000–20,000 U/day for 2 mo.
	Deficiency without corneal changes	Infants <1 yr of age: 100,000 U/day orally, q4–6 mo. Children 1–8yr of age: 200,000 U/day orally, q4–6 mo. Children >8yr and adults: 100,000 U/day for 3 days, followed by 50,000 U/day for 10 days.
	Deficiency	IM given only to those patients with malabsorption in whom oral dosing is not possible. Infants: 7,500–15,000 U/day for 10 days. Children 1–8yr of age: 17,500–35,000 U/day for 10 days. Children >8yr of age and adults: 100,000 U/day for 3 days, then 50,000 U/day for 14 days. Give follow-up oral multivitamin that contains vitamin A: LBW infants: no dose established, children ≤8yr of age: 5,000–10,000 U/day, children >8yr of age and adults: 10,000–20,000 U daily.
	Malabsorption syndrome (prophylaxis)	Children >8yr of age and adults: oral 10,000–50,000 U/day of water-miscible product.
	Cystic fibrosis	1,500–10,000 U/day prophylaxis (CF Foundation).
	Measles	WHO recommendations: single dose, repeating the dose next day and at 4 wk for children with eye findings: 6 mo–1 yr of age: 100,000 U; >1 yr of age: 200,000 U.
Vitamin D	Liver disease	4,000–8,000 U/day ergocalciferol.
	Malabsorption	1000 U/day ergocalciferol
	Nutritional rickets and osteomalacia	Ergocalciferol: children and adults with normal absorption: 1,000–5,000 U/day. Children with malabsorption: 10,000–25,000 U/day. Adults with malabsorption: 10,000–300,000 U/day.
	Renal disease and failure	Ergocalciferol: child: 4,000–40,000 U/day; adults: 20,000 U/day.
	Cystic fibrosis	Ergocalciferol: 400–800 U/day PO (CF Foundation).
	Hypoparathyroidism	Children: 50,000–200,000 U/day ergocalciferol and calcium supplements. Adults: 25,000–200,000 U/day ergocalciferol and calcium supplements.
	Vitamin D–dependent rickets	Children: 3,000–5,000 U/day ergocalciferol; max: 60,000 U/day. Adults: 10,000–60,000 U/day ergocalciferol.
	Vitamin D–resistant rickets	Children: initial 40,000–80,000 U/day with phosphate supplements, daily dosage is increased at 3–4 mo intervals in 10,000–20,000 U increments. Adults: 10,000–60,000 U/day with phosphate supplements.
Vitamin E	Premature infant, neonates, infants of low birthweight	D-α-tocopherol: 25–50 U/day for 1 wk orally.
	Fat malabsorption and liver disease	10–25 U/kg/day of water-miscible vitamin E preparation.
	Cystic fibrosis	<1 yr of age: 25–50 U/day; 1–2yr of age: 100 U/day; >2yr of age: 100 U/day bid or 200 U daily orally (CF Foundation).
	Sickle cell disease	450 U/day orally.
	β-thalassemia	750 U/day orally.
Vitamin K	Hemorrhagic disease of the newborn	Phytonadione: 0.5–1.0 mg SC or IM as prophylaxis within 1 hr of birth, may repeat 6–8 hr later; 1–2 mg/day as treatment.
	Deficiency	Infants and children: 2.5–5 mg/day orally, or 1–2 mg/dose SC, IM, IV as a single dose; adults: 5–25 mg/day or 10 mg IM, IV.
	Cystic fibrosis	2.5 mg, twice a week (CF Foundation).

Continued

TABLE 31.3 Treatment of Vitamin Deficiencies—cont'd

	CLINICAL FEATURES	SUGGESTED DOSES
Folate, folic acid, and folacin	Deficiency	Infants: 50 µg daily. Children 1–10 yr of age: 1 mg/day initially, then 0.1–0.4 mg/day as maintenance. Children >11 yr of age and adults: 1 mg/day initially, then 0.5 mg/day as maintenance.
	Hemolytic anemia	May require higher doses than those listed previously.
Niacin	Pellagra	Children: 50–100 mg tid. Adults: 50–100 mg/day, max 100 mg/day.
Pyridoxine (B ₆)	Seizures	Neonates and infants: initial 50–100 mg/day orally, IM, IV, SC.
	Drug-induced deficiencies	Children: 10–50 mg/day as treatment, 1–2 mg/kg/day as prophylaxis. Adults: 100–200 mg/day as treatment, 25–100 mg/day as prophylaxis.
	Dietary deficiency	Children: 5–25 mg/day for 3 wk, then 1.5–2.5 mg/day in a multivitamin product. Adults: 10–20 mg/day for 3 wk.
Riboflavin (B ₂)		Children: 2.5–10 mg/day in divided doses. Adults: 5–30 mg/day in divided doses.
Thiamine (B ₁)	Beriberi: critically ill	Children: 10–25 mg/day IM or IV. Adults: 5–30 mg/dose IM, IV tid, then 5–30 mg/day orally in a single or three divided doses for 1 mo.
	Beriberi: not critically ill	Children: 10–50 mg/day orally for 2 wk, then 5–10 mg/day for 1 mo.
	Metabolic disease	Adults: 10–20 mg/day orally.
	Wernicke encephalopathy	Adults: initially 100 mg IV, then 50–100 mg/day IM/IV until eating a balanced diet.
Cyanocobalamin (B ₁₂)	Nutritional deficiency	Intranasal gel: 500 µg once a week. Orally: 25–250 µg/wk.
	Anemia	Give IM or deep SC; oral route not recommended because of poor absorption, and IV route not recommended because of more rapid elimination.
	Pernicious anemia	If evidence of neurologic involvement in neonates and infants (congenital), 1,000 µg/day IM, SC, for at least 2 wk, and then maintenance, 50–100 µg/mo or 100 µg/day for 6–7 days. If clinical improvement, give 100 µg every other day for 7 doses, then every 3–4 days for 2–3 wk, followed by 100 µg/mo for life. Administer with folic acid if needed (1 mg/day for 1 mo concomitantly). Children: 30–50 µg/day for 2 or more wk (total dose of 1000 µg) IM, SC, then 100 µg/mo as maintenance. Adults: 100 µg/day for 6–7 days; if improvement, administer same dose on alternate days for 7 doses, then every 3–4 days for 2–3 wk. Once hematologic values are normal, give maintenance doses of 100 µg/mo parenterally.
	Hematologic remission	No evidence of neurologic involvement: use intranasal gel: 500 µg/wk.
	Vitamin B ₁₂ deficiency	Children with neurologic signs: 100 µg/day for 10–15 days (total dose of 1–1.5 mg), then 1–2/wk for several mo and taper to 60 µg/mo. Children with hematologic signs: 10–50 µg/day for 5–10 days, followed by 100–250 µg/day every 2–4 wk. Adults: 30 µg/day for 5–10 days, followed by maintenance doses of 100–200 µg/mo.
Ascorbic acid	Scurvy	Children: 100–300 mg/day in divided doses orally, IM, IV, or SC for several days. Adults: 100–250 mg/day 1–2 times/day.

bid, Two times per day; *CF*, cystic fibrosis; *IM*, intramuscular; *IV*, intravenous; *LBW*, low birthweight; *PO*, by mouth; *q*, every; *SC*, subcutaneous; *tid*, three times per day; *WHO*, World Health Organization.

Data from Lexi-Comp Inc., Hudson, Ohio; 2004; table from Kronel S, Mascarenhas MR. Vitamin deficiencies and excesses. In: Burg FD, Ingelfinger JR, Polin RA, et al., eds. Current Pediatric Therapy. Philadelphia: Elsevier; 2006:104–105 [Table 3].

of mental changes characterize the progression of the illness. Anemia secondary to bleeding, decreased iron absorption, or abnormal folate metabolism are also seen in chronic scurvy. Treatment is noted in [Table 31.3](#).

B Vitamins

The B vitamins thiamine, riboflavin, and niacin are routinely added to enriched grain products; deficiencies in normal hosts are rare in the United States. Levels from human milk reflect maternal intake, and deficiency can develop in breast-fed infants of deficient mothers.

Thiamine

Vitamin B₁ functions as a coenzyme in biochemical reactions related to carbohydrate metabolism, decarboxylation of α -keto acids and pyruvate, and transketolase reactions of the pentose pathway. Thiamine also is involved in the decarboxylation of branched-chain amino acids. Thiamine is lost during milk pasteurization and sterilization.

Thiamine deficiency occurs in alcoholics and has been reported in adolescents who have undergone bariatric surgery for severe obesity. **Infantile beriberi** occurs between 1 and 4 months of age in breast-fed infants whose mothers have a thiamine deficiency, in infants with protein-calorie malnutrition, in infants receiving unsupplemented hyperalimentation fluid, and in infants receiving boiled milk. Acute **wet beriberi** with cardiac symptoms and signs predominates in infantile beriberi. Anorexia, apathy, vomiting, restlessness, and pallor progress to dyspnea, cyanosis, and death from heart failure. Infants with beriberi have a characteristic aphonic cry; they appear to be crying, but no sound is uttered. Other signs include peripheral neuropathy and paresthesias. For treatment see [Table 31.3](#).

Riboflavin

Vitamin B₂ is a constituent of two coenzymes, riboflavin 5'-phosphate and flavin-adenine dinucleotide, essential components of glutathione reductase and xanthine oxidase, which are involved in electron transport. A deficiency of riboflavin affects glucose, fatty acid, and amino acid metabolism. Riboflavin and its phosphate are decomposed by exposure to light and by strong alkaline solutions.

Ariboflavinosis is characterized by an angular stomatitis, glossitis, cheilosis, seborrheic dermatitis around the nose and mouth, and eye changes that include reduced tearing, photophobia, corneal vascularization, and the formation of cataracts. Subclinical riboflavin deficiencies have been found in diabetic subjects, children in families with low socioeconomic status, children with chronic cardiac disease, and infants undergoing prolonged phototherapy for hyperbilirubinemia.

Niacin

Niacin consists of the compounds nicotinic acid and nicotinamide (niacinamide). Nicotinamide, the predominant form of the vitamin, functions as a component of the coenzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). Niacin is involved in multiple metabolic processes, including fat synthesis, intracellular respiratory metabolism, and glycolysis.

In determining the needs for niacin, the content of tryptophan in the diet must be considered because tryptophan is

converted to niacin. Niacin is stable in foods and withstands heating and prolonged storage. Approximately 70% of the total niacin equivalents in human milk are derived from tryptophan. **Pellagra**, or niacin-deficiency disease, is characterized by weakness, lassitude, dermatitis, photosensitivity, inflammation of mucous membranes, diarrhea, vomiting, dysphagia, and, in severe cases, dementia.

Vitamin B₆

Vitamin B₆ refers to three naturally occurring pyridines: pyridoxine (pyridoxol), pyridoxal, and pyridoxamine. The phosphates of the latter two pyridines are metabolically and functionally related and are converted in the liver to the coenzyme form, pyridoxal phosphate. The metabolic functions of vitamin B₆ include interconversion reactions of amino acids, conversion of tryptophan to niacin and serotonin, metabolic reactions in the brain, carbohydrate metabolism, immune development, and the biosynthesis of heme and prostaglandins. The pyridoxal and pyridoxamine forms of the vitamin are destroyed by heat; heat treatment was responsible for vitamin B₆ deficiency and seizures in infants fed improperly processed formulas. *Goat's milk is deficient in vitamin B₆.*

Dietary deprivation or malabsorption of vitamin B₆ in children results in hypochromic microcytic anemia, vomiting, diarrhea, failure to thrive, listlessness, hyperirritability, and seizures. Children receiving isoniazid or penicillamine may require additional vitamin B₆ because the drug binds to the vitamin. Vitamin B₆ is unusual as a water-soluble vitamin, in that very large doses (≥ 500 mg/day) have been associated with a sensory neuropathy.

Folate

A variety of chemical forms of folate are nutritionally active. Folate functions in transport of single-carbon fragments in synthesis of nucleic acids and for normal metabolism of certain amino acids and in conversion of homocysteine to methionine. Food sources include green leafy vegetables, oranges, and whole grains; folate fortification of grains is now routine in the United States.

Folate deficiency, characterized by **hypersegmented neutrophils**, **macrocytic anemia**, and glossitis, may result from a low dietary intake, malabsorption, or vitamin-drug interactions. Deficiency can develop within a few weeks of birth because infants require 10 times as much folate as adults relative to body weight but have scant stores of folate in the newborn period. Folate is particularly heat labile. Heat-sterilizing home-prepared formula can decrease the folate content by half. *Evaporated milk and goat's milk are low in folate.* Patients with chronic hemolysis (sickle cell anemia, thalassemia) may require extra folate to avoid deficiency because of the relatively high requirement of the vitamin to support erythropoiesis. Other conditions with risk of deficiency include pregnancy, alcoholism, and treatment with anticonvulsants (phenytoin) or antimetabolites (methotrexate). First occurrence and recurrence of **neural tube defects** are reduced significantly by maternal supplementation during embryogenesis. Because closure of the neural tube occurs before usual recognition of pregnancy, all women of reproductive age are recommended to have a folate intake of at least 400 μ g/day as prophylaxis.

Vitamin B₁₂

Vitamin B₁₂ is one of the most complex vitamin molecules, containing an atom of cobalt held in a *corrin ring* (similar to that of iron in hemoglobin). The cobalt ion is at the active center of the ring and serves as the site for attachment of alkyl groups during their transfer. The vitamin functions in single-carbon transfers and is intimately related to folate function and interconversions. Vitamin B₁₂ is essential for normal lipid and carbohydrate metabolism in energy production and in protein biosynthesis and nucleic acid synthesis.

In contrast to other water-soluble vitamins, absorption of vitamin B₁₂ is complex, involving cleavage of the vitamin from dietary protein and binding to a glycoprotein called *intrinsic factor*, which is secreted by the gastric mucosa (parietal cells). The cobalamin–intrinsic factor complex is efficiently absorbed from the distal ileum.

When vitamin B₁₂ is absorbed into the portal circulation, it is transported bound to a specific protein, transcobalamin II. Its large stores in the liver also are unusual for a water-soluble vitamin. Efficient enterohepatic circulation normally protects from deficiency for months to years. Dietary sources of the vitamin are animal products only. Strict vegetarians should take a vitamin B₁₂ supplement.

Vitamin B₁₂ deficiency in children is rare. Early diagnosis and treatment of this disorder in childhood are important because of the danger of irreversible neurologic damage. Most cases in childhood result from a specific defect in absorption (see Table 31.2). Such defects include **congenital pernicious anemia** (absent intrinsic factor), **juvenile pernicious anemia** (autoimmune), and deficiency of transcobalamin II transport. Gastric or intestinal resection and small bowel bacterial overgrowth also cause vitamin B₁₂ deficiency. Exclusively breast-fed infants ingest adequate vitamin B₁₂ unless the mother is a strict vegetarian without supplementation.

Depression of serum vitamin B₁₂ and the appearance of hypersegmented neutrophils and macrocytosis (indistinguishable from folate deficiency) are early clinical manifestations of deficiency. Vitamin B₁₂ deficiency also causes **neurologic manifestations**, including depression, peripheral neuropathy, posterior spinal column signs, dementia, and eventual coma. The neurologic signs do not occur in folate deficiency, but administration of folate may mask the hematologic signs of vitamin B₁₂ deficiency, while the neurologic manifestations progress. Patients with vitamin B₁₂ deficiency also have increased urine levels of methylmalonic acid. Most cases of vitamin B₁₂ deficiency in infants and children are not of dietary origin and require treatment throughout life. Maintenance therapy consists of repeated monthly intramuscular injections, although a form of vitamin B₁₂ is administered intranasally.

FAT-SOLUBLE VITAMINS

Fat-soluble vitamins generally have stores in the body, and dietary deficiencies generally develop more slowly than for water-soluble vitamins. Absorption of fat-soluble vitamins depends on normal fat intake, digestion, and absorption. The complexity of normal fat absorption and the potential for perturbation in many disease states explains the more common occurrence of deficiencies of these vitamins.

Vitamin A

The basic constituent of the vitamin A group is retinol. Ingested plant carotene or animal tissue retinol esters release retinol after hydrolysis by pancreatic and intestinal enzymes. Chylomicron-transported retinol esters are stored in the liver as retinol palmitate. Retinol is transported from the liver to target tissues by retinol-binding protein, releasing free retinol to the target tissues. The kidney then excretes the retinol-binding protein. Diseases of the kidney diminish excretion of retinol-binding protein, whereas liver parenchymal disease or malnutrition lowers the synthesis of retinol-binding protein. Specific cellular binding proteins facilitate the uptake of retinol by target tissues. In the eye, retinol is metabolized to form **rhodopsin**; the action of light on rhodopsin is the first step of the visual process. Retinol also influences the growth and differentiation of epithelia. The clinical manifestations of vitamin A deficiency in humans appear as a group of ocular signs termed **xerophthalmia**. The earliest symptom is **night blindness**, which is followed by **xerosis** of the conjunctiva and cornea. Untreated, xerophthalmia can result in ulceration, necrosis, keratomalacia, and a permanent corneal scar. Clinical and subclinical vitamin A deficiencies are associated with **immunodeficiency**; increased risk of infection, especially measles; and increased risk of mortality, especially in developing nations. Xerophthalmia and vitamin A deficiency should be urgently treated. *Hypervitaminosis A* also has serious sequelae, including headaches, pseudotumor cerebri, hepatotoxicity, and teratogenicity.

Vitamin E

Eight naturally occurring compounds have vitamin E activity. The most active of these, α -tocopherol, accounts for 90% of the vitamin E present in human tissues and is commercially available as an acetate or succinate. Vitamin E acts as a biologic **antioxidant** by inhibiting the peroxidation of polyunsaturated fatty acids present in cell membranes. It scavenges free radicals generated by the reduction of molecular oxygen and by the action of oxidative enzymes.

Vitamin E deficiency occurs in children with fat malabsorption secondary to liver disease, untreated celiac disease, cystic fibrosis, and abetalipoproteinemia. In these children, without vitamin E supplementation, a syndrome of progressive **sensory and motor neuropathy** develops; the first sign of deficiency is loss of deep tendon reflexes. Deficient preterm infants at 1–2 months of age have hemolytic anemia characterized by an elevated reticulocyte count, an increased sensitivity of the erythrocytes to hemolysis in hydrogen peroxide, peripheral edema, and thrombocytosis. All the abnormalities are corrected after oral, lipid, or water-soluble vitamin E therapy.

Vitamin D

Cholecalciferol (vitamin D₃) is the mammalian form of vitamin D and is produced by ultraviolet irradiation of inactive precursors in the skin. Ergocalciferol (vitamin D₂) is derived from plants. Vitamin D₂ and vitamin D₃ require further metabolism to become active. They are of equivalent potency. Clothing, lack of sunlight exposure, and skin pigmentation decrease generation of vitamin D in the epidermis and dermis.

Vitamin D (D_2 and D_3) is metabolized in the liver to calcidiol, or 25-hydroxyvitamin D (25[OH]D); this metabolite, which has little intrinsic activity, is transported by a plasma-binding globulin to the kidney, where it is converted to the most active metabolite calcitriol, or 1,25-dihydroxyvitamin D (1,25[OH₂]D). The action of 1,25(OH₂)D results in a decrease in the concentration of messenger RNA (mRNA) for collagen in bone and an increase in the concentration of mRNA for vitamin D-dependent calcium-binding protein in the intestine (directly mediating increased intestinal calcium transport). The antirachitic action of vitamin D probably is mediated by provision of appropriate concentrations of calcium and phosphate in the extracellular space of bone and by enhanced intestinal absorption of these minerals. Vitamin D also may have a direct anabolic effect on bone. 1,25(OH₂)D has direct feedback to the parathyroid gland and inhibits secretion of parathyroid hormone.

Vitamin D deficiency appears as **rickets** in children and as **osteomalacia** in postpubertal adolescents. Inadequate direct sun exposure and vitamin D intake are sufficient causes, but other factors, such as various drugs (phenobarbital, phenytoin) and malabsorption, may increase the risk of development of vitamin-deficiency rickets. Breast-fed infants, especially those with dark-pigmented skin, are at risk for vitamin D deficiency.

The pathophysiology of rickets results from defective bone growth, especially at the epiphyseal cartilage matrix, which fails to mineralize. The uncalcified osteoid results in a wide, irregular zone of poorly supported tissue, the rachitic metaphysis. This soft, rather than hardened, zone produces many of the skeletal deformities through compression and lateral bulging or flaring of the ends of bones.

The **clinical manifestations** of rickets are most common during the first 2 years of life and may become evident only after several months of a vitamin D-deficient diet. **Craniotabes** is caused by thinning of the outer table of the skull, which when compressed feels like a Ping-Pong ball to the touch. Enlargement of the costochondral junction (**rachitic rosary**) and thickening of the wrists and ankles may be palpated. The anterior fontanel is enlarged, and its closure may be delayed. In advanced rickets, scoliosis and exaggerated lordosis may be present. Bowlegs or knock-knees may be evident in older infants, and greenstick fractures may be observed in long bones.

The **diagnosis** of rickets is based on a history of poor vitamin D intake and little exposure to direct ultraviolet sunlight. The serum calcium usually is normal but may be low; the serum phosphorus level usually is reduced, and serum alkaline phosphatase activity is elevated. When serum calcium levels decline to less than 7.5 mg/dL, tetany may occur. Levels of 24,25(OH₂)D are undetectable, and serum 1,25(OH₂)D levels are commonly less than 7 ng/mL, although 1,25(OH₂)D levels also may be normal. The best measure of vitamin D status is the level of 25(OH)D. Characteristic **radiographic** changes of the distal ulna and radius include widening; concave cupping; and frayed, poorly demarcated ends. The increased space seen between the distal ends of the radius and ulna and the metacarpal bones is the enlarged, non-ossified metaphysis.

Breast-fed infants born of mothers with adequate vitamin D stores usually maintain adequate serum vitamin D levels for at least 2 months, but rickets may develop subsequently if these infants are not exposed to the sun or do not receive

supplementary vitamin D. Vitamin D supplementation is recommended for all breast-fed infants in the amount of 400 IU/day, started soon after birth and given until the infant is taking more than 1,000 mL/day of formula or vitamin D-fortified milk (for age >1 year). *Toxic effects of excessive chronic vitamin D* may include hypercalcemia, muscle weakness, polyuria, and nephrocalcinosis.

Vitamin K

The plant form of vitamin K is phyloquinone, or vitamin K₁. Another form is menaquinone, or vitamin K₂, one of a series of compounds with unsaturated side chains synthesized by intestinal bacteria. Plasma factors II (prothrombin), VII, IX, and X in the cascade of blood coagulation factors depend on vitamin K for synthesis and for post-translational conversion of their precursor proteins. The post-translational conversion of glutamyl residues to carboxyglutamic acid residues of a prothrombin molecule creates effective calcium-binding sites, making the protein active.

Other vitamin K-dependent proteins include proteins C, S, and Z in plasma and γ -carboxyglutamic acid-containing proteins in several tissues. Bone contains a major vitamin K-dependent protein, osteocalcin, and lesser amounts of other glutamic acid-containing proteins.

Phylloquinone is absorbed from the intestine and transported by chylomicrons. The rarity of dietary vitamin K deficiency in humans with normal intestinal function suggests that the absorption of menaquinones is possible. Vitamin K deficiency has been observed in subjects with impaired fat absorption caused by obstructive jaundice, pancreatic insufficiency, and celiac disease; often these problems are combined with the use of antibiotics that change intestinal flora.

Hemorrhagic disease of the newborn, a disease more common among breast-fed infants, occurs in the first few weeks of life. It is rare in infants who receive prophylactic intramuscular vitamin K on the first day of life. Hemorrhagic disease of the newborn usually is marked by generalized ecchymoses, gastrointestinal hemorrhage, or bleeding from a circumcision or umbilical stump; intracranial hemorrhage can occur but is uncommon. It is recommended that parenteral vitamin K (0.5–1 mg) be given to all newborns shortly after birth.

MINERALS

The *major minerals* are those that require intakes of more than 100 mg/day and contribute at least 0.1% of total body weight. There are seven essential major minerals: calcium, phosphorus, magnesium, sodium, potassium, chloride, and sulfur. Ten *trace minerals*, which constitute less than 0.1% of body weight, have essential physiologic roles. Characteristics of trace mineral deficiencies are listed in [Table 31.4](#).

Calcium

Calcium is the most abundant major mineral. Ninety-nine percent of calcium is in the skeleton; the remaining 1% is in extracellular fluids, intracellular compartments, and cell membranes. Non-skeletal calcium has a role in nerve conduction, muscle contraction, blood clotting, and membrane permeability. There are two distinct bone calcium phosphate

TABLE 31.4 Trace Elements				
ELEMENT	PHYSIOLOGY	EFFECTS OF DEFICIENCY	EFFECTS OF EXCESS	DIETARY SOURCES
Chromium	Potentiates the action of insulin	Impaired glucose tolerance, peripheral neuropathy, and encephalopathy	Unknown	Meat, grains, fruits, and vegetables
Copper	Absorbed via specific intestinal transporter Circulates bound to ceruloplasmin Enzyme cofactor (superoxide dismutase, cytochrome oxidase, and enzymes involved in iron metabolism and connective tissue formation)	Microcytic anemia, osteoporosis, neutropenia, neurologic symptoms, depigmentation of hair and skin	Acute: nausea, emesis, abdominal pain, coma, and hepatic necrosis Chronic toxicity (liver and brain injury) occurs in Wilson disease and secondary to excess intake	Vegetables, grains, nuts, liver, margarine, legumes, corn oil
Fluoride	Incorporated into bone	Dental caries	Chronic: dental fluorosis	Toothpaste, fluoridated water
Iodine	Component of thyroid hormone	Hypothyroidism	Hypothyroidism and goiter; maternal excess can cause congenital hypothyroidism and goiter	Saltwater fish, iodized salt
Iron	Component of hemoglobin, myoglobin, cytochromes, and other enzymes	Anemia, decreased alertness, impaired learning	Acute: nausea, vomiting, diarrhea, abdominal pain, and hypotension Chronic excess usually secondary to hereditary disorders; causes organ dysfunction.	Meat, fortified foods Deficiency can also result from blood loss (hookworm infestation, menorrhagia, GI bleeding)
Manganese	Enzyme cofactor	Hypercholesterolemia, weight loss, decreased clotting proteins*	Neurologic manifestations, cholestatic jaundice	Nuts, meat, grains, tea
Molybdenum	Enzyme cofactor (xanthine oxidase and others)	Tachycardia, tachypnea, night blindness, irritability, coma*	Hyperuricemia and increased risk of gout	Legumes, grains, liver
Selenium	Enzyme cofactor (prevents oxidative damage)	Cardiomyopathy (Keshan disease), myopathy	Nausea, diarrhea, neurologic manifestations, nail and hair changes, garlic odor	Meat, seafood, whole grains, garlic
Zinc	Enzyme cofactor Constituent of zinc-finger proteins, which regulate gene transcription	Decreased growth, dermatitis of extremities and around orifices, impaired immunity, poor wound healing, hypogonadism, diarrhea Supplements are beneficial in diarrhea and improve neurodevelopmental outcomes	Abdominal pain, diarrhea, vomiting Can worsen copper deficiency	Meat, shellfish, whole grains, legumes, cheese

*These deficiency states have been reported only in case reports associated with parenteral nutrition or highly unusual diets.
GI, Gastrointestinal.

From Greenbaum LA. Micronutrient mineral deficiencies. In Kliegman RM, ed. Nelson Textbook of Pediatrics. 21st ed. Philadelphia: Elsevier, 2020:387 [Table 67.1].

pools—a large, crystalline form and a smaller, amorphous phase. Bone calcium constantly turns over, with concurrent bone reabsorption and formation. Approximately half of **bone mineral accretion** occurs during adolescence. Bone mineral density peaks in early adulthood and is influenced by prior and concurrent dietary calcium intake, exercise, and hormone status (testosterone, estrogen).

Calcium intake can come from a variety of sources, with dairy products providing the most common and concentrated source. The calcium equivalent of 1 cup of milk (about 300 mg of calcium) is $\frac{3}{4}$ cup of plain yogurt, 1.5 oz of cheddar cheese, 2 cups of ice cream, $\frac{4}{5}$ cup of almonds, or 2.5 oz of sardines. Other sources of calcium include some leafy green vegetables (broccoli, kale, collards), lime-processed tortillas,

calcium-precipitated tofu, and calcium-fortified juices, cereals, and breads.

There is no classic calcium deficiency syndrome because blood and cell levels are closely regulated. The body can mobilize skeletal calcium and increase the absorptive efficiency of dietary calcium. **Osteoporosis** that occurs in childhood is related to protein-calorie malnutrition, vitamin C deficiency, steroid therapy, endocrine disorders, immobilization and disuse, celiac disease, osteogenesis imperfecta, or calcium deficiency (in premature infants). It is believed that the primary method of prevention of **postmenopausal osteoporosis** is to ensure maximum peak bone mass by providing optimal calcium intake during childhood and adolescence. Bone mineral status can be monitored by dual-energy x-ray absorptiometry.

No adverse effects are observed in adults with dietary calcium intakes of 2.5 g/day. There is concern that higher intakes may increase the risk of urinary stone formation, constipation, and decreased renal function and may inhibit intestinal absorption of other minerals (iron, zinc).

Iron

Iron, the most abundant trace mineral, is used in the synthesis of hemoglobin, myoglobin, and enzyme iron. Body iron content is regulated primarily through modulation of iron absorption, which depends on the state of body iron stores, the form and amount of iron in foods, and the mixture of foods in the diet. There are two categories of iron in food. The first is *heme iron*, present in hemoglobin and myoglobin, which is supplied by meat and rarely accounts for more than one fourth of the iron ingested by infants. The absorption of heme iron is relatively efficient and is not influenced by other constituents of the diet. The second category is **non-heme iron**, which represents the preponderance of iron intake consumed by infants and exists in the form of iron salts. The absorption of non-heme iron is influenced by the composition of consumed foods. Enhancers of non-heme iron absorption are ascorbic acid, meat, fish, and poultry. Inhibitors are bran, polyphenols (including the tannates in tea), and phytic acid, a compound found in legumes and whole grains. The percent intestinal absorption of the small amount of iron in human milk is 10%; 4% is absorbed from iron-fortified cow's milk formula and from iron-fortified infant dry cereals.

In a normal term infant, there is little change in total body iron and little need for exogenous iron before 4 months of age. Iron deficiency is rare in term infants during the first 4 months, unless there has been substantial blood loss (see Chapter 62). After about 4 months of age, iron reserves become marginal, and, unless exogenous sources of iron are provided, the infant becomes progressively at risk for anemia as the iron requirement to support erythropoiesis increases (see Chapter 150). Premature or low birthweight infants have a lower amount of stored iron because significant amounts of iron are transferred from the mother in the third trimester. In addition, their postnatal iron needs are greater because of rapid rates of growth and when frequent phlebotomy occurs. Iron needs can be met by supplementation (ferrous sulfate) or by iron-containing complementary foods. Under normal circumstances, iron-fortified formula should be the only alternative to breast milk in infants younger than 1 year of age. Premature infants fed human milk may develop iron-deficiency anemia earlier unless they receive iron supplements. Formula-fed preterm infants should receive iron-fortified formula.

In older children, iron deficiency may result from inadequate iron intake with excessive cow's milk intake or from intake of foods with poor iron bioavailability. Iron deficiency also can result from blood loss from such sources as cow milk protein allergic colitis, menses, gastric ulceration, or inflammatory bowel disease. Iron deficiency affects many tissues (muscle and central nervous system) in addition to producing anemia. **Iron deficiency** and **anemia** have been associated with lethargy and decreased work capacity and **impaired neurocognitive development**, the deficits of which may be irreversible when onset is in the first 2 years of life.

The diagnosis of iron-deficiency anemia is established by the presence of low serum ferritin levels, low serum iron levels, a microcytic hypochromic anemia, reduced transferrin saturation, normal to elevated red blood cell width distribution, and enhanced iron-binding capacity. The mean corpuscular volume and red blood cell indices are reduced, and the reticulocyte count is low. Iron deficiency may be present without anemia. Clinical manifestations are noted in Table 31.4.

Treatment of iron-deficiency anemia includes changes in the diet to provide adequate iron and the administration of 3–6 mg iron/kg per 24 hours (as ferrous sulfate) divided tid. Reticulocytosis is noted within 3–7 days of starting treatment. Oral treatment should be continued for 5 months. Rarely, intravenous iron therapy is needed if oral iron cannot be given. Parenteral iron therapy should be administered according to a strict protocol, including a test dose.

Zinc

Zinc is the second most abundant trace mineral and is important in protein metabolism and synthesis, in nucleic acid metabolism, and in stabilization of cell membranes. Zinc functions as a cofactor for more than 200 enzymes and is essential to numerous cellular metabolic functions. Adequate zinc status is especially crucial during periods of growth and for tissue proliferation (immune system, wound healing, skin, and gastrointestinal tract integrity); physiologic functions for which zinc is essential include normal growth, sexual maturation, and immune function.

Dietary zinc is absorbed (20–40%) in the duodenum and proximal small intestine. The best dietary sources of zinc are animal products, including human milk, from which it is readily absorbed. Whole grains and legumes also contain moderate amounts of zinc, but phytic acid inhibits absorption from these sources. On a global basis, poor bioavailability secondary to phytic acid is thought to be a more important factor than low intake in the widespread occurrence of zinc deficiency. Excretion of zinc occurs from the gastrointestinal tract. In the presence of ongoing losses, such as in chronic diarrhea, requirements can drastically increase.

Zinc deficiency dwarfism syndrome was first described in a group of children in the Middle East with low levels of zinc in their hair, poor appetite, diminished taste acuity, hypogonadism, and short stature. Zinc supplementation reduces morbidity and mortality from **diarrhea** and **pneumonia** and enhances growth in developing countries. Mild to moderate zinc deficiency is considered to be highly prevalent in developing countries, particularly in populations with high rates of **stunting**. Mild zinc deficiency occurs in older breast-fed infants without adequate zinc intake from complementary foods or in young children with poor total or bioavailable zinc intake in the general diet. A high infectious burden also may increase the risk of zinc deficiency in developing countries. Acute, acquired severe zinc deficiency occurs in patients receiving total parenteral nutrition without zinc supplementation and in premature infants fed human milk without fortification. **Clinical manifestations** of mild zinc deficiency include anorexia, growth faltering, and immune impairment. Moderately severe manifestations include delayed sexual maturation, rough skin, and hepatosplenomegaly. The signs of

severe deficiency include acral and periorificial erythematous scaling dermatitis, growth and immune impairment, diarrhea, mood changes, alopecia, night blindness, and photophobia.

Diagnosis of zinc deficiency is challenging. Plasma zinc concentrations are most commonly used, but levels are frequently normal in conditions of mild deficiency; levels in moderate to severe deficiency are typically less than 60 µg/dL. Acute infection also can result in depression of circulating zinc levels. The standard for the diagnosis of deficiency is response to a trial of supplementation, with outcomes such as improved linear growth or weight gain, improved appetite, and improved immune function. Because there is no pharmacologic effect of zinc on these functions, a positive response to supplementation is considered evidence of a preexisting deficiency. Clinically an empirical trial of zinc supplementation (1 µg/kg/day) is a safe and reasonable approach in situations in which deficiency is considered possible.

Acrodermatitis enteropathica is an autosomal recessive disorder that begins 2–4 weeks after infants have been weaned from breast milk. It is characterized by an acute perioral and perianal dermatitis, alopecia, and failure to thrive. The disease is caused by severe zinc deficiency from a specific defect of intestinal zinc absorption. Plasma zinc levels are markedly reduced, and serum alkaline phosphatase activity is low. **Treatment** is with high-dose oral zinc supplements. A relatively uncommon condition associated with presentation of severe zinc deficiency is due to a defect in the secretion of zinc from the mammary gland, resulting in abnormally low milk zinc concentrations. Breast-fed infants, especially those born prematurely, present with classic signs of zinc deficiency: growth failure, diarrhea, and dermatitis. Because there is no defect in the infant's ability to absorb zinc, treatment consists of supplementing the infant with zinc for the duration of breast-feeding, which can be successfully continued. Subsequent infants born to the mother will also need zinc supplementation if breast-fed. Zinc is relatively nontoxic. Excess intake produces nausea, emesis, abdominal pain, headache, vertigo, and seizures.

Fluoride

Dental enamel is strengthened when fluoride is substituted for hydroxyl ions in the hydroxyapatite crystalline mineral matrix of the enamel. The resulting fluoroapatite is more resistant to chemical and physical damage. Fluoride is incorporated into the enamel during the mineralization stages of tooth formation and by surface interaction after the tooth has erupted. Fluoride is similarly incorporated into bone mineral and may protect against osteoporosis later in life.

Because of concern about the risk of **fluorosis**, infants should not receive fluoride supplements before 6 months of

age. Commercial formulas are made with defluoridated water and contain small amounts of fluoride. The fluoride content of human milk is low and is not influenced significantly by maternal intake. Practitioners should evaluate all potential fluoride sources and conduct a caries risk assessment before prescribing fluoride supplementation.

PEARLS FOR PRACTITIONERS

CHAPTER 27

Diet of the Normal Infant

- Proper nutrition is essential for normal growth, a healthy immune system, appropriate eating habits, and optimal neurologic and cognitive development.
- The American Academy of Pediatrics recommends human milk as the sole source of nutrition for the first 6 months of life, with continued intake for the first year, and as long as desired thereafter.
- A multilevel approach is necessary to promote and support breast-feeding: federal and state government policy making, hospital policies, health care providers contributing to policy making, and parental guidance and support.
- Breast-feeding has protective effects for the well-being of children and adults.
- All breast-fed infants need 400 IU/day of vitamin D supplementation.
- Breast tenderness, engorgement, and cracked nipples are the most common problems encountered by breast-feeding mothers.
- Feeding frequency during the first 3 days of life of breast-fed infants is inversely related to the level of bilirubin; frequent feedings stimulate meconium passage and excretion of bilirubin in the stool.
- Breast milk jaundice is an indirect hyperbilirubinemia that is usually benign and peaks at 1–2 weeks of age. Kernicterus is very rare.
- Complementary foods are recommended by approximately 6 months of age.
- Early caries of childhood is caused by a misbalance of increased sugars and bacteria in the mouth and decreased saliva flow, as early as 6 months of age. Eating a healthy diet and regular brushing will control the sugar factor and bacteria.

CHAPTER 28

Diet of the Normal Child and Adolescent

- A healthy diet helps children grow, thrive, and learn and helps prevent obesity and weight-related diseases such as diabetes.
- Learning healthy eating behaviors at an early age is an important preventive measure.
- Cow's milk should be introduced at 12 months of age. Low-fat (2%) or whole milk is recommended until 2 years of age, after which fat-free or 1% milk is recommended.
- Excessive milk intake (>24 oz/day) should be avoided in toddlers.
- The avoidance of foods with high allergic potential in infancy (e.g., fish, tree nuts, peanuts, dairy products, and eggs) is no longer supported. Early introduction may actually help prevent food allergies.

- No juice is recommended during infancy (<1 year), 4 oz after 2 years, and 6 oz after 7 years.
- ChooseMyPlate by the U.S. Department of Agriculture can provide parents with a general guideline for the types of healthy food to feed their child.
- American children have high salt intake. Daily salt intake recommended is 1,900–2,300 mg.
- Poor calcium intake during adolescence has significant consequences for long-term bone health. Good sources include milk, yogurt, fortified orange juice, cheese, soybeans, and tofu.
- Iron deficiency may reappear in menstruating teens.

CHAPTER 29

Obesity

- Childhood obesity is an epidemic in the United States with 17% of children obese.
- The definition of obesity above 2 years is a body mass index (BMI) higher than 95% on the Centers for Disease Control and Prevention BMI-for-age growth chart.
- Overweight and obese children are more likely to stay obese into adulthood and to develop chronic diseases.
- Sixty minutes of physical activities are recommended every day.
- Obesity during childhood can have a harmful effect on the body in a variety of ways and can affect virtually every major organ system. Prevention is the key to success for obesity control.
- More aggressive therapies such as bariatric surgery are considered only for those who have no response to other interventions and preventions.

CHAPTER 30

Pediatric Undernutrition

- Pediatric undernutrition results from inadequate food supply, access (food insecurity), or utilization; poor access to health and sanitation; chronic health conditions; and/or inappropriate feeding, behavioral issues, or child-care practices.
- International references are established that allow normalization of anthropometric measures in terms of z scores.
- Primary protein-energy malnutrition (PEM) is caused by social or economic factors that result in a lack of adequate intake.
- Secondary PEM occurs in children with various conditions associated with increased caloric requirements (infection, trauma, cancer), caloric loss (malabsorption), reduced intake (anorexia, cancer, oral intake restriction, social factors), or a combination of these.

- Marasmus results from the body's physiologic response to inadequate calories and nutrients.
- Kwashiorkor results from inadequate protein intake in the presence of fair to good caloric intake.
- Vitamin A and zinc deficiency often accompany malnutrition.
- Dermatitis may be seen with protein-calorie malnutrition as well as riboflavin, biotin, and essential fatty acid deficiencies.
- Neuropathy may be seen in thiamin and vitamin B₆, B₁₂, and E deficiencies.
- Parenteral vitamin K (0.5–1 mg) should be given to all newborns shortly after birth.
- Niacin (vitamin B₃) deficiency results in pellagra: a combination of weakness, photosensitivity, dermatitis, vomiting, diarrhea, and dementia.
- Deficiency of vitamin B₁₂ results in megaloblastic anemia, peripheral neuropathy, posterior column disease, and vitiligo.
- Folate deficiency results in hypersegmented neutrophils, macrocytic anemia, and neural tube defects.
- Scurvy, a combination of irritability, purpura, bleeding gums, periosteal hemorrhage, and aching bones, results from a deficiency of ascorbic acid (vitamin C).
- Vitamin D deficiency appears as rickets in children and osteomalacia in postpubertal adolescents.
- The diagnosis of iron-deficiency anemia is established by the presence of a microcytic hypochromic anemia, low serum ferritin levels, low serum iron levels, reduced transferrin saturation, normal to elevated red blood cell width distribution, and enhanced iron-binding capacity.
- Because of concern about the risk of fluorosis, infants should not receive fluoride supplements before 6 months of age.

CHAPTER 31

Vitamin and Mineral Deficiencies

- Risk factors for micronutrient deficiencies in developed countries include exclusion of entire food groups, malabsorption syndromes, and conditions causing high physiologic requirements.
- Exclusively breast-fed term infants are at higher risk for vitamin D and K deficiencies.
- Vitamin D supplementation (400 IU/day) should be started soon after birth for all breast-fed infants.

FLUIDS AND ELECTROLYTES

Jackson T. Londeree | Larry A. Greenbaum

CHAPTER 32

Maintenance Fluid Therapy

BODY COMPOSITION

Water is the most plentiful constituent of the human body. **Total body water (TBW)** as a percentage of body weight varies with age. The fetus has a high TBW, which gradually decreases to about 75% of birthweight for a term infant; TBW is higher in premature infants. During the first year of life, TBW decreases to about 60% of body weight and basically remains at this level until puberty. At puberty, the fat content of females increases more than that of males, who acquire more muscle mass than females. Because fat has low water content and muscle has high water content, by the end of puberty, TBW in males remains at 60%, but it decreases to 50% of body weight in females. During dehydration, TBW decreases and is a smaller percentage of body weight.

TBW has two main compartments: **intracellular fluid (ICF)** and **extracellular fluid (ECF)**. In the fetus and newborn, the ECF volume is larger than the ICF volume. The normal postnatal diuresis causes an immediate decrease in the ECF volume, which is then followed by continued expansion of the ICF volume because of cellular growth. By 1 year of age, the ratio of the ICF volume to the ECF volume approaches adult levels. The ECF volume is 20–25% of body weight, and the ICF volume is 30–40% of body weight (Fig. 32.1). With puberty, the increased muscle mass of males results in a higher ICF volume than in females.

The ECF is divided further into **plasma water** and **interstitial fluid** (see Fig. 32.1). Plasma water is about 5% of body weight. The blood volume, given a hematocrit of 40%, is usually 8% of body weight, although it is higher in newborns and young infants. The interstitial fluid, normally 15% of body weight, can increase dramatically in diseases associated with edema, such as heart failure, liver failure, and nephrotic syndrome.

The composition of solutes in the ICF and ECF is different. Sodium and chloride are the dominant cation and anion in the ECF. Potassium is the most abundant cation in the ICF, and proteins, organic anions, and phosphate are the most plentiful anions in the ICF. The dissimilarity between the anions in the ICF and the ECF is determined largely by the presence of intracellular molecules that do not cross the cell membrane, the barrier separating the ECF and the ICF. In contrast,

the difference in the distribution of cations—sodium and potassium—is due to the activity of the Na^+, K^+ -ATPase pump, which extrudes sodium from cells in exchange for potassium.

REGULATION OF INTRAVASCULAR VOLUME AND OSMOLALITY

Proper cell functioning requires close regulation of plasma osmolality and intravascular volume; these are controlled by independent systems for water balance which determines osmolality, and sodium balance which determines volume status. Maintenance of a normal **osmolality** depends on control of water balance. Control of **volume status** depends on regulation of sodium balance.

The plasma osmolality is tightly controlled between 285 and 295 mOsm/kg through regulation of water intake and urinary water losses. A small increase in the plasma osmolality stimulates thirst. Urinary water losses are regulated by the secretion of **antidiuretic hormone (ADH)**, which increases in response to an increasing plasma osmolality. ADH, by stimulating renal tubular reabsorption of water, decreases urinary water losses. Control of osmolality is subordinate to maintenance of an adequate intravascular volume. When significant volume depletion is present, ADH secretion and thirst are stimulated, regardless of the plasma osmolality.

Volume depletion and volume overload may cause significant morbidity and mortality. Because sodium is the principal extracellular cation and is restricted to the ECF, adequate body sodium is necessary for maintenance of intravascular volume. The kidney determines sodium balance because there is little homeostatic control of sodium intake, although salt craving occasionally occurs, typically in children with chronic renal salt loss or adrenal insufficiency. The kidney regulates sodium balance by altering the percentage of filtered sodium that is reabsorbed along the nephron. The **renin-angiotensin system** is an important regulator of renal sodium reabsorption and excretion. The juxtaglomerular apparatus produces renin in response to decreased *effective* intravascular volume. Renin cleaves angiotensinogen, producing angiotensin I, which angiotensin-converting enzyme converts into angiotensin II. The actions of angiotensin II include direct stimulation of the proximal tubule to increase sodium reabsorption and stimulation of the adrenal gland to increase aldosterone secretion, which increases sodium reabsorption in the distal nephron. In contrast, volume expansion stimulates the synthesis of **atrial natriuretic peptide**, which increases urinary sodium excretion.

FIGURE 32.1 Compartments of total body water, expressed as percentage of body weight, in an older child or adult. (From Greenbaum LA. Pathophysiology of body fluids and fluid therapy. In Kliegman RM, St Geme JW, eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier, 2020:390.)

MAINTENANCE FLUIDS

Maintenance intravenous (IV) fluids are used in children who cannot be fed enterally. Along with maintenance fluids, children may require concurrent **replacement fluids** if they have excessive **ongoing losses**, such as may occur with diarrhea, vomiting, or drainage from an enteral feeding tube. In addition, if dehydration is present, the patient also needs to receive deficit replacement (see [Chapter 33](#)).

Maintenance fluids are composed of a solution of water, glucose, sodium, potassium, and chloride. This solution replaces electrolyte losses from the urine and stool, as well as water losses from the urine, stool, skin, and lungs. The glucose in maintenance fluids provides approximately 20% of normal caloric needs. This is enough to prevent the development of starvation ketoacidosis and diminishes the protein degradation that would occur if the patient received no calories.

Maintenance fluids do not provide adequate calories, protein, fat, minerals, or vitamins. Patients should not remain on maintenance therapy indefinitely; parenteral nutrition (see [Chapter 34](#)) should be used for children who cannot be fed enterally for more than a few days.

Daily water losses are measurable (urine and stool) and not measurable (*insensible losses* from the skin and lungs). Failure to replace these losses leads to a thirsty child and, ultimately,

TABLE 32.1 Body Weight Method for Calculating Maintenance Fluid Volume and Rate

BODY WEIGHT (kg)	VOLUME PER DAY	HOURLY RATE
0–10	100 mL/kg	4 mL/kg/hr
11–20	1,000 mL + 50 mL/kg for each 1 kg >10 kg	40 mL/hr + 2 mL/kg/hr × (wt–10)
>20	1,500 mL + 20 mL/kg for each 1 kg >20 kg*	60 mL/hr + 1 mL/kg/hr × (wt–20) [†]

*The maximum total fluid per day is normally 2,400 mL.

[†]The maximum fluid rate is normally 100 mL/hr.

a dehydrated child. [Table 32.1](#) provides a system for calculating **24-hour maintenance water** needs based on the patient's weight.

After calculation of water needs and electrolyte needs, children typically receive D5 in Normal Saline plus 20 mEq/L of KCl as a maintenance solution. This assumes that there is no disease process present that would require an adjustment in either the volume or the electrolyte composition of maintenance fluids. Children with renal insufficiency may be hyperkalemic or unable to excrete potassium and may not tolerate 20 mEq/L of KCl. In children with complicated pathophysiologic derangements, it may be necessary to adjust the electrolyte composition and rate of maintenance fluids empirically based on electrolyte measurements and assessment of fluid balance.

PEARLS FOR PRACTITIONERS

See *Fluids and Electrolytes: Pearls for Practitioners* at the end of this section.

CHAPTER 33

Dehydration and Replacement Therapy

REPLACEMENT THERAPY

There are three sources of normal water loss—the components of maintenance water (see [Chapter 32](#)): urine (60%), **insensible losses** from the skin and lungs (35%), and stool (5%) ([Table 33.1](#)). Sweating is not insensible and, in contrast to evaporative losses, sweat contains water and electrolytes.

A variety of clinical situations modify normal maintenance water balance ([Table 33.2](#)). Evaporative skin water losses can be higher in neonates, especially premature infants who are

TABLE 33.1 Components of Maintenance Water

Urine	60%
Insensible losses (skin and lungs)	35%
Stool	5%

SOURCE	CAUSES OF INCREASED WATER NEEDS	CAUSES OF DECREASED WATER NEEDS
Skin	Radiant warmer Phototherapy Fever Sweat Burns Extensive exfoliative dermatitis*	Incubator (premature infants)
Lungs	Tachypnea Tracheostomy	Humidified ventilator
Gastrointestinal	Diarrhea Emesis Nasogastric suction	
Renal	Polyuria	Oliguria/anuria
Miscellaneous	Surgical drain Third space losses	Hypothyroidism

*Epidermolysis bullosa, toxic epidermal necrolysis.

AVERAGE COMPOSITION	APPROACH TO REPLACEMENT
DIARRHEA	REPLACEMENT OF ONGOING STOOL LOSSES
Sodium: 55 mEq/L	Solution: 5% dextrose in ¼ normal saline + 20 mEq/L sodium bicarbonate + 20 mEq/L potassium chloride Replace stool mL/mL every 1–6 hr
Potassium: 25 mEq/L	
Bicarbonate: 15 mEq/L	
GASTRIC FLUID	REPLACEMENT OF ONGOING GASTRIC LOSSES
Sodium: 60 mEq/L	Solution: normal saline + 10 mEq/L potassium chloride Replace output mL/mL every 1–6 hr
Potassium: 10 mEq/L	
Chloride: 90 mEq/L	

under radiant warmers or undergoing phototherapy. Burns can result in massive losses of water and electrolytes (see Chapter 44). Fever increases insensible losses. Tachypnea or a tracheostomy increases evaporative losses from the lungs.

The gastrointestinal tract is potentially a source of considerable water and electrolyte losses. A child who has large amounts of gastrointestinal losses should have these losses measured and replaced with an appropriate **replacement solution** (Table 33.3).

Urine output is normally the largest cause of *water* loss. Diseases such as renal failure and the syndrome of inappropriate antidiuretic hormone (SIADH) can lead to a decrease in

OLIGURIA/ANURIA	POLYURIA
Place the patient on insensible fluids (~1/3 maintenance)	Place the patient on insensible fluids (~1/3 maintenance)
Replace urine output mL/mL with half normal saline	Measure urine electrolytes
	Replace urine output mL/mL with a solution that is based on the measured urine electrolytes

urine volume. Maintenance fluids in a patient with oliguria or anuria may produce fluid overload if the cause is acute kidney injury. In contrast, other conditions produce an increase in urine volume; these include the polyuric phase of acute kidney injury, diabetes mellitus, and diabetes insipidus. When the urine output is excessive, the patient must receive more than standard maintenance fluids to prevent dehydration.

The approach to decreased or increased urine output is similar (Table 33.4). Insensible losses are replaced by a solution that is administered at a rate one third of the normal maintenance rate. Placing the **anuric** child on “insensibles” theoretically maintains an even fluid balance, with the caveat that one third of maintenance fluid is only an *estimate* of insensible losses. This rate may need to be adjusted based on monitoring of the patient’s weight and hydration status. An **oliguric** child needs to receive a urine replacement solution. Most children with **polyuria** (except for children with diabetes mellitus [see Chapter 171]) should be placed on insensible fluids plus urine replacement.

Output from surgical drains and chest tubes, when significant, should be measured and replaced. **Third space losses** manifest with edema and ascites and are due to a shift of fluid from the intravascular space into the interstitial space. Third space losses cannot be quantitated. Nonetheless, these losses can be large and lead to intravascular volume depletion, despite weight gain from edema or ascites. Replacement of third space fluid is empirical but should be anticipated in patients who are at risk, such as children who have sepsis, shock, burns, or abdominal surgery. Third space losses and chest tube output are isotonic and usually require replacement with an **isotonic fluid**, such as normal saline (NS) or Ringer lactate. Adjustments in the amount of replacement fluid for third space losses are based on continuing assessment of the patient’s intravascular volume status (heart rate, blood pressure, urine output).

DEHYDRATION

Dehydration, most often due to gastroenteritis, is common in children. The first step in caring for a dehydrated child is to assess the degree of dehydration. The degree of dehydration dictates the urgency of the situation and the volume of fluid needed for rehydration. Table 33.5 summarizes the clinical features that are present with varying degrees of dehydration.

A patient with **mild dehydration** has few clinical signs or symptoms. The history may describe decreased intake but more often increased fluid losses. An infant with **moderate dehydration** has demonstrable physical signs and symptoms. The patient needs fairly prompt intervention. A patient with **severe dehydration** is gravely ill. The decrease in blood pressure

TABLE 33.5 Assessment of Degree of Dehydration

	MILD	MODERATE	SEVERE
Infant	5%	10%	15%
Adolescent	3%	6%	9%
Infants and young children	Thirsty, alert; restless	Thirsty; restless or lethargic; irritable	Drowsy; limp, cold, sweaty, cyanotic extremities; may be comatose
Older children	Thirsty, alert	Thirsty, alert (usually)	Usually conscious (but at reduced level), apprehensive; cold, sweaty, cyanotic extremities; wrinkled skin on fingers and toes; muscle cramps
SIGNS AND SYMPTOMS			
Tachycardia	Absent	Present	Present
Palpable pulses	Present	Present (weak)	Decreased
Blood pressure	Normal	Orthostatic hypotension	Hypotension
Cutaneous perfusion	Normal	Normal	Reduced and mottled
Skin turgor	Normal	Slight reduction	Reduced
Fontanelle	Normal	Slightly depressed	Sunken
Mucous membrane	Moist	Dry	Very dry
Tears	Present	Present or absent	Absent
Respirations	Normal	Deep, may be rapid	Deep and rapid
Urine output	Normal	Oliguria	Anuria and severe oliguria

Data from World Health Organization.

indicates that vital organs may be receiving inadequate perfusion (shock) (see [Chapter 40](#)). Such a patient should receive immediate and aggressive intravenous (IV) therapy. Clinical assessment of dehydration is only an estimate; the patient must be continually re-evaluated during therapy. The degree of dehydration is underestimated in hypernatremic dehydration because the osmotically driven shift of water from the intracellular space to the extracellular space helps to preserve the intravascular volume.

Laboratory Evaluation

Serum blood urea nitrogen (BUN) and creatinine concentrations are useful in assessing a child with dehydration. Volume depletion without renal insufficiency may cause a disproportionate increase in the BUN, with little or no change in the creatinine concentration. This is secondary to increased passive reabsorption of urea in the proximal tubule caused by appropriate renal conservation of sodium and water. This increase in the BUN may be absent or blunted in a child with poor protein intake because urea production depends on protein degradation. Conversely, the BUN may be disproportionately increased in a child with increased urea production, as occurs in a child with a gastrointestinal bleed or a child who is receiving glucocorticoids. A significant elevation of the creatinine concentration suggests renal injury.

The urine specific gravity is usually elevated (≥ 1.025) in cases of significant dehydration but decreases after rehydration. With dehydration, a urinalysis may show hyaline and

granular casts, a few white blood cells and red blood cells, and 30–100 mg/dL of proteinuria. These findings usually are not associated with significant renal pathology, and they remit with therapy. Hemoconcentration from dehydration increases the hematocrit and hemoglobin.

Calculation of Fluid Deficit

A child with dehydration has lost water; there is usually a concurrent loss of sodium and potassium. The fluid deficit is the percentage of dehydration multiplied by the patient's weight (for a 10-kg child, 10% of 10 kg = 1 L deficit).

Approach to Dehydration

The child with dehydration requires acute intervention to ensure that there is adequate tissue perfusion (see [Chapter 40](#)). This resuscitation phase requires rapid restoration of the circulating intravascular volume, which should be done with an isotonic solution, such as NS or Ringer lactate. Blood is an appropriate fluid choice for a child with acute blood loss but is not always available at the start of fluid resuscitation. The child is given a fluid bolus, usually 20 mL/kg of the isotonic solution, over about 20 minutes. A child with severe dehydration may require multiple fluid boluses and may need to receive fluid at a faster rate. The initial resuscitation and rehydration is complete when signs of intravascular volume depletion resolve. The child typically becomes more alert and has a lower heart rate, normal blood pressure, and improved perfusion.

TABLE 33.6 Fluid Management of Dehydration

Restore intravascular volume
Normal saline: 20 mL/kg over 20 min
Repeat as needed
Rapid volume repletion: 20 mL/kg normal saline (maximum = 1 L) over 2 hr
Calculate 24-hr fluid needs: maintenance + deficit volume
Subtract isotonic fluid already administered from 24-hr fluid needs
Administer remaining volume over 24 hr using D5 normal saline + 20 mEq/L KCl

Clinical signs of fluid volume depletion or overload
Electrolytes

With adequate intravascular volume, it is now appropriate to plan the fluid therapy for the next 24 hours (Table 33.6). To ensure that the intravascular volume is restored, the patient receives an additional 20 mL/kg bolus of isotonic fluid over 2 hours. The child's total fluid needs are added together (maintenance + deficit). The volume of isotonic fluids the patient has received as acute resuscitation is subtracted from this total. The remaining fluid volume is then administered over 24 hours. Potassium usually is not included in the IV fluids until the patient voids, unless significant hypokalemia is present. *Children with significant ongoing losses also need to receive an appropriate replacement solution.*

MONITORING AND ADJUSTING THERAPY

All calculations in fluid therapy are only approximations. Thus the patient needs to be monitored during treatment with therapy modifications based on the clinical situation (Table 33.7).

Hyponatremic dehydration occurs in children who have diarrhea and consume a hypotonic fluid (water or diluted formula). Volume depletion stimulates secretion of antidiuretic hormone, preventing the water excretion that should correct the hyponatremia. Some patients develop symptoms, predominantly neurologic, from the hyponatremia (see Chapter 35). Most patients with hyponatremic dehydration do well with

the same general approach outlined in Table 33.6. Overly rapid correction of hyponatremia (>10 mEq/L per 24 hours) should be avoided because of the remote risk of **central pontine myelinolysis**.

Hypernatremic dehydration is usually a consequence of an inability to take in fluid because of a lack of access, a poor thirst mechanism (neurologic impairment), intractable emesis, or anorexia. The movement of water from the intracellular space to the extracellular space during hypernatremic dehydration partially protects the intravascular volume losses. Urine output may be preserved longer, and there may be less tachycardia. Children with hypernatremic dehydration are often lethargic and irritable. Hypernatremia may cause fever, hypertonicity, hyperreflexia, and seizures. More severe neurologic symptoms may develop if cerebral bleeding or dural sinus thrombosis occurs.

Overly rapid treatment of hypernatremic dehydration may cause significant morbidity and mortality. **Idiogenic osmoles** are generated within the brain during the development of hypernatremia. Idiogenic osmoles increase the osmolality within the cells of the brain, providing protection against brain cell shrinkage secondary to movement of water out of cells into the hypertonic extracellular fluid. These idiogenic osmoles dissipate slowly during correction of hypernatremia. With rapid lowering of the extracellular osmolality during correction of hypernatremia, a new gradient may be created that causes water movement from the extracellular space into the cells of the brain, producing **cerebral edema**. Possible manifestations of the resultant cerebral edema include headache, altered mental status, seizures, and potentially lethal brain herniation.

To minimize the risk of cerebral edema during correction of hypernatremic dehydration, the serum sodium concentration should not decrease more than 12 mEq/L every 24 hours (Fig. 33.1). The choice and rate of fluid replacement are not nearly as important as vigilant monitoring of the serum sodium concentration and adjustment of the therapy based on the result (see Fig. 33.1). Nonetheless, the initial resuscitation-rehydration phase of therapy remains the same as for other types of dehydration.

Oral Rehydration

Mild to moderate dehydration from diarrhea of any cause can be treated effectively using a simple, oral rehydration solution (ORS) containing glucose and electrolytes (see Chapter 112). The ORS relies on the coupled transport of sodium and glucose in the intestine. Oral rehydration therapy has significantly reduced the morbidity and mortality from acute diarrhea but is underused in developed countries. It should be attempted for most patients with mild to moderate diarrheal dehydration. Oral rehydration therapy is less expensive than IV therapy and has a lower complication rate. IV therapy may still be required for patients with severe dehydration; patients with uncontrollable vomiting; patients unable to drink because of extreme fatigue, stupor, or coma; or patients with gastric or intestinal distention. Rapidly absorbed sublingual ondansetron may be used to treat vomiting, thus facilitating oral rehydration.

As a guideline for oral rehydration, 50 mL/kg of the ORS should be given within 4 hours to patients with mild dehydration, and 100 mL/kg should be given over 4 hours to patients

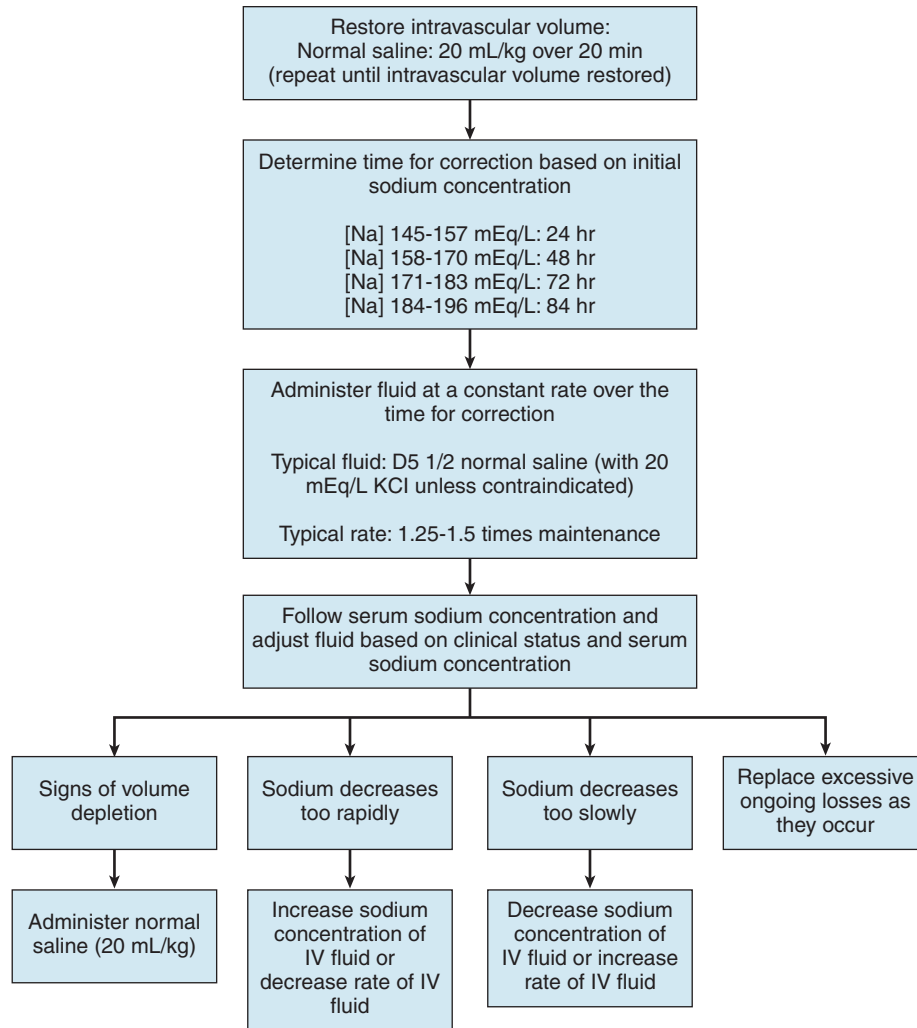

FIGURE 33.1 Strategy for correcting hypernatremic dehydration.

with moderate dehydration. Supplementary ORS is given to replace ongoing losses from diarrhea or emesis. An additional 10 mL/kg of ORS is given for each stool. Fluid intake should be decreased if the patient appears fully hydrated earlier than expected or develops periorbital edema. After rehydration, patients should resume their usual diet (breast milk, formula).

When rehydration is complete, maintenance therapy should be started, using 100 mL of ORS/kg in 24 hours until the diarrhea stops. Breast-feeding or formula-feeding should be maintained and not delayed for more than 24 hours. Patients with more severe diarrhea require continued supervision. The volume of ORS ingested should equal the volume of stool losses. If stool volume cannot be measured, an intake of 10–15 mL of ORS/kg per hour is appropriate.

CHAPTER 34

Parenteral Nutrition

Parenteral nutrition (PN) is necessary when enteral feeding is inadequate to meet the nutritional needs of a patient. Enteral nutrition is always preferred because it is more physiologic, less expensive, and associated with fewer complications. Fewer complications are expected if at least some nutrition can be provided enterally.

INDICATIONS

A variety of clinical situations necessitate PN (Table 34.1). Acute PN is frequently given in an intensive care unit when there is poor tolerance of enteral feeds, potentially secondary to a transient ileus, concerns regarding bowel ischemia, or the risk of aspiration pneumonia. **Short bowel syndrome** is the

most common indication for long-term PN; it may be caused by a congenital gastrointestinal anomaly or acquired after necrotizing enterocolitis (see Chapter 63). Some patients with a chronic indication for PN eventually may be transitioned to partial or full enteral feedings.

ACCESS FOR PARENTERAL NUTRITION

PN can be given via either a peripheral intravenous (IV) line or a central venous line (CVL). Long-term PN should be given via a CVL. Acute PN may be given peripherally, although a temporary CVL is often used. Most children with cancer or receiving a bone marrow transplant have a CVL. A **peripherally inserted central catheter** is an excellent source of central access for acute PN because of the lower risk for complications than with a standard CVL.

A peripheral IV line has two major limitations. First, it frequently fails, necessitating interruption of PN and potentially painful placement of a new line. Second, high-osmolality solutions cause **phlebitis** of peripheral veins; this limits the dextrose and amino acid content of peripheral PN. The dextrose content of peripheral PN cannot be greater than 12%, with a lower limit if the amino acid concentration is high. Lipid emulsion has a low osmolality; therefore it can be administered peripherally via the same IV line as the dextrose and amino acid solution. Patients can receive adequate nutrition via a peripheral IV line, but the volume of PN needs to be higher than is necessary when central access is available because of the limitations on dextrose and amino acid concentration. This situation may be problematic in patients who cannot tolerate larger fluid volumes.

COMPOSITION OF PARENTERAL NUTRITION

PN can provide calories, amino acids, electrolytes, minerals, essential fatty acids, vitamins, iron, and trace elements. The **calories** in PN are from dextrose and fat. The amino acids in

PN are a potential source of calories, but they should be used predominantly for protein synthesis. PN is given as two separate solutions: a dextrose plus amino acid solution and a 20% lipid emulsion. The dextrose solution has all of the components of PN except for fat.

The dextrose concentration of peripheral PN is typically 10–12%, whereas central PN has a concentration of about 20%, although it may be increased to 25–30% in patients who are fluid restricted. To avoid hyperglycemia, the dextrose delivery is increased gradually when starting PN. Protein delivery in PN is via amino acids in the dextrose solution. The goal is 0.8–2 g protein/kg per 24 hours for older children, 1.5–3 g/kg per 24 hours for full-term and older infants, and 2.5–3.5 g/kg per 24 hours for preterm infants.

The electrolyte and mineral composition of PN depends on the age and the underlying illness. The 20% lipid emulsion provides essential fatty acids and calories. The lipid emulsion is started at a rate of 0.5–1 g/kg per 24 hours, gradually increasing the rate so that the patient receives adequate calories; this typically requires 2.5–3.5 g/kg per 24 hours. The lipid emulsion usually provides 30–40% of the required calories; it should not exceed 60%. The serum triglyceride concentration is monitored as the rate of lipid emulsion is increased, with reduction of the lipid emulsion rate if significant hypertriglyceridemia develops.

COMPLICATIONS

There are many potential complications of PN. CVLs are associated with complications during insertion (pneumothorax or bleeding) and long-term issues (thrombosis). **Catheter-related sepsis**, most commonly due to coagulase-negative staphylococci, is common and, on occasion, necessitates catheter removal. Other potential pathogens are *Staphylococcus aureus*, gram-negative bacilli, and fungi. Electrolyte abnormalities, nutritional deficiencies, hyperglycemia, and complications from excessive protein intake (azotemia or hyperammonemia) can be detected with careful monitoring.

The most concerning complication of long-term PN is **cholestatic liver disease**, which can lead to jaundice, cirrhosis, and, occasionally, liver failure. Current PN decreases the risk of liver disease by including reduced amounts of hepatotoxic amino acids and possibly the use of fish-based lipids. The best preventive strategy is early use of the gastrointestinal tract, even if only trophic feeds are tolerated.

CHAPTER 35

Sodium Disorders

The kidney regulates sodium balance and is the principal site of sodium excretion. Sodium is unique among electrolytes because **water balance**, not sodium balance, usually determines its concentration. When the sodium concentration increases,

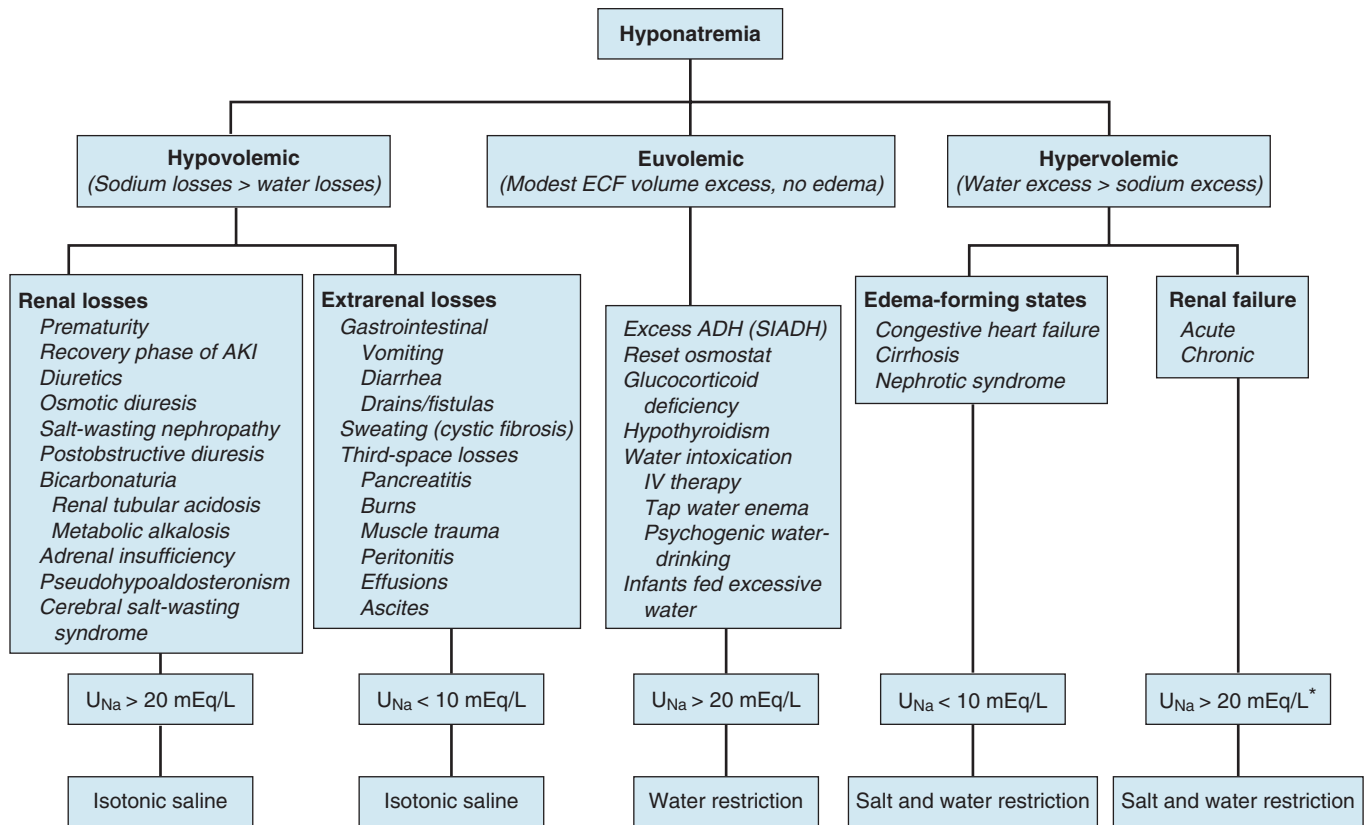

FIGURE 35.1 Classification, diagnosis, and treatment of hyponatremic states. *In water intoxication the urine sodium is often <20 mEq/L. †Urinary sodium is <10 mEq/L in acute renal failure secondary to glomerular disease. ADH, Antidiuretic hormone; AKI, acute kidney injury; ECF, extracellular fluid; IV, intravenous; SIADH, syndrome of inappropriate antidiuretic hormone secretion. (Modified from Berl T, Anderson RJ, McDonald KM, et al. Clinical disorders of water metabolism. *Kidney Int.* 1976;10:117–132 [fig. 2].)

the resultant higher plasma osmolality causes increased thirst and increased secretion of antidiuretic hormone (ADH), which leads to renal conservation of water. Both of these mechanisms increase the water content of the body, and the sodium concentration returns to normal. During hyponatremia, the fall in plasma osmolality decreases ADH secretion, and consequent renal water excretion leads to an increase in the sodium concentration. Although water balance is usually regulated by osmolality, volume depletion also stimulates thirst, ADH secretion, and renal conservation of water. In fact, volume depletion takes precedence over osmolality; volume depletion stimulates ADH secretion, even if a patient has hyponatremia.

The excretion of sodium by the kidney is not determined by the plasma osmolality. The patient's effective plasma volume regulates the amount of sodium in the urine through a variety of regulatory systems, including the renin-angiotensin-aldosterone system. In hyponatremia or hypernatremia, the underlying pathophysiology determines the urinary sodium concentration, not the serum sodium concentration.

HYPONATREMIA

Etiology

Different mechanisms can cause hyponatremia (Fig. 35.1). **Pseudohyponatremia** is a laboratory artifact that is present when the plasma contains high concentrations of protein or

lipid. It does not occur when a direct ion-selective electrode determines the sodium concentration, a technique that is increasingly used in clinical laboratories. In true hyponatremia, the *measured* osmolality is low, whereas it is normal in pseudohyponatremia. **Hyperosmolality**, resulting from mannitol infusion or hyperglycemia, causes a low serum sodium concentration, because water moves down its osmotic gradient from the intracellular space into the extracellular space, diluting the sodium concentration. For every 100 mg/dL increment of the serum glucose, the serum sodium decreases by 1.6 mEq/L. Because the manifestations of hyponatremia are due to the low plasma osmolality, patients with hyponatremia caused by hyperosmolality do not have symptoms of hyponatremia and do not require the correction of hyponatremia.

Classification of true hyponatremia is based on the patient's volume status (see Fig. 35.1). In **hypovolemic hyponatremia**, the child has lost sodium from the body. Water balance may be positive or negative, but there has been a higher net sodium loss than water loss; this is often due to oral or intravenous (IV) water intake, with water retention by the kidneys to compensate for the intravascular volume depletion. If the sodium loss is due to a nonrenal disease (e.g., diarrhea), the urine sodium concentration is very low, as the kidneys attempt to preserve the intravascular volume by conserving sodium. In renal diseases, the urine sodium is inappropriately elevated.

Patients with hyponatremia and no evidence of volume overload or volume depletion have **euvolemic hyponatremia**.

These patients typically have an excess of total body water and a slight decrease in total body sodium. Some of these patients have an increase in weight, implying that they are volume overloaded. Nevertheless, they usually appear normal or have only subtle signs of fluid overload. In the **syndrome of inappropriate ADH (SIADH)**, there is secretion of ADH that is not inhibited by either low serum osmolality or expanded intravascular volume. Retention of water causes hyponatremia, and the expansion of the intravascular volume results in an increase in renal sodium excretion. SIADH is associated with physiologic stress, pneumonia, mechanical ventilation, meningitis, and other central nervous system disorders (trauma). Ectopic (tumor) production of ADH is rare in children. SIADH should be distinguished from **cerebral salt wasting**, which is a form of hypovolemic hyponatremia often associated with tuberculosis meningitis or intracranial hemorrhage. Infants can develop euvolemic hyponatremia as a result of excessive water consumption or inappropriately diluted formula.

In **hypervolemic hyponatremia**, there is an excess of total body water and sodium, although the increase in water is greater than the increase in sodium. In renal failure, there is an inability to excrete sodium or water; the urine sodium may be low or high, depending on the cause of the renal insufficiency. In other causes of hypervolemic hyponatremia, there is a decrease in the effective blood volume because of either third space fluid loss or poor cardiac output (see [Chapter 145](#)). In response to the low effective blood volume, ADH causes renal water retention, and the kidneys also retain sodium, which leads to a low urine sodium concentration. The patient's serum sodium concentration decreases when water intake exceeds sodium intake, and ADH prevents the normal loss of excess water.

Clinical Manifestations

Hyponatremia causes a fall in the osmolality of the extracellular space. Because the intracellular space then has a higher osmolality, water moves from the extracellular space to the intracellular space to maintain osmotic equilibrium. The increase in intracellular water may cause cells to swell. **Brain cell swelling** is responsible for most of the symptoms of hyponatremia. Neurologic symptoms of hyponatremia include anorexia, nausea, emesis, malaise, lethargy, confusion, agitation, headache, seizures, coma, and decreased reflexes. Patients may develop hypothermia, Cheyne-Stokes respirations, muscle cramps, and weakness. Symptoms are more severe when hyponatremia develops rapidly; chronic hyponatremia can be asymptomatic because of a compensatory decrease in brain cell osmolality, which limits cerebral swelling.

Treatment

Rapid correction of hyponatremia can produce **central pontine myelinolysis**. Avoiding more than a 10 mEq/L increase in the serum sodium every 24 hours is prudent, especially in chronic hyponatremia. Treatment of hypovolemic hyponatremia requires administration of IV fluids with sodium to provide maintenance requirements and deficit correction, and to replace ongoing losses (see [Chapter 33](#)). For children with SIADH, water restriction is the cornerstone of therapy, although vaptan drugs, which are ADH antagonists, have a role in some patients. Children with hyponatremia secondary to hypothyroidism or cortisol deficiency need specific

hormone replacement. **Acute water intoxication** rapidly self-corrects with the transient restriction of water intake, which is followed by introduction of a normal diet. Treatment of hypervolemic hyponatremia centers on restriction of water and sodium intake, but disease-specific measures, such as dialysis in renal failure, may also be necessary.

Emergency treatment of **symptomatic hyponatremia**, such as seizures, uses IV hypertonic saline to rapidly increase the serum sodium concentration, which leads to a decrease in brain edema. One milliliter per kilogram of 3% sodium chloride increases the serum sodium by approximately 1 mEq/L. A child often improves after receiving 4–6 mL/kg of 3% sodium chloride.

HYPERNATREMIA

Etiology

There are three basic mechanisms of hypernatremia ([Fig. 35.2](#)). **Sodium intoxication** is frequently iatrogenic in a hospital setting, resulting from correction of metabolic acidosis with sodium bicarbonate. In hyperaldosteronism, there is renal retention of sodium and resultant hypertension; the hypernatremia is mild.

Hypernatremia resulting from water losses develops only if the patient does not have access to water or cannot drink adequately because of neurologic impairment (adipsia), emesis, or anorexia. Infants are at high risk because of their inability to control their own water intake. Ineffective breast-feeding, often in a primiparous mother, can cause severe hypernatremic dehydration. High insensible losses of water are especially common in premature infants; the losses increase further as a result of radiant warmers or phototherapy for hyperbilirubinemia. Children with extrarenal causes of water loss have high levels of ADH and very concentrated urine.

Children with diabetes insipidus have inappropriately diluted urine. Hereditary **nephrogenic diabetes insipidus** causes massive urinary water losses. Because it is most commonly an X-linked disorder due to a mutation in the gene for the ADH receptor, it usually occurs in males, who may have episodes of severe hypernatremic dehydration and failure to thrive. *Acquired nephrogenic diabetes insipidus* may be secondary to interstitial nephritis, sickle cell disease, hypercalcemia, hypokalemia, or medications (lithium). If the defect is due to **central diabetes insipidus**, urine output decreases and urine osmolality increases in response to administration of an ADH analog. Central causes of ADH deficiency include tumor, infarction, or trauma. There is no response to an ADH analog in a child with nephrogenic diabetes insipidus.

Diarrhea results in sodium and water depletion. Most children with gastroenteritis do not develop hypernatremia because they drink enough hypotonic fluid to compensate at least partially for stool water losses. Hypernatremia is most likely in a child with diarrhea who has inadequate intake because of emesis, lack of access to water, or anorexia. Some renal diseases, including obstructive uropathy, renal dysplasia, and juvenile nephronophthisis, can cause losses of sodium and water, potentially producing hypernatremia if the patient consumes insufficient water.

In situations with combined sodium and water deficits, analysis of the urine differentiates renal and nonrenal etiologies. When the losses are extrarenal, the kidney responds to volume depletion with low urine volume, a concentrated

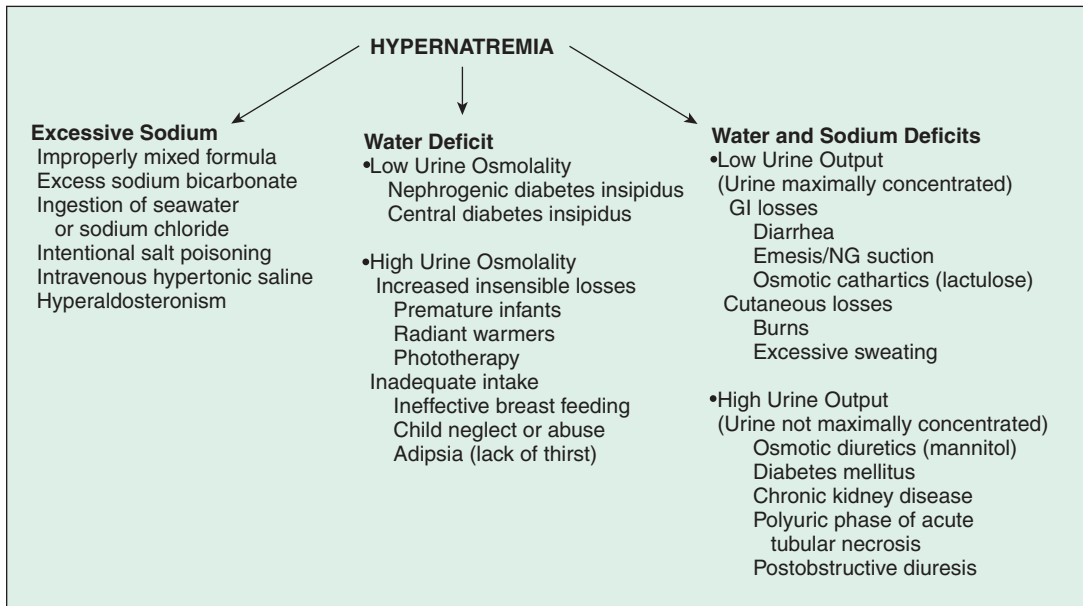

FIGURE 35.2 Differential diagnosis of hypernatremia by mechanism. GI, Gastrointestinal; NG, nasogastric.

urine, and sodium retention (urine sodium <10 mEq/L). With renal causes, the urine volume is usually high, the urine is not maximally concentrated, and the urine sodium may be inappropriately elevated.

Clinical Manifestations

Most children with hypernatremia are dehydrated and have the typical signs and symptoms of dehydration (see [Chapter 33](#)). Children with hypernatremic dehydration tend to have better preservation of intravascular volume owing to the shift of water from the intracellular space to the extracellular space. Hypernatremic infants potentially become more dehydrated before seeking medical attention. Probably because of intracellular water loss, the pinched abdominal skin of a dehydrated, hypernatremic infant has a *doughy* feel.

Hypernatremia, even without dehydration, causes central nervous system symptoms that tend to parallel the degree of sodium elevation and the acuity of the increase. Patients are irritable, restless, weak, and lethargic. Some infants have a high-pitched cry and hyperpnea; hypernatremia may cause fever. Alert patients are very thirsty, although nausea may be present.

Brain hemorrhage is the most devastating consequence of hypernatremia. As the extracellular osmolality increases, water moves out of brain cells, resulting in a decrease in brain volume. This decrease in volume can result in tearing of intracerebral veins and bridging blood vessels as the brain moves away from the skull and the meninges. Patients may have subarachnoid, subdural, and parenchymal hemorrhage. Seizures and coma are possible sequelae of the hemorrhage.

Treatment

As hypernatremia develops, the brain generates idiogenic osmoles to increase the intracellular osmolality and prevent the loss of brain water. This mechanism is not instantaneous and is most prominent when hypernatremia has developed gradually. If the serum sodium concentration is lowered

rapidly, there is movement of water from the serum into the brain cells to equalize the osmolality in the two compartments. The resultant brain swelling manifests as seizures or coma. Because of these dangers, hypernatremia should be corrected slowly. The goal is to decrease the serum sodium by less than 12 mEq/L every 24 hours (see [Fig. 33.1](#)). The most important components of correcting moderate or severe hypernatremia are restoring the effective intravascular volume and then frequently monitoring the serum sodium to allow adjustment of fluid therapy and to provide adequate correction that is neither too slow nor too fast.

In a child with hypernatremic dehydration, as in any child with dehydration, the first priority is restoration of intravascular volume with isotonic fluid. [Fig. 33.1](#) outlines a general approach for correcting hypernatremic dehydration secondary to gastroenteritis. If the hypernatremia and dehydration are secondary to water loss, as occurs with diabetes insipidus, a more hypotonic IV fluid is appropriate. A child with central diabetes insipidus should receive an ADH analog to prevent further excessive water loss. A child with nephrogenic diabetes insipidus requires a urine replacement solution to offset ongoing water losses. Chronically, reduced sodium intake, thiazide diuretics, and nonsteroidal antiinflammatory drugs can decrease water losses in nephrogenic diabetes insipidus.

Acute, severe hypernatremia, usually secondary to sodium administration, can be corrected more rapidly because idiogenic osmoles have not had time to accumulate; this balances the high morbidity and mortality from severe, acute hypernatremia with the dangers of overly rapid correction. When hypernatremia is due to sodium intoxication, and the hypernatremia is severe, it may be impossible to administer enough water to rapidly correct the hypernatremia without worsening volume overload. Some patients require the use of a loop diuretic or dialysis.

PEARLS FOR PRACTITIONERS

See *Fluids and Electrolytes: Pearls for Practitioners* at the end of this section.

CHAPTER 36

Potassium Disorders

The kidneys are the principal regulator of potassium balance, adjusting excretion based on intake. Factors affecting renal potassium excretion include aldosterone, acid-base status, serum potassium concentration, and renal function. The intracellular potassium concentration is approximately 30 times the extracellular potassium concentration. A variety of conditions alter the distribution of potassium between the intracellular and extracellular compartments, potentially causing either hypokalemia or hyperkalemia. The plasma concentration does not always reflect the total body potassium content.

HYPOKALEMIA

Etiology

Hypokalemia is common in children, with most cases related to gastroenteritis. Spurious hypokalemia occurs in

patients with leukemia and elevated white blood cell counts if plasma for analysis is left at room temperature, permitting the white blood cells to take up potassium from the plasma. There are four basic mechanisms of hypokalemia (Table 36.1). Low intake, nonrenal losses, and renal losses all are associated with total body potassium depletion. With a **transcellular shift**, total body potassium is normal unless there is concomitant potassium depletion secondary to other factors.

The transcellular shift of potassium after initiation of insulin therapy in children with diabetic ketoacidosis (see Chapter 171) can be dramatic. These patients have reduced total body potassium because of urinary losses, but they often have a normal serum potassium level before insulin therapy from a transcellular shift into the extracellular space secondary to insulin deficiency and metabolic acidosis. Children receiving aggressive doses of β -adrenergic agonists (albuterol) for asthma can develop hypokalemia resulting from the intracellular movement of potassium. Poor intake is an unusual cause of hypokalemia, unless it is also associated with significant weight loss (anorexia nervosa).

TABLE 36.1 Causes of Hypokalemia

Spurious	With metabolic alkalosis
High white blood cell count	Low urine chloride
Transcellular shifts	Emesis/nasogastric suction
Alkalemia	Pyloric stenosis
Insulin	Chloride-losing diarrhea
β -adrenergic agonists	Cystic fibrosis
Drugs/toxins (theophylline, barium, toluene)	Low-chloride formula
Hypokalemic periodic paralysis	Posthypercapnia
Refeeding syndrome	Previous loop or thiazide diuretic use
Decreased intake	High urine chloride and normal blood pressure
Extrarenal losses	Gitelman syndrome
Diarrhea	Bartter syndrome
Laxative abuse	Loop and thiazide diuretics
Sweating	High urine chloride and high blood pressure
Renal losses	Adrenal adenoma or hyperplasia
With metabolic acidosis	Glucocorticoid-remediable aldosteronism
Distal RTA	Renovascular disease
Proximal RTA	Renin-secreting tumor
Uretersigmoidostomy	17 α -hydroxylase deficiency
Diabetic ketoacidosis	11 β -hydroxylase deficiency
Without specific acid-base disturbance	Cushing syndrome
Tubular toxins (amphotericin, cisplatin, aminoglycosides)	11 β -hydroxysteroid dehydrogenase deficiency
Interstitial nephritis	Licorice ingestion
Diuretic phase of acute tubular necrosis	Liddle syndrome
Postobstructive diuresis	
Hypomagnesemia	
High urine anions (e.g., penicillin or penicillin derivatives)	

RTA, Renal tubular acidosis.

	TYPE 1 BARTTER SYNDROME	TYPE 2 BARTTER SYNDROME	TYPE 3 BARTTER SYNDROME	TYPE 4 BARTTER SYNDROME	TYPE 5 BARTTER SYNDROME	GITELMAN SYNDROME

AR, Autosomal recessive.

Diarrhea has a high concentration of potassium, and the resulting hypokalemia is usually associated with a metabolic acidosis secondary to stool losses of bicarbonate. With emesis or nasogastric suction, there is gastric loss of potassium, but this is fairly minimal given the low potassium content of gastric fluid (~10 mEq/L). More important is the gastric loss of hydrochloride, leading to a metabolic alkalosis and a state of volume depletion. Metabolic alkalosis and volume depletion increase urinary losses of potassium.

Urinary potassium wasting may be accompanied by a metabolic acidosis (proximal or distal renal tubular acidosis; see Chapter 37). Loop and thiazide diuretics lead to hypokalemia and a metabolic alkalosis. **Bartter syndrome** and **Gitelman syndrome** are autosomal recessive disorders resulting from defects in tubular transporters and are associated with hypokalemia and a metabolic alkalosis. Bartter syndrome is usually associated with hypercalciuria, often with nephrocalcinosis; children with Gitelman syndrome have low urinary calcium losses, but hypomagnesemia secondary to urinary losses (Table 36.2).

In the presence of a high aldosterone level, there is urinary loss of potassium, hypokalemia, and a metabolic alkalosis. There also is renal retention of sodium, leading to hypertension. A variety of genetic and acquired disorders can cause high aldosterone levels. **Liddle syndrome**, an autosomal dominant disorder caused by constitutively active sodium channels, has the same clinical features as hyperaldosteronism, but the serum aldosterone level is low.

Clinical Manifestations

The heart and skeletal muscle are especially vulnerable to hypokalemia. **Electrocardiographic (ECG) changes** include a flattened T wave, a depressed ST segment, and the appearance of a U wave, which is located between the T wave (if still visible) and P wave. Ventricular fibrillation and torsades de pointes may occur, although usually only in the context of underlying heart disease.

The clinical consequences in skeletal muscle include muscle weakness and cramps. **Paralysis** is a possible complication

(generally only at potassium levels <2.5 mEq/L). Paralysis usually starts with the legs, followed by the arms. Respiratory paralysis may require mechanical ventilation.

Some hypokalemic patients develop **rhabdomyolysis**, especially following exercise. Hypokalemia slows gastrointestinal motility; potassium levels less than 2.5 mEq/L may cause an ileus. Hypokalemia impairs bladder function, potentially leading to urinary retention. Hypokalemia causes polyuria by producing secondary nephrogenic diabetes insipidus. Chronic hypokalemia may cause kidney damage, including interstitial nephritis and renal cysts.

Diagnosis

It is important to review the child's diet, history of gastrointestinal losses, and medications. Emesis and diuretic use can be surreptitious. The presence of hypertension suggests excess mineralocorticoids. Concomitant electrolyte abnormalities are useful clues. The combination of hypokalemia and metabolic acidosis is characteristic of diarrhea, and proximal or distal renal tubular acidosis. A concurrent metabolic alkalosis is characteristic of gastric losses, aldosterone excess, diuretics, Bartter syndrome, or Gitelman syndrome.

Treatment

Factors that influence the therapy of hypokalemia include the potassium level, clinical symptoms, renal function, presence of transcellular shifts of potassium, ongoing losses, and the patient's ability to tolerate oral potassium. Severe, symptomatic hypokalemia requires aggressive treatment. Supplementation is more cautious if renal function is decreased because of the kidney's limited ability to excrete excessive potassium. The plasma potassium level does not always provide an accurate estimation of the total body potassium deficit because there may be shifts of potassium from the intracellular space to the plasma. Clinically, this shift occurs most commonly with metabolic acidosis and as a result of the insulin deficiency of diabetic ketoacidosis; the plasma potassium underestimates the degree of total body potassium depletion. When these

TABLE 36.3 Causes of Hyperkalemia

Spurious laboratory value	Acquired Addison disease
Hemolysis	21-hydroxylase deficiency
Tissue ischemia during blood drawing	3 β -hydroxysteroid-dehydrogenase deficiency

Decreased excretion	NSAIDs
Renal failure	Trimethoprim
Primary adrenal disease	

ACE, Angiotensin-converting enzyme; IV, intravenous; NSAIDs, nonsteroidal antiinflammatory drugs; PO, oral.

problems are corrected, potassium moves into the intracellular space, and these patients require more potassium supplementation to correct the hypokalemia. Patients who have ongoing losses of potassium need correction of the deficit and replacement of the ongoing losses.

Because of the risk of hyperkalemia, intravenous (IV) potassium should be used cautiously. Oral potassium is safer in nonurgent situations. The dose of IV potassium is 0.5–1 mEq/kg, usually given over 1 hour. The adult maximum dose is 40 mEq. Conservative dosing is generally preferred. For patients with excessive urinary losses, potassium-sparing diuretics are effective. When hypokalemia, metabolic alkalosis, and volume depletion are present, restoration of intravascular volume decreases urinary potassium losses.

HYPERKALEMIA

Etiology

Three basic mechanisms cause hyperkalemia (Table 36.3). In the individual patient, the etiology is sometimes multifactorial.

Factitious hyperkalemia is usually due to hemolysis during phlebotomy, but it can be the result of prolonged tourniquet application or fist clenching during phlebotomy, which causes local potassium release from muscle. Falsely elevated serum potassium levels can occur when serum levels are measured in patients with markedly elevated white blood cell or platelet counts; a promptly analyzed plasma sample usually provides an accurate result.

Because of the kidney's ability to excrete potassium, it is unusual for excessive intake, by itself, to cause hyperkalemia. This mechanism can occur in a patient who is receiving large quantities of IV or oral potassium for excessive losses that are no longer present. Frequent or rapid blood transfusions can increase the potassium level acutely secondary to the high potassium content of stored blood. Increased intake may precipitate hyperkalemia if there is an underlying defect in potassium excretion.

The intracellular space has a high potassium concentration, so a **shift of potassium from the intracellular space** to the extracellular space can have a significant impact on the plasma

potassium. This shift occurs with acidosis, cell destruction (rhabdomyolysis or tumor lysis syndrome), insulin deficiency, medications (succinylcholine, β blockers), malignant hyperthermia, and hyperkalemic periodic paralysis.

Hyperkalemia secondary to decreased excretion occurs with renal insufficiency. The risk of hyperkalemia secondary to medications that decrease renal potassium excretion is greatest in patients with underlying renal insufficiency.

Aldosterone deficiency or unresponsiveness to aldosterone causes hyperkalemia, often with associated metabolic acidosis (see Chapter 37) and hyponatremia. A form of congenital adrenal hyperplasia, **21-hydroxylase deficiency**, is the most frequent cause of aldosterone deficiency in children. Untreated patients have hyperkalemia, metabolic acidosis, hyponatremia, and volume depletion.

Renin, via angiotensin II, stimulates aldosterone production. A deficiency in renin, resulting from kidney damage, can lead to decreased aldosterone production. These patients typically have hyperkalemia and a metabolic acidosis, without hyponatremia. Some patients have impaired renal function, partially accounting for the hyperkalemia, but the impairment in potassium excretion is more extreme than expected for the degree of renal insufficiency.

Children with **pseudohypoaldosteronism (PHA) type 1** have hyperkalemia, metabolic acidosis, and salt wasting, leading to hyponatremia and volume depletion; aldosterone levels are elevated. In the autosomal recessive variant, there is a defect in the renal sodium channel that is normally activated by aldosterone. In the autosomal dominant form, patients have a defect in the aldosterone receptor, and the disease is milder, often remitting in adulthood. **PHA type 2**, also called **Gordon syndrome**, is an autosomal dominant disorder characterized by hypertension secondary to salt retention and impaired excretion of potassium and acid, leading to hyperkalemia and metabolic acidosis. PHA type 2 responds to a thiazide diuretic.

Clinical Manifestations

The most important effects of hyperkalemia are due to the role of potassium in membrane polarization. The cardiac conduction system is usually the dominant concern. **ECG changes** begin with peaking of the T waves. As the potassium level increases, an increased P-R interval, flattening of the P wave, and widening of the QRS complex occur; this eventually can progress to ventricular fibrillation. Asystole also may occur. Some patients have paresthesias, weakness, and tingling, but cardiac toxicity usually precedes these clinical symptoms.

Diagnosis

The etiology of hyperkalemia is often readily apparent. Spurious hyperkalemia is common in children, so a repeat potassium level is often appropriate. If there is a significant elevation of the white blood cells or platelets, the repeat sample should be from plasma that is evaluated promptly. Initially, the history should focus on potassium intake, risk factors for transcellular shifts of potassium, medications that cause hyperkalemia, and the presence of signs of renal insufficiency, such as oliguria or an abnormal urinalysis. Initial laboratory evaluation should include serum creatinine and assessment of acid-base status. Many causes of hyperkalemia, such as renal insufficiency and

IV, Intravenous; PO, oral.

aldosterone insufficiency or resistance, cause a metabolic acidosis. Cell destruction, as seen in rhabdomyolysis or tumor lysis syndrome, can cause concomitant hyperphosphatemia, hyperuricemia, and an elevated serum lactate dehydrogenase.

Treatment

The plasma potassium level, the ECG, and the risk of the problem worsening determine the aggressiveness of the therapeutic approach. A high serum potassium level with ECG changes requires more vigorous treatment. An additional source of concern is a patient with increasing plasma potassium despite minimal intake. This situation can occur if there is cellular release of potassium (tumor lysis syndrome), especially in the setting of diminished excretion (renal failure).

The first action in a child with a concerning elevation of plasma potassium is to stop all sources of additional potassium (oral and IV). If the potassium level is greater than 6.5 mEq/L, an ECG should be obtained to help assess the urgency of the situation. Therapy of hyperkalemia has two basic goals:

1. Prevent life-threatening arrhythmias
2. Remove potassium from the body (Table 36.4)

Treatments that acutely prevent arrhythmias all work quickly (within minutes), but do not remove potassium from the body.

Long-term management of hyperkalemia includes reducing intake via dietary changes and eliminating or reducing medications that cause hyperkalemia. Some patients require medications, such as sodium polystyrene sulfonate and loop or thiazide diuretics, to increase potassium losses. The disorders that are due to a deficiency in aldosterone respond to replacement therapy with fludrocortisone, which is a mineralocorticoid.

PEARLS FOR PRACTITIONERS

See *Fluids and Electrolytes: Pearls for Practitioners* at the end of this section.

CHAPTER 37

Acid-Base Disorders

Close regulation of pH is necessary for cellular enzymes and other metabolic processes, which function optimally at a normal pH (7.35–7.45). Chronic, mild derangements in acid-base status may interfere with normal growth and development, whereas acute, severe changes in pH can be fatal. Control of acid-base balance depends on the kidneys, the lungs, and the intracellular and extracellular buffers.

The lungs and kidneys maintain a normal acid-base balance. Carbon dioxide (CO₂) generated during normal metabolism is a weak acid. The lungs prevent an increase in the partial pressure of CO₂ (P_{CO₂}) in the blood by excreting the CO₂. Production of CO₂ varies depending on the body's metabolic needs. The rapid pulmonary response to changes in CO₂ concentration occurs via central sensing of the P_{CO₂}, and a subsequent increase or decrease in ventilation to maintain a normal P_{CO₂} (35–45 mm Hg).

The kidneys excrete endogenous acids. An adult normally produces about 1–2 mEq/kg per day of hydrogen ions, whereas a child produces 2–3 mEq/kg per day. The hydrogen ions from endogenous acid production are neutralized by bicarbonate, potentially causing the bicarbonate concentration to fall. The kidneys regenerate this bicarbonate by secreting hydrogen ions, maintaining the serum bicarbonate concentration in the normal range (20–28 mEq/L).

CLINICAL ASSESSMENT OF ACID-BASE DISORDERS

Acidemia is a pH below normal (<7.35), and **alkalemia** is a pH above normal (>7.45). **Acidosis** is a pathologic process that causes an increase in the hydrogen ion concentration, and **alkalosis** is a pathologic process that causes a decrease in the hydrogen ion concentration. A **simple acid-base disorder** is a single primary disturbance. During a simple metabolic disorder, there is respiratory compensation; the P_{CO₂} decreases during metabolic acidosis and increases during metabolic alkalosis. With metabolic acidosis, the decrease in the pH increases the ventilatory drive, causing a decrease in the P_{CO₂}. The fall in the CO₂ concentration leads to an increase in the pH. This **appropriate respiratory compensation** for a metabolic process happens quickly and is complete within 12–24 hours.

During a primary respiratory process, there is metabolic compensation mediated by the kidneys. The kidneys respond to a respiratory acidosis by increasing hydrogen ion excretion, increasing bicarbonate generation, and raising the serum bicarbonate concentration. The kidneys increase bicarbonate excretion to compensate for a respiratory alkalosis; the serum bicarbonate concentration decreases. In contrast to a rapid respiratory compensation, it takes 3–4 days for the kidneys to complete **appropriate metabolic compensation**. However, there is a small and rapid compensatory change in the bicarbonate concentration during a primary respiratory process. The expected appropriate metabolic compensation for a respiratory disorder depends on whether the process is acute or chronic.

A **mixed acid-base disorder** is present when there is more than one primary acid-base disturbance. An infant with bronchopulmonary dysplasia may have respiratory acidosis from chronic lung disease and metabolic alkalosis from a diuretic used to treat the chronic lung disease. Formulas are available for calculating the appropriate metabolic or respiratory compensation for the six primary simple acid-base disorders (Table 37.1). Appropriate compensation is expected in a simple disorder; it is not optional. If a patient does not have appropriate compensation, a mixed acid-base disorder is present.

METABOLIC ACIDOSIS

Metabolic acidosis occurs frequently in hospitalized children; diarrhea is the most common cause. For a patient with an unknown medical problem, the presence of metabolic acidosis is often diagnostically helpful because it suggests a relatively narrow differential diagnosis (Table 37.2).

TABLE 37.1 Appropriate Compensation During Simple Acid-Base Disorders

DISORDER	EXPECTED COMPENSATION*
Metabolic acidosis	$P_{CO_2} = 1.5 \times [HCO_3^-] + 8 \pm 2$
Metabolic alkalosis	P _{CO₂} increases by 7 mm Hg for each 10 mEq/L increase in the serum [HCO ₃ ⁻]
Respiratory acidosis	
Acute	[HCO ₃ ⁻] increases by 1 for each 10 mm Hg increase in the P _{CO₂}
Chronic	[HCO ₃ ⁻] increases by 3.5 for each 10 mm Hg increase in the P _{CO₂}
Respiratory alkalosis	
Acute	[HCO ₃ ⁻] falls by 2 for each 10 mm Hg decrease in the P _{CO₂}
Chronic	[HCO ₃ ⁻] falls by 4 for each 10 mm Hg decrease in the P _{CO₂}

*[HCO₃⁻] is expressed in mEq/L.

TABLE 37.2 Causes of Metabolic Acidosis

NORMAL ANION GAP
Diarrhea
Renal tubular acidosis
Urinary tract diversions
Posthypocapnia
Ammonium chloride intake
INCREASED ANION GAP
Lactic acidosis (shock or inborn errors of metabolism)
Ketoacidosis (diabetic, starvation, or alcoholic)
Kidney failure
Poisoning (e.g., ethylene glycol, methanol, or salicylates)
Inborn errors of metabolism

Etiology

The plasma **anion gap** is useful for evaluating patients with metabolic acidosis. It divides patients into two diagnostic groups: normal anion gap and increased anion gap. The following formula determines the anion gap:

$$\text{Anion Gap} = \text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)$$

A normal anion gap is 9 ± 4 mEq/L.

Normal anion gap metabolic acidosis occurs in the setting of diarrhea and renal tubular acidosis (RTA). Diarrhea causes a loss of bicarbonate from the body. The amount of bicarbonate lost in the stool depends on the volume of diarrhea and the bicarbonate concentration of the stool, which tends to increase with more severe diarrhea. Diarrhea often causes volume depletion because of losses of sodium and water, potentially exacerbating the acidosis by causing hypoperfusion (shock) and a lactic acidosis.

There are three forms of RTA:

1. Distal (type I)
2. Proximal (type II)
3. Hyperkalemic (type IV)

In distal RTA (dRTA), children may have accompanying hypokalemia, hypercalciuria, nephrolithiasis, and nephrocalcinosis; rickets is a less common finding. Failure to thrive, resulting from chronic metabolic acidosis, is the most common presenting complaint. Autosomal dominant (relatively mild) and autosomal recessive (more severe) forms of dRTA exist. Autosomal recessive dRTA is often associated with deafness secondary to a defect in the gene for an H^+ -ATPase that is present in the kidney and the inner ear. dRTA also may be secondary to medications or congenital or acquired renal disease. Patients with dRTA cannot acidify their urine and can have a urine pH greater than 5.5, despite metabolic acidosis.

Proximal RTA is rarely present in isolation. In most patients, proximal RTA is part of **Fanconi syndrome**, a generalized dysfunction of the proximal tubule. Along with renal wasting of bicarbonate, Fanconi syndrome causes glycosuria, aminoaciduria, and excessive urinary losses of phosphate and uric acid. The chronic hypophosphatemia is more clinically significant because it ultimately leads to rickets in children. Rickets or failure to thrive may be the presenting complaint. Fanconi syndrome is rarely an isolated genetic disorder, with pediatric cases usually secondary to an underlying genetic disorder, most commonly **cystinosis**. Medications, such as ifosfamide, deferasirox, or valproate, may cause Fanconi syndrome. The ability to acidify the urine is intact in proximal RTA, and untreated patients have a urine pH less than 5.5.

In **hyperkalemic RTA**, renal excretion of acid and potassium is impaired because of either an absence of aldosterone or an inability of the kidney to respond to aldosterone. In severe aldosterone deficiency, as occurs with congenital adrenal hyperplasia secondary to 21α -hydroxylase deficiency, the hyperkalemia and metabolic acidosis are accompanied by hyponatremia and volume depletion from renal salt wasting. Incomplete aldosterone deficiency causes less severe electrolyte disturbances; children may have isolated hyperkalemic RTA, hyperkalemia without acidosis, or isolated hyponatremia.

Distal and hyperkalemic RTA are similar in that distal tubular acidification is impaired. Conversely, in proximal

RTA, distal tubular acidification is intact, but leads to metabolic acidosis due to bicarbonate wasting.

Increased anion gap metabolic acidosis occurs with lactic acidosis, ketoacidosis, chronic renal failure, and toxic ingestions. Lactic acidosis most commonly occurs when inadequate oxygen delivery to the tissues leads to anaerobic metabolism and excess production of lactic acid. Lactic acidosis may be secondary to shock, severe anemia, or hypoxemia. Inborn errors of carbohydrate metabolism produce a severe lactic acidosis (see [Chapter 52](#)). In diabetes mellitus, inadequate insulin leads to hyperglycemia and diabetic ketoacidosis (see [Chapter 171](#)). Renal failure (see [Chapter 165](#)) causes metabolic acidosis because the kidneys are unable to excrete the acid produced by normal metabolism.

A variety of **toxic ingestions** cause metabolic acidosis. Acute **salicylate** intoxication occurs after a large overdose. Chronic salicylate intoxication is possible because of the gradual buildup of the drug. Patients may also have a respiratory alkalosis. Other symptoms of salicylate intoxication include fever, seizures, lethargy, and coma. Hyperventilation may be particularly marked. Tinnitus, vertigo, and hearing impairment are more likely with chronic salicylate intoxication. **Ethylene glycol**, a component of antifreeze, is converted in the liver to glyoxylic and oxalic acids, causing a severe metabolic acidosis. Excessive oxalate excretion causes calcium oxalate crystals to appear in the urine, and calcium oxalate precipitation in the kidney tubules can cause renal failure. The toxicity of **methanol** ingestion also depends on liver metabolism; formic acid is the toxic end product that causes the metabolic acidosis and other sequelae, which include damage to the optic nerve and central nervous system.

There are many **inborn errors of metabolism** that may cause metabolic acidosis (see [Section 10](#)). Metabolic acidosis may be due to excessive production of ketoacids, lactic acid, or other organic anions. Some patients may have accompanying hyperammonemia. In most patients, acidosis occurs only episodically during acute decompensations, which may be precipitated by the ingestion of specific dietary substrates (proteins), the stress of a mild illness (fasting, catabolism), or poor adherence with dietary or medical therapy.

Clinical Manifestations

The underlying disorder usually produces most of the signs and symptoms in children with a mild or moderate metabolic acidosis. The clinical manifestations of the acidosis are related to the degree of acidemia; patients with appropriate respiratory compensation and less severe acidemia have fewer manifestations than patients with a concomitant respiratory acidosis. At a serum pH less than 7.20, there is impaired cardiac contractility and an increased risk of arrhythmias, especially if underlying heart disease or other predisposing electrolyte disorders are present. With acidemia, there is a decrease in the cardiovascular response to catecholamines, potentially exacerbating hypotension in children with volume depletion or shock. Acidemia causes vasoconstriction of the pulmonary vasculature, which is especially problematic in neonates with primary pulmonary hypertension of the newborn (see [Chapter 61](#)). The normal respiratory response to metabolic acidosis—compensatory hyperventilation—may be subtle with mild metabolic acidosis, but it causes discernible increased respiratory effort with worsening acidemia. Chronic metabolic acidosis causes failure to thrive.

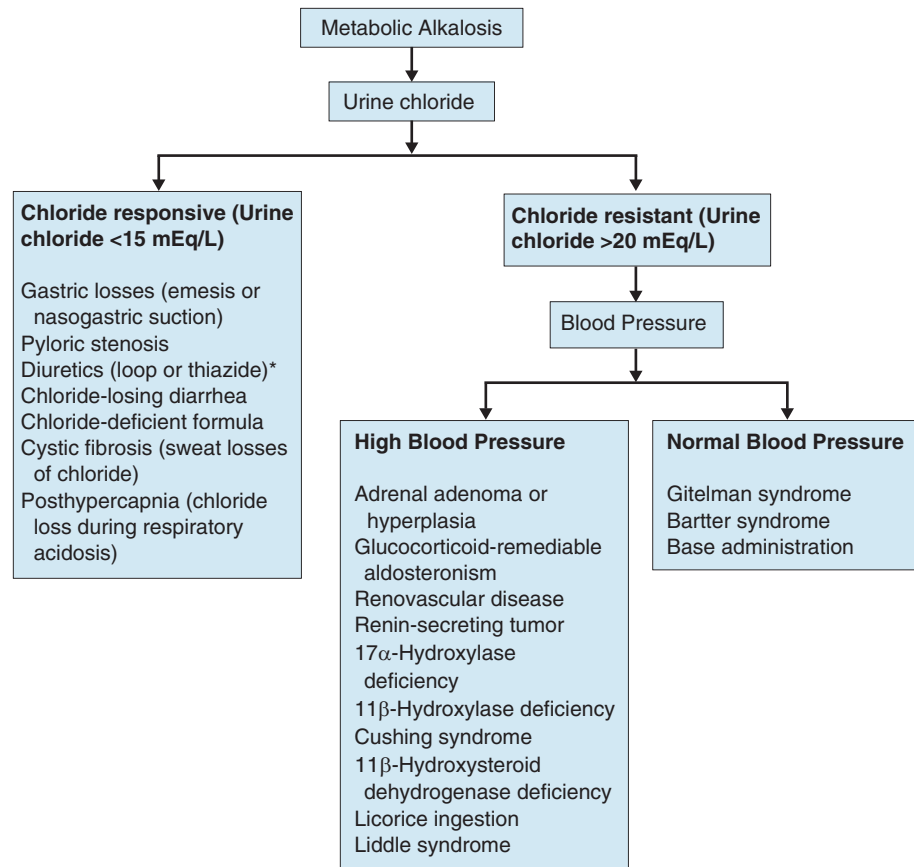

FIGURE 37.1 Causes of a metabolic alkalosis. *Diuretics are associated with an elevated urinary chloride (>20 mEq/L) when the patient is receiving the diuretic, but a low urinary chloride (<15 mEq/L) when the effect has worn off, but are chloride responsive and hence grouped with these disorders.

Diagnosis

Calculating the anion gap can help narrow the differential diagnosis for acidosis. However, the anion gap should not be interpreted in dogmatic isolation; consideration of other laboratory abnormalities and the clinical history improves its diagnostic utility. A decrease in the albumin concentration of 1 g/dL decreases the anion gap by roughly 4 mEq/L. Similarly, albeit less commonly, an increase in unmeasured cations, such as calcium, potassium, or magnesium, decreases the anion gap. Conversely, a decrease in unmeasured cations is a rare cause of an increased anion gap. Because of these variables, the broad range of a normal anion gap and other factors, the presence of a normal or increased anion gap is not always reliable in differentiating the causes of a metabolic acidosis, especially when the metabolic acidosis is mild. Some patients have more than one explanation for their metabolic acidosis, such as a child with diarrhea and lactic acidosis secondary to shock.

Treatment

The most effective therapeutic approach for patients with a metabolic acidosis is correction of the underlying disorder, if possible. The administration of insulin in diabetic ketoacidosis or restoration of adequate perfusion in lactic acidosis from shock eventually results in normalization of acid-base balance. The use of bicarbonate therapy is indicated when the

underlying disorder is irreparable; examples include RTA and chronic renal failure. In salicylate poisoning, alkali administration increases renal clearance of salicylate and decreases the amount of salicylate in brain cells. Short-term base therapy is often necessary in other poisonings and inborn errors of metabolism.

METABOLIC ALKALOSIS

Etiology

The causes of a metabolic alkalosis are divided into two categories based on the urinary chloride (Fig. 37.1). The alkalosis in patients with a low urinary chloride is maintained by volume depletion. They are called **chloride responsive** because volume repletion with fluid containing sodium chloride and potassium chloride is necessary to correct the metabolic alkalosis. Emesis, which causes loss of hydrochloride and volume depletion, is the most common cause of a metabolic alkalosis. Diuretic use increases chloride excretion in the urine. Consequently, while a patient is receiving diuretics, the urinary chloride is typically high (>20 mEq/L). After the diuretic effect resolves, the urinary chloride is low (<15 mEq/L) because of appropriate renal chloride retention in response to volume depletion. Categorization of diuretics based on urinary

chloride depends on the timing of the measurement. The metabolic alkalosis from diuretics is clearly chloride responsive; it corrects after adequate volume repletion. This is the rationale for including it among the chloride-responsive causes of a metabolic alkalosis.

The **chloride-resistant** causes of metabolic alkalosis can be subdivided based on blood pressure. Patients with the rare disorders that cause metabolic alkalosis and hypertension either have increased aldosterone or act as if they have increased aldosterone. Patients with Bartter syndrome or Gitelman syndrome (see Chapter 36) have metabolic alkalosis, hypokalemia, and normal blood pressure secondary to renal tubular defects, which cause continuous urinary losses of chloride.

Clinical Manifestations

The symptoms in patients with metabolic alkalosis often are related to the underlying disease and associated electrolyte disturbances. Hypokalemia is often present and occasionally severe (see Chapter 36). Children with chloride-responsive causes of metabolic alkalosis often have symptoms related to volume depletion (see Chapter 33). In contrast, children with chloride-unresponsive causes may have symptoms related to hypertension. Severe alkalemia may cause arrhythmias, hypoxia secondary to hypoventilation, or decreased cardiac output.

Diagnosis

Measurement of the urinary chloride concentration is the most helpful test in differentiating among the causes of metabolic alkalosis. The history usually suggests a diagnosis, although no obvious explanation may be present in the patient with bulimia or surreptitious diuretic use. Patients with Bartter syndrome or Gitelman syndrome usually have a history of polyuria and may have salt craving.

Treatment

The approach to therapy of metabolic alkalosis depends on the severity of the alkalosis and the underlying etiology. In children with mild metabolic alkalosis ($[\text{HCO}_3^-] < 32$ mEq/L), intervention is often unnecessary. Patients with chloride-responsive metabolic alkalosis respond to the correction of hypokalemia and volume repletion with sodium and potassium chloride, but aggressive volume repletion may be contraindicated if mild volume depletion is medically necessary in the child receiving diuretic therapy. In children with chloride-resistant causes of metabolic alkalosis that are associated with hypertension, volume repletion is contraindicated because it exacerbates the hypertension and does not repair the metabolic alkalosis. Treatment focuses on eliminating or blocking the action of the excess mineralocorticoid. In children with Bartter syndrome or Gitelman syndrome, therapy includes oral sodium and potassium supplementation.

RESPIRATORY ACID-BASE DISTURBANCES

During respiratory acidosis, there is a decrease in the effectiveness of CO_2 removal by the lungs. The causes of respiratory

TABLE 37.3 Causes of Respiratory Acidosis

Central nervous system depression (encephalitis or narcotic overdose)
Disorders of the spinal cord, peripheral nerves, or neuromuscular junction (botulism or Guillain-Barré syndrome)
Respiratory muscle weakness (muscular dystrophy)
Pulmonary disease (pneumonia or asthma)
Upper airway disease (laryngospasm)

TABLE 37.4 Causes of Respiratory Alkalosis

Hypoxemia or tissue hypoxia (carbon monoxide poisoning or cyanotic heart disease)
Lung receptor stimulation (pneumonia or pulmonary embolism)
Central stimulation (anxiety or brain tumor)
Mechanical ventilation
Hyperammonemias

acidosis are either pulmonary or nonpulmonary (Table 37.3). A respiratory alkalosis is an inappropriate reduction in the blood CO_2 concentration. A variety of stimuli can increase the ventilatory drive and cause respiratory alkalosis (Table 37.4). Treatment of respiratory acid-base disorders focuses on correction of the underlying disorder. Mechanical ventilation may be necessary in a child with refractory respiratory acidosis.

PEARLS FOR PRACTITIONERS

CHAPTER 32

Maintenance Fluid Therapy

- Maintenance of normal plasma osmolality within the extracellular compartment depends on the regulation of water balance, which is controlled by antidiuretic hormone (ADH); water intake due to thirst has an important role when the osmolality is elevated.
- Control of osmolality is subordinate to the maintenance of an adequate intravascular volume. When significant volume depletion is present, ADH secretion and thirst are stimulated, regardless of the plasma osmolality.
- Control of volume status depends on the regulation of sodium balance. Excretion of sodium by the kidneys is driven by effective plasma volume rather than by serum osmolality or sodium.
- Maintenance intravenous fluids in patients who cannot be fed enterally replace insensible, stool, and urinary losses of water, and urinary and stool losses of electrolytes.
- The glucose in maintenance fluids provides approximately 20% of normal caloric needs to prevent the development of starvation ketoacidosis and diminish the protein degradation that would occur if the patient received no calories, but maintenance fluids are not a long-term replacement for nutrition.
- Maintenance solutions are usually D5 in normal saline plus 20 mEq/L KCl.

CHAPTER 33

Dehydration and Replacement Therapy

- Insensible water losses from the skin and lungs are about 35% of normal water losses.
- An anuric child who is not dehydrated and is not being fed enterally only requires insensible fluids to maintain euolemia.
- Children with excessive losses (stool, urine, other) may need a replacement solution to avoid volume depletion.
- A 20 mL/kg bolus of an isotonic fluid (normal saline, Ringer lactate) is given over approximately 20 minutes in a child with significant dehydration.
- The blood urea nitrogen (BUN) is elevated out of proportion to the serum creatinine in patients with volume depletion.
- Hyponatremic dehydration occurs when hypotonic fluids such as water or diluted formula are given to a child with gastroenteritis.
- Hypernatremic dehydration occurs in children with poor thirst, poor fluid intake, or excessive urine water losses (diabetes insipidus).

- Mild to moderate diarrheal dehydration can be treated with oral rehydration solution.

CHAPTER 34

Parenteral Nutrition

- Parenteral nutrition (PN) is necessary when enteral feeding is inadequate to meet nutritional needs.
- Short bowel syndrome is a common disorder requiring PN.
- Calories from PN are predominantly from dextrose and fat. Amino acids should mostly be used for protein synthesis.
- Complications of PN include thrombosis and line infection.
- The most concerning complication of long-term PN is cholestatic liver disease, but the risk is reduced by utilization of the gastrointestinal tract even if just for trophic feeds.

CHAPTER 35

Sodium Disorders

- Most disorders of sodium are secondary to abnormalities in water balance.
- The symptoms of hyponatremia, such as seizures, are principally due to water movement into brain cells.
- The symptoms of hypernatremia are due to water movement out of brain cells, which may lead to brain hemorrhage if the hypernatremia is severe.
- Symptoms of hyponatremia are much more likely if the hyponatremia develops rapidly.
- Diagnosing the etiology of hyponatremia should begin by assessing a patient's volume status (hypovolemic, euvoletic, or hypervolemic).
- Most cases of hyponatremia are due to gastroenteritis, but the syndrome of inappropriate antidiuretic hormone secretion (SIADH) or hypervolemic causes (heart failure, cirrhosis) should be considered.
- Most cases of hypernatremia are due to gastroenteritis, but diabetes insipidus must be considered.
- Overly rapid correction of hyponatremia can lead to central pontine myelinolysis; it is optimal to increase the serum sodium less than 10 mEq/L per 24 hours.
- Due to the presence of idiogenic osmoles, overly rapid correction of hypernatremia can lead to cerebral edema, and thus the target decrease in serum sodium is less than 12 mEq/L per 24 hours.
- Acute water intoxication producing hyponatremia often self-corrects once excessive water intake has stopped.
- The emergency treatment of symptomatic hyponatremia involves the use of intravenous hypertonic saline to decrease brain edema.

CHAPTER 36

Potassium Disorders

- The kidneys are the principal regulator of potassium balance.
- Hypokalemia is secondary to renal losses, nonrenal losses (diarrhea), low intake, or transcellular shifts.
- Transcellular potassium shifts are seen in treated diabetic ketoacidosis and patients with asthma treated with albuterol.
- Severe hypokalemia causes muscle cramps and muscle weakness, which may proceed to paralysis.
- Hypokalemia with a metabolic acidosis suggests diarrhea or renal tubular acidosis.
- Hypokalemia with a metabolic alkalosis is most commonly due to emesis or nasogastric losses but may also be due to Bartter or Gitelman syndrome or diuretic use.
- Arrhythmias, which may be fatal, are often the initial clinical manifestation of hyperkalemia.
- Hyperkalemia is most commonly due to decreased excretion or a transcellular shift, although increased intake may cause or contribute.
- Hyperkalemia may be seen in disorders with decreased renin, decreased aldosterone (congenital adrenal hyperplasia), or lack response to aldosterone (decreased aldosterone effect).
- Hyperkalemia is associated with peaked T waves and may produce paresthesia and muscle weakness.
- The two goals of treating hyperkalemia, which require different therapeutic approaches, are to prevent cardiac toxicity and to decrease total body potassium.
- Total body potassium may be reduced by loop or thiazide diuretics, dialysis, or potassium-binding resins.

CHAPTER 37

Acid-Base Disorders

- Acute, severe changes in pH can be fatal, while chronic, mild derangements may interfere with growth and development.
- The lungs and the kidneys maintain normal acid-base balance. The lungs (respiratory) regulate CO₂ concentration, and the kidneys (metabolic) regulate bicarbonate concentration.
- During a primary respiratory process, the kidneys compensate, but full compensation takes a few days.
- During a primary metabolic process, the lungs compensate rapidly (within hours).
- Appropriate compensation is expected in a simple acid-base disorder; it is not optional. If a patient does not have appropriate compensation, a mixed acid-base disorder is present.
- The plasma anion gap divides patients with metabolic acidosis into two categories: normal anion gap and increased anion gap.
- Normal anion gap metabolic acidosis occurs in the setting of diarrhea and renal tubular acidosis.
- Increased anion gap metabolic acidosis occurs with lactic acidosis, ketoacidosis, chronic renal failure, and toxic ingestions.
- The differential diagnosis of metabolic alkalosis begins by measuring the urine chloride and separating patients based on whether the urinary chloride is low or high.
- Patients with a metabolic alkalosis and a low urine chloride are volume depleted, and the alkalosis responds to administration of sodium or potassium chloride (chloride responsive).
- Patients with chloride-resistant metabolic alkalosis (urine chloride not low) are subdivided based on the presence of a normal or elevated blood pressure.

THE ACUTELY ILL OR INJURED CHILD

Tara L. Petersen | Abigail M. Schuh

CHAPTER 38

Assessment and Resuscitation

INITIAL ASSESSMENT

Initial assessment of an acutely ill or injured child includes rapid identification of physiologic derangements in **tissue perfusion and oxygenation**. Once identified, immediate resuscitation must be implemented before pursuing the usual information needed to develop a differential diagnosis. Initial resuscitation measures are directed at achieving and maintaining adequate tissue perfusion and oxygenation. **Oxygen delivery** depends on cardiac output, hemoglobin concentration, and hemoglobin-oxygen saturation. The latter depends on air movement, alveolar gas exchange, pulmonary blood flow, and hemoglobin-oxygen binding characteristics.

HISTORY

In the initial assessment of an acutely ill or traumatically injured child, access to historical information may be limited. Characterization of the onset of symptoms, event details, and a brief identification of underlying medical problems should be sought by members of the team not actively involved in the resuscitation. The mnemonic AMPLE can be employed to help direct a focused history during this time: A, Allergies; M, Medications; P, Past medical history; L, Last meal; and E, Events leading up to patient presentation. Attempts at identifying historical issues that affect the physiologic derangements are useful but should not delay intervention if tissue oxygenation and perfusion are markedly impaired.

PHYSICAL EXAMINATION

Initial examination must focus on the responsiveness of a patient followed by assessment of the airway, breathing, and circulation (Table 38.1) to systematically address the issues of oxygen delivery to tissues. In 2010, the American Heart Association (AHA) guidelines recommended a change from the traditional sequence of airway, breathing, circulation (ABCs) to a CAB sequence (circulation, airway, breathing) to decrease the time to the initiation of chest compression and reduce “no blood flow” time for all patients. Since this change, the survival impact of initiating resuscitation with a C-A-B versus an A-B-C sequence specifically in the pediatric population remains unclear. It is important to note that the leading

cause of cardiopulmonary arrest in children is most often of respiratory etiology (compared to a cardiac etiology in adults), and thus rapid initial assessment of the airway and breathing is vital. Regardless of the sequence approach utilized, it is best to use a consistent, algorithmic method to ensure effective and efficient cardiopulmonary assessment.

Assessment of airway patency should include evaluation of the neurologically injured child’s ability to protect the airway. Protection of the cervical spine should be initiated at this step in any child with traumatic injury or who presents with altered mental status of uncertain etiology. Assessment of breathing includes observation of respiratory effort, rate, and chest rise, plus the auscultation of air movement and the application of a pulse oximeter (when available) to identify current oxygenation status. Circulatory status is assessed by palpation for distal and central pulses, focusing on the presence and quality of the pulses. Bounding pulses and a wide pulse pressure are often the first sign of the vasodilatory phase of shock and require immediate resuscitation measures. Weak, thready, or absent pulses are indicators for fluid resuscitation, initiation of chest compressions, or both. When assessment of the ABCs is complete and measures have been taken to achieve an acceptable level of tissue oxygenation, a more complete physical examination is performed. The sequence of this examination depends on whether the situation involves an acute medical illness or trauma. In trauma patients, the examination follows the **ABCDE pathway**. **D** stands for disability and prompts assessment of the neurologic system and evaluation for major traumatic injuries. **E** stands for exposure; the child is disrobed and examined for evidence of any life-threatening or limb-threatening problems. For the acutely ill and the injured child, the physical examination should identify evidence of organ dysfunction, starting with areas suggested in the chief complaint and progressing to a thorough and systematic investigation of the entire patient.

COMMON MANIFESTATIONS

The physiologic responses to acute illness and injury are mechanisms that attempt to correct inadequacies of tissue oxygenation and perfusion. When initial changes, such as increasing heart and respiratory rates, fail to meet the body’s needs, other manifestations of impending cardiopulmonary failure occur (Table 38.2). **Respiratory failure**, the most common cause of acute deterioration in children, may result in inadequate tissue oxygenation and in respiratory acidosis. Signs and symptoms of respiratory failure (tachypnea, tachycardia, increased work of breathing, abnormal mentation) progress as tissue

oxygenation becomes more inadequate. Inadequate perfusion (shock) leads to inadequate oxygen delivery and a resulting metabolic acidosis. **Shock** is characterized by signs of inadequate tissue perfusion (pallor, cool skin, poor pulses, delayed capillary refill, oliguria, and abnormal mentation). The presence of any of these symptoms demands careful assessment and intervention to correct the abnormality and to prevent further deterioration.

TABLE 38.2	Warning Signs and Symptoms Suggesting the Need for Resuscitation
SYSTEM	SIGNS AND SYMPTOMS
Central nervous system	Lethargy, agitation, delirium, obtundation, confusion
Respiratory	Apnea, grunting, nasal flaring, dyspnea, retracting, tachypnea, poor air movement, stridor, wheezing
Cardiovascular	Arrhythmia, bradycardia, tachycardia, weak pulses, poor capillary refill, hypotension
Skin and mucous membranes	Mottling, pallor, cyanosis, diaphoresis, poor membrane turgor, dry mucous membranes

**Action would seldom be taken if only one or two of these signs and symptoms were present, but the occurrence of several in concert foreshadows grave consequences. Intervention should be directed at the primary disorder.*

INITIAL DIAGNOSTIC EVALUATION

Screening Tests

During the initial phase of resuscitation, monitoring vital signs and physiologic status is the key screening activity. Continuous monitoring with attention to changes may indicate response to therapy or further deterioration requiring additional intervention. During the initial rapid assessment, diagnostic evaluation often is limited to pulse oximetry and bedside measurement of glucose levels. The latter is important in any child with altered mental status or at risk for inadequate glycogen stores (infants, malnourished patients). After resuscitation measures, further diagnostic tests and imaging are often necessary.

Diagnostic Tests and Imaging

The choice of appropriate diagnostic tests and imaging is determined by the mechanism of injury/disease and the results of evaluation after initial resuscitation. The initial evaluation of major trauma patients is focused on identifying evidence of hemorrhage and organ and tissue injury. For an acutely ill child with respiratory distress, a chest x-ray is important. Appropriate cultures (such as blood, urine, cerebrospinal fluid, and/or wound) should be obtained when sepsis is suspected. Children with historical or physical evidence of inadequate intravascular volume should have serum electrolyte levels obtained, including bicarbonate, blood urea nitrogen, and creatinine.

RESUSCITATION

Resuscitation is focused on correcting identified abnormalities of oxygenation and perfusion and preventing further deterioration. **Oxygen supplementation** may improve oxygen saturation but may not completely correct tissue oxygenation. When oxygen supplementation is insufficient or air exchange is inadequate, assisted ventilation must be initiated. Inadequate perfusion is usually best managed initially by providing a fluid bolus. **Isotonic crystalloids** (normal saline or a balanced crystalloid solution such as lactated Ringer or Plasma-Lyte) are the initial fluids of choice. A bolus

of 10–20 mL/kg should be delivered in monitored conditions. Improvement, but not correction, after an initial bolus should prompt repeated boluses until circulation has been re-established. Because most children with shock have non-cardiac causes, fluid administration of this magnitude is well tolerated. If hemorrhage is known or highly suspected, administration of packed red blood cells is appropriate. Monitoring for deteriorating physiologic status during fluid resuscitation (increase in heart rate or decrease in blood pressure) identifies children who may have diminished cardiac function. In these cases, as fluid resuscitation increases the preload, impaired cardiac function may worsen, and pulmonary edema can result. If deterioration occurs, fluid administration should be interrupted, and further resuscitation should be aimed at improving cardiac function.

When respiratory support and fluid resuscitation are insufficient, introduction of **vasoactive substances** is the next step. The choice of which agent to use depends on the type of shock present. Hypovolemic shock (when further volume is contraindicated) and distributive shock benefit from drugs that increase systemic vascular resistance (drugs with α -agonist activity, such as epinephrine or norepinephrine). The treatment of cardiogenic shock is more complex. To improve cardiac output by increasing the heart rate, drugs with positive chronotropy are used (epinephrine, norepinephrine, and dopamine). Afterload reduction, using drugs such as dobutamine, nitroprusside, or milrinone, also may be needed. Measuring central mixed venous oxygen saturation, central venous pressure, and regional oxygen saturations can also guide therapy.

CARDIOPULMONARY ARREST

The outcome of cardiopulmonary arrest in children is poor; survival to hospital discharge is ~6% for out-of-hospital arrest and ~27% for in-hospital arrest, with most survivors having some degree of permanent neurologic disability. The ability to anticipate or recognize pre-cardiopulmonary arrest conditions and initiate prompt and appropriate therapy is not only lifesaving but can also preserve functional status (see Table 38.2).

Children who require cardiopulmonary resuscitation (CPR) usually suffered a primary respiratory arrest. Hypoxia can initiate a cascade of further physiologic deterioration with subsequent organ dysfunction or damage (Table 38.3). The approach to cardiopulmonary arrest extends beyond CPR and includes efforts to preserve vital organ function. The goal in resuscitating a pediatric patient following a cardiopulmonary arrest should be to optimize **cardiac output** and tissue oxygen delivery, which may be accomplished by using artificial ventilation, chest compressions, and judicious administration of pharmacologic agents.

Pediatric Advanced Life Support and Cardiopulmonary Resuscitation

The 2010 AHA revised recommendations for resuscitation of adults, children, and infants advocated for initiation of chest compressions immediately, rather than beginning with airway and breathing (i.e., compressions-airway-breathing/ventilation [C-A-B]). The 2015 AHA update reiterated this recommendation.

TABLE 38.3 Target Organs for Hypoxic-Ischemic Damage

ORGAN	EFFECT
Brain	Seizures, cerebral edema, infarction, herniation, anoxic damage, SIADH, diabetes insipidus
Cardiovascular	Heart failure, myocardial infarct
Lung and pulmonary vasculature	Acute respiratory distress syndrome, pulmonary hypertension
Liver	Infarction, necrosis, cholestasis
Kidney	Acute tubular necrosis, acute cortical necrosis
Gastrointestinal tract	Gastric ulceration, mucosal damage
Hematologic	Disseminated intravascular coagulation

SIADH, Syndrome of inappropriate secretion of antidiuretic hormone.

Circulation

Chest compressions should be initiated if a pulse cannot be palpated or if the heart rate is less than 60 beats/min with concurrent signs of poor systemic perfusion. Chest compressions should be performed immediately by one person while a second person prepares to begin ventilation. **Ventilation** is extremely important in pediatric arrests given the high likelihood of a primary respiratory cause; however, ventilation requires equipment and is therefore sometimes delayed. For this reason, the recommendation is to start chest compressions first while preparing for ventilation.

For optimal chest compressions, the child should be supine on a flat, hard surface. Effective CPR requires a compression depth of one third to one half of the anterior-posterior diameter of the chest with complete recoil after each compression. The compression rate should be at least 100/min with breaths delivered 8–10 times/min. If an advanced airway is in place, compressions should not pause for ventilation; both should continue simultaneously.

Airway

Ventilation requires a **patent airway**. In children, airway patency often is compromised by a loss of muscle tone, allowing the mandibular block of tissue, including the tongue, bony mandible, and the soft surrounding tissues, to rest against the posterior pharyngeal wall. The head tilt–chin lift maneuver should be used to open the airway in children with no sign of head or neck trauma. In children with signs of head or neck trauma, the jaw thrust maneuver should be used.

Bag-mask ventilation can be as effective as, and possibly safer than, endotracheal intubation for short periods of time in an out-of-hospital setting. If skilled personnel and proper equipment are available, pediatric patients requiring resuscitation should be endotracheally intubated. Before intubation, the patient should be ventilated with 100% oxygen using a bag and mask. Cricoid pressure can be used to minimize inflation of the stomach. Many conscious patients may benefit from the use of induction medications (sedatives, analgesics, and neuromuscular blockade) to assist intubation, but caution is necessary to prevent further cardiovascular compromise from

TABLE 38.4 Drug Doses for Cardiopulmonary Resuscitation

DRUG	INDICATION	DOSE
Adenosine	Supraventricular tachycardia	IV: 0.1 mg/kg (maximum 6 mg); second dose: 0.2 mg/kg (maximum 12 mg)
Amiodarone	Pulseless VF/VT	IV/IO: 5 mg/kg; may repeat twice up to 15 mg/kg; maximum single dose 300 mg
	Perfusing tachyarrhythmias	Dose as above but administer slowly over 20–60 min. Expert consultation strongly recommended
Atropine	Supraventricular or junctional bradycardia	IV/IO/IM: 0.02 mg/kg; ET: 0.04–0.06 mg/kg; maximum single dose: 0.5 mg; higher doses needed in organophosphate poisoning
Bicarbonate	Hyperkalemia, some toxidromes	IV/IO: 1 mEq/kg bolus; ensure adequate ventilation; monitor ABGs; can repeat every 10 min
Calcium chloride (10%)	Hypocalcemia, calcium channel blocker overdose, hypermagnesemia, hyperkalemia	IV/IO: 20 mg/kg; maximum single dose 2 g; administer slowly
Dextrose	Hypoglycemia	IV/IO: Newborns: 5–10 mL/kg of 10% dextrose; infants and children: 2–4 mL/kg of 25% dextrose; adolescents: 1–2 mL/kg of 50% dextrose
Epinephrine	Hypotension, chronotropy, inotropy	IV/IO: 0.01 mg/kg (0.1 mL/kg 1:10,000); ET: 0.1 mg/kg (0.1 mL/kg 1:1,000); may repeat every 3–5 min; may promote arrhythmias
Fluid	Hypovolemia, sepsis	IV/IO: Administer crystalloid in 20 mL/kg boluses titrated to patient's physiologic needs
Lidocaine	VT	IV/IO: 1 mg/kg/bolus followed by 20–50 µg/kg/min continuous infusion; ET: Loading dose: 2–3 mg/kg/dose; flush with 5 mL of NS and follow with five assisted manual ventilations

ABG, Arterial blood gas; ET, endotracheal tube; IM, intramuscular; IO, intraosseous; IV, intravenous; VF, ventricular fibrillation; VT, ventricular tachycardia. Data from the American Heart Association. Web-based integrated guidelines for cardiopulmonary and emergency cardiovascular care—part 12. Pediatric advanced life support. <https://eccguidelines.heart.org/index.php/circulation/cpr-ecc-guidelines-2/part-12-pediatric-advanced-life-support/>.

vasodilating effects of many of these agents. The correct size of the tube may be estimated according to the size of the child's mid-fifth phalanx or the following formula: 4 + (patient age in years/4).

When the endotracheal tube is in place, the adequacy of ventilation and the position of the tube must be assessed. Use of both clinical assessment and confirmatory devices is recommended. Clinical assessment includes looking for adequate chest wall movement and auscultation of the chest to detect bilateral and symmetric breath sounds. Confirmatory devices, such as end-tidal carbon dioxide (CO₂) monitoring devices, are useful for the validation of endotracheal placement, but low levels of detected CO₂ may be seen secondary to lack of pulmonary circulation. If the patient's condition fails to improve or deteriorates, consider the possibilities of tube Displacement or Obstruction, Pneumothorax, or Equipment failure (mnemonic DOPE).

Breathing

The major role of endotracheal intubation is to protect or maintain the airway and ensure the delivery of adequate oxygen to the patient. Because hypoxemia is the final common pathway in pediatric cardiopulmonary arrests, providing oxygen is more important than correcting the respiratory acidosis. The clinician should deliver 100% oxygen at a rate of 8–10 breaths/min during CPR, or 20–30 breaths/min for a patient who has a perfusing rhythm. Use only the tidal volume necessary to produce visible chest rise. Care should be taken not to hyperventilate the patient.

Medications

When mechanical means fail to re-establish adequate circulation, pharmacologic intervention is essential (Table 38.4). If intravascular access is not present or rapidly established, administration through an intraosseous route is recommended. Some drugs can also be administered effectively through the endotracheal tube or intramuscularly.

Epinephrine, a catecholamine with mixed α -agonist and β -agonist properties, constitutes the mainstay of drug therapy for CPR. The α -adrenergic effects are most important during acute phases of resuscitation, causing an increase in systemic vascular resistance that improves coronary blood flow. Standard dose therapy is recommended for the first and subsequent boluses. There is no benefit offered by high-dose epinephrine. Vasopressin, an endogenous hormone, causes constriction of capillaries and small arterioles and may be useful. Data are insufficient to support its routine use; however, vasopressin may be considered in children failing standard medication administration.

The routine use of **sodium bicarbonate** is currently not recommended. Sodium bicarbonate may be judiciously used to treat toxidromes or hyperkalemic arrest; however, oxygen delivery and elimination of CO₂ must be established first. Side effects include hypernatremia, hyperosmolality, hypokalemia, metabolic alkalosis (shifting the oxyhemoglobin curve to the left and impairing tissue oxygen delivery), reduced ionized calcium level, and impaired cardiac function.

Routine administration of **calcium** is not recommended. It may be useful in cases of documented hypocalcemia, calcium channel blocker overdose, hypermagnesemia, or hypokalemia but is otherwise not beneficial and is potentially harmful.

TABLE 38.5 Recommendations for Defibrillation and Cardioversion in Children**DEFIBRILLATION**

Place self-adhesive defibrillation pads or paddles with electrode gel at the apex of the heart and the upper right side of the chest.

- Use infant paddles or self-adhesive pads for children <10 kg; adult size for children >10 kg.

Notify all participating personnel before discharging paddles so that no one is in contact with patient or bed.

Begin with 2 J/kg; resume chest compressions immediately.

If unsuccessful, increase to 4 J/kg and repeat.

Higher energy levels may be considered, not to exceed 10 J/kg or the adult maximum dose.

CARDIOVERSION

Consider sedation if possible.

For symptomatic supraventricular tachycardia* or ventricular tachycardia with a pulse, synchronize signal with ECG.

Choose paddles, position pads, and notify personnel as above.

Begin with 0.5–1 J/kg.

If unsuccessful, use 2 J/kg.

*Consider adenosine first (see Table 38.4).
ECG, Electrocardiogram.

Hypoglycemia is common in infants and children who sustain cardiac arrest. Blood glucose should be checked, and hypoglycemia should be promptly treated with **glucose**.

Prompt electrical **defibrillation** is indicated when ventricular fibrillation or pulseless ventricular tachycardia is noted (Table 38.5). CPR should continue until immediately before defibrillation and resume immediately afterward, minimizing interruptions in compressions. If a second attempt at defibrillation is necessary, it should be followed by a dose of epinephrine. Children failing two episodes of defibrillation may benefit from administration of amiodarone or lidocaine. Defibrillation should be distinguished from **cardioversion** of supraventricular tachycardias (which can also cause cardiovascular compromise). Cardioversion requires a lower starting dose and synchronization of the discharge to the electrocardiogram to prevent discharging during a susceptible period, which may convert supraventricular tachycardia to ventricular tachycardia or fibrillation.

PEARLS FOR PRACTITIONERS

See *The Acutely Ill or Injured Child: Pearls for Practitioners at the end of this section.*

($P_{aCO_2} > 50$ mm Hg in previously healthy children), hypoxemic ($P_{aO_2} < 60$ mm Hg in previously healthy children without an intracardiac shunt), or both. **Hypoxemic respiratory failure** is frequently caused by ventilation-perfusion mismatch (perfusion of lung that is not adequately ventilated) and shunting (deoxygenated blood bypasses ventilated alveoli). **Hypercarbic respiratory failure** results from inadequate alveolar ventilation secondary to decreased minute ventilation (tidal volume \times respiratory rate) or an increase in dead space ventilation (ventilation of areas receiving no perfusion).

Respiratory failure may occur with **acute respiratory distress syndrome (ARDS)**. The pediatric-specific definition for acute respiratory distress syndrome (PARDS) builds on the adult-based Berlin definition but has been modified to account for differences between adults and children with ARDS. Pediatric ARDS, and its severity, is defined by (1) timing: onset within 7 days of known clinical insult; (2) respiratory failure not fully explained by cardiac failure or fluid overload; (3) chest imaging findings of new infiltrate(s) consistent with acute pulmonary parenchymal disease; and (4) impairment in oxygenation (as described in Table 39.1). Pediatric ARDS can be triggered by a variety of insults including sepsis, pneumonia, shock, burns, or traumatic injury, all resulting in inflammation and increased vascular permeability leading to pulmonary edema. Numerous mediators of inflammation (tumor necrosis factor, interferon- γ , nuclear factor κ B, and adhesion molecules) as well as surfactant action may be involved in the development of ARDS.

EPIDEMIOLOGY

Acute respiratory failure is frequently caused by bronchiolitis, often caused by respiratory syncytial virus (RSV), asthma, pneumonia, upper airway obstruction, and systemic inflammation resulting in ARDS. Notably, bronchiolitis and asthma are the most common causes of acute respiratory failure in pediatric patients. RSV infects 90% of children within the first 2 years of life and frequently reinfects older children and adults. The World Health Organization estimates that RSV is responsible for ~33 million lower respiratory tract illnesses, 3 million hospitalizations, and up to 199,000 childhood deaths each year. Asthma is the most common chronic condition among children, currently affecting an estimated 6.1 million children under 18 years in the United States, of which 3.5 million suffered from an asthma attack or episode in 2016. Environmental factors (exposure to cigarette smoke) and prior disease characteristics (severity of asthma, exercise intolerance, delayed start of therapy, and previous intensive care unit admissions) affect the rate of hospitalization and near-fatal episodes.

Chronic respiratory failure (with acute exacerbations) is often due to chronic lung disease (bronchopulmonary dysplasia, cystic fibrosis), neurologic or neuromuscular abnormalities, and congenital anomalies.

CLINICAL MANIFESTATIONS

Early signs of hypoxic respiratory failure include **tachypnea** and **tachycardia** which are physiologic compensatory mechanisms to improve minute ventilation and cardiac output to maintain delivery of oxygenated blood to the tissues. Further progression of disease may result in dyspnea, nasal flaring,

CHAPTER 39

Respiratory Failure

ETIOLOGY

Acute respiratory failure occurs when the pulmonary system is unable to maintain adequate gas exchange to meet metabolic demands. The resulting failure can be classified as hypercarbic

TABLE 39.1 Pediatric Acute Respiratory Distress Syndrome Severity Based on Oxygenation

NONINVASIVE MECHANICAL VENTILATION PARDS (no severity stratification)	INVASIVE MECHANICAL VENTILATION PARDS (severity per OI or OSI)
Full face mask: bilevel positive airway pressure or continuous positive airway pressure ≥ 5 H ₂ O: PF ratio ≤ 300 SF ratio ≤ 264	Mild: $4 \leq \text{OI} < 8$; $5 \leq \text{OSI} < 7.5$ Moderate: $8 \leq \text{OI} < 16$; $7.5 \leq \text{OSI} < 12.3$ Severe: $\text{OI} > 16$; $\text{OSI} \geq 12.3$

PF ratio = $\text{PaO}_2/\text{FiO}_2$; if PaO_2 is not available, wean FiO_2 to maintain $\text{SpO}_2 \leq 97\%$ to calculate the SF ratio = $\text{SpO}_2/\text{FiO}_2$.

OI = oxygenation index = $[\text{FiO}_2 \times \text{mean airway pressure} \times 100]/\text{PaO}_2$; if PaO_2 is not available, wean FiO_2 to maintain $\text{SpO}_2 \leq 97\%$ to calculate the oxygen saturation index (OSI); $[\text{FiO}_2 \times \text{mean airway pressure} \times 100]/\text{SpO}_2$.

PARDS, Pediatric acute respiratory distress syndrome.

Modified from Khemani RG, Smith LS, Zimmerman JJ, et al. Pediatric acute respiratory distress syndrome: definition, incidence and epidemiology: proceeding from the Pediatric Acute Lung Injury Consensus Conference. *Pediatr Crit Care Med*. 2015;16(5 suppl 1):S23–S40 [fig. 2].

grunting, use of accessory muscles of respiration, and diaphoresis. Late signs of inadequate oxygen delivery include **cyanosis** and **altered mental status** (initially confusion and agitation). Signs and symptoms of hypercarbic respiratory failure include signs of increased minute ventilation (tachypnea and increased depth of breathing) and altered mental status (somnolence).

LABORATORY AND IMAGING STUDIES

A chest radiograph may show evidence of the etiology of respiratory failure. The detection of atelectasis, hyperinflation, infiltrates, or pneumothoraces assists with ongoing management. Diffuse infiltrates or pulmonary edema may suggest ARDS. The chest radiograph may be normal when upper airway obstruction or impaired respiratory controls are the etiology. In patients presenting with stridor or other evidence of upper airway obstruction, a lateral neck film or CT may delineate anatomic defects. Direct visualization through flexible bronchoscopy allows the identification of dynamic abnormalities of the anatomic airway. Helical CT helps diagnose a pulmonary embolus.

Pulse oximetry allows noninvasive, continuous assessment of oxygenation but is unable to provide information about ventilation abnormalities. Determination of CO₂ levels requires a blood gas measurement (venous, capillary, or arterial). An **arterial blood gas** is the gold standard for measurement of serum CO₂ levels and allows for analysis of the severity of oxygenation defect through calculation of an alveolar-arterial oxygen difference. A normal PaCO₂ in a patient who is hyperventilating should heighten concern about the risk of further deterioration.

DIFFERENTIAL DIAGNOSIS

Hypoxic respiratory failure resulting from impairment of alveolar-capillary function is seen in ARDS; cardiogenic pulmonary edema; interstitial lung disease; aspiration pneumonia; bronchiolitis; bacterial, fungal, or viral pneumonia; and sepsis. It also can be due to intracardiac or intrapulmonary shunting seen with atelectasis and pulmonary embolism.

Hypercarbic respiratory failure can occur when the respiratory center fails as a result of drug use (opioids, barbiturates, anesthetic agents), neurologic or neuromuscular junction abnormalities (cervical spine trauma, demyelinating diseases, anterior horn cell disease, botulism), chest wall injuries, or

diseases that cause increased resistance to airflow (croup, vocal cord paralysis, post-extubation edema). Maintenance of ventilation requires adequate function of the chest wall and diaphragm. Disorders of the neuromuscular pathways, such as muscular dystrophy, myasthenia gravis, and botulism, result in inadequate chest wall movement, development of atelectasis, and respiratory failure. Scoliosis, although rarely, can result in significant chest deformity that leads to restrictive pulmonary function. Similar impairments of air exchange may result from distention of the abdomen (postoperatively or due to ascites, obstruction, or a mass) and thoracic trauma (flail chest).

Mixed forms of respiratory failure are common and occur when disease processes result in more than one pathophysiologic change. Increased secretions seen in asthma often lead to atelectasis and hypoxia, whereas restrictions of expiratory airflow may lead to hypercarbia. Progression to respiratory failure results from peripheral airway obstruction, extensive atelectasis, and resultant hypoxemia and retention of CO₂.

TREATMENT

Initial treatment of patients in respiratory distress includes addressing the ABCs (see Chapter 38). **Bag-mask ventilation** must be initiated for patients with apnea. In other patients, oxygen therapy is administered using appropriate methods (e.g., nasal cannula). In patients with mild distress, oxygen therapy administered by nasal cannula or simple mask may be appropriate. However, administration of oxygen by these methods allows the patient to entrain a mixture of room air and supplemental oxygen, making it an insufficient delivery method for most children in respiratory failure. Delivery methods, including intubation and mechanical ventilation, should be employed if there is an inability to increase oxygen saturation or ventilate appropriately.

Patients presenting with hypercarbic respiratory failure are often hypoxic as well. When oxygenation is established, measures should be taken to address the underlying cause of hypercarbia. Patients who are hypercarbic without signs of respiratory fatigue or somnolence may not require intubation based on the PCO₂ alone; however, patients with marked increase in the work of breathing or inadequate respiratory effort may require assistance with ventilation.

After identification of the etiology of respiratory failure, specific interventions and treatments are tailored to the needs

of the patient. External support of oxygenation and ventilation may be provided by **noninvasive ventilation** methods (heated humidified high-flow nasal cannula, continuous positive airway pressure, biphasic positive airway pressure, or negative pressure ventilation) or through invasive methods (traditional **mechanical ventilation**, high-frequency oscillatory ventilation, or extracorporeal membrane oxygenation). Elimination of CO₂ is achieved through manipulation of minute ventilation (tidal volume and respiratory rate). Oxygenation is improved by altering variables that affect oxygen delivery (fraction of inspired oxygen) or mean airway pressure (positive end-expiratory pressure [PEEP], peak inspiratory pressure, inspiratory time, gas flow).

COMPLICATIONS

The major complication of hypoxic respiratory failure is the development of organ dysfunction. **Multiple organ dysfunction** includes the development of two or more of the following: respiratory failure, cardiac failure, renal insufficiency/failure, gastrointestinal or hepatic insufficiency, disseminated intravascular coagulation, and hypoxic-ischemic brain injury. Mortality rates increase with increasing numbers of involved organs (see Table 38.3).

Complications associated with mechanical ventilation include pressure-related and volume-related lung injury. Both overdistention and insufficient lung distention (loss of functional residual capacity) are associated with lung injury. Pneumomediastinum and pneumothorax are potential complications of both the disease process and iatrogenic overdistention. Inflammatory mediators may play a role in the development of chronic fibrotic lung diseases in ventilated patients.

PROGNOSIS

Prognosis varies with the etiology of respiratory failure. Less than 1% of previously healthy children with bronchiolitis die. Asthma mortality rates, although still low, have increased. Population-based studies report a variable mortality rate for pediatric ARDS from 18–35% depending on the study population.

PREVENTION

Prevention strategies are explicit to the etiology of respiratory failure. Some infectious causes can be prevented through active immunization against organisms causing primary respiratory disease (pertussis, pneumococcus, *Haemophilus influenzae* type b, seasonal influenza) and sepsis (pneumococcus, *H. influenzae* type b). Passive immunization with respiratory syncytial virus immunoglobulins prevents severe illness in highly susceptible patients (prematurity, bronchopulmonary dysplasia). Primary prevention of traumatic injuries may decrease the incidence of pediatric ARDS. Compliance with appropriate therapies for asthma may decrease the number of episodes of respiratory failure (see Chapter 78).

PEARLS FOR PRACTITIONERS

See *The Acutely Ill or Injured Child: Pearls for Practitioners at the end of this section.*

CHAPTER 40

Shock

ETIOLOGY AND EPIDEMIOLOGY

Shock is the inability to provide sufficient perfusion of oxygenated blood and substrate to tissues to meet metabolic demands. **Oxygen delivery** is directly related to the arterial oxygen content (oxygen saturation and hemoglobin concentration) and to cardiac output (stroke volume and heart rate). Changes in metabolic needs are met primarily by adjustments in cardiac output. Stroke volume is related to myocardial end-diastolic fiber length (preload), myocardial contractility (inotropy), and resistance of blood ejection from the ventricle (afterload; see [Chapter 145](#)). In a young infant whose myocardium possesses relatively less contractile tissue, increased demand for cardiac output is met primarily by a neurally mediated increase in heart rate. In older children and adolescents, cardiac output is most efficiently augmented by increasing stroke volume through neurohormonally mediated changes in vascular tone, resulting in increased venous return to the heart (increased preload), decreased arterial resistance (decreased afterload), and increased myocardial contractility.

Once the initial assessment of an acutely ill child is completed, the constellation of clinical characteristics can suggest one of the five broad classifications of shock: hypovolemic, distributive, cardiogenic, obstructive, and dissociative.

HYPOVOLEMIC SHOCK

Acute hypovolemia is the most common cause of shock in children. It results from loss of fluid from the intravascular space secondary to inadequate intake or excessive losses (vomiting and diarrhea, blood loss, capillary leak syndromes, or pathologic renal fluid losses) ([Table 40.1](#)). Reduced blood volume decreases preload, stroke volume, and cardiac output. Hypovolemic shock results in increased sympathoadrenal activity, producing an increased heart rate and enhanced myocardial contractility. Neurohormonally mediated constriction of the arterioles and capacitance vessels maintains blood pressure, augments venous return to the heart to improve preload, and redistributes blood flow from nonvital to vital organs. If hypovolemic shock remains untreated, the increased heart rate may impair coronary blood flow and ventricular filling, while elevated systemic vascular resistance increases myocardial oxygen consumption, resulting in worsening myocardial function. Ultimately, intense systemic vasoconstriction and hypovolemia produce tissue ischemia, impairing cell metabolism and releasing potent vasoactive mediators from injured cells. Cytokines and other vasoactive peptides can change myocardial contractility and vascular tone and promote release of other inflammatory mediators that increase capillary permeability and impair organ function further.

DISTRIBUTIVE SHOCK

Distributive shock results from a relative inadequacy of intravascular volume caused by venous or arterial vasodilation. This maldistribution of blood flow can result in profound inadequacies in tissue perfusion, even in the presence of a normal

TYPE	PRIMARY CIRCULATORY DERANGEMENT	COMMON CAUSES
Hypovolemic	Decreased circulating blood volume	Hemorrhage Diarrhea Diabetes insipidus, diabetes mellitus Burns Adrenogenital syndrome Capillary leak
Distributive	Vasodilation → venous pooling → decreased preload Maldistribution of regional blood flow	Sepsis Anaphylaxis CNS/spinal injury Drug intoxication
Cardiogenic	Decreased myocardial contractility	Congenital heart disease Arrhythmia Hypoxic/ischemic injuries Cardiomyopathy Metabolic derangements Myocarditis Drug intoxication Kawasaki disease
Obstructive	Mechanical obstruction to ventricular filling or outflow	Cardiac tamponade Massive pulmonary embolus Tension pneumothorax Cardiac tumor
Dissociative	Oxygen not appropriately bound or released from hemoglobin	Carbon monoxide poisoning Methemoglobinemia

CNS, Central nervous system.

or high cardiac output. Septic shock is the most common type of distributive shock in children. Other causes include anaphylaxis, neurologic injury, and ingestion of certain drugs or poisons (see Table 40.1).

Distributive shock may present with the **systemic inflammatory response syndrome** (SIRS), defined as two or more of the following: temperature greater than 38°C or less than 36°C; heart rate greater than 90 beats/min or more than two standard deviations above normal for age; tachypnea; or white blood cell count that is greater than 12,000 cells/mm³, less than 4,000 cells/mm³, or has greater than 10% immature forms. Although SIRS is part of the criteria for pediatric sepsis (SIRS + proven or suspected infection = sepsis), it can also be seen in non-infectious states such as trauma or postoperatively.

CARDIOGENIC SHOCK

Cardiogenic shock is caused by an abnormality in myocardial function and is expressed as depressed myocardial contractility and cardiac output with poor tissue perfusion. Compensatory mechanisms may contribute to the progression of shock by depressing cardiac function further. Neurohormonal vasoconstrictor responses increase afterload and add to the work of the failing ventricle. Tachycardia may impair coronary blood flow, which decreases myocardial oxygen delivery. Increased central blood volume is caused by sodium and water retention and by incomplete emptying of the ventricles during systole. This results in elevated left ventricular volume and pressure, which then impairs subendocardial blood flow. As compensatory mechanisms are overcome, the failing left ventricle produces increased ventricular end-diastolic volume and pressure, which leads to increased left atrial pressure, resulting in pulmonary edema. This sequence also contributes to right ventricular failure because of increased pulmonary artery pressure and increased right ventricular afterload.

Primary cardiogenic shock may occur in children who have congenital heart disease. Cardiogenic shock also may occur in previously healthy children secondary to viral myocarditis, dysrhythmias, toxic or metabolic abnormalities, or after hypoxic-ischemic injury (see Chapters 142, 145, and 147; see Table 40.1).

OBSTRUCTIVE SHOCK

Obstructive shock results from mechanical obstruction of the great vessels or of the heart itself. The pathophysiology of obstructive shock can be classified according to the location of the obstruction within the vascular system in relation to the heart. These extravascular, intravascular, or luminal obstructions result in a shock state due to reduced cardiac outflow and the associated critical drop in global oxygen supply. Etiologies of obstructive shock include both congenital lesions (such as coarctation of the aorta, interrupted aortic arch, and severe aortic valvular stenosis) and acquired diseases (such as pulmonary embolus and cardiac tamponade) (see Table 40.1).

DISSOCIATIVE SHOCK

Dissociative shock refers to conditions in which tissue perfusion is normal, but cells are unable to utilize oxygen because the hemoglobin has an abnormal affinity for oxygen, preventing its release to the tissues (see Table 40.1).

CLINICAL MANIFESTATIONS

All forms of shock produce evidence that tissue perfusion and/or oxygenation are insufficient (increased heart rate, abnormal blood pressure, alterations of peripheral pulses). The etiology of shock may alter the initial presentation of these signs and symptoms.

Hypovolemic Shock

Hypovolemic shock is distinguished from other causes of shock by history and the absence of signs of heart failure or sepsis. In addition to the signs of sympathoadrenal activity (tachycardia, vasoconstriction), clinical manifestations include signs of dehydration (dry mucous membranes, decreased

urine output) or blood loss (pallor). Recovery depends on the degree of hypovolemia, the patient's pre-existing status, and rapid diagnosis and treatment. The prognosis is good, with a low mortality in uncomplicated cases.

Distributive Shock

Patients with distributive shock usually have tachycardia and alterations of peripheral perfusion. In early stages, when cytokine release results in vasodilation, pulses may be bounding and vital organ function may be maintained (an alert patient, with rapid capillary refill and some urine output in *warm shock*). As the disease progresses untreated, extremities become cool and mottled with a delayed capillary refill time. At this stage, the patient has hypotension and vasoconstriction.

Cardiogenic Shock

Cardiogenic shock results when the myocardium is unable to supply the cardiac output required to support tissue perfusion and organ function. Because of this self-perpetuating cycle, heart failure progressing to death may be rapid. Patients with cardiogenic shock have tachycardia and tachypnea. The liver is usually enlarged, a gallop is often present, and jugular venous distention may be noted. Because renal blood flow is poor, sodium and water are retained, resulting in anasarca.

Obstructive Shock

Restriction of cardiac output results in an increase in heart rate and an alteration of stroke volume. The pulse pressure is narrow (making pulses harder to feel), and capillary refill is delayed. The liver is often enlarged, and jugular venous distention may be evident.

Dissociative Shock

The principal abnormality in dissociative shock is the inability to deliver oxygen to tissues. Symptoms include tachycardia, tachypnea, alterations in mental status, and ultimately cardiovascular collapse.

LABORATORY AND IMAGING STUDIES

Shock requires immediate resuscitation before obtaining comprehensive laboratory or diagnostic studies. Following initial stabilization (including glucose administration if hypoglycemia is present), the type of shock dictates the necessary laboratory studies. Patients with shock may benefit from the determination of a baseline pH via arterial blood gas and blood lactate level to assess the degree of tissue oxygenation impairment. Measurement of a central **mixed venous oxygen saturation** aids in the assessment of the adequacy of oxygen delivery. Notably, in contrast to other forms of shock, patients with vasodilated distributive shock (such as in gram-negative rod sepsis) often have high mixed venous saturation values due to impairment of mitochondrial function and inability of tissues to extract oxygen. A complete blood count (CBC) can reveal altered bone marrow function or provide evidence of disseminated intravascular coagulation (DIC) and may also aid in assessing the severity of blood loss following equilibration in hemorrhagic shock (of note, a CBC may not reveal the true

degree of blood loss in the early acute phase of hemorrhagic shock). Electrolyte measurements in patients with hypovolemic shock may identify abnormalities from losses. Patients presenting in septic shock require appropriate bacterial and viral cultures to aid in identification of a causative pathogen. If cardiogenic or obstructive shock is suspected, an echocardiogram assists with the diagnosis and, in the case of tamponade, assists with placement of a pericardial drain to relieve the fluid. Patients with dissociative shock require detection of the causative agent (carbon monoxide, methemoglobin). The management of shock also requires ongoing monitoring of mixed venous oxygen saturations and arterial blood gases for assessment of oxygenation, ventilation (CO₂), and degree of acidosis. Frequent re-assessment of serum electrolytes and biochemical markers of end-organ impairment, such as liver and renal function panels as well as coagulation factors and CBC, may aid in subsequent therapeutic interventions.

DIFFERENTIAL DIAGNOSIS

See Table 40.1.

TREATMENT

General Principles

The key to therapy is the recognition of shock in its early, partially compensated state, when many of the hemodynamic and metabolic alterations may be reversible. Initial therapy for shock follows the ABCs of resuscitation (see Chapter 38). Later, therapy can then be directed at the underlying cause. Therapy should minimize cardiopulmonary work, while ensuring cardiac output, adequate perfusion, and gas exchange. Intubation, combined with mechanical ventilation with oxygen supplementation, improves oxygenation and decreases or eliminates the work of breathing but may impede venous return if distending airway pressures (positive end-expiratory pressure [PEEP] or peak inspiratory pressure) are excessive. Blood pressure support is crucial in promoting adequate end-organ perfusion.

Monitoring a child in shock requires maintaining access to the arterial and central venous circulation to record pressure measurements, perform blood sampling, and measure systemic blood pressure continuously. These measurements facilitate the estimation of preload and afterload. Regional monitoring with near infrared spectroscopy (NIRS) may allow early, noninvasive detection of alterations in perfusion.

Organ-Directed Therapeutics

Fluid Resuscitation

Alterations in preload have a dramatic effect on cardiac output. In hypovolemic and distributive shock, decreased preload significantly impairs cardiac output. In these cases, early and aggressive fluid resuscitation is important and greatly affects outcome. In cardiogenic shock, an elevated preload contributes to pulmonary edema.

Selection of fluids for resuscitation and ongoing use is dictated by clinical circumstances. Crystalloid volume expanders are generally recommended as initial choices because they are effective, inexpensive, and often readily available. Most acutely ill children with signs of shock may safely receive, and usually benefit greatly from, rapid administration of a 20 mL/kg bolus

TABLE 40.2 Medications Used to Improve Cardiac Output

	POSITIVE INOTROPE	POSITIVE CHRONOTROPE	DIRECT PRESSOR	VASOCONSTRICTOR	VASODILATOR
Dopamine	++	+	±	++ (high dose)	+ (low dose)
Dobutamine	++	±	–	–	+
Epinephrine	+++	+++	+++	++ (high dose)	+ (low dose)
Norepinephrine	+++	+++	+++	+++	–
Milrinone	+	–	–	–	+

of an isotonic crystalloid. This dose may be repeated until a response is noted. Colloids contain larger molecules that may stay in the intravascular space longer than crystalloid solutions and exert oncotic pressure, drawing fluid out of the tissues into the vascular compartment. However, the long-term risks of colloids may exceed the benefits. Care must be exercised in treating cardiogenic shock with volume expansion as the ventricular filling pressures may rise without improvement or with deterioration of cardiac performance. Careful monitoring of cardiac output via vital signs, clinical exam (repeatedly evaluate for development of rales and/or hepatomegaly), and central venous pressure (if available) guides safe volume replacement.

Cardiovascular Support

In an effort to improve cardiac output after volume resuscitation, or when further volume replacement may be dangerous, a variety of inotropic and vasodilator drugs may be useful (Table 40.2). Therapy is directed first at increasing myocardial contractility, then at decreasing left ventricular afterload. The hemodynamic status of the patient dictates the choice of the agent.

Therapy may be initiated with dopamine at 5–20 µg/kg per minute; however, epinephrine or norepinephrine may be preferable in patients with decompensated shock. In addition to improving contractility, certain catecholamines cause an increase in systemic vascular resistance. The addition of a vasodilator drug may improve cardiac performance by decreasing the resistance against which the heart must pump (afterload). Afterload reduction may be achieved with dobutamine, milrinone, amrinone, nitroprusside, nitroglycerin, and angiotensin-converting enzyme inhibitors. The use of these drugs may be particularly important in the later stages of shock, when vasoconstriction is prominent.

Respiratory Support

The lung is a target organ for inflammatory mediators in SIRS and shock. Respiratory failure may develop rapidly and become progressive. Intervention requires endotracheal intubation and mechanical ventilation accompanied by the use of supplemental oxygen and PEEP. Care must be taken with the process of intubation as a child with compensated shock may suddenly decompensate upon administration of sedative medications that reduce systemic vascular resistance or with converting to positive pressure ventilation. Severe cardiopulmonary failure may be managed with inhaled nitric oxide and, if necessary, extracorporeal membrane oxygenation.

Renal Salvage

Poor cardiac output accompanied by decreased renal blood flow may cause prerenal azotemia and oliguria/anuria. Severe hypotension may produce **acute tubular necrosis** and **acute renal failure**. Prerenal azotemia is corrected when blood volume deficits are replaced or myocardial contractility is improved, but acute tubular necrosis does not improve immediately when shock is corrected. Prerenal azotemia is associated with a serum blood urea nitrogen (BUN)-to-creatinine ratio of greater than 10:1 and a urine sodium level less than 20 mEq/L; acute tubular necrosis has a BUN-to-creatinine ratio of 10:1 or less and a urine sodium level between 40 and 60 mEq/L (see Chapter 165). Aggressive fluid replacement is often necessary to improve oliguria associated with prerenal azotemia. Because the management of shock requires administering large volumes of fluid, maintaining urine output greatly facilitates patient management.

Prevention of acute tubular necrosis and the subsequent complications associated with acute renal failure (hyperkalemia, acidosis, hypocalcemia, fluid overload) is important. The use of pharmacologic agents to augment urine output is indicated when the intravascular volume has been replaced. The use of loop diuretics, such as furosemide, or combinations of a loop diuretic and a thiazide agent, may enhance urine output. Nevertheless, if hyperkalemia, refractory acidosis, hypervolemia, or altered mental status associated with uremia occurs, dialysis or hemofiltration should be initiated.

COMPLICATIONS

Shock results in impairment of tissue perfusion and oxygenation and activation of inflammation and cytokine pathways. The major complication of shock is multiple organ system failure, defined as the dysfunction of more than one organ, including respiratory failure, renal failure, liver dysfunction, coagulation abnormalities, or cerebral dysfunction. Patients with shock and multiple organ failure have a higher mortality rate and, for survivors, a longer hospital stay.

PROGNOSIS

Early recognition and **goal-directed intervention** in patients with shock improves survival. Delays in treatment of hypotension, however, increase the incidence of multiple organ failure and mortality.

PREVENTION

Prevention strategies for shock are focused, for the most part, on shock associated with causative exposures (infection, trauma, and ingestion). Some forms of septic shock can be prevented through the use of immunizations (such as *Haemophilus influenzae* type b, meningococcal, pneumococcal vaccines). Decreasing the risk of sepsis in a hospitalized patient requires adherence to strict handwashing, isolation practices, and minimizing the duration of indwelling devices. Measures to decrease pediatric trauma do much to minimize hemorrhage-induced hypovolemic shock. Preventative health measures surrounding environmental toxins (carbon monoxide) and medication storage/administration can aid in the prevention of some forms of dissociative, distributive, and cardiogenic shock (see Table 40.1).

PEARLS FOR PRACTITIONERS

See *The Acutely Ill or Injured Child: Pearls for Practitioners at the end of this section.*

CHAPTER 41

Injury Prevention

EPIDEMIOLOGY AND ETIOLOGY

Unintentional injury is the leading pediatric cause of death in the developed world. In 2017, unintentional injury accounted for 17,000 deaths of children, adolescents, and young adults 0–24 years of age in the United States. Between 2000 and 2009, the unintentional injury death rate for children under 19 years declined by 29% in the United States (from 15.5 to 11 per 100,000). In 2016, this rate declined even further to 10.1 per 100,000. This decline has been attributed to increased use of child safety seats and seat belts, increased use of child-resistant packaging, reduction in drunk driving, enhanced safety awareness, and improved medical care.

The most common causes of fatal injuries differ among age groups. For instance, suffocation is the most common type of fatal injury among infants (84% of unintentional deaths in 2017); however, it accounts for only 1% of unintentional fatalities among 15- to 19-year-olds. Conversely, motor vehicle collisions account for 6% of fatal injuries among infants, whereas they account for 66% of adolescent fatal injuries. Drowning is the most common cause of fatal injury among children ages 1–4 years (31%), while it accounts for 7% of fatal injuries among adolescents. Notably, differences in geography, climate, population density (access to care), and population traits affect the frequency, etiology, and severity of these injuries.

Injury occurs through interaction of the **host** (child) with the **agent** (e.g., car and driver) through a vector and an **environment** (e.g., roadways, weather) that is conducive to exposure. The age of the child may determine the exposure to various agents and environments. For example, most injuries in infants and toddlers occur in the home as the result of exposure to agents found there (water heaters, bathtubs, soft bedding). Gender affects exposure to injury, with boys having a fatal injury rate greater than that of girls.

EDUCATION FOR PREVENTING INJURIES

The recognition that much of the morbidity and mortality are determined at the scene of an injury has stimulated the development of prevention measures. The **Haddon matrix** combines the epidemiologic components (host, agent, physical and social environments) with time factors (before, during, and after the event) to identify effective interventions focused on different aspects of the injury event. Primary strategies (preventing the event), secondary strategies (minimizing the severity of injury), and tertiary strategies (minimizing long-term impact) can be targeted for each epidemiologic component. Such strategies typically fall into one of three areas: education, enforcement, and environment (including engineering).

Education is often the first strategy considered, but it requires behavioral change and action on the part of people. Most educational strategies are not well evaluated.

Despite the reliance on an action by the individuals involved, some active strategies benefit from enforcement. Children wearing bicycle helmets experience a significantly lower incidence of traumatic brain injury and death. The enforcement of seatbelt laws increases seatbelt use and may decrease injuries.

Automatic strategies require no action on the part of the population and often change the environment (speed bumps) or involve engineering (child-resistant pill bottles, air bags). Automatic strategies have more consistently resulted in a significant reduction in injuries. The most successful approaches to preventing injury have combined strategies (education, environmental changes, and engineering changes focused on the host, agent, and environment in all three time phases).

PEARLS FOR PRACTITIONERS

See The Acutely Ill or Injured Child: Pearls for Practitioners at the end of this section.

CHAPTER 42

Major Trauma

ASSESSMENT AND RESUSCITATION

The general goal of **prehospital trauma care** is rapid assessment, support of the ABCs (airway, breathing, and circulation), immobilization, and transportation. Outcomes of patients with major or life-threatening trauma are significantly improved when they receive care in a pediatric trauma center or in an adult center with pediatric trauma certification compared with level I or II adult trauma centers. However, many children live too far from a pediatric trauma center to seek care at those facilities so it is imperative that all emergency providers understand the unique aspects of pediatric trauma patients.

Once the injured child arrives at the emergency department, the trauma team must initiate an organized and synchronized response. The initial assessment of a seriously injured child should involve a systematic approach, including a primary survey, resuscitation, secondary survey, post-resuscitation

ACTIVITY	BEST RESPONSE	SCORE	
Eye opening	Spontaneous	4	
	To verbal stimuli	3	
	To pain	2	
	None	1

monitoring, and definitive care. The **primary survey** focuses on the **ABCDEs** of emergency care, as modified for trauma from the ABCs of cardiopulmonary resuscitation (see [Chapter 38](#)). The airway and breathing assessments should include immobilization of the cervical spine (especially if the patient has an altered mental status); evaluation for injuries to the face, neck, or chest that could impair air entry or gas exchange; and consideration of the patient's aspiration risk based upon last reported or suspected meal. If the airway is not patent or breathing is not spontaneous, measures should immediately be taken to secure an airway with an endotracheal tube prior to further interventions. Circulation can be assessed via observation (heart rate, skin color, mental status) or palpation (pulse quality, capillary refill, skin temperature). To restore circulation, bleeding should be controlled with direct pressure and two large bore peripheral intravenous (IV) lines should be placed, when possible, to allow for administration of IV fluids and blood products. Assessment for **disabilities (D)**, including neurologic status, includes examination of pupil size and reactivity, a brief mental status assessment, and examination of extremity movement to assess for spinal cord injury. The **Glasgow Coma Scale (GCS)** can direct decisions regarding the initiation of further interventions in patients with suspected closed head injuries ([Table 42.1](#)). **Exposure (E)** requires completely disrobing the child for a detailed visual examination of the entire body. The examiner should ensure a neutral thermal environment to prevent hypothermia during this exam.

On completion of the primary survey, a more detailed head-to-toe examination (the **secondary survey**) should ensue, along with efforts to obtain a more complete history. The purpose of this careful re-examination is to identify

life-threatening and limb-threatening injuries, as well as less serious injuries. Coincident with the secondary survey and depending, in part, on the assessed physiologic status of the patient, certain procedures and resuscitative measures are initiated. The prioritization of definitive care needs is determined by the injury findings gathered from the primary and secondary surveys, the child's physiologic response to resuscitation, and the data from continuous monitoring. A **tertiary survey**, including repeat primary and secondary surveys along with a review of the laboratory tests and radiologic studies, should be performed within 24 hours.

ETIOLOGY AND EPIDEMIOLOGY

See [Chapter 41](#).

LABORATORY AND IMAGING STUDIES

Screening laboratory studies during the initial resuscitation often include the tests listed in [Table 42.2](#). Radiographic studies are determined by the pattern of identified potential injuries. A head CT scan should be obtained in patients with GCS of 14 or less or other signs of altered mental status, external evidence of head trauma, or a history of loss of consciousness, vomiting, or severe mechanism of injury. Patients with evidence of abdominal wall trauma including a seatbelt sign or who have significant abdominal tenderness after blunt trauma may benefit from a CT scan. The focused assessment with sonography for trauma (FAST) has gained popularity because of concerns about radiation exposure but has not yet been shown to decrease rates of CT utilization in pediatric blunt abdominal trauma. Diagnostic peritoneal lavage has limited utility and is rarely performed in pediatric patients. CT angiography should be performed if there is concern about thoracic aortic injury.

CLINICAL MANIFESTATIONS AND TREATMENT

Head injuries and injuries to the limbs are the most common injuries seen in blunt trauma. Multiple organ system involvement is also common, and penetrating trauma is becoming more prevalent. After initial evaluation and stabilization, the team focuses on the involved organ systems.

Head Trauma

See Chapter 184.

Spinal Cord Trauma

Although spinal cord injury is not common in pediatric trauma patients, it is potentially devastating when it occurs. Cervical spine immobilization should be maintained until a spinal cord injury is ruled out. The National Emergency X-Radiography Utilization Study (NEXUS) criteria may be used to identify patients at low risk for cervical spine injury. For patients with midline tenderness, altered mental status, a distracting injury, or a neurologic deficit, cervical spine radiographs should be obtained. However, in patients with continued symptoms, cervical spine radiographs are not sufficient to rule out a spinal cord injury because the immature vertebral column in children may allow stretching of the cord or nerve roots with no radiologic abnormality (spinal cord injury without radiologic abnormality [SCIWORA]). When initial imaging is negative but the mechanism of injury or clinical presentation is concerning for spinal cord injury, MRI should be performed to evaluate for SCIWORA.

Thoracic Trauma

Thoracic injury is the second leading cause of pediatric trauma death. While many life-threatening thoracic injuries may be identified clinically during the primary survey, chest radiograph helps to identify other injuries such as pulmonary contusion, pneumothorax, and rib fractures. Patients with pulmonary parenchymal injury should receive supportive treatment to ensure adequate oxygenation and ventilation. Most pediatric blunt thoracic injuries can be managed without surgery. Injury to the heart and great vessels is rare but requires urgent diagnosis and treatment. Great vessel injury should be suspected if a widened mediastinum is seen on chest radiograph.

Abdominal Trauma

The relative size and closer proximity of intraabdominal organs in children increase the risk of significant injury after blunt trauma. Presentations of children with penetrating traumatic injuries range from no symptoms to hypovolemic shock.

Imaging studies such as abdominal CT and serial physical examinations are the primary methods of obtaining information on which to base decisions regarding operative intervention. Abdominal wall bruising, specifically the “seat-belt sign,” is an important physical examination finding and is associated with significant intraabdominal injury in more than 10% of patients. Most blunt solid organ injury is handled nonoperatively with close clinical observation. Operative intervention may be required in patients whose vital signs are persistently unstable despite aggressive fluid resuscitation,

even in the absence of extravascular volume loss or an enlarging abdomen.

The spleen is the most frequently injured abdominal organ in children. Suspicion of a splenic injury should be heightened if there are left upper quadrant abrasions or tenderness. Pain may also be referred to the left shoulder due to diaphragmatic irritation by the ruptured spleen (*Kehr sign*). CT scans are used to identify and grade the severity of splenic injury.

Nonoperative management with serial examinations and laboratory studies is the treatment of choice for most serious splenic injuries. If there is continued large blood loss or hemodynamic instability, emergent laparotomy for total or partial splenectomy is indicated. If a splenectomy is performed, patients should receive penicillin prophylaxis as well as pneumococcal and *Haemophilus influenzae* vaccines due to increased risk of infection with encapsulated bacteria in the setting of asplenia.

Liver Trauma

Blunt trauma to the liver is a leading cause of mortality. Severe hemorrhage is more common in patients with liver injury than with other abdominal injuries because of its dual blood supply. As with splenic injury, severity is graded based on the pattern of injury, and nonoperative management is recommended but requires close clinical observation for signs of ongoing blood loss or hemodynamic instability.

Renal Injury

The kidney is less frequently injured than the liver or spleen. Kidney injuries can be seen with high-energy mechanisms or direct blows to the back and are often associated with other injuries. A young child’s kidney is more vulnerable to trauma than an adult’s because of their more compliant rib cage and relatively immature abdominal muscle development. Diagnosis is based on clinical findings (flank tenderness or ecchymosis) coupled with urinalysis showing blood and increased protein levels. CT with IV contrast is the recommended imaging modality; ultrasound may also be useful. Low-grade renal injury is usually managed conservatively, but surgery may be required for falling hemoglobin levels, refractory shock, or urinary obstruction caused by clots.

Pancreatic Injury

Injuries of the pancreas are less common in children than in adults. This type of injury is seen in bicycle handlebar injuries, motor vehicle crashes, and nonaccidental trauma. The diagnosis is difficult unless there is obvious injury to overlying structures, such as the stomach or duodenum. Diffuse abdominal tenderness, pain, and vomiting may be accompanied by elevations of amylase and lipase; however, pancreatic enzymes are not sensitive or specific in blunt trauma and may be normal in up to 30% of patients with pancreatic injury. Abdominal CT may not be sufficient to evaluate ductal injury and may miss pancreatic injuries in the initial postinjury period. Nonoperative management is appropriate for contusions, but surgical intervention may be required in patients with ductal injuries. Pancreatic injuries with parenchymal disruption may lead to pseudocyst formation, which often requires surgical drainage as well.

Intestinal Injury

Injury to the intestine occurs less frequently than injury to solid intraabdominal organs. Intestinal injury results from acceleration-deceleration (shearing) forces which occur at points of fixation (the ligament of Treitz, the ileocecal valve, and the ascending and descending peritoneal reflections). These injuries are difficult to diagnose with CT, so pneumoperitoneum should prompt surgical exploration. Serial physical examinations are useful when the clinical picture is uncertain.

Duodenal hematoma can occur in the absence of perforation and may not present until 48–72 hours after the injury. Affected patients often present with persistent pain and bilious emesis. Most hematomas respond to nonoperative management with gastric decompression and parenteral nutrition.

COMPLICATIONS

Patients requiring hospitalization for multiple traumatic injuries are at risk for a variety of complications based on the type and severity of injury. Sepsis and multiple organ failure may occur in children with polytrauma. The presence of ileus can result in delayed initiation of enteral nutrition which may further increase the risk of sepsis secondary to translocation of bacteria across injured or inflamed intestinal mucosa. Renal failure secondary to myoglobinuria may be seen in children who sustain crushing or electrical injuries. Deep venous thrombosis is less common in the pediatric population; however, prophylaxis for children who will be immobilized because of injury should be provided.

PROGNOSIS

Unintentional injury is the leading cause of death for children aged 1–18; however, many of these deaths occur in the field immediately after the injury. Once admitted to the hospital, mortality rates are much lower. Morbidities are numerous and include hypoxic-ischemic brain injury, loss of limbs, and psychologic trauma.

PREVENTION

See Chapter 41.

PEARLS FOR PRACTITIONERS

See *The Acutely Ill or Injured Child: Pearls for Practitioners at the end of this section.*

Initially, submersion or immersion results in aspiration of small amounts of fluid into the larynx, triggering breath holding or laryngospasm. In many cases, the laryngospasm resolves, and larger volumes of water or gastric contents are aspirated into the lungs, destroying surfactant and causing alveolitis and dysfunction of the alveolar-capillary gas exchange. The resulting hypoxemia leads to hypoxic brain injury that is exacerbated by ischemic injury after circulatory collapse.

EPIDEMIOLOGY

In 2016, an estimated 320,000 people died from drowning worldwide; in the United States, drowning is the second leading cause of injury death for children ages 1–14 years. For every pediatric drowning death, another five receive emergency department care for nonfatal submersion injuries. Boys are four times more likely than girls to drown. The most common location of drowning varies by age, with drowning in natural bodies of water becoming more frequent in older age groups.

CLINICAL MANIFESTATIONS

Hypoxemia is the result of laryngospasm and aspiration during drowning. Victims may also develop respiratory distress secondary to **pulmonary endothelial injury, increased capillary permeability, and destruction of surfactant**. Clinical manifestations include tachypnea, tachycardia, increased work of breathing, and decreased breath sounds with or without crackles. The hypoxic-ischemic injury that may occur can lead to depressed myocardial function resulting in tachycardia, impaired perfusion, and, potentially, cardiovascular collapse. After resuscitation, acute respiratory distress syndrome is common. Altered mental status may be present and requires frequent monitoring of neurologic status. Following submersion in cold water, hypothermia may result in relative bradycardia and hypotension, and place the child at risk for cardiac dysrhythmias.

LABORATORY AND IMAGING STUDIES

After resuscitation, arterial blood gas measurement assists in assessing pulmonary gas exchange. A chemistry profile may reveal elevated liver enzymes if hypoxemia and ischemia were of long duration and provide baseline renal function. Electrolytes are often obtained, although alterations of serum electrolytes are minimal, even in freshwater drowning.

TREATMENT

Resuscitation of a drowning victim includes the basic ABCs (see Chapter 38). Victims of unwitnessed drowning require stabilization of the cervical spine because of the possibility of a fall or diving injury. Optimizing oxygenation and maintaining cerebral perfusion are two of the major foci of treatment. Rewarming the hypothermic patient requires careful attention to detail, including acid-base and cardiac status as well as avoidance of hyperthermia. Further treatment is based on the patient's response to initial resuscitation. Some children begin breathing spontaneously and awaken before arrival at an emergency department. If the episode was significant,

CHAPTER 43

Drowning

ETIOLOGY

Drowning, as defined by the World Congress on Drowning in 2002, is the process of experiencing respiratory impairment from submersion/immersion in liquid. Outcomes may be categorized as death, morbidity, or no morbidity. Other terms such as near drowning, secondary drowning, or dry drowning should be abandoned.

these children still require careful observation for pulmonary complications over the subsequent 4–6 hours. Children who have evidence of lung injury, cardiovascular compromise, or neurologic compromise should be monitored in an intensive care unit. Pulmonary dysfunction often results in hypoxemia. Oxygen supplementation should be implemented to maintain normal oxygen saturations. Mechanical ventilation may be needed in patients with significant pulmonary or neurologic dysfunction. Cardiovascular compromise is often the result of impaired cardiac contractility secondary to hypoxic-ischemic injury. The use of intracranial pressure monitoring devices as well as medical management with therapeutic hypothermia and sedation is controversial and has not been shown to improve outcomes. Prophylactic antibiotics have not been shown to be beneficial, but in patients who develop delayed pulmonary infection, broad antibiotic coverage should include *Aeromonas* species.

PROGNOSIS

The outcome of drowning is determined by the success of immediate resuscitation efforts and the severity of **hypoxic-ischemic injury** to the brain. Patients who have regained consciousness on arrival at the hospital will likely survive with intact neurologic function. Unfavorable prognostic markers include submersion lasting longer than 5 minutes, delayed resuscitation, the need for continued cardiopulmonary resuscitation (CPR) at the hospital, Glasgow Coma Scale of 5 or less, fixed and dilated pupils, seizures, and coma for more than 72 hours.

PREVENTION

Despite the decreased incidence of drowning since the 1990s, only five major prevention strategies are evidence based. In decreasing order of efficacy, these include installation of four-sided fencing around pools, life jackets, swim lessons, supervision, and lifeguards. While evidence for other prevention strategies such as pool covers and pool alarms is lacking, these may play a role as experts advocate for multiple layers of environmental protection to prevent drowning.

PEARLS FOR PRACTITIONERS

See *The Acutely Ill or Injured Child: Pearls for Practitioners at the end of this section.*

and protein catabolism. This hypermetabolic state may continue for up to a year after injury.

Burns usually are classified based on four criteria:

- Depth of injury
- Percent of body surface area involved
- Location of the burn
- Association with other injuries

EPIDEMIOLOGY

More than 100,000 children sustain a burn injury each year. While the majority of burns are not life threatening, burns remain a significant cause of morbidity. Boys are more likely to sustain a burn injury, as are children age 4 and under. Scald burns are more common in younger children than in older children. Overall, thermal burns secondary to scald or flame are much more common than electrical or chemical burns. Most fire-related childhood deaths and injuries occur in homes.

CLINICAL MANIFESTATIONS

The depth of injury should be assessed by the clinical appearance. Categories of first degree, second degree, and third degree are commonly used; however, classification by depth (superficial, superficial partial thickness, deep partial thickness, and full thickness) conveys more information about the structures injured and the likely need for surgical treatment and may be more clinically useful.

Superficial (first-degree) burns are red, painful, and dry. They are commonly seen with sun exposure or mild scald injuries, and these burns involve injury to the epidermis only. They heal in 5–7 days without scarring and are not included in burn surface area calculations. **Superficial partial-thickness** (second-degree) burns involve the entire epidermis and superficial dermis. These burns have fluid-containing blisters. After debridement, the underlying dermis appears erythematous and wet, is painful, and blanches under pressure. Healing is dependent on the uninjured dermis and usually occurs within 7–21 days without the need for skin grafting and without scarring. **Deep partial-thickness** (also second-degree) burns involve the entire epidermis and deeper portions of the dermis. These burns may also have blistering, but the dermal base is less blanching, mottled pink or white, and less painful than superficial partial-thickness burns. They behave more like full-thickness burns and often require excision and grafting. **Full-thickness** (third-degree and fourth-degree) burns involve all skin layers. They appear dry, white, dark red, brown, or black in color. They do not blanch and are usually insensate. Full-thickness burns require surgical management. Fourth-degree burns involve underlying fascia, muscle, or bone and may require reconstruction in addition to grafting. **Inhalation injuries** should be suspected if there are facial burns, singed nasal hairs, or carbonaceous sputum. Hoarseness on vocalization also is consistent with a supraglottic injury. Inhalation injuries may result in bronchospasm, airway inflammation, and impaired pulmonary function.

One of the multiple methods used for calculating the percentage of skin surface involved in a burn in children of various ages is presented in Fig. 44.1. The extent of skin involvement of older adolescent and adult patients may be estimated as follows: each upper extremity, 9%; each lower extremity, 18%; anterior trunk, 18%; posterior trunk, 18%; head, 9%; and perineum, 1%.

CHAPTER 44

Burns

ETIOLOGY

The pathophysiology of burn injury is caused by disruption of the three key functions of the skin: regulation of heat loss, preservation of body fluids, and barrier to infection. Burn injury releases inflammatory and vasoactive mediators resulting in increased capillary permeability, decreased plasma volume, and decreased cardiac output. The body then becomes hypermetabolic with increased resting energy expenditure

PERCENTAGE OF SURFACE AREA OF HEAD AND LEGS AT VARIOUS AGES

AREA IN DIAGRAM	AGE IN YEARS				
	0	1	5	10	15
A = 1/2 of head	9 1/2	8 1/2	6 1/2	5 1/2	4 1/2
B = 1/2 of one thigh	2 3/4	3 1/4	4	4 1/4	4 1/2
C = 1/2 of one lower leg	2 1/2	2 1/2	2 3/4	3	3 1/4

FIGURE 44.1 This chart of body areas, together with the table inserted in the figure showing the percentage of surface area of head and legs at various ages, can be used to estimate the surface area burned in a child. (From Solomon JR. Pediatric burns. *Crit Care Clin.* 1985;1:159–174.)

The location of the burn is important in assessing the risk of disability. The risk is greatest when the face, eyes, ears, feet, perineum, or hands are involved. Inhalation injuries not only cause respiratory compromise but also may result in difficulty in eating and drinking.

LABORATORY AND IMAGING STUDIES

Initial laboratory testing, including complete blood count, type and cross match for blood, coagulation studies, basic chemistry profile, arterial blood gas, and chest radiograph, can be helpful for patients with major burns. A carboxyhemoglobin assessment should be performed for any suspected inhalation exposure (a house or closed-space fire or a burn victim who requires cardiopulmonary resuscitation). Cyanide levels should be considered in children who sustain smoke inhalation and have altered mental status. Unusual patterns of burns may increase suspicion of child abuse and initiate further evaluation to assess for nonaccidental trauma to the skeleton or central nervous system.

TREATMENT

For severe burns, care is best managed by a multidisciplinary team in a qualified burn center. The American Burn Association criteria for patients who should be transferred to a burn center are as follows: partial-thickness burns greater than

10% total body surface area (TBSA); partial- and full-thickness burns involving the face, hands, feet, genitalia, perineum, or major joints; full-thickness burns in any age group; electrical burns (including lightning injury); chemical burns; inhalation injury; burn injury in patients with pre-existing medical conditions that could complicate management, prolong recovery, or affect mortality; any burn with concomitant trauma in which the burn injury poses the greatest risk; burn injury in children admitted to hospitals without qualified personnel or equipment for pediatric care; burn injury in patients requiring special social, emotional, or rehabilitative support, including child abuse cases.

Initial treatment should follow the ABCs of resuscitation (see Chapter 38). **Airway management** should include assessment for the presence of airway or inhalation injury, with early intubation if such an injury is suspected. Smoke inhalation may be associated with carbon monoxide toxicity; 100% humidified oxygen should be given if hypoxia or inhalation is suspected.

The systemic capillary leak that occurs after a serious burn makes initial fluid and electrolyte support of a burned child crucial. The first priority is to support the circulating blood volume, which requires the administration of intravenous fluids to provide maintenance fluid and electrolyte requirements and to replace ongoing burn-related losses. Formulas exist to help guide **fluid management**; however, no formula accurately predicts the fluid needs of every burn patient. Children with a significant burn should receive a rapid bolus of 20 mL/kg of lactated Ringer solution. Thereafter, the resuscitation formula for fluid therapy is determined by the percent of body surface burned. Total fluids are 2–4 mL/kg per percent burn per 24 hours, with half the estimated amount administered during the first 8 hours and the remaining half over the subsequent 16 hours. (If resuscitation is delayed, half of the fluid replacement should be completed by the end of the eighth hour postinjury.) Fluids should be titrated to achieve adequate perfusion, one marker of which is urine output greater than 1 mL/kg per hour. Controversy exists over whether and when to administer colloid during fluid resuscitation, but colloid therapy may be needed for patients with extensive burns.

Because burn injury produces a **hypermetabolic** response, children with significant burns require immediate nutritional support. Enteral feeds should be started early unless there is a specific contraindication. Children with critical burn injury may require parenteral nutrition if unable to tolerate full enteral feeds. Consider supplementation of vitamins and trace elements. Other factors that may improve the hypermetabolic state include pain control, blood glucose control, and the use of medications including anabolic steroids such as oxandrolone and β blockers such as propranolol.

Wound care starts with cleaning and debriding the wound. Effective pain control is important to allow for complete debridement. Topical agents and dressings are then applied to control bacterial colonization, decrease evaporative losses, and aid in pain control. Various grafts, such as cadaver allografts, porcine xenografts, or skin substitutes, have been used initially to cover wounds. For full-thickness burns, skin autografting and skin substitutes are required for eventual closure.

COMPLICATIONS

See Table 44.1.

TABLE 44.1 Complications of Burns

PROBLEM	TREATMENT
Sepsis	Monitor for infection, avoid prophylactic antibiotics
Hypovolemia	Fluid replacement
Hypothermia	Adjust ambient temperature: dry blankets in field
Laryngeal edema	Endotracheal intubation, tracheostomy
Carbon monoxide poisoning	100% oxygen, hyperbaric oxygen
Cyanide poisoning	100% O ₂ plus amyl nitrate, sodium nitrate, and sodium thiosulfate
Cardiac dysfunction	Inotropic agents, diuretics
Gastric ulcers	H ₂ -receptor antagonist, antacids
Compartment syndrome	Escharotomy incision
Contractures	Physical therapy
Hypermetabolic state	Enteral and parenteral nutritional support, pain control, glucose control, consider β blockers and anabolic steroids
Renal failure	Supportive care, dialysis
Transient antidiuresis	Expectant management
Anemia/thrombocytopenia	Transfusions as indicated
Psychologic trauma	Psychologic rehabilitation
Pulmonary infiltrates	PEEP, ventilation, oxygen
Pulmonary edema	Avoid overhydration, give diuretics
Pneumonia	Antibiotics
Bronchospasm	β -agonist aerosols

PEEP, Positive end-expiratory pressure.

PROGNOSIS

Most children who sustain burns recover without significant disability, but estimation of morbidity is difficult to ascertain from databases. Physical scarring and emotional impact of disfiguring burns are long-term consequences of burn injuries.

PREVENTION

Most burns occur in the home. Prevention is possible by using smoke and fire alarms, having identifiable escape routes and a fire extinguisher, and reducing hot water temperature to 49°C (120°F). Immersion full-thickness burns develop after 1 second at 70°C (158°F), after 5 seconds at 60°C (140°F), after 30 seconds at 54.5°C (130°F), and after 10 minutes at 49°C (120°F).

PEARLS FOR PRACTITIONERS

See *The Acutely Ill or Injured Child: Pearls for Practitioners at the end of this section.*

CHAPTER 45

Poisoning

ETIOLOGY AND EPIDEMIOLOGY

The most common agents ingested by young children include cosmetics, personal care products, cleaning solutions, and analgesics. In 2018, fatal childhood poisonings were most commonly caused by analgesics, fumes/gases/vapors, antihistamines, and cardiovascular medications.

More than 2 million human exposures are called into poison control centers in the United States each year. More than half of all exposures are in children (59% in 2018) with a male predominance in children under 13 years, but a female predominance in adolescence. Most ingestions in young children are unintentional, with intentional ingestions becoming more common in children 13 years and older.

CLINICAL MANIFESTATIONS

Any child who presents with unexplained symptoms including altered mental status, seizure, cardiovascular compromise, or metabolic abnormality should be considered to have ingested a poison until proven otherwise. A thorough history and physical examination often provide sufficient clues to distinguish between toxic ingestion and organic disease (Table 45.1). Determination of all substances that the child was exposed to, including type of medication, amount of medication, and time of exposure, is crucial in directing interventions. Available data often are incomplete or inaccurate, requiring a careful physical examination and laboratory approach. A complete physical examination, including vital signs, is necessary. Certain complexes of symptoms and signs are relatively specific to a given class of drugs (toxidrome) (Table 45.2).

COMPLICATIONS

A poisoned child can exhibit any one of six basic clinical patterns: coma, direct toxicity to a particular organ system, metabolic acidosis, heart rhythm aberrations, gastrointestinal symptoms, and seizures.

Coma

Coma is perhaps the most striking symptom of a poison ingestion, but it also may be seen as a result of several other causes including trauma, a cerebrovascular accident, asphyxia, or significant infection. A careful history and clinical examination are needed to distinguish among these alternatives.

Direct Toxicity

Hydrocarbon ingestion occasionally may result in systemic toxicity, but more often it leads to pulmonary toxicity. Hydrocarbons with low viscosity, low surface tension, and high volatility pose the greatest risk of producing aspiration pneumonia; however, when swallowed, they pose no risk unless emesis is induced. Emesis or lavage should *not* be initiated in a child who has ingested volatile hydrocarbons.

Caustic ingestions with acids or alkalis may cause dysphagia, epigastric pain, oral mucosal burns, and low-grade fever.

TABLE 45.1 Historical and Physical Findings in Poisoning

ODOR	
Bitter almonds	Cyanide
Acetone	Isopropyl alcohol, methanol, paraldehyde, salicylate
Alcohol	Ethanol
Wintergreen	Methyl salicylate
Garlic	Arsenic, thallium, organophosphates, selenium
Violets	Turpentine
OCULAR SIGNS	
Miosis	Narcotics (except propoxyphene, meperidine, and pentazocine), organophosphates, muscarinic mushrooms, clonidine, phenothiazines, chloral hydrate, barbiturates (late)
Mydriasis	Atropine, cocaine, amphetamines, antihistamines, cyclic antidepressants, PCP, LSD
Nystagmus	Phenytoin, barbiturates, ethanol, carbamazepine, PCP, ketamine, dextromethorphan
Lacrimation	Organophosphates, irritant gas or vapors
Retinal hyperemia	Methanol
Poor vision	Methanol, botulism, carbon monoxide
CUTANEOUS SIGNS	
Needle tracks	Heroin, PCP, amphetamine
Dry, hot skin	Anticholinergic agents, botulism
Diaphoresis	Organophosphates, muscarinic mushrooms, aspirin, cocaine
Alopecia	Thallium, arsenic, lead, mercury
Erythema	Boric acid, mercury, cyanide, anticholinergics
ORAL SIGNS	
Salivation	Organophosphates, salicylate, corrosives, strychnine, ketamine
Dry mouth	Amphetamine, anticholinergics, antihistamine
Burns	Corrosives, oxalate-containing plants
Gum lines	Lead, mercury, arsenic
Dysphagia	Corrosives, botulism
INTESTINAL SIGNS	
Diarrhea	Antimicrobials, arsenic, iron, boric acid, cholinergics
Constipation	Lead, narcotics, botulism
Hematemesis	Corrosives, iron, salicylates, NSAIDs
CARDIAC SIGNS	
Tachycardia	Atropine, aspirin, amphetamine, cocaine, cyclic antidepressants, theophylline
Bradycardia	Digitalis, narcotics, clonidine, organophosphates, β blockers, calcium channel blockers
Hypertension	Amphetamine, LSD, cocaine, PCP
Hypotension	Phenothiazines, barbiturates, cyclic antidepressants, iron, β blockers, calcium channel blockers, clonidine, narcotics
RESPIRATORY SIGNS	
Depressed respiration	Alcohol, narcotics, barbiturates
Increased respiration	Amphetamines, aspirin, ethylene glycol, carbon monoxide, cyanide
Pulmonary edema	Hydrocarbons, organophosphates
CENTRAL NERVOUS SYSTEM SIGNS	
Ataxia	Alcohol, barbiturates, anticholinergics, narcotics
Coma	Sedatives, narcotics, barbiturates, salicylate, cyanide, carbon monoxide, cyclic antidepressants, alcohol
Hyperpyrexia	Anticholinergics, salicylates, amphetamine, cocaine
Muscle fasciculation	Organophosphates, theophylline
Muscle rigidity	Cyclic antidepressants, PCP, phenothiazines, haloperidol
Peripheral neuropathy	Lead, arsenic, mercury, organophosphates
Altered behavior	LSD, PCP, amphetamines, cocaine, alcohol, anticholinergics

LSD, Lysergic acid diethylamide; MSG, monosodium glutamate; NSAID, nonsteroidal antiinflammatory drug; PCP, phencyclidine.

TABLE 45.2 Toxic Syndromes

AGENT	MANIFESTATIONS
Acetaminophen	Nausea, vomiting, pallor, delayed jaundice—hepatic failure (72–96 hr)
Amphetamine, cocaine, and sympathomimetics	Tachycardia, hypertension, hyperthermia, psychosis and paranoia, seizures, mydriasis, diaphoresis, piloerection, aggressive behavior
Anticholinergics	Mania, delirium, fever, red dry skin, dry mouth, tachycardia, mydriasis, urinary retention
Carbon monoxide	Headache, dizziness, coma, weakness, nausea/vomiting, chest pain
Cyanide	Coma, convulsions, hyperpnea, bitter almond odor
Ethylene glycol (antifreeze)	Metabolic acidosis, hyperosmolarity, hypocalcemia, oxalate crystalluria
Iron	Vomiting (bloody), diarrhea, hypotension, hepatic failure, leukocytosis, hyperglycemia, radiopaque pills on KUB, late intestinal stricture, <i>Yersinia</i> sepsis
Narcotics	Coma, respiratory depression, hypotension, pinpoint pupils, bradycardia
Cholinergics (organophosphates, nicotine)	Miosis, salivation, urination, diaphoresis, lacrimation, bronchospasm (bronchorrhea), muscle weakness and fasciculations, emesis, defecation, coma, confusion, pulmonary edema, bradycardia
Salicylates	Tachypnea, fever, lethargy, coma, vomiting, diaphoresis, alkalosis (early), acidosis (late)
Cyclic antidepressants	Coma, convulsions, mydriasis, hyperreflexia, arrhythmia (prolonged Q-T interval), cardiac arrest, shock

KUB, Kidney-ureter-bladder radiograph.

Patients with esophageal lesions may have no oral burns or may have significant signs and symptoms. Treatment depends on the agent ingested and the presence or absence of esophageal injury. Alkali agents may be solid, granular, or liquid. Liquid agents are tasteless and produce full-thickness liquefaction necrosis of the esophagus or oropharynx. When the esophageal lesions heal, strictures form. Ingestion of these agents also creates a long-term risk of esophageal carcinoma. Treatment includes antibiotics if there are signs of infection and dilation of strictures which form 2–3 weeks later.

Ingested button batteries also may produce a caustic mucosal injury. Batteries that remain in the esophagus may cause esophageal burns and erosion and should be removed with an endoscope. In addition, acid agents can injure the lungs (with hydrochloric acid fumes), oral mucosa, esophagus, and stomach. Because acids taste sour, children usually stop drinking the solution, limiting the injury. Acids produce a coagulation necrosis, which limits the chemical from penetrating into deeper layers of the mucosa and damages tissue less severely than alkali. The signs, symptoms, and therapeutic measures are similar to those for alkali ingestion.

TABLE 45.3 Screening Laboratory Clues in Toxicologic Diagnosis

ANION GAP METABOLIC ACIDOSIS (MNEMONIC = MUDPILES)
Methanol,* metformin
Uremia*
Diabetic ketoacidosis*
Paraldehyde,* phenformin
Isoniazid, iron
Lactic acidosis (cyanide, carbon monoxide)
Ethanol,* ethylene glycol*
Salicylates, starvation, seizures
HYPOGLYCEMIA
Ethanol
Isoniazid
Insulin
Propranolol
Oral hypoglycemic agents
HYPERGLYCEMIA
Salicylates
Isoniazid
Iron
Phenothiazines
Sympathomimetics
HYPOCALCEMIA
Oxalate
Ethylene glycol
Fluoride
RADIOPAQUE SUBSTANCE ON KUB (MNEMONIC = CHIPPED)
Chloral hydrate, calcium carbonate
Heavy metals (lead, zinc, barium, arsenic, lithium, bismuth as in Pepto-Bismol)
Iron
Phenothiazines
Play-Doh, potassium chloride
Enteric-coated pills
Dental amalgam

*Indicates hyperosmolar condition.

KUB, Kidney-ureter-bladder radiograph.

Metabolic Acidosis

A poisoned child may also have a high anion gap metabolic acidosis (mnemonic, *MUDPILES*) (Table 45.3), which is assessed easily by measuring arterial blood gases, serum electrolyte levels, and urine pH. An osmolar gap, if present, strongly suggests

TABLE 45.4 Drugs Associated with Major Modes of Presentation

COMMON TOXIC CAUSES OF CARDIAC ARRHYTHMIA	
QTc Prolongation	
Amiodarone	
Amphetamine	
Antipsychotics	
Antiarrhythmics	
Antifungals	
Citalopram	
Diphenhydramine	
Macrolide antibiotics	
Methadone	
Pheothiazines	
PR Interval Prolongation	
Digoxin	
Lithium	
QRS Prolongation	
Carbamazepine	
Chloroquine, hydroxychloroquine	
Diphenhydramine	
Digoxin	
Lamotrigine	
Phenothiazines	
Propranolol	
Quinine, quinidine	
Tricyclic antidepressants	
CAUSES OF COMA	
Alcohol	
Anticholinergics

Methemoglobinemia*	
Methyldopa	
Narcotics	
Phencyclidine	
Phenothiazines	
Salicylates	
COMMON AGENTS CAUSING SEIZURES (MNEMONIC = CAPS)	
Camphor	
Carbamazepine	
Carbon monoxide	
Cocaine	
Cyanide	
Aminophylline	
Amphetamine	
Anticholinergics	
Antidepressants (cyclic)	
Pb (lead) (also lithium)	
Pesticide (organophosphate)	
Phencyclidine	
Phenol	
Phenothiazines	
Propoxyphene	
Salicylates	

*Causes of methemoglobinemia: amyl nitrite, aniline dyes, benzocaine, bismuth subnitrate, dapsone, primaquine, quinones, spinach, sulfonamides.

the presence of an unmeasured component such as methanol or ethylene glycol. These ingestions require thorough assessment and prompt intervention.

Dysrhythmias

Dysrhythmias may be prominent signs of a variety of toxic ingestions, although ventricular arrhythmias are rare. Because

many drug and chemical overdoses may lead to sinus tachycardia, this is not a useful or discriminating sign; however, sinus bradycardia suggests ingestion of a β blocker, calcium channel blocker, clonidine, opioids, digoxin, or organophosphates. An electrocardiogram is an important study in cases of potential ingestion, and evidence of a prolonged PR interval, QTc prolongation, or widened QRS complex can be a clue to which drug was ingested (Table 45.4).

TABLE 45.5 Drugs Amenable to Therapeutic Monitoring for Drug Toxicity

ANTIBIOTICS
Aminoglycosides—gentamicin, tobramycin, and amikacin
Chloramphenicol
Vancomycin
IMMUNOSUPPRESSION
Methotrexate
Cyclosporine
ANTIPYRETICS
Acetaminophen
Salicylate
OTHER
Digoxin
Lithium
Theophylline
Anticonvulsant drugs
Serotonin uptake inhibitor agent

Gastrointestinal Symptoms

Gastrointestinal symptoms of poisoning include emesis, nausea, abdominal cramps, and diarrhea. These symptoms may be the result of direct toxic effects on the intestinal mucosa or of systemic toxicity after absorption.

Seizures

Seizures are the sixth major mode of presentation for children with toxic ingestions, but poisoning is an uncommon cause of afebrile seizures. When seizures do occur with intoxication, they may be life threatening and require aggressive therapeutic intervention.

LABORATORY AND IMAGING STUDIES

Laboratory studies helpful in initial management include specific toxin-drug assays; measurement of arterial blood gases and electrolytes, osmoles, and glucose; and calculation of the anion or osmolar gap. A full 12-lead electrocardiogram should be part of the initial evaluation in all patients suspected of ingesting toxic substances. Urine and serum screens for drugs of abuse or to confirm suspected ingestion of medications in the home may be revealing.

Quantitative toxicology assays are important for some agents (Table 45.5), not only for identifying the specific drug but also for providing guidance for therapy, anticipating complications, and estimating the prognosis.

TREATMENT

The four foci of treatment for poisonings are supportive care, decontamination, enhanced elimination, and specific antidotes.

Supportive Care

Supportive care is the mainstay of treatment in most cases. Prompt attention must be given to protecting and maintaining the airway, establishing effective breathing, and supporting the circulation. This management sequence takes precedence over other diagnostic or therapeutic procedures. If the level of consciousness is depressed and a toxic substance is suspected, glucose, 100% oxygen, and naloxone should be administered.

Gastrointestinal Decontamination

The intent of gastrointestinal decontamination is to prevent the absorption of a potentially toxic ingested substance and, in theory, to prevent the poisoning. There has been great controversy about which methods are the safest and most efficacious. Recommendations from the American Academy of Clinical Toxicology (AACT) and the European Association of Poison Centres and Clinical Toxicologists (EAPCCCT) follow. **Syrup of ipecac** should not be administered routinely to poisoned patients because of potential complications and lack of evidence that it improves outcome. Likewise, **gastric lavage** should not be used routinely, if ever, in the management of poisoned patients because of the lack of efficacy and potential complications. **Single-dose activated charcoal** decreases drug absorption when used within 1 hour of ingestion; however, it has not been shown to improve clinical outcome. Thus it should be used selectively in the management of a poisoned patient. Charcoal is ineffective against caustic or corrosive agents, hydrocarbons, heavy metals (arsenic, lead, mercury, iron, lithium), glycols, and water-insoluble compounds.

The administration of a cathartic (sorbitol or magnesium citrate) alone has no role in the management of the poisoned patient. The AACT has stated that based on available data, the use of a cathartic in combination with activated charcoal is not recommended.

Whole-bowel irrigation using polyethylene glycol (GoLYTELY) as a nonabsorbable cathartic may be effective for toxic ingestion of sustained-release or enteric-coated drugs. The AACT does not recommend the routine use of whole-bowel irrigation. However, there is theoretical benefit in its use for potentially toxic ingestions of iron, lead, zinc, or packets of illicit drugs.

Enhanced Elimination

Multiple-dose activated charcoal should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. **Alkalinization of urine** may be helpful for salicylate or methotrexate ingestion. **Dialysis** may be used for substances that have a low volume of distribution, low molecular weight, low protein binding, and high degree of water solubility, such as methanol, ethylene glycol, salicylates, theophylline, bromide, and lithium.

Specific Antidotes

See Table 45.6.

For recommendations on specific therapy, contact one of the U.S. Poison Control Centers at 1-800-222-1222.

TABLE 45.6 Sample of Specific Antidotes

POISON	ANTIDOTE	PEDIATRIC DOSAGE	COMMENTS
Acetaminophen	N-acetylcysteine	Oral Regimen: Loading dose 140mg/kg PO, then 70mg/kg PO q4h x 17 doses IV Regimen: Loading dose 150mg/kg over 1 hr (max 15 g/dose), then 50mg/kg over (max 5 g/dose), followed by 100 mg/ kg (max 10 g/dose)	Most effective within 16 hr of ingestion
Benzodiazepine	Flumazenil	0.2 mg IV, repeat to 1 mg max total dose and 3 mg in 1 hr	Possible seizures, arrhythmias, DO NOT USE FOR UNKNOWN INGESTIONS
β-blocking agents	Glucagon	0.05 mg/kg IV, followed by infusion of 0.05–0.15 mg/kg/hr	
Carbon monoxide	Oxygen	100% F _{IO} ₂ ; hyperbaric O ₂	Half-life of carboxyhemoglobin is 5 hr in room air but 1.5 hr in 100% O ₂
Tricyclic antidepressants	Sodium bicarbonate	Bolus 1–2 mEq/kg IV, followed by repeated bolus dosing as needed to keep QRS <110 msec	Follow potassium levels and replace as needed
Iron	Deferoxamine	Infusion of 5–15 mg/kg/hr IV (max 6 g/24 hr)	Hypotension (worse with rapid infusion rates)
Lead	Edetate calcium disodium (EDTA)	35–50 mg/kg/day IV x 5 days; continuous infusion or divided q12hr	
	British anti-Lewisite (BAL; dimercaprol)	4 mg/kg/dose IM q4hr x 2–7 days	May cause sterile abscesses Prepared in peanut oil, do not use in patients with peanut allergy
	Succimer (2,3-dimercaptosuccinic acid [DMSA])	10 mg/kg/dose PO tid x 5 days, then 10 mg/kg/dose PO bid x 14 days	Few toxic effects, requires lead-free home plus compliant family
Nitrites/ methemoglobinemia*	Methylene blue	1–2 mg/kg IV, repeat every 30–60 min if needed; treat for levels >30%	Exchange transfusion may be needed for severe methemoglobinemia; methylene blue overdose also causes methemoglobinemia
Opiates	Naloxone	0.1 mg/kg IV, ET, SC, IM for children, up to 2 mg, repeat as needed	Naloxone causes no respiratory depression
Organophosphates	Atropine	0.05–1 mg/kg IV/IO, repeat every 5–15 min as needed	Physiologic: blocks acetylcholine
	Pralidoxime (2 PAM; Protopam)	25–50 mg/kg IV over 5–10 min (max 2000 mg/dose); may repeat after 1–2 hr, then q10–12 hr as needed	Specific: disrupts phosphate- cholinesterase bond

*See Table 45.4 for causes of methemoglobinemia.

ET, Endotracheal; IM, intramuscular; IV, intravenous; PO, oral; SC, subcutaneous.

From Kliegman RM, St. Geme J, eds. Nelson Textbook of Pediatrics. 21st ed. Philadelphia: Elsevier; 2020:490-510. Please see this reference for a comprehensive list of antidotes.

PROGNOSIS

Most poisonings result in minimal or no toxicity or have minor effects. Intentional ingestions result in a much higher rate (5.2%) of major effects or death compared with unintentional ingestions (0.2%). Adolescents are more likely to have a moderate, major, or fatal effect from ingestion compared to younger children (17.3% of teens compared with 1.1% of children under 6 years).

PREVENTION

Properly educating parents regarding safe storage of medications and household toxins is necessary for preventing ingestions. If a child has ingested poison, a poison control center should be called.

PEARLS FOR PRACTITIONERS

See *The Acutely Ill or Injured Child: Pearls for Practitioners at the end of this section.*

CHAPTER 46

Sedation and Analgesia

An acutely ill pediatric patient may have pain, discomfort, and anxiety resulting from injury, surgery, and invasive procedures (intubation, bone marrow aspiration, venous access placement) or during mechanical ventilation. Clear goals should be identified to allow provision of optimal analgesia or sedation without compromising the physiologic status of the patient. Anxiolysis, cooperation, amnesia, immobility, and lack of awareness all are goals of sedation and can be accomplished with various drugs (Table 46.1). Many of these goals can be achieved with behavioral techniques (preprocedural teaching), but sedation is often a necessary adjunct for painful procedures. Pain may be expressed by verbal or visible discomfort, crying, agitation, tachycardia, hypertension, and tachypnea.

TABLE 46.1 Agents that Produce Sedation

SEDATIVES	EFFECT	CONCERNS
Midazolam	Anxiolysis, sedation, muscle relaxation, amnesia	Tolerance is possible; apnea, hypotension, depressed myocardial function; short acting
Lorazepam	Anxiolysis, sedation, muscle relaxation, amnesia	Same as midazolam; longer acting
Dexmedetomidine	Sedation without respiratory depression	May cause bradycardia
Ketamine	Anesthesia, analgesia, amnesia	Dissociative reactions, tachycardia, hypertension, increased bronchial secretions, emergent delirium, hallucinations; increases intracranial pressure
Chloral hydrate	Sedative	Emesis, hypotension, arrhythmias, hepatic dysfunction
Propofol	Rapid-onset sedative for induction and maintenance of anesthesia	Metabolic acidosis in children; may depress cardiac function

TABLE 46.2 Agents that Produce Analgesia

ANALGESIC	EFFECT	COMPLICATIONS
Acetaminophen and NSAIDs	Moderate analgesia, antipyresis	Ceiling effect
		NSAIDs—gastrointestinal bleed, ulceration
Opioids		No ceiling effect; respiratory depression, sedation, pruritus, nausea/vomiting, decreased gastric motility, urinary retention, tolerance with abuse potential
Morphine	Analgesia	May cause myocardial depression
Codeine	Analgesia	Nausea/vomiting
Fentanyl, alfentanil, sufentanil	Analgesia, sedation	No adverse effects on cardiovascular system; stiff chest syndrome
Methadone	Analgesia	

NSAIDs, Nonsteroidal antiinflammatory drugs.

A variety of scales have been developed in an attempt to quantify pain and allow more directed therapy. Pain caused by procedural interventions should always be treated with analgesics in addition to sedation (Table 46.2).

ASSESSMENT

Procedural Sedation

A medical evaluation must be performed for any patient receiving procedural sedation to identify underlying medical conditions that may affect the choice of sedative agents. Specific attention must be paid to assessment of the airway (for ability to maintain a patent airway) and respiratory system (chronic lung disease, recent respiratory illness, loose teeth), cardiovascular status (especially adequacy of volume status), factors affecting drug metabolism (renal or liver disease), and risk of aspiration (adequate nothing-by-mouth status, gastroesophageal reflux). During the administration of procedural sedation, assessment of the patient must include monitoring of oxygen saturation, heart rate, and respiratory rate, as well as some assessment of effectiveness of ventilation such as capnography. This assessment must be performed by someone

who is not involved in the procedure and who will record vital signs and drugs administered on a time-based graph. Monitoring must be continued until the child has returned to baseline. Patients who are receiving long-term sedation (e.g., to maintain endotracheal tube placement) may need only local anesthesia for painful procedures but may benefit from additional sedation or analgesia as well.

Nonprocedural Sedation

Many ventilated pediatric patients require sedation and some analgesia while intubated. Dexmedetomidine, a centrally acting selective α_2 -receptor agonist, is a popular choice due to its ability to provide sedation without respiratory depression. Longer acting benzodiazepines and opioids are also commonly used. Avoidance of oversedation is important. Use of appropriate pain and sedation scores allows for titration of medications to achieve goals of the sedation plan. Long-term use of benzodiazepines and opioids leads to tolerance, a problematic occurrence that must be considered as medications are added and weaned. Medications used for sedation and analgesia may also contribute to delirium, a phenomenon that is being increasingly recognized in critically ill patients.

PAIN AND ANALGESIA

The subjective aspect of pain requires that self-reporting be used for assessment. The color analog scale (CAS) and Faces Pain Scale–Revised (FPS-R) have been validated for use in older children. Pain scales for younger children such as the faces, legs, activity, cry, consolability (FLACC) scale often incorporate behavioral and physiologic parameters, despite the imprecision of physiologic responses.

Local anesthetics, such as lidocaine, can be used for minor procedures. However, lidocaine requires subcutaneous or intradermal injection. The use of topical anesthetic creams such as EMLA (lidocaine and prilocaine) or LMX (lidocaine) is less effective than intradermal lidocaine but is preferred by many pediatric patients.

Patient-controlled analgesia is an effective method for providing balanced analgesia care in older children and adolescents. Children using patient-controlled analgesia have better pain relief and experience less sedation than patients receiving intermittent, nurse-controlled, bolus analgesics. Analgesics can be administered through the patient-controlled analgesia pump with continuous basal infusions, bolus administration, or both. Morphine and hydromorphone are the most frequent opioids used for patient-controlled analgesia. Monitoring of oxygen saturations and respiratory rate are crucial with continuous opioid infusions because of the shift in CO₂ response

curve and potential to decrease ventilatory response to hypoxia.

Epidural analgesia decreases the need for inhalation anesthetics during surgery and can provide significant analgesia without sedation in the postoperative period. Decreased costs and length of stay also may be benefits of epidural analgesic approaches. Medications used in epidurals often include a combination of local anesthetic such as bupivacaine and narcotic such as morphine. Adverse effects include nausea and vomiting, motor blockade, and technical problems requiring catheter removal. Infection and permanent neurologic deficits are rare.

PEARLS FOR PRACTITIONERS

American Heart Association. CPR and first aid emergency cardiovascular care guidelines. Available at <https://eccguidelines.heart.org/index.php/circulation/cpr-ecc-guidelines-2/part-11-pediatric-basic-life-support-and-cardiopulmonary-resuscitation-quality/>.

Kliegman RM, St. Geme J, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia: Elsevier; 2020.

PEARLS FOR PRACTITIONERS

CHAPTER 38

Assessment and Resuscitation

- Initial assessment focuses on the ABCs—airway, breathing, and circulation—of an acutely ill or injured child.
- Respiratory failure is the most common cause of acute deterioration in children.
- In cardiopulmonary arrest:
 - The goal should be to optimize cardiac output and tissue oxygen delivery.
 - Begin chest compressions immediately, followed by support of the airway and breathing/ventilation (C-A-B).
- Monitoring vital signs and physiologic status is the key screening activity.
 - The choice of appropriate diagnostic tests and imaging is determined by the mechanism of disease and results of evaluation after initial resuscitation.

CHAPTER 39

Respiratory Failure

- Acute respiratory failure occurs when the pulmonary system is unable to maintain adequate gas exchange to meet metabolic demands.
- Respiratory failure:
 - Can be classified as hypercarbic, hypoxemic, or both.

- Is frequently caused by bronchiolitis, asthma, pneumonia, upper airway obstruction, and/or systemic inflammation resulting in acute respiratory distress syndrome (ARDS).
- Pediatric ARDS and its severity are defined by (1) onset within 7 days of known clinical insult; (2) respiratory failure not fully explained by cardiac failure or fluid overload; (3) chest imaging findings of new infiltrate(s); and (4) impairment in oxygenation.
- Pulse oximetry allows noninvasive, continuous assessment of oxygenation but is unable to provide information about ventilation abnormalities.

CHAPTER 40

Shock

- Shock is the inability to provide sufficient perfusion of oxygenated blood and substrate to tissues to meet metabolic demands.
 - Acute hypovolemia is the most common cause of shock in children.
 - Other forms of shock include distributive shock, cardiogenic shock, hemorrhagic shock, obstructive shock, and dissociative shock.
- Shock requires immediate resuscitation before obtaining laboratory or diagnostic studies.

- The key to therapy is the recognition of shock in its early compensated/partially compensated state, when many of the hemodynamic and metabolic alterations may be reversible.

CHAPTER 41

Injury Prevention

- Injury occurs through interaction of the host with an agent through a vector and an environment that is conducive to exposure.
- Unintentional injury is the leading cause of death in children 1–18 years of age.
- The most common causes of fatal injuries differ among age groups.
- The Haddon matrix combines the epidemiologic components with time factors to identify effective interventions focused on different aspects of the injury event.

CHAPTER 42

Major Trauma

- Injury is the leading cause of death in children ages 1–18 years.
- Primary survey is focused on assessment of ABCDE—airway, breathing, circulation, disability (including neurologic status), and exposure (including disrobing the child and performing a detailed assessment of the entire body).
- Secondary survey is focused on a more detailed head-to-toe examination along with obtaining more history.
- Resuscitative measures are performed concurrently with primary and secondary surveys.
- Most blunt abdominal organ injury is managed nonoperatively.

CHAPTER 43

Drowning

- Drowning is defined as respiratory impairment from submersion/immersion in liquid and is the second leading cause of injury-related death for children ages 1–14 years.
- Other terms, including near drowning, secondary drowning, and dry drowning, should not be used.

- Outcomes are categorized as death, morbidity, or no morbidity and are closely linked to the degree of hypoxic-ischemic brain injury.
- Treatment is focused on optimizing oxygenation and perfusion, especially cerebral perfusion.

CHAPTER 44

Burns

- Classification by depth (superficial, superficial partial thickness, deep partial thickness, and full thickness) conveys more information about the structures injured and the likely need for surgical treatment than the commonly used first-degree, second-degree, and third-degree burn designations.
- For severe burns, care is best managed by a multidisciplinary team in a qualified burn center.
- Severe burn injury results in a hypermetabolic state.

CHAPTER 45

Poisoning

- Consider poisoning in any child who presents with unexplained altered mental status, seizure, cardiovascular compromise, or metabolic abnormality.
- A poisoned child can exhibit any one of six basic clinical patterns: coma, toxicity, metabolic acidosis, heart rhythm aberrations, gastrointestinal symptoms, and/or seizures.
- The four foci of treatment for poisonings are supportive care, decontamination, enhanced elimination, and specific antidotes.

CHAPTER 46

Sedation and Analgesia

- Sedation and analgesia are necessary to treat the pain, discomfort, and anxiety experienced by many acutely ill and injured pediatric patients.
- Clear goals should be identified to allow provision of optimal analgesia or sedation without compromising the physiologic status of the patient.
- Long-term use of benzodiazepines and opioids leads to tolerance.

HUMAN GENETICS AND DYSMORPHOLOGY

Margo Sheck Breilyn | Paul A. Levy

CHAPTER 47

Patterns of Inheritance

TYPES OF GENETIC DISORDERS

Approximately 3% of infants born in the United States have **congenital malformations**, abnormalities of form or function identifiable at birth. The number approaches 7% at 1 year of age because some anomalies may not be identifiable until after the neonatal period. The prevalence of congenital malformations is much greater in inpatient pediatric populations; 30–50% of hospitalized children have congenital anomalies or genetic disorders.

Clinical geneticists attempt to identify the etiology, mode of inheritance, and risk that a disorder might occur in the affected child's siblings. In evaluating children with congenital malformations, the condition's etiology may be classified into one of six different categories:

1. Single-gene abnormalities, occurring in 2–7.5% of children with congenital anomalies
2. Chromosomal abnormalities, accounting for approximately 12%
3. Multifactorially inherited conditions, accounting for 21%
4. Conditions during pregnancy (infections, phenylketonuria [PKU], thyroid dysfunction, diabetes), accounting for 2–3%
5. Conditions caused by exposure to teratogens, accounting for 6–15%
6. Unknown or idiopathic anomalies, accounting for 43–51% of cases

INTRODUCTION TO GENETICS AND GENOMICS

DNA is composed of four nucleotide building blocks: adenine, guanine, cytosine, and thymine. Each nucleotide is linked to other nucleotides, forming a chain. The DNA molecule consists of two chains of nucleotides held together by hydrogen bonds. The purine nucleotides, adenine and guanine, cross link by hydrogen bonds to the pyrimidines, thymine and cytosine. Because of this cross linking, the nucleotide sequence of one strand sets the other strand's sequence. Separating the two strands permits complementary nucleotides to bind to each DNA strand; this copies the DNA and replicates the sequence.

DNA exists as multiple fragments that, together with a protein skeleton (chromatin), form chromosomes. Human cells

have 23 pairs of chromosomes, with one copy of each chromosome inherited from each parent. Twenty-two pairs of chromosomes are **autosomes**; the remaining pair consists of **sex chromosomes**. Females have two X chromosomes; males have one X and one Y.

Spread along the chromosomes like beads on a string, DNA sequences form **genes**, the basic units of heredity. A typical gene contains a promoter sequence, an untranslated region, and an open reading frame. In the open reading frame, every three nucleotides represent a single **codon**, coding for a particular amino acid. In this way, the sequence of bases dictates the sequence of amino acids in the corresponding protein. Some codons, rather than coding for specific amino acids, act as “start” signals; others serve as “stop” signals. Between the start and stop codons, genes consist of two major portions: **exons**, regions containing the code that ultimately corresponds to a sequence of amino acids, and **introns** (intervening sequence), which do not become part of the amino acid sequence but may regulate gene function.

Genes are **transcribed** into messenger RNA (mRNA), then **translated** into proteins. During transcription, RNA is processed to remove introns. The mRNA serves as a template to construct the protein.

Human genetic material contains 3 billion bases. Less than 2% of the DNA codes for proteins, comprising the genome's 20,000–24,000 genes. Through a mechanism called **alternative splicing**, these genes may create more than 100,000 proteins. The remainder of the DNA, the portion not involved in protein formation, was once termed *junk DNA*, but much of this presumed *junk DNA* is functional and likely serves regulatory functions.

Disease may be caused by changes or **mutations** (pathologic variant) in the DNA sequence, with the **point mutation**, a change in a single DNA base, being the most common type. A point mutation that changes a codon and the resulting amino acid that goes into the protein is referred to as a **missense mutation**. A **nonsense mutation** is a point mutation that changes the codon to a “stop” signal so that transcription ends prematurely. A **frameshift mutation** often stems from the loss or addition of one or more bases; this causes a shift in how the DNA is transcribed and generally leads to premature stop codons.

Pedigree Drawing

To identify specific patterns of inheritance, geneticists construct and analyze **pedigrees**, pictorial representations of a family history. Males are represented by squares and females

by circles. Matings are connected with a solid line between each partner's symbols. Children from a couple are represented below their parents and are the next generation.

Grandparents, uncles, aunts, and cousins are added in similar fashion. Ages or birthdays may be written next to or underneath each symbol. The proband (the patient who is being evaluated) is indicated with an arrow. Affected individuals are indicated by shading or some other technique, which should be explained in a key. Carriers for a disorder (e.g., sickle cell disease) usually are indicated by a dot in the center of their symbol (Fig. 47.1).

Pedigrees should include representatives of at least three generations of family members.

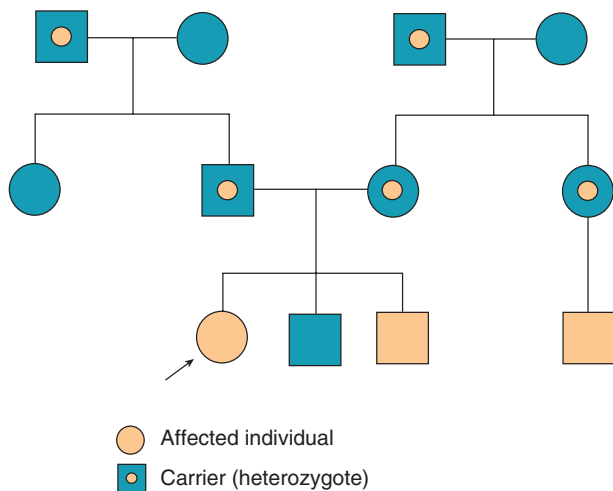

FIGURE 47.1 Pedigree showing affected individuals and carriers.

Autosomal Dominant Disorders

If a single copy of a gene bearing a pathologic variant is sufficient to cause disease and that gene is not on one of the sex chromosomes, that condition is inherited in an autosomal dominant (AD) fashion (Table 47.1). In AD disorders, each child of an affected parent has a 50% chance of inheriting the mutated gene (Fig. 47.2; Table 47.2). Possessing one *working* gene and one *nonworking* gene is termed **heterozygous**. If both copies are the same, they are referred to as **homozygous**.

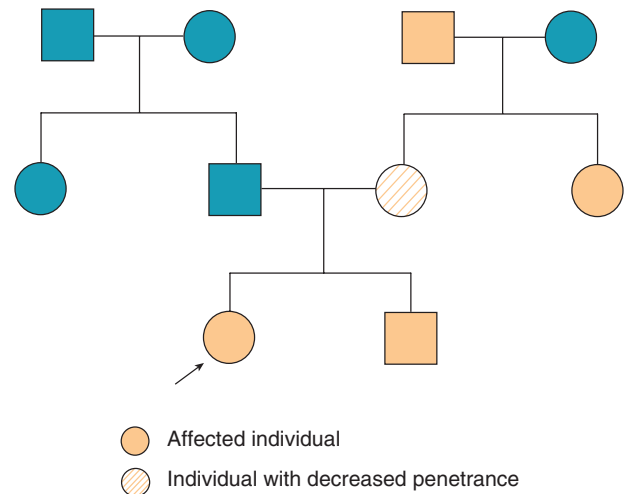

FIGURE 47.2 Pedigree showing decreased penetrance for an autosomal dominant disorder. Proband (arrow) is affected. Maternal grandfather also is affected. The individual's mother is presumed to be the carrier of the gene, even though she may show only slight symptoms of disease.

TABLE 47.1 Examples of Autosomal Dominant Diseases

DISEASE	FREQUENCY	COMMENTS
Achondroplasia Thanatophoric dysplasia Crouzon syndrome with acanthosis nigricans Nonsyndromic craniosynostosis	~1:25,000	Mutations are in the gene for <i>fibroblast growth factor receptor-3</i> on chromosome 4p16.3; 80% of cases are new mutations. (Different mutations in the same gene cause achondroplasia, thanatophoric dysplasia, Crouzon syndrome with acanthosis, and nonsyndromic craniosynostosis.)
Neurofibromatosis 1	1:3,000	About 50% of cases result from new mutations in the gene for neurofibromin, a tumor suppressor gene located at 17q11.2. Expression is quite variable.
Neurofibromatosis 2 (NF2)	1:25,000	The <i>NF2</i> gene is a tumor suppressor gene located at 22q12.2 that codes for a protein called "Merlin." Associated with bilateral acoustic neuromas.
Huntington disease (HD)	Variable in populations, 1:5,000–1:20,000	Caused by a (CAG) repeat expansion in the "Huntington" protein gene on chromosome 4p16.3.
Myotonic dystrophy type 1 (DM1, Steinert disease)	1:500 in Quebec 1:8,000–20,000 worldwide	Caused by a (CTG) repeat expansion in the DM protein kinase gene at chromosome 19q13.3. The condition shows genetic anticipation with successive generations.
Marfan syndrome	1:10,000	The syndrome is caused by mutations in the fibrillin 1 (<i>FBN1</i>) gene on chromosome 15q21.1; there is variable expression.
Hereditary angioedema (HAE; deficiency of C-1 esterase inhibitor that regulates the C-1 component of complement)	1:50,000	The gene is located on chromosome 11q11–q13.2. The phenotype of episodic and variable subcutaneous and submucosal swelling and pain is caused by diminished or altered esterase inhibitor protein, which can result from any one of many mutations in the gene.

TABLE 47.2 Rules of Autosomal Dominant Inheritance

Trait appears in every generation.
Each child of an affected parent has a 1-in-2 chance of being affected.
Males and females are equally affected.
Male-to-male transmission occurs.
Traits generally involve mutations in genes that code for regulatory or structural proteins (collagen).

Some people who are obligate carriers of a pathologic variant known to cause an AD disorder do not show clinical signs of the condition, while other such individuals manifest symptoms. This phenomenon is referred to as **penetrance**. If all individuals who carry a pathologic variant for an AD disorder show signs of that disorder, the gene is said to have complete penetrance. Many AD disorders show decreased (or incomplete) penetrance.

Often, AD disorders show variability in symptoms expressed in different individuals carrying the same variant gene. Some individuals have only mild clinical symptoms, whereas others have more severe disease. This phenomenon is referred to as **variable expressivity**.

AD disorders sometimes appear in a child of unaffected parents because of a **spontaneous mutation** (the mutation is new in the child's DNA and not inherited). Known in some cases to be associated with advanced paternal age (>40 years of age), spontaneous mutations may account for most individuals with some disorders. For instance, 80% of children born with achondroplasia (ACH) have a spontaneous pathologic variant in the fibroblast growth factor receptor type 3 (*FGFR3*) gene. The following are examples of AD disorders.

Achondroplasia

Caused by a defect in cartilage-derived bone, ACH is the most common skeletal dysplasia in humans. The bony abnormalities lead to short stature, macrocephaly, a flat midface with a prominent forehead, and rhizomelic ("root of the limb") shortening of the limbs. The disorder occurs in approximately 1 in 25,000 births.

ACH is caused by a pathologic variant in *FGFR3*. Early in development, this gene is expressed during endochondral bone formation. More than 95% of cases of ACH are caused by one of two pathologic variants in the same base pair (site 1138). This site, extremely active for variants, is known as a mutational **hot spot**.

As they grow, children with ACH often develop associated medical and psychologic problems. Hydrocephalus and central apnea may occur because of narrowing of the foramen magnum and compression of the brainstem and may present a life-threatening complication in infancy. Bowing of the legs may occur later in childhood because of unequal growth of the tibia and fibula. Dental malocclusion, obstructive apnea, and hearing loss due to middle ear dysfunction are common in later childhood. During later childhood and adolescence, the psychologic effects of the short stature may manifest. In adulthood, further complications include compression of nerve roots and sciatica. People with ACH have normal life spans and normal intelligence.

The diagnosis of ACH is based on clinical findings, and characteristic x-ray abnormalities confirm the diagnosis. Molecular testing is available, and prenatal diagnosis is possible using fetal cells obtained through amniocentesis or chorionic villus sampling.

Neurofibromatosis Type 1

One of the most common AD disorders, neurofibromatosis type 1 (NF1) is present in 1 in 3,000 individuals. The condition is caused by a pathologic mutation in the *NF1* gene, which codes for the protein neurofibromin.

Although the penetrance of NF1 is 100%, the expression is extremely variable, and many affected individuals have features so mild that they are never diagnosed.

See [Chapter 186](#).

Marfan Syndrome

A condition that occurs in approximately 1 in 10,000 individuals, Marfan syndrome (MFS) shows pleiotropy, a condition in which abnormalities in multiple organ systems are caused by a pathologic variant in a single gene. Marfan syndrome is caused by a pathologic variant in *FBNI*, the gene for fibrillin (a connective tissue protein). Clinical symptoms mainly involve three systems: **skeletal**, **ophthalmologic**, and **cardiac**.

Skeletal findings include dolichostenomelia (a tall, thin body habitus), long thin fingers and toes (arachnodactyly), abnormalities of the sternum (pectus excavatum or carinatum), scoliosis, pes planus, and joint laxity.

Eye findings include ectopia lentis (dislocation of the lens), early and severe myopia, flat lens, hypoplastic iris, and ciliary muscle hypoplasia. Patients with MFS are at increased risk of retinal detachment. Although cataracts do not occur more frequently in MFS, they tend to occur at a younger age.

Cardiac findings include aortic insufficiency and progressive dilatation of the aortic root, leading to increased risk of aortic dissection which is a life-threatening complication. Other clinical features include dural ectasia, abnormal pulmonary septation, and striae. Diagnostic criteria for MFS are summarized in [Table 47.3](#).

New pathologic variants in *FBNI* account for 25% of cases of MFS. The gene is large and complex, and more than 1,300 variants have been identified in affected individuals. Many of the symptoms of MFS are caused not by the defect in the fibrillin protein itself but by an excess in transforming growth factor β (TGF- β), a protein usually bound by fibrillin.

Autosomal Recessive Disorders

Disorders that are inherited in an autosomal recessive (AR) manner manifest only when *both* copies of a gene pair located on a non-sex chromosome have a pathologic variant ([Tables 47.4 and 47.5](#)). Children affected with AR disorders are usually born to unaffected parents, each of whom carries one copy of the variant. If both members of a couple are carriers (or heterozygotes) for this variant, each of their offspring has a 25% chance of being affected ([Fig. 47.3](#)).

Sickle Cell Disease

See [Chapter 150](#).

Tay-Sachs Disease

See [Chapters 56 and 185](#).

X-Linked Disorders

Approximately 900 genes have been identified on the X chromosome, whereas only 55 are believed to be present on the Y chromosome. Females, whose cells have two X chromosomes, possess two copies of each of these genes, whereas males, who

have one X chromosome and one Y chromosome, have only one copy. Early in female development, one X chromosome is randomly inactivated in each cell; this is called **X chromosome inactivation**. There are many X-linked disorders (colorblindness, Duchenne muscular dystrophy, hemophilia A) in which

TABLE 47.4 Examples of Autosomal Recessive Diseases

DISEASE	FREQUENCY	COMMENTS
Classic congenital adrenal hyperplasia (CAH; 21-hydroxylase deficiency)	1:15,000 (classic CAH)	Phenotype variation corresponds roughly to allelic variation. A deficiency causes virilization in females. The gene is located at 6p21.3 within the human leukocyte antigen (HLA) complex and within 0.005 centimorgans (cM) of HLA B.
Phenylketonuria (PKU; phenylalanine hydroxylase deficiency)	1:10,000	There are hundreds of disease-causing mutations in the PAH gene located on chromosome 12q22–q24.1. The first population-based newborn screening was a test for PKU because the disease is treatable by diet.
Cystic fibrosis (CF)	1:2,500 Whites	The gene <i>CF transmembrane conductance regulator</i> (CFTR) is on chromosome 7q31.2.
Friedreich ataxia (FA)	1:40,000	Frataxin is a mitochondrial protein involved with iron metabolism and respiration. The gene is on chromosome 9q13–q21, and the common mutation is a GAA expanded triplet repeat located in the first <i>intron</i> of the gene. FA does not show anticipation.
Gaucher disease, all types (glucocerebrosidase deficiency)	1:1000 Ashkenazi Jews	The gene is located on chromosome 1q21. There are many mutations; some mutations lead to neuropathic disease, but most are milder in expression.
Sickle cell disease (SCD)	1:365 Blacks	A single base change results in an amino acid substitution of valine for glutamic acid at position 6 of the β chain of hemoglobin, with resulting hemolytic anemia. The gene is on chromosome 11p15.5 and is associated with multiple sickle cell syndromes (see Chapter 150)

TABLE 47.5 Rules of Autosomal Recessive Inheritance

Trait appears in siblings, not in their parents or their offspring.
On average, 25% of siblings of the proband are affected (at the time of conception, each sibling has a 25% chance of being affected).
A normal sibling of an affected individual has a two-thirds chance of being a carrier (heterozygote).
Males and females are likely to be affected equally.
Rare traits are likely to be associated with parental consanguinity.
Traits generally involve mutations in genes that code for enzymes (e.g., phenylalanine hydroxylase—deficient in PKU) and are associated with serious illness and shortened life span.

PKU, Phenylketonuria.

heterozygous (carrier) females show some manifestations of the disorder due to skewed X chromosome inactivation.

X-Linked Recessive Inheritance

Most disorders involving the X chromosome show recessive inheritance. With only one copy of the X chromosome, males are more likely to manifest these diseases than females. Each son born to a female carrier of an X-linked recessive trait has a 50% chance of inheriting the trait, but none of her daughters would be expected to be affected (each daughter has a 50% chance of being a carrier). An affected father transmits the mutation to all his daughters, who are carriers, but not to his sons; having received their father's Y chromosome, they would not be affected (thus there is no male-to-male transmission) (Tables 47.6 and 47.7; Fig. 47.4).

Duchenne Muscular Dystrophy

See Chapter 182.

Hemophilia A

See Chapter 151.

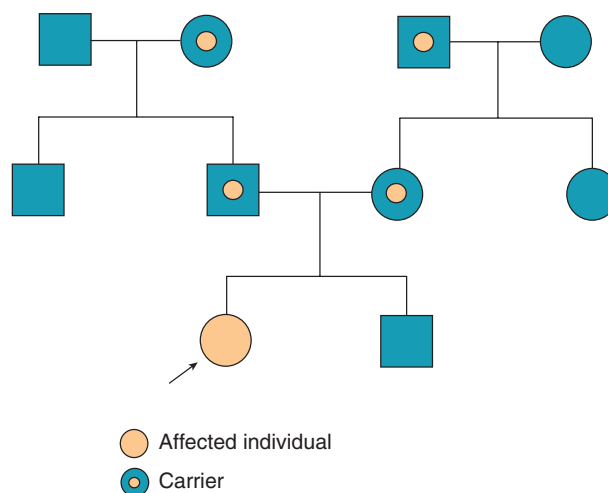

FIGURE 47.3 Pedigree of family showing autosomal recessive inheritance.

X-Linked Dominant Inheritance

Only a few examples of X-linked dominantly inherited disorders have been described. Both males and females are affected by this group of disorders, but females have less severe symptoms due to X chromosome inactivation. This is the case for **X-linked vitamin D-resistant rickets** (hypophosphatemic rickets), a disorder in which the kidney's ability to reabsorb phosphate is impaired. Phosphate levels and resulting rickets are not as severe in females as in males.

Some X-linked dominant disorders are lethal in males, with death occurring before birth. Affected mothers can have affected or normal daughters but only normal sons. This is the case in **incontinentia pigmenti**, caused by a pathologic variant in the *NEMO* or *IKBKG* gene, which has a characteristic swirling skin pattern of hyperpigmentation that develops after a perinatal skin rash with blistering. Affected females also have

TABLE 47.6 Examples of X-Linked Recessive Diseases		
DISEASE	FREQUENCY	COMMENTS
Fragile X syndrome (FRAX; numerous other names)	1:4,000 males	The gene is located at Xq27.3. The condition is attributable to a CGG triplet expansion that is associated with localized methylation (inactivation) of distal genes. Females may have some expression. Instability of the site may lead to tissue mosaicism; lymphocyte genotype and phenotype may not correlate.
Duchenne muscular dystrophy (DMD; pseudohypertrophic progressive MD, dystrophinopathy, Becker variants)	1:3,500 males	The gene is located at Xp21. The gene is relatively large, with 79 exons, and mutations and deletions may occur anywhere. The gene product is called <i>dystrophin</i> . Dystrophin is absent in DMD but abnormal in Becker MD.
Hemophilia A (factor VIII deficiency, classic hemophilia)	1:5,000 males	The gene is located at Xq28. Factor VIII is essential for normal blood clotting. Phenotype depends on genotype and the presence of any residual factor VIII activity.
Color blindness (partial deutan series, green color blindness [75%]; partial protan series, red color blindness [25%])	1:12 males	The gene is located at Xq28 (proximal) for deutan color blindness and at Xq28 (distal) for protan color blindness.
Adrenoleukodystrophy (ALD, XL-ALD)	1:10,000–1:17,000	The gene is located at Xq28. The disease involves a defect in peroxisome function relating to <i>very long-chain fatty acid CoA synthetase</i> with accumulation of C-26 fatty acids. Phenotype is variable, from rapid childhood progression to later onset and slow progression.
Glucose-6-phosphate dehydrogenase deficiency (G6PD)	1:10 Blacks 1:5 Kurdish Jews	The gene is located at Xq28. There are numerous variants in which oxidants cause hemolysis. Variants can confer partial resistance to severe malaria.

TABLE 47.7 Rules of X-Linked Recessive Inheritance	
Incidence of the trait is higher in males than in females.	
Trait is passed from carrier females, who may show mild expression of the gene, to half of their sons, who are more severely affected.	
Each son of a carrier female has a 1-in-2 chance of being affected.	
Trait is transmitted from affected males to all their daughters; it is never transmitted father to son.	
Because the trait can be passed through multiple carrier females, it may skip generations.	

variable involvement of the central nervous system, hair, nails, teeth, and eyes. In **Rett syndrome**, caused by variants in the *MECP2* gene, females are normal at birth but later in the first year of life develop microcephaly, developmental regression, and often a seizure disorder. Females are often diagnosed with autism and, by 2 years of age, adopt a *handwashing* posture that causes them to lose all purposeful hand movements.

OTHER TYPES OF GENETIC DISORDERS

Multifactorial Disorders

Also known as **polygenic inheritance**, multifactorially inherited disorders result from the interplay of genetic and environmental factors. In addition to 20% of congenital

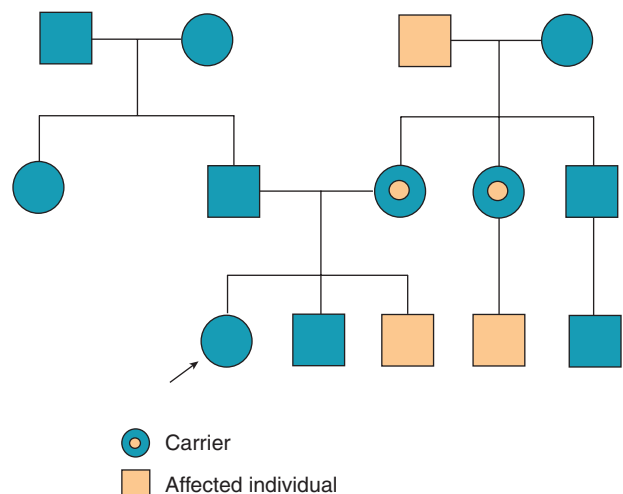

FIGURE 47.4 Pedigree showing X-linked recessive inheritance.

malformations, including cleft lip and palate and spina bifida, most common disorders of childhood and adult life, such as asthma, atherosclerosis, diabetes, and cancer, result from an interaction between genes and the environment. Though these disorders do not follow simple Mendelian modes of inheritance, affected individuals tend to cluster in families. The disorders occur more often in first- and second-degree relatives than would be expected by chance, and they are more likely to be concordant (although not 100%) in monozygotic twins than in dizygotic twins.

Hypertrophic Pyloric Stenosis

Occurring in about 1 in 300 children, hypertrophic pyloric stenosis (HPS) is five times more likely to occur in males than in females. When a child with HPS is born, the recurrence risk in future progeny is 5–10% for males and 1.5–2% for females. In adulthood, the risk of an affected male having an affected child is markedly increased over the general population; 4% of sons and 1% of daughters of such men would be likely to be affected. Even more striking is the risk to children born to affected females; 17–20% of sons and 7% of daughters are affected.

The thickness of the pyloric muscle may be distributed across a bell-shaped curve; the position on the bell-shaped curve is determined by many factors, including the expression of multiple, unknown genes. HPS may result when individuals' genetic and environmental influences cause them to fall to an extreme position on this curve, past a certain point called a **threshold**. In HPS, this threshold is farther to the left for males than it is for females.

Neural Tube Defects, Including Myelomeningocele

The frequency of myelomeningocele is 1 in 2,500 newborns. Multiple genetic and nongenetic factors dictate the speed with which the neural tube closes, as follows:

1. The frequency of neural tube defects (NTDs) varies greatly in different ethnic groups. They are more common in the British Isles, where, in 1990, they occurred in 1 in 250 live births, and are far less common in Asia, where the frequency was 1 in 4,000. These ethnic differences suggest a **genetic** component.
2. Couples from the British Isles who move to the United States have a risk intermediate between the risks in the United Kingdom and the United States, suggesting an **environmental** component.
3. The occurrence of NTDs exhibits seasonality. In the United States, affected infants are more likely to be born during late fall and early winter, again suggesting an **environmental** component or a folate responsive gene effect.
4. Periconceptional supplementation with folic acid has significantly lowered the risk of having an infant with an NTD. This nutritional influence suggests an **environmental** or gene modifying component.
5. Parents who have one child with an NTD are 20–40 times more likely to have a second affected child; this provides further evidence of a **genetic** component.

Disorders with Unusual Patterns of Inheritance

Mitochondrial Inheritance

Mitochondrial DNA (mtDNA) is nonnuclear DNA contained within human cells. This mtDNA is circular, 16.5 kb in length, and replicates independently of nuclear DNA. Involved in energy production used to run the cell, mtDNA codes for a few respiratory chain proteins (most mitochondrial proteins are coded on **nuclear** DNA) and for a set of transfer RNAs unique to mitochondrial protein synthesis. Virtually all mitochondria are supplied by the oocyte, which means that mtDNA is maternally derived. A female with a variant in mtDNA passes this variant to all her children. More than one population of

mitochondria may be present in the oocyte, a phenomenon called **heteroplasmy**. The mtDNA variant may be present in a few or many mitochondria. When the fertilized egg divides, mitochondria are distributed randomly. The presence of symptoms in the offspring, and their severity, depends on the ratio of variant to wild type mtDNA present in a particular tissue. If an abundance of variant mitochondria exists in tissue that has high energy requirements (brain, muscle, and liver), clinical symptoms occur (Fig. 47.5). If fewer variant mitochondria are present, few clinical symptoms may be seen.

Mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS) is an example of a mitochondrial disorder. Asymptomatic in early childhood, individuals affected with MELAS develop episodic vomiting, seizures, and recurrent cerebral insults that resemble strokes between 5 and 10 years of age. In 80% of cases, analysis of the mtDNA reveals a specific variant (A3243G) in *MTTL1*, a gene that codes for a mitochondrial transfer RNA.

In families in which MELAS occurs, a range of symptoms is seen in first-degree relatives, including **progressive external ophthalmoplegia**, hearing loss, cardiomyopathy, and diabetes mellitus. Although all offspring of a woman who carries a mutation would be affected, because of heteroplasmy the severity of disease varies depending on the percentage of mitochondria bearing the variant that is present.

Uniparental Disomy

Evaluation of a child with uniparental disomy (UPD) reveals a normal karyotype. However, chromosomal markers for one particular chromosome are identical to the markers found on the chromosomes of the patient's mother or father (but not both as is normal). In UPD, the individual inherits two copies of one parent's chromosome and no copy from the other parent.

UPD probably occurs through a few mechanisms, but the most common results from a spontaneous *rescue* mechanism. At the time of conception, through nondisjunction, the fertilized egg is trisomic for a particular chromosome, with two copies of one parent's chromosome and one copy of the other parent's chromosome; conceptuses with trisomy often miscarry early in development. Fetuses with UPD survive because they spontaneously lose one of three copies of the affected chromosome. If the single chromosome from one parent is lost, the patient has UPD.

An alternate explanation involves monosomy for a chromosome rather than trisomy. Had the conceptus, at the time of conception, inherited only a single copy of a chromosome, spontaneous duplication of the single chromosome would lead to UPD.

Prader-Willi and Angelman Syndromes

Prader-Willi syndrome (PWS), which occurs in 1 in 17,500 infants, is characterized by neonatal hypotonia, postnatal growth delay, a characteristic appearance including almond-shaped eyes and small hands and feet, developmental disability, hypogonadotropic hypogonadism, and obesity after infancy. Early in life, affected infants are so hypotonic that they cannot consume enough calories to maintain their weight. Nasogastric feeding is invariably necessary, and failure to thrive is common. During the first year of life, muscle tone improves, and children develop a voracious appetite with resulting obesity. Between 60% and 70% of individuals with PWS have a small deletion

FIGURE 47.5 The range of affected tissues and clinical phenotypes associated with mutations in mitochondrial DNA (mtDNA). (Modified from Chinnery PF, Turnbull DM. Mitochondrial DNA and disease. *Lancet* 1999;345:S117–S121.)

of chromosome 15 (15q11). In individuals without a deletion, 25% have UPD of chromosome 15.

Angelman syndrome (AS) is a condition with moderate to severe intellectual disability, absence of speech, ataxic movements of the arms and legs, a characteristic craniofacial appearance, and a seizure disorder that is characterized by inappropriate laughter. AS is also characterized by a deletion in the 15q11 region in 70% of affected individuals; UPD for chromosome 15 can be demonstrated in approximately 5% of AS patients.

If the deletion occurs in paternal chromosome 15, the affected individual will develop PWS, whereas AS results from a deletion occurring only in the maternal chromosome 15. When UPD is responsible, maternal UPD results in PWS, whereas paternal UPD results in AS. To summarize, if a copy of paternal chromosome 15q11.2 is lacking, PWS occurs; if maternal chromosome 15q11.2 is lacking, AS results.

This phenomenon is explained by **genomic imprinting**. Imprinting is an **epigenetic** phenomenon, a nonheritable change in the DNA that causes an alteration in gene expression based on parental origin of the gene. PWS is caused by deficiency of the protein product of the gene *SNRPN* (small nuclear ribonucleoprotein). Although present on both maternally and paternally derived chromosome 15, *SNRPN* is expressed only in the paternally derived chromosome.

Expression is blocked in the maternal chromosome because the bases of the open reading frame are methylated; this physical change in the DNA prevents gene expression. PWS results whenever a paternal chromosome 15 is missing, either through deletion or through UPD.

AS results from a lack of expression of ubiquitin-protein ligase E3A (*UBE3A*), a second gene in the chromosome 15q11.2 region. *UBE3A* is normally expressed only in the maternally derived chromosome 15. Although present in paternal chromosome 15, *UBE3A* is methylated, and gene expression is blocked. Therefore, if either the critical region of maternal chromosome 15 is deleted or paternal UPD occurs, the individual will manifest symptoms of AS.

Expansion of a Trinucleotide Repeat

More than 50% of human DNA appears as repeat sequences, two or three bases repeated over and over again. Disorders caused by expansion of trinucleotide repeats include **fragile X syndrome (FRAX)**, **Huntington disease**, **myotonic dystrophy**, **Friedreich ataxia**, and the **spinocerebellar ataxias**. Although an increase in the number of the three repeated bases is at the heart of each disorder, the molecular mechanism differs.

FRAX, which occurs with a frequency of approximately 1 in 4,000 children, is the most common cause of inherited

intellectual disability. Features include characteristic craniofacial findings (large head; prominent forehead, jaw, and ears); macro-orchidism with testicular volume twice normal in adulthood; a mild connective tissue disorder, including joint laxity, patulous eustachian tubes, and mitral valve prolapse; and a characteristic neurobehavioral profile, including intellectual disability (ranging from mild to profound) and autism spectrum disorders.

Positional cloning in the Xq27 region identified a triplet repeat region composed of one cytosine and two guanine residues (CGG). These repeats occur in the promoter region of the gene *FMRI*. Unaffected individuals who have no family history of FRAX have 0–45 CGG repeats (most have 25–35). In individuals with FRAX, the number of repeats is greater than 200; such people are said to have a *full mutation*. Between these two categories, a third group has 56–200 repeats; these individuals, known as **premutation carriers**, have typical development.

FRAX results from a failure to express FMRP, the protein product of the *FMRI* gene, which is expressed primarily in the central nervous system and testes during early embryonic development. Although FMRP is produced in unaffected individuals and premutation carriers, in those with the full mutation, FMRP transcription of the protein is blocked because the large number of CGG repeats become methylated (an epigenetic phenomenon). Thus FRAX occurs as a consequence of a **loss-of-function mutation**—the failure of expression of FMRP because of methylation of the promoter sequence.

In female premutation carriers, an expansion in the number of repeats from the premutation to the full mutation range may occur during gametogenesis. The cause of this expansion is not understood. Although premutation carriers do not show symptoms and signs of FRAX, women may manifest primary ovarian insufficiency and early menopause, and men and women may develop a movement disorder, known as fragile X tremor/ataxia syndrome later in life.

TERATOGENIC AGENTS

Approximately 6–15% of all birth defects are attributed to teratogens—chemical, physical, or biologic agents that have the potential to damage embryonic tissue and result in congenital malformations. Agents known to be teratogenic include drugs (prescription and nonprescription); intrauterine infections (rubella); maternal diseases, such as diabetes mellitus; and environmental substances, such as alcohol and heavy metals. Knowledge of teratogenic agents and their effect on the developing fetus is important because limiting exposure to these agents is an effective way to prevent birth defects (see Chapter 59).

Maternal Infections

Rubella was the first maternal infection known to cause a pattern of malformations in fetuses affected in utero. Cytomegalovirus, *Toxoplasma gondii*, herpes simplex, Zika virus, and varicella are additional potentially teratogenic in utero infections (see Chapter 66).

Maternal Disease

Maternal diabetes mellitus and *maternal* PKU can result in congenital anomalies in the fetus. Strict control of these

disorders before and during pregnancy protects the developing child (see Chapter 59).

Medications and Chemicals

Fetal alcohol spectrum disorders are the most common causes of preventable intellectual disability. Prevalence estimates vary with a range of 0.3–9 cases per 1,000 children in the United States. Features include prenatal and postnatal growth deficiency, developmental disabilities, microcephaly, skeletal and cardiac anomalies, and a characteristic facial appearance. While the amount of alcohol consumed and timing of consumption is often linked to the severity of symptoms, no safe threshold of alcohol consumption in pregnancy has been identified; it is recommended that pregnant women avoid all prenatal alcohol exposure.

Warfarin, retinoic acid, and phenytoin are additional teratogenic agents (see Chapter 59).

Radiation

High-dose radiation exposure during pregnancy in Hiroshima and Nagasaki, Japan, was shown to increase the rate of spontaneous abortion and result in children born with microcephaly, intellectual disability, and skeletal malformations. Estimates of exposure to cause these effects were approximately 25 rad. *The dose from routine radiologic diagnostic examinations is in the millirad range.*

PEARLS FOR PRACTITIONERS

See *Human Genetics and Dysmorphology: Pearls for Practitioners at the end of this section.*

CHAPTER 48

Genetic Assessment and Diagnosis

Individuals referred to a geneticist because of suspicion of a genetic disorder are called **probands**; individuals who come for genetic counseling are **consultands**. Referral for genetic evaluation may be made for a wide variety of reasons and at different stages of life (fetus, neonate, childhood, pregnancy, adulthood).

PRECONCEPTION AND PRENATAL COUNSELING

Familial Factors

Families with relatives affected with genetic disorders may have questions about how a disorder is inherited and whether their progeny may be at risk. The inheritance pattern and the risk of having an affected child can be discussed with a geneticist.

In some cultures, it is common, even desirable, for relatives to marry. This relatedness or **consanguinity** increases the likelihood that offspring may be born with a rare autosomal recessive (AR) condition, as both parents may be carriers of

the same pathologic gene. Generally, the closer the relation between the partners, the greater the chance that the couple shares one or more mutated genes in common, increasing the risk that offspring will have an AR disorder. The risk of first cousins having a child with an AR disorder is 1 in 64. In evaluating these couples, it is important to determine which ethnic group they belong to and to test for conditions commonly found in that group.

Screening

It is common for couples to be screened for disorders that may occur more commonly in their ethnic group. People of Ashkenazi Jewish background may choose to be screened for heterozygosity for an expanding panel of AR disorders, including Tay-Sachs and Niemann-Pick diseases, Bloom and Gaucher syndromes, Canavan disease, cystic fibrosis, Fanconi anemia, and familial dysautonomia. Individuals from Western and sub-Saharan Africa may choose to be screened for sickle cell disease. People whose ancestors originated in the Mediterranean basin may be screened for thalassemia. It is not uncommon for couples to have carrier screening for 400 or more recessive disorders.

Historically, prenatal screening has involved invasive and noninvasive testing. Invasive testing includes amniocentesis and chorionic villus sampling (CVS). Noninvasive testing includes sonography, which is utilized routinely throughout pregnancies, and the use of a series of biochemical markers present in the mother's blood. Elevated maternal serum α -fetoprotein (MS AFP) is used to identify pregnancies in which the fetus is affected with neural tube defects, omphalocele, or gastroschisis. An additional association between low levels of MS AFP and fetal aneuploidy is known. Approximately 50% of fetuses with autosomal trisomies (trisomy 21 [Down syndrome], trisomy 18, trisomy 13) can be detected by low levels of MS AFP.

Additional proteins—unconjugated estriol (uE3), inhibin A, and human chorionic gonadotropin (HCG)—are evaluated with MS AFP to create a biochemical profile known as the **quad screen** which correctly identifies about 80% of women who are carrying a baby with Down syndrome.

The quad screen is performed in the second trimester. During the first trimester, measurement of the fetal nuchal fold by sonogram can be used to identify risk for aneuploidy; increase in the nuchal thickness is a marker not only for fetal chromosomal anomalies but for certain genetic and structural abnormalities as well. The detection rate for aneuploidy using this technique alone is 70%. The addition of testing for abnormalities in free β -HCG and PAPP-A (pregnancy-associated plasma protein) increases first trimester screening to a detection rate of almost 90%. However, positive predictive values remain low at less than 5%.

Although the risk of nondisjunction resulting in aneuploidy rises with maternal age, all pregnant women should be individually counseled as to their risk for aneuploidy and other fetal abnormalities. A combination of first and second trimester screening together with the women's age produces an individualized risk factor. *It is important to emphasize that screening tests are just that—tests used to identify individuals who are at increased risk.* If the risk is high or if concerns exist about the presence of a fetal anomaly, a more definitive test, either CVS or amniocentesis, can be offered as further testing.

Fetal cells are usually tested for chromosomal abnormalities by cytogenetic techniques, with the option of chromosomal microarray for increased precision. Biochemical testing for a known family history of an inherited metabolic disorder and molecular screening for known familial mutations can also be performed on fetal cells.

Noninvasive prenatal screening (NIPS, also referred to as noninvasive prenatal testing [NITS]) uses cell-free fetal DNA in maternal blood to determine the risk of certain trisomies, and sometimes microdeletion syndromes, in the fetus. NIPS allows use of a maternal blood sample without an invasive test (amniocentesis, CVS) and offers predictive values around 50–80% depending on a priori risk; it is important to note that NIPS is a screening test rather than a diagnostic test and requires confirmation by amniocentesis or CVS. This low-risk screening method is likely to replace other forms of prenatal genetic screening and testing as it becomes more widely available.

Maternal Factors

The presence of either acute or chronic maternal illness during pregnancy may lead to complications in the developing fetus. Chronic conditions may expose the fetus to maternal medications that are potentially teratogenic. Acute illnesses, especially from the TORCH agents (toxoplasmosis, rubella, cytomegalovirus, herpes virus, and “other,” including syphilis, varicella, and Zika virus), expose the fetus to infectious agents that may cause birth defects. Other factors, such as maternal smoking, alcohol use, and maternal exposure to radiation or chemicals, also may necessitate genetic counseling.

Postnatal—Newborn and Infant

About 3% of newborns have a genetic abnormality or congenital malformation (see [Chapter 47](#)). The broad definition of malformations includes not only visible abnormalities but also functional defects that might not be apparent at birth.

Congenital malformations and genetic disorders have a significant impact on childhood morbidity and mortality. Almost 11% of childhood deaths can be traced to a genetic cause. If contributing genetic factors related to childhood deaths are considered, this increases to nearly 25%. Consultation with a geneticist for a newborn or infant may be prompted by many different findings, including the presence of a malformation, abnormal results on a routine newborn screening test, abnormalities in growth (e.g., failure to gain weight, increase in length, or abnormal head growth), developmental delay, blindness or deafness, the knowledge of a family history of a genetic disorder or chromosomal abnormality, or (as a result of prenatal testing) the presence of a genetic disorder or chromosomal abnormality in the infant.

Adolescent and Adult

Adolescents and adults may be seen by a geneticist for evaluation of a genetic disorder that has later onset. Some neurodegenerative disorders, such as Huntington disease and adult-onset spinal muscular atrophy, present later in life. Some forms of hereditary blindness (retinal degenerative diseases) and deafness (Usher syndrome, neurofibromatosis type 2) may not show significant symptoms until adolescence

or early adulthood. Similarly, inherited cardiac disorders such as hypertrophic cardiomyopathy and long QT syndrome may not be identifiable until adulthood. Genetic consultation also may be prompted for a known family history of a **hereditary cancer syndrome** (breast, thyroid, colon, and ovarian cancers). Individuals may wish to have testing done to determine if they carry a mutation for these syndromes and are at risk for developing certain types of cancers. A known family history or personal history of a genetic disorder or chromosomal abnormality might prompt testing in anticipation of pregnancy planning.

GENERAL APPROACH TO PATIENTS

Family History

A pedigree usually is drawn to help visualize various inheritance patterns. A detailed family history determines if there is an autosomal dominant (AD), AR, X-linked, or sporadic disorder segregating in the family. When a child is affected with the new onset of an AD disorder, it is necessary to closely examine the parents for the presence of manifestations. If the parents are unaffected, the child's condition is most likely the result of a new mutation, in which case the risk of recurrence is extremely low (although not 0, because of the possibility of gonadal mosaicism in one of the parents). When one parent is affected (even mildly so, due to varying expressivity), the recurrence risk rises to 50% for each subsequent pregnancy. With X-linked disorders, the focus is on the maternal family history to determine if there is a significant enough risk to warrant testing.

Questions about the couple's age are important to ascertain the risk related to maternal age for chromosome abnormalities and paternal age for new mutations leading to AD and X-linked disorders. A history of more than two spontaneous abortions increases the risk that one of the parents carries a balanced translocation and the spontaneous abortions are due to chromosomal abnormalities in the fetus.

Pregnancy

During a genetic consultation, it is important to gather information about the pregnancy (see [Chapters 58, 59, and 60](#)). A maternal history of a chronic medical condition, such as a seizure disorder or diabetes, has known consequences in the fetus. Medication used in pregnancy can be teratogenic; the pregnant woman's exposure to toxic chemicals (work related) or use of alcohol, cigarettes, or drugs of abuse can have serious effects on the developing fetus. Maternal infection during pregnancy with TORCH agents (see [Chapter 66](#)), among others, has been found to cause malformations in the fetus.

Information about the pregnancy may provide clues as to the health of the fetus. For more information about this, please see [Chapter 50](#).

Follow-up is needed if prenatal testing revealed abnormal results.

Delivery and Birth

An infant born prematurely is likely to have more complications than a term infant. An infant can be small, appropriate, or large for gestational age; each of these has implications for the child (see [Chapters 58 and 60](#)).

Medical History

The medical history can provide clues to an underlying disorder. Children with inborn errors of metabolism who have intermittent symptoms often have a history of multiple hospitalizations for dehydration or vomiting, often with encephalopathy. Children with neuromuscular disorders may have a normal period followed by increasing weakness or ataxia. Children with lysosomal storage diseases, such as the mucopolysaccharidoses, often have recurrent ear infections and can develop sleep apnea.

Development

Many genetic disorders are associated with developmental disabilities. However, the onset of the disability may not always be present from the newborn period; many inborn errors of metabolism, including storage disorders, cause developmental regression after a period of normal development (see [Chapters 7 and 8](#)). Some adult-onset disorders have no symptoms until the teens or later. Assessing school problems is important. The type of learning problem, age at onset, and whether there is improvement with intervention or continued decline all are important for proper assessment.

Physical Examination

A careful and thorough physical examination is necessary for all patients with signs, symptoms, or suspicion of genetic disease. Sometimes subtle clues may lead to an unsuspected diagnosis. Features suggestive of a syndrome are discussed in more detail in [Chapter 50](#).

Laboratory Evaluation

Chromosome Analysis

An individual's chromosome complement, known as the karyotype, can be analyzed using cells capable of dividing. In pediatrics, lymphocytes obtained from peripheral blood are the usual source for such cells, but cells obtained from bone marrow aspiration, skin biopsy (fibroblasts), or, prenatally, from amniotic fluid or chorionic villi also can be used. Cells are placed in culture medium and stimulated to grow using a mitogen; their division is arrested in either metaphase or prophase using a spindle poison; slides are made, the chromosomes are stained with Giemsa or other dyes, and the chromosomes are examined and analyzed under a microscope.

In metaphase, chromosomes are short, squat, and easy to count. Metaphase analysis should be ordered in children whose features suggest a known aneuploidy syndrome, such as a trisomy or monosomy. Chromosomes analyzed in prophase are long, thin, and drawn out; analysis gives far more details than are seen in metaphase preparations. Prophase analysis is ordered in individuals with multiple congenital anomalies without an obvious disorder.

Fluorescent In Situ Hybridization

Fluorescent in situ hybridization (FISH) allows the identification of the presence, absence, or rearrangement of a specific region of DNA. A complementary DNA probe specific for the region in question is generated, and a fluorescent marker is attached. The probe is incubated with cells from the subject

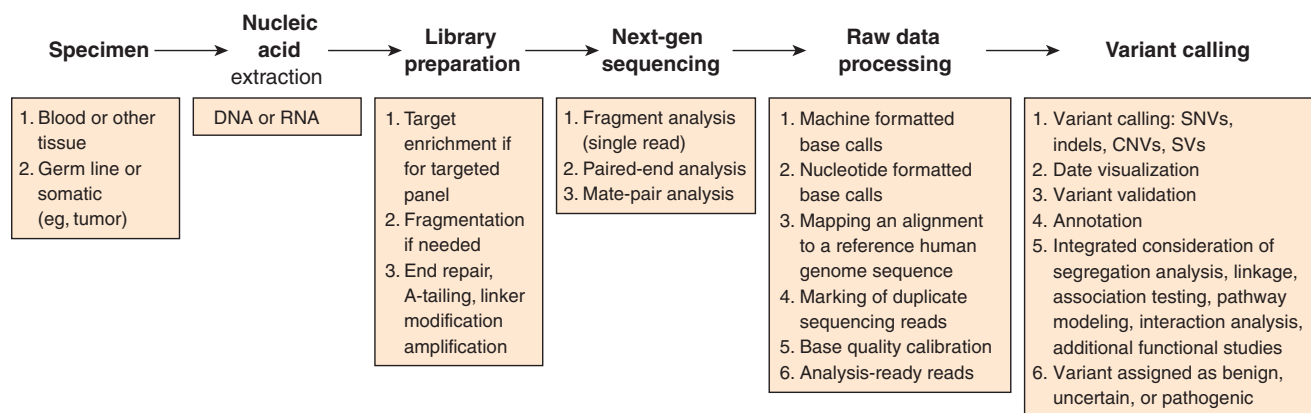

FIGURE 48.1 Overview of the next-generation DNA sequencing workflow. CNV, Copy number variant; *Indels*, insertions and deletions; SNV, single nucleotide variant; *SV*, structural variant. (Adapted from Casey G, Conti D, Haile R, et al. Next generation sequencing and a new era of medicine. *Gut* 2013;62(6):920–932.)

and viewed under a microscope. The bound probe fluoresces, allowing the number of copies of the DNA segment in question to be counted. This technique is useful in Prader-Willi and Angelman syndromes, in which a deletion in a segment of 15q11.2 occurs, in Williams syndrome, known to be associated with a deletion in 7q11.2, in velocardiofacial (DiGeorge) syndrome, which is associated with a deletion of 22q11.2, and in other disorders in which a small duplication or deletion is known to occur.

Microarray Comparative Genomic Hybridization

Microarray comparative genomic hybridization (array CGH) has essentially supplanted prophase analysis in cases in which a subtle copy number variant (chromosomal deletion or duplication) is suspected. DNA from the individual being studied and a normal control are labeled with fluorescent markers and hybridized to thousands of FISH-like probes for sequences spread around the genome. The probes are derived from known genes and noncoding regions. By analyzing the ratio of intensity of the fluorescent marker at each site, it is possible to determine whether the individual has any difference in copy number compared with the control DNA.

DNA Sequencing

Sequencing technologies allow for examination of DNA for alterations at the nucleotide level. Sanger sequencing and next-generation sequencing (NGS) are two clinically available sequencing technologies. NGS allows for massively parallel sequencing reactions, which has reduced cost and increased efficiency. Despite its many advantages, NGS is not as successful at sequencing repetitive regions as Sanger sequencing. Sanger sequencing examines only a single DNA fragment at a time; it is slower but more accurate. Results of NGS are therefore often validated with Sanger sequencing. Allele-specific polymerase chain reaction (PCR) and hybridization technologies allow one to detect the presence or absence of a specific allele or pathologic variants.

Sequencing tests permit targeted approaches that can test for a familial or common variant within a gene, an entire gene

or panel of genes, or even all the exons with exome sequencing (ES). The websites <https://www.ncbi.nlm.nih.gov/gtr/> (government) and www.concertgenetics.com (commercial) list disorders in which sequencing is available and identifies laboratories performing such testing.

Exome Sequencing

ES permits examination of the exonic regions of all 20,000–24,000 genes that compose the human genome (Fig. 48.1). When possible, the test is ordered as a trio (patient plus both parental specimens) so that the proband's results can be further clarified. Using PCR and other techniques developed during the Human Genome Project, ES isolates DNA from an individual, looks for variations in the exomes or coding sequences of the genes, and compares identified variation with the DNA from the individual's parents. Variation found in the subject that is not present in either parent suggests a spontaneous (de novo) mutation; two copies of a pathologic variant in an individual whose parents are each found to be carriers of the variant suggests that the subject is affected with an autosomal recessively inherited disorder. Despite several shortcomings in ES (it is expensive and the interpretation is complicated with thousands of variations often identified), its benefit as a diagnostic tool is incredible.

Whole Genome Sequencing

Whole genome sequencing (WGS) involves analysis of both exonic (coding) and intronic (noncoding) regions of a patient's genome. This results in an ability to detect variants in regulatory regions that may have been missed by ES. WGS can also detect copy number variants (like a chromosomal microarray). This technology is newer to clinical care but is likely to predominate as it becomes increasingly available and affordable.

PEARLS FOR PRACTITIONERS

See *Human Genetics and Dysmorphology: Pearls for Practitioners* at the end of this section.

CHAPTER 49

Chromosomal Disorders

Errors that occur in meiosis during the production of gametes can lead to abnormalities of chromosome structure or number. Syndromes caused by chromosomal abnormalities include trisomy 21 (Down syndrome [DS]), trisomy 13, trisomy 18, Turner syndrome (TS), and Klinefelter syndrome (KS), as well as rarer chromosomal duplications, deletions, or inversions.

Chromosomal abnormalities occur in approximately 8% of fertilized ova but in only 0.6% of liveborn infants. Fifty percent of spontaneous abortuses have a chromosomal abnormality, the most common being 45,X (TS); an estimated 99% of 45,X fetuses are spontaneously aborted. The fetal loss rate for DS, the most viable of the autosomal aneuploidies, approaches 80%. Most other chromosomal abnormalities also adversely affect fetal viability. In newborns and older children, features that suggest the presence of a chromosome anomaly include low birthweight (small for gestational age), failure to thrive, developmental disability, and the presence of three or more congenital malformations.

ABNORMALITIES IN NUMBER (ANEUPLOIDY)

During meiosis or mitosis, failure of a chromosomal pair to separate properly results in nondisjunction. **Aneuploidy** is a change in the number of chromosomes that results from nondisjunction. A cell may have one (**monosomy**) or three (**trisomy**) copies of a particular chromosome.

Trisomies

Down Syndrome

DS is the most common abnormality of chromosomal number in liveborn infants. It occurs in approximately 1 of every 700 births. Most cases (95%) are due to nondisjunction; in most cases, the nondisjunctional event occurs in maternal meiosis phase I. As a result of nondisjunction, the fertilized egg contains three copies of chromosome 21 (trisomy 21). Using standard cytogenetic nomenclature, trisomy 21 is designated 47,XX,+21 or 47,XY,+21. In 3% of cases, the extra chromosome is part of a **Robertsonian translocation**, which occurs when the long arms (q) of two acrocentric chromosomes (numbers 13, 14, 15, 21, or 22) fuse at the centromeres, and the short arms (p), containing copies of ribosomal RNA, are lost. The most common Robertsonian translocation leading to DS involves chromosomes 14 and 21; standard nomenclature is 46,XX,t(14q21q) or 46,XY,t(14q21q). The parents of infants with DS who have translocations should have a karyotype to exclude a balanced translocation.

In 2% of children with DS, **mosaicism** occurs. These individuals have two populations of cells: one with trisomy 21 and one with a normal chromosome complement. Mosaicism results either from a nondisjunctional event that occurs sometime after fertilization or from **trisomic rescue**. The loss of this aneuploidy returns the cell to 46,XX or 46,XY. In either case the individual is referred to as a mosaic for these two populations of cells and is designated 47,XX,+21/46XX or

47,XY,+21/46,XY. Although it is widely believed that individuals with mosaic DS are more mildly affected, there are wide variations in clinical findings.

Children with DS are usually diagnosed in the newborn period. They tend to have normal birthweight and length, but they are hypotonic. The characteristic facial appearance, with brachycephaly, flattened occiput, hypoplastic midface, flattened nasal bridge, upslanting palpebral fissures, epicanthal folds, and large protruding tongue, is often apparent at birth. Infants also have short broad hands, often with a single transverse palmar crease, and a wide gap between the first and second toes. Hypotonia may cause feeding problems and decreased activity. Intellectual disability is noted in almost all patients with DS.

Almost half of all children with DS have **congenital heart disease**, including atrioventricular canal, ventriculoseptal or atrioseptal defects, and valvular disease. Between 5% and 10% of newborns with DS have **gastrointestinal tract anomalies**; the three most common defects are duodenal atresia, annular pancreas, and imperforate anus.

Congenital **hypothyroidism** occurs in 4–18% of infants with DS. Acquired hypothyroidism is a more common problem. Thyroid function should be checked at birth, 6 months of age, and then annually.

Polycythemia at birth (hematocrit levels >70%) is common and may require treatment. Some infants with DS show a leukemoid reaction, with markedly elevated white blood cell counts. Although this resembles congenital leukemia, it is a self-limited condition, resolving on its own over the first month of life. Nonetheless, children with DS also have an increased risk of **leukemia**, with a 10- to 20-fold increase in risk compared with individuals without DS. In children with DS who are younger than 2 years of age, the type is generally acute megakaryoblastic leukemia; in individuals older than 3 years of age, the types of leukemia are similar to those of other children, with acute lymphoblastic leukemia being the predominant type.

Children with DS are more susceptible to infection, more likely to develop cataracts, and between 10% and 30% have atlantoaxial instability, an increased distance between the first and second cervical vertebrae that may predispose to spinal cord injury. Many individuals older than 35 years of age develop Alzheimer-like features.

The recurrence risk for parents who have had a child with DS depends on the child's cytogenetic findings. If the child has trisomy 21, the empiric recurrence risk is 1% for women up to 35 years of age; after 35, the age-specific risk alone is used for subsequent pregnancies. If the child has a Robertsonian translocation, chromosomal analysis of both parents must be performed. In approximately 65% of cases, the translocation is found to have arisen de novo (i.e., spontaneously, with both parents having normal karyotypes), and recurrence risk is low. When a parent is identified as having a Robertsonian translocation, the recurrence risk depends on which parent is the carrier: If the mother is the carrier, the risk is 10–15%; if the father is the carrier, the recurrence risk is 2–5%.

Trisomy 18

Trisomy 18 (47,XX,+18 or 47,XY,+18) is the second most common autosomal trisomy, occurring in approximately 1 in 6,000 live births. Virtually all cases of trisomy 18 are due to

	TRISOMY 13	TRISOMY 18
Head and face	Scalp defects (e.g., cutis aplasia) Microphthalmia, corneal abnormalities Cleft lip and palate in 60–80% of cases Microcephaly Sloping forehead Holoprosencephaly (arrhinencephaly) Capillary hemangiomas Deafness	Small and premature appearance Tight palpebral fissures Narrow nose and hypoplastic nasal alae Narrow bifrontal diameter Prominent occiput Micrognathia Cleft lip or palate

nondisjunction. More than 95% of conceptuses with trisomy 18 are lost as spontaneous abortuses in the first trimester; females are far more likely to survive to term than males; the ratio of male to female liveborns with trisomy 18 is 1:4. Infants with trisomy 18 rarely survive; only 12% will reach their first birthday. Most infants with trisomy 18 are small for gestational age. Clinical features include hypertonia, prominent occiput, micrognathia, low-set and malformed ears, short sternum, rocker-bottom feet, hypoplastic nails, and characteristic clenching of fists—the second and fifth digits overlap the third and fourth digits (Table 49.1).

Trisomy 13

The third of the common trisomies, trisomy 13 (47,XX,+13 or 47,XY,+13), occurs in 1 in 10,000 live births. As in trisomy 18, trisomy 13 is usually fatal in the first year of life, with only 20% of infants surviving beyond their first birthday.

As in DS, trisomy 13 can be caused by nondisjunction (seen in 75% of cases) or a Robertsonian translocation (in 20%). The most common translocation involves chromosomes 13 and

14. Counseling regarding recurrence risk for future progeny is similar to that described earlier for trisomy 21.

Infants with trisomy 13 have numerous malformations (see Table 49.1). They are small for gestational age and microcephalic. Midline facial defects such as cleft lip and palate are common, as are midline central nervous system anomalies, such as alobar holoprosencephaly. The forehead is generally sloping, ears are often small and malformed, and microphthalmia or anophthalmia may occur. Postaxial polydactyly of the hands is common, as are overlapping fingers and hyperconvex nails. Hypospadias and cryptorchidism are common in boys, whereas girls generally have hypoplasia of the labia minora. In addition, most infants with trisomy 13 have congenital heart disease. Many infants with trisomy 13 have a punched-out scalp lesion over the occiput called **aplasia cutis congenita**; when seen in conjunction with polydactyly and some or all the facial features, this finding is essentially pathognomonic for the diagnosis of trisomy 13.

Klinefelter Syndrome

Occurring in 1 in 580 newborn males, KS is the most common genetic cause of hypogonadism and infertility in men. It is caused by the presence of an extra X chromosome (47,XXY). The extra chromosome arises from nondisjunction in either the sperm or egg. About 15% of males with features of KS are found to be mosaic, with 46,XY/47,XXY mosaicism being the most common. Before puberty, males with KS are phenotypically indistinguishable from the rest of the population.

The diagnosis is often made in adolescence when the hallmark of the condition, under androgenation in the presence of testes that remain infantile in volume, should alert the clinician. Young adults with KS tend to be tall with long limbs. During adolescence or adulthood, gynecomastia may occur.

Because of failure of growth and maturation of the testes, males with KS have hypergonadotropic hypogonadism and failure to produce viable sperm. Low production of testicular testosterone results in failure to completely develop secondary sexual characteristics, such as facial hair, deepening of the voice, and libido. In adulthood, osteopenia and osteoporosis develop. Because of these findings, testosterone supplementation is indicated.

Most males with KS are infertile because they produce few viable sperm. Through the use of microdissection testicular sperm extraction, a technique in which viable sperm are isolated from testicular tissue, coupled with in vitro fertilization and intracytoplasmic sperm injection, it is possible for men with KS to father children; all children born to these men using this technology have had a normal chromosome complement.

Monosomies

Turner Syndrome

TS is the only condition in which a monosomic conceptus survives to term; however, 99% of embryos with 45,X are spontaneously aborted. TS is seen in up to 10% of first trimester pregnancy losses. Occurring in 1 in 3,200 liveborn females, TS is notable for its relatively mild phenotype. Affected women tend to have typical intelligence and normal life expectancy.

Females with TS typically have a characteristic facial appearance with low-set, mildly malformed ears, triangular face, flattened nasal bridge, and epicanthal folds. There is

webbing of the neck, with or without cystic hygroma, a shield-like chest with widened inter nipple distance, and puffiness of the hands and feet. Internal malformations may include congenital heart defect in 45% of patients (bicuspid aortic valve is most common followed by coarctation of the aorta; later in life, post-stenotic aortic dilatation with aneurysm may develop). Renal anomalies, including horseshoe kidney, are seen in more than 50% of patients. Short stature is a cardinal feature of this condition, and acquired hypothyroidism is estimated to occur five times more frequently in women with TS than in the general population.

The presence of **streak gonads** (gonadal dysgenesis) instead of well-developed ovaries leads to estrogen deficiency, which often results in incomplete development of secondary sex characteristics and amenorrhea. Although 10% of females with TS may have normal pubertal development and are even fertile, most affected women require estrogen replacement to complete secondary sexual development.

Infertility in these females is not corrected by estrogen replacement. Assisted reproductive technology using donor ova has permitted women with TS to bear children. During pregnancy, these females must be followed carefully because post-stenotic dilatation of the aorta, leading to dissecting aneurysm, may occur.

Many females with TS escape detection during the newborn period because phenotypic features are subtle. While most patients with TS are diagnosed in the newborn period because of the presence of physical features, some are diagnosed in childhood during a work-up for short stature (for which they may receive growth hormone therapy); others are diagnosed during adolescence or adulthood when they fail to develop secondary sexual characteristics or during work-ups for infertility.

The karyotypic spectrum in patients with TS is wide. Approximately 50% have a 45,X karyotype; another 30–40% are mosaic (45,X/46,XX or 45,X/46,XY). The remainder have structural X chromosome abnormalities involving a deletion of a portion of one X chromosome. Deletions involving the short (p) arm of the X chromosome (Xp22) produce short stature and congenital malformations, whereas deletions of the long arm (Xq) cause gonadal dysgenesis.

Although monosomy X is caused by nondisjunction, TS is not associated with advanced maternal age. Rather, it is believed that the 45,X karyotype results from a loss of either an X or a Y chromosome after conception; that is, it is a post-conceptual mitotic (rather than meiotic) nondisjunctional event.

SYNDROMES INVOLVING CHROMOSOMAL DELETIONS

Cri du Chat Syndrome

A deletion in the short arm of chromosome 5 is responsible for cri du chat syndrome, with its characteristic catlike cry during infancy, the result of tracheal hypoplasia. Other clinical features include low birthweight, postnatal failure to thrive, hypotonia, developmental disability, microcephaly, and craniofacial dysmorphism, including ocular hypertelorism, epicanthal folds, downward obliquity of the palpebral fissures, and low-set malformed ears. Clefts of the lip and palate, congenital heart disease, and other malformations may be seen.

The clinical severity of cri du chat syndrome depends on the size of the deletion, with larger deletions associated with more severe expression. Most cases arise de novo, with rare cases related to a balanced reciprocal chromosome translocation in a parent. When it arises de novo, the deletion is usually in chromosome 5 inherited from the father.

Williams Syndrome

Caused by a 1.55 megabase deletion in chromosome 7q11.2 that contains at least 28 genes, Williams syndrome is associated with a unique phenotype. Features associated with the condition include congenital heart disease (in 80%), with supravalvar aortic stenosis being the most common anomaly; growth delay with short stature; a distinctive facial appearance, with median flare of the eyebrows, fullness of the perioral and periorbital region, blue irides with a stellate pattern of pigment, and depressed nasal bridge with anteversion of the nares; moderate intellectual disability (average IQ 57) with strengths in personal social skills and deficiencies in cognitive areas; and hypercalcemia (in ~20%).

Individuals with Williams syndrome often have a striking personality. Loquacious and gregarious, they are often described as having a *cocktail party* personality. However, at least 10% of children with Williams syndrome have features of autism spectrum disorder. Patients occasionally have unusual musical ability. Most children with Williams syndrome have a de novo deletion. In rare cases, the deletion is inherited from a parent in an autosomal dominant pattern.

Aniridia Wilms Tumor Association

WAGR syndrome (**W**ilms tumor, **a**niridia, **g**enitourinary anomalies, and intellectual disability [formerly referred to as mental retardation]) is caused by a deletion of 11p13. The deletion usually arises de novo, with rare cases being associated with a balanced translocation in one of the parents. Genitourinary abnormalities include cryptorchidism and hypospadias. Patients often have short stature, and 50% have microcephaly. Wilms tumor develops in 50% of patients with WAGR syndrome (see Chapter 159).

Prader-Willi Syndrome

See Chapter 47.

Angelman Syndrome

See Chapter 47.

Chromosome 22q11.2 Deletion Syndromes (22q11DS)

Deletions of chromosome 22q11.2 are responsible for a group of findings that have been called by several names, including **velocardiofacial syndrome**, **conotruncal anomaly face syndrome**, **Shprintzen syndrome**, and **DiGeorge syndrome**. These conditions represent a continuum of findings, virtually all of which are due to the same chromosomal deletion.

Although 22q11DS can be inherited in an autosomal dominant fashion, most cases arise de novo. Common features include clefting of the palate with velopharyngeal insufficiency, conotruncal cardiac defects (including truncus arteriosus,

ventriculoseptal defect, tetralogy of Fallot, and right-sided aortic arch), and a facial appearance characterized by a prominent nose and broad nasal root. Speech and language difficulties are common, as is mild intellectual impairment. More than 200 additional abnormalities have been identified in individuals with these conditions. About 70% have immunodeficiency, largely related to T-cell dysfunction. A wide spectrum of psychiatric disturbances, including schizophrenia and bipolar disorder, has been seen in at least one third of affected adults.

Damage to the third and fourth pharyngeal pouches, embryonic structures that form parts of the cranial portion of the developing embryo, leads to abnormalities in the developing face (clefting of the palate, micrognathia), the thymus gland, the parathyroid glands, and the conotruncal region of the heart. This spectrum of findings, called the **DiGeorge malformation** sequence, is an important part of 22q11DS.

Confirmation of the deletion requires either fluorescence in situ hybridization (FISH) or chromosomal microarray analysis. The region, composed of about 3 million bases, contains between 30 and 40 genes. Although many of these deleted genes probably contribute to the phenotype, special attention has been focused on *TBX1* and *COMT*, which are believed to be responsible for many of the features of the condition.

SYNDROMES INVOLVING CHROMOSOME DUPLICATION

Duplications and deletions occur secondary to misalignment and unequal crossing over during meiosis. Small extra chromosomes are found in a small percentage of the population. These “marker” chromosomes may be associated with intellectual disabilities and other abnormalities, but they often have no apparent phenotypic effects.

Inverted Duplication Chromosome 15

Chromosome 15 is the most common of all marker chromosomes, and its inverted duplication accounts for almost 40% of this group of chromosomal abnormalities. Features seen in children with 47,XX,+inv dup (15q) or 47,XY,+inv dup (15q) depend on the size of the extra chromosomal material present: the larger the region, the worse the prognosis. Common features seen include varying degrees of developmental disability, autism spectrum disorders, seizures, and behavioral issues. Minimal dysmorphic features may be seen, including a sloping forehead, short and downward-slanting palpebral fissures, a prominent nose with a broad nasal bridge, a long and well-defined philtrum, a midline crease in the lower lip, and micrognathia.

Cat-Eye Syndrome

Named for the iris coloboma that gives patients' eyes a cat-like appearance, cat-eye syndrome is caused by the presence of a small extra chromosome composed of an inversion duplication of 22q11. The two copies of 22q11 on this extra chromosome plus the two normal copies of chromosome 22 result in four copies of this region. Although the colobomas name the syndrome, they occur in fewer than 50% of individuals with the marker chromosome. Other clinical features include mild intellectual disability, behavioral disturbances,

ocular hypertelorism, downward-slanting palpebral fissures, micrognathia, auricular pits and/or tags, anal atresia with rectovestibular fistula, and renal agenesis.

PEARLS FOR PRACTITIONERS

See *Human Genetics and Dysmorphology: Pearls for Practitioners* at the end of this section.

CHAPTER 50

Approach to the Dysmorphic Child

Dysmorphology is the study of congenital malformation and the recognition of patterns of malformations that occur in syndromes (Table 50.1).

Syndromes are collections of abnormalities, including **malformations**, **deformations**, dysmorphic features, and abnormal behaviors that result from a unifying, identifiable etiology. This etiology may be the presence of a pathogenic variant (mutation) in a single gene, as is the case in **Rettsyndrome**, a disorder caused by a mutation in *MECP2*, a gene on Xq28; by the deletion or duplication of genetic material, as in **Prader-Willi syndrome**, caused by the deletion of the paternal copy of the *SNRPN* gene on chromosome 15q11.2; or by exposure to a teratogenic substance during embryonic development, as in fetal alcohol spectrum disorder.

DEFINITIONS

Congenital **malformations** are defined as clinically significant abnormalities in either form or function that are identifiable at birth. They result from localized **intrinsic** defects in morphogenesis, which were caused by an event that occurred in embryonic or early fetal life. This event may have been a disturbance of development from some unknown cause, but often mutations in developmental genes lead to the abnormality. **Extrinsic** factors may cause **disruptions** of development resulting from disturbances to the development of apparently normal tissues. These disruptions may include amniotic bands, disruption of blood supply to developing tissues, or exposure to teratogens. A **malformation sequence** is a spectrum of abnormalities, including malformations, deformations, and disruptions that result from the effects of a single malformation. For instance, in the **Pierre Robin sequence**, a primary malformation, the failure of growth of the mandible during the first weeks of gestation results in micrognathia, which forces the normal-sized tongue into an unusual position. The abnormally positioned tongue blocks the fusion of the palatal shelves, which normally come together in the midline to produce the hard and soft palate; this leads to the presence of a U-shaped cleft palate. After delivery, the normal-sized tongue in the smaller-than-normal sized oral cavity leads to airway obstruction, a potentially life-threatening complication.

Malformation sequences can occur alone or may be part of a multiple malformation syndrome. For instance, individuals

TABLE 50.1 Glossary of Selected Terms Used in Dysmorphology**TERMS PERTAINING TO THE FACE AND HEAD**

Brachycephaly: Condition in which head shape is shortened from front to back along the sagittal plane; the skull is rounder than normal

Canthus: The lateral or medial angle of the eye formed by the junction of the upper and lower lids

Columella: The fleshy tissue of the nose that separates the nostrils

Glabella: Bony midline prominence of the brows

Nasal alae: The lateral flaring of the nostrils

Nasolabial fold: Groove that extends from the margin of the nasal alae to the lateral aspects of the lips

Ocular hypertelorism: Increased distance between the pupils of the two eyes

Palpebral fissure: The shape of the eyes based on the outline of the eyelids

Philtrum: The vertical groove in the midline of the face between the nose and the upper lip

Plagiocephaly: Condition in which head shape is asymmetric in the sagittal or coronal planes; can result from asymmetry in suture closure or from asymmetry of brain growth

Scaphocephaly: Condition in which the head is elongated from front to back in the sagittal plane; most normal skulls are scaphocephalic

Synophrys: Eyebrows that meet in the midline

Telecanthus: A wide space between the medial canthi

TERMS PERTAINING TO THE EXTREMITIES

Brachydactyly: Condition of having short digits

Camptodactyly: Condition in which a digit is bent or fixed in the direction of flexion (a “trigger finger”-type appearance)

Clinodactyly: Condition in which a digit is crooked and curves toward or away from adjacent digits

Hypoplastic nail: An unusually small nail on a digit

Melia: Suffix meaning “limb” (e.g., amelia—missing limb; brachymelia—short limb)

Polydactyly: The condition of having six or more digits on an extremity

Syndactyly: The condition of having two or more digits at least partially fused (can involve any degree of fusion, from webbing of skin to full bony fusion of adjacent digits)

with Pierre Robin sequence may have it as part of **Stickler syndrome**, an autosomal dominant disorder caused by mutations in collagen genes. Stickler syndrome also manifests with ocular and musculoskeletal abnormalities.

Deformations arise as a result of environmental forces acting on normal structures. They occur later in pregnancy or after delivery. For instance, **plagiocephaly** (rhomboid-shaped head) may result from intrauterine positioning or from torticollis experienced in the newborn period. Deformations often resolve with minimal intervention, but malformations often require surgical and medical management.

Minor malformations, variants of normal that occur in less than 3% of the population, include findings such as single transverse palmar creases, low-set ears, or ocular hypertelorism (wide-spaced eyes); when isolated, they have no clinical significance. A **multiple malformation syndrome** is the recognizable pattern of anomalies that results from a single identifiable underlying cause. It may involve a series of malformations, malformation sequences, and deformations. These syndromes often prompt a consultation with a clinical geneticist.

An **association** is a recognizable pattern of anomalies that occur together more often than would be expected by chance alone, but no single underlying etiology has been identified. The **VACTERL** association (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb anomalies) is an example of a group of malformations that occur more commonly together than might be expected by chance. No single unifying etiology explains this condition, so it is considered an association.

About 3% of live births have congenital malformations. These are due to chromosomal abnormalities, single gene defects, multifactorial effects, or exposure to teratogens. The cause of many malformations is often unknown.

HISTORY AND PHYSICAL EXAMINATION**Pregnancy History**

In attempting to solve the puzzle, the history of the pregnancy and birth can reveal multiple factors that may prove helpful to the dysmorphologist. Infants who are small for gestational age may have a chromosome anomaly or may have been exposed to a teratogen. Large for gestational age infants may be infants of diabetic mothers or have an overgrowth syndrome, such as Beckwith-Wiedemann syndrome. When evaluating an older child with intellectual disabilities, complications of extreme prematurity may account for the child's problems. Postmaturity also is associated with some chromosome anomalies (e.g., trisomy 18) and anencephaly. Infants born from breech presentation are more likely to have congenital malformations than those born from vertex presentation.

As a woman gets older, there is increased risk of nondisjunction leading to trisomies. Advanced paternal age may be associated with the risk of a new mutation leading to an autosomal dominant trait. Maternal medical problems and exposures (medications, drugs, cigarette smoking, and alcohol use) are associated with malformations (see [Chapters 48 and 59](#)).

An increased amount of amniotic fluid may be associated with intestinal obstruction or a central nervous system anomaly that leads to poor swallowing. A decreased amount of fluid may be the result of a chronic amniotic fluid leak or point to a urinary tract abnormality that results in a failure to produce urine.

Family History

A pedigree comprising at least three generations should be constructed, searching for similar or dissimilar abnormalities in first- and second-degree relatives. A history of pregnancy

or neonatal losses should be documented. For a more detailed discussion of pedigrees, see [Chapter 47](#).

Physical Examination

When examining children with dysmorphic features, the following approach should be used.

Growth

The height (length), weight, and head circumference should be measured carefully and plotted on appropriate growth curves.

The clinician should note if the child is proportionate. Limbs that are too short for the head and trunk imply the presence of a short-limbed bone dysplasia, such as achondroplasia. A trunk and head that are too short for the extremities suggest a disorder affecting the vertebrae, such as spondyloepiphyseal dysplasia.

Craniofacial

Careful examination of the head and face is crucial for the diagnosis of many congenital malformation syndromes. Head shape should be carefully assessed; if the head is not normal in size and shape (normocephalic), it may be long and thin (**dolichocephalic**), short and wide (**brachycephalic**), or asymmetric or lopsided (**plagiocephalic**).

Any asymmetry of facial features should be noted. Asymmetry may be due to a deformation related to intrauterine position or a malformation of one side of the face. The face should be divided into four regions, which are evaluated separately. The **forehead** may show overt prominence as with achondroplasia, or deficiency (often described as a sloping appearance, which occurs in children with primary microcephaly). The **midface**, extending from the eyebrows to the upper lip and from the outer canthi of the eyes to the commissures of the mouth, is especially important. Careful assessment of the distance between the **eyes** (inner canthal distance) and the pupils (interpupillary distance) may confirm the impression of hypotelorism (eyes that are too close together), which suggests a defect in midline brain formation, or **hypertelorism** (eyes that are too far apart). The length of the palpebral fissure should be noted and may help define whether the opening for the eye is short, as is found with fetal alcohol syndrome, or excessively long, as in **Kabuki syndrome** (short stature, intellectual disability, long palpebral fissures with eversion of lateral portion of lower lid).

Other features of the eyes should be noted. The obliquity (slant) of the palpebral fissures may be upward (as seen with Down syndrome) or downward (as in Treacher Collins syndrome). The presence of epicanthal folds (Down syndrome and fetal alcohol syndrome) is also important. Features of the **nose**—especially the nasal bridge, which can be flattened in Down syndrome, fetal alcohol syndrome, and many other syndromes, or prominent as in velocardiofacial (22q11 deletion) syndrome—should be noted.

The **malar** region of the face is examined next. It extends from the ear to the midface. The ears should be checked for size (measured and checked against appropriate growth charts), shape, position (low-set ears are below a line drawn from the outer canthus to the occiput), and orientation (posterior rotation is where the ear appears turned toward the rear of the head). Ears may be low set because they are small (or microtic) or because of a malformation of the mandibular region.

The **mandibular region** is the area from the lower portion of the ears bounded out to the chin by the mandible. In most newborns, the chin is often slightly retruded (i.e., slightly behind the vertical line extending from the forehead to the philtrum). If this retrusion is pronounced, the child may have the Pierre Robin malformation sequence. In addition, the mouth should be examined. The number and appearance of the teeth should be noted, the tongue should be observed for abnormalities, and the palate and uvula checked for defects.

Neck

Examination of the neck may reveal webbing, a common feature in Turner and Noonan syndromes, or shortening, as is seen occasionally in some skeletal dysplasias and in conditions in which anomalies of the cervical spine occur, such as Klippel-Feil syndrome. The position of the posterior hairline also should be evaluated. The size of the thyroid gland should be assessed.

Trunk

The chest may be examined for shape (shieldlike chest in Noonan and Turner syndromes) and for symmetry. The presence of a pectus deformity should be noted and is common in Marfan syndrome. The presence of scoliosis should be assessed; it is common in Marfan syndrome and many other syndromes.

Extremities

Many congenital malformation syndromes are associated with anomalies of the extremities. All joints should be examined for range of motion. The presence of single or multiple joint contractures suggests either intrinsic neuromuscular dysfunction, as in some forms of muscular dystrophy, or external deforming forces that limited motion of the joint in utero. Multiple contractures also are found with **arthrogryposis multiplex congenita** and are due to a variety of causes. **Radioulnar synostosis**, an inability to pronate or supinate the elbow, occurs in fetal alcohol spectrum disorder and in some X chromosome aneuploidy syndromes.

Examination of the hands is important. **Polydactyly** (the presence of extra digits) usually occurs as an isolated autosomal dominant trait but also can be seen in trisomy 13. **Oligodactyly** (a deficiency in the number of digits) is seen in Fanconi anemia (see [Chapter 150](#)) in which it is generally part of a more severe limb reduction defect, or secondary to intrauterine amputation, which may occur with amniotic band disruption sequence. **Syndactyly** (a joining of two or more digits) is common to many syndromes, including Smith-Lemli-Opitz syndrome.

Dermatoglyphics include palmar crease patterns. A transverse palmar crease, indicative of hypotonia during early fetal life, is seen in approximately 50% of children with Down syndrome (and 10% of individuals in the general population). A characteristic palmar crease pattern is also seen in fetal alcohol spectrum disorder.

Genitalia

Genitalia should be examined closely for abnormalities in structure. In boys, if the penis appears short, it should be measured and compared with known age-related data. Ambiguous genitalia often are associated with endocrinologic disorders, such as congenital adrenal hyperplasia, or chromosomal

disorders such as 45,X/46,XY mosaicism or possibly secondary to a multiple congenital anomaly syndrome (see [Chapter 177](#)). Although hypospadias, which occurs in 1 in 300 newborn boys, is a common congenital malformation that often occurs as an isolated defect, if it is associated with other anomalies, especially cryptorchidism, there is a strong possibility of a syndrome.

LABORATORY EVALUATION

Chromosome analysis should be ordered for children with multiple congenital anomalies, the involvement of one major organ system and the presence of multiple dysmorphic features, or the presence of intellectual disability. *Microarray comparative genomic hybridization has supplanted routine or high-resolution chromosome analysis in most situations.* For a complete discussion of chromosome analysis, see [Chapter 48](#).

DNA sequencing technologies can be utilized to identify specific pathogenic variants. It is necessary to use web-based resources to keep up to date. Helpful websites include <https://www.ncbi.nlm.nih.gov/gtr/> (government) and www.concertgenetics.com (commercial) which provide information about the availability of testing for specific conditions and identify laboratories performing testing.

Exome sequencing (ES) has begun to supplant targeted sequencing approaches for identification of pathogenic variants associated with an individual's specific phenotype. In this technique, analysis of all coding sequences (exomes) of all genes within the genome is performed. For a description of this and related techniques, please see discussion in [Chapter 48](#).

Radiologic imaging plays an important role in the evaluation of children with dysmorphic features. Individuals found to have multiple external malformations should have a careful evaluation to search for the presence of internal malformations. Testing includes **ultrasound exams** of the head and abdomen to look for anomalies in the brain, kidney, bladder, liver, and spleen. **Skeletal radiographs** should be performed if there is concern about a possible skeletal dysplasia. The presence of a heart murmur should trigger a cardiology consultation; an **electrocardiogram** and **echocardiogram** may be indicated. **MRI** may be indicated in children with neurologic abnormalities or a spinal defect. Suspicion of craniosynostosis may warrant a **CT scan** of the head.

For those patients for whom testing does not yield a diagnosis, exome sequencing or whole genome sequencing are powerful tools.

DIAGNOSIS

Although the presence of characteristic findings may make the diagnosis of a multiple malformation syndrome straightforward, in most cases no specific diagnosis is immediately evident. Some constellations of findings are rare and finding a “match” may prove difficult. In many cases, all laboratory tests

are normal, and confirmation relies on subjective findings. Clinical geneticists have attempted to resolve this difficulty by developing scoring systems, cross-referenced tables of anomalies that help in the development of a differential diagnosis, and computerized diagnostic programs. An accurate diagnosis is important for the following reasons:

1. It offers an explanation to the family why their child was born with congenital anomalies. This may help allay guilt for parents, who often believe they are responsible for their child's problem.
2. With well-described natural histories of many disorders, a diagnosis allows anticipation of medical problems associated with a particular syndrome and appropriate screening. It also provides reassurance that other medical problems are no more likely to occur than they might with other children who do not have the diagnosis.
3. It permits genetic counseling to be done to identify the risk to future children and permits prenatal testing to be done for the disorders for which it is available.

Diagnosis enables the clinician to provide the family with educational materials about the diagnosis and facilitate contact with support groups for particular disorders. The Internet has become an important source for such information. Care should be exercised, as information on the Internet is not subject to editorial control and may be inaccurate. A good site is the National Organization for Rare Disorders (<http://www.rarediseases.org>), a clearinghouse for information about rare diseases and their support groups. Genetic testing information is available at the National Institutes of Health (NIH) testing website (<https://www.ncbi.nlm.nih.gov/gtr/>) or at a commercial website (www.concertgenetics.com).

PEARLS FOR PRACTITIONERS

CHAPTER 47

Patterns of Inheritance

DNA Basics

- The four DNA nucleotides—adenine, guanine, thymine, and cytosine—are linked together to form a DNA strand.
- Two strands form a DNA molecule.
- Pyrimidines (thymine and cytosine) are cross linked to purines (adenosine and guanine) by hydrogen bonds.
- Chromosomes are strands of DNA wound tightly with a protein skeleton (chromatin) and histones.
- Human cells have 23 pairs of chromosomes, one set of 23 from each parent.
- Twenty-two of the chromosomes are autosomes, and the 23rd pair are the sex chromosomes. Females have two X chromosomes (46,XX), and males have a Y chromosome (46,XY).
- Genes are stretches of DNA that code for a protein. A typical gene has a promoter sequence, an untranslated region, and an open reading frame.
- Every three nucleotides represent a single codon that codes for a particular amino acid.
- Some codons act as a start signal and others as a stop signal for transcription.
- Within the gene there are regions—exons—that code for the sequence of the protein, and introns, which are not incorporated into the transcribed messenger RNA (mRNA) but may have important regulatory roles.
- Less than 2% of the 3.1 billion DNA bases code for proteins. These regions represent about 20,000–24,000 genes. Alternative splicing of the transcribed mRNA can generate a possible 100,000 proteins.
- Changes in the DNA sequence (variants) can lead to changes in the amino acid in a protein (missense variant or mutation) or to a premature stop codon (nonsense variant or mutation).
- A third change in the DNA is frameshift variant, which is the result of the addition or deletion of one or more DNA bases that “shift” the reading frame of the codons usually resulting in production of a new stop codon that is before the end of the gene and is considered “premature.”

Pedigrees

- Pedigrees are symbolic depictions of a family’s history with symbols for males (squares) and females (circles).
- Pedigrees permit a quick visual determination of an inheritance pattern in a family.

Autosomal Dominant Disorders

- A single copy of a mutation not on a sex chromosome that results in disease.
- Affected parents have a 50% chance of passing mutation on to each child.
- The phenomenon where some patients with the mutation show clinical symptoms and others may not is called penetrance. Many autosomal dominant (AD) disorders can show decreased penetrance.

- Variable expressivity describes the phenomenon where different family members may vary in the severity of clinical symptoms and which clinical symptoms manifest.
- Often, patients with an AD disorder may be new mutations (they have unaffected parents).

Autosomal Recessive Disorders

- Both copies of gene on a non-sex chromosome have a mutation.
- Affected patients usually have unaffected parents, each of whom is a carrier for the disorder.

X-linked Disorders (General)

- Females have two copies of the X chromosome; males have one X chromosome and a Y chromosome.
- The X chromosome has approximately 2,000 genes, the Y about 200.
- Females randomly inactivate one of their X chromosomes (lyonization).

X-linked Recessive Inheritance

- Most X chromosome disorders show recessive inheritance.
- Males, having one X chromosome, are more likely to manifest disease than females.
- Sons of carrier females have a 50% chance of being affected; daughters have a 50% chance of being a carrier.
- Daughters of affected males have a 50% chance of being a carrier; all sons are unaffected.

X-linked Dominant

- Females with these disorders show symptoms.
- Females are usually less affected than males due to X chromosome inactivation.
- Some X-linked dominant disorders are lethal in males with death before birth.

Mitochondrial Inheritance

- Mitochondrial DNA (mtDNA) replicates independently from nuclear DNA.
- Virtually all mitochondria are supplied by the oocyte.
- mtDNA has a few genes that code for respiratory complex proteins (most are coded on the nuclear DNA) and a set of tRNAs that are needed for protein synthesis within the mitochondria.
- Disorders involving the mtDNA are maternally inherited.
- There are many mitochondria in each cell. If the DNA is different in some of these mitochondria (two populations), this is referred to as heteroplasm.
- Some disorders are due to loss or deficiency of mitochondria. This is referred to as mitochondrial depletion.

Uniparental Disomy

- Patients with uniparental disomy have a normal karyotype with a normal number of chromosomes.
- Both copies of the affected chromosome will come from one parent—without a copy from the other parent.
- Some genes are methylated (“inactivated”) depending on their parental origin. Uniparental disomy might result in both copies of the gene being inappropriately activated or inactivated.

Multifactorial Inheritance

- Result from the interplay of genetic and environmental factors.
- About 20% of congenital malformations are due to multifactorial inheritance.
- Disorders include asthma, atherosclerosis, diabetes, and cancer.
- Do not follow Mendelian rules of inheritance but occur in first- and second-degree relatives more frequently than would be expected by chance and are more likely to be concordant in monozygotic twins than dizygotic twins.

Nucleotide Repeats

- Much of human DNA consists of two or three DNA bases repeated over and over.
- Some disorders are due to expansion of trinucleotide repeats (fragile X syndrome, Huntington disease, myotonic dystrophy, Friedreich ataxia, and the spinocerebellar ataxias).

Exposure to Teratogenic Agents

- Up to 15% of birth defects can be attributed to exposure to teratogens.
- Teratogens can be chemical, physical, or biologic.
- Examples include alcohol, infections, and lead.

CHAPTER 48

Genetic Assessment and Diagnosis

- Individuals referred to a geneticist because of suspicion of a genetic disease are called **probands**.
- **Consultands** are individuals referred for genetic counseling.
- There are many reasons for referral to genetics. Referral may occur at different stages of life (fetus, neonate, childhood, pregnancy, or adulthood).

Preconception and Prenatal Counseling

- Families with relatives affected with a genetic disorder may wonder if their children are at risk.
- A family history may uncover a pattern of inheritance. A known disorder will have a pattern of inheritance that can be discussed with a geneticist or genetic counselor.
- **Consanguinity** is when couples are related. This increases the likelihood that offspring could be born with a rare autosomal recessive condition.
- Couples may be screened for disorders that affect their particular ethnic group (Western and sub-Saharan African ancestry may suggest screening for sickle cell, Mediterranean ancestry screening for thalassemia, Ashkenazi Jewish ancestry screening for Tay-Sachs, Gaucher).
- Next-generation sequencing has made screening for whole panels of genes relatively inexpensive.

Prenatal Screening and Prenatal Testing

- Screening helps identify an increased risk for an abnormality.
- Many pregnant women are screened to see if they are carriers for sickle cell disease, cystic fibrosis, and increasingly, spinal muscular atrophy (SMA).
- First trimester screening—a maternal blood test to measure PAPP-A (pregnancy-associated plasma protein A) and human chorionic gonadotropin (HCG) together with measurement of the fetus's nuchal (neck) fold by

ultrasound—can be used to assess risk for chromosomal abnormality (Down syndrome) and possible cardiac abnormalities.

- Second trimester maternal serum screening (quad screen) measures AFP (α -fetoprotein), uE3 (unconjugated estriol), inhibin A, and HCG.
- Abnormal first and second trimester screening reveals an increased risk. Diagnostic testing on cells from amniocentesis or chorionic villus sampling (CVS) may be suggested as follow-up.
- If the parents are found to be carriers of a recessive disease, testing of the amniocytes can determine if the fetus is affected.
- The use of cell-free fetal DNA (cfDNA) from a maternal blood sample is quickly replacing other screening tests for chromosomal aneuploidy.
- Abnormalities on noninvasive prenatal screening (NIPS) with cfDNA from a maternal blood sample require confirmation by amniocentesis.
- Screening for fetal malformations by ultrasound is performed in the second trimester.

Postnatal—Newborn and Infant

- Of newborns, 2–4% may have a genetic abnormality or “birth defect.”
- This includes malformations (2–3%), inherited disorders (1%), and chromosomal abnormalities (0.5%).
- Consultation with a geneticist may be prompted by the presence of a malformation, abnormal newborn screening results, abnormalities of growth (poor weight gain, poor linear growth, poor head growth), developmental delay, blindness or deafness, or a family history of a genetic disorder.

Adolescent and Adult

- Adolescents and adults may be referred for evaluation of a later onset genetic disorder. Many neurodegenerative disorders have onset later in life (e.g., Huntington disease, spinocerebellar ataxia, and spinal muscular atrophy).
- A family history of a hereditary cancer (breast, colon, thyroid) may also prompt an evaluation by a geneticist.

General Approach to Patients

- Family History
 - A pedigree is drawn to look for a pattern of inheritance.
 - If there is suspected new onset of an autosomal disorder, examine the parents carefully for signs of the disorder.
 - If a new mutation, recurrence risk is about 1% due to gonadal mosaicism.
 - If one of the parents is even mildly affected, the recurrence risk is 50%.
 - For prenatal counseling, the age of the couple is important.
 - Increased paternal age has an increased risk for AD and X-linked disorders.
 - Increased maternal age has an increased risk for chromosomal disorders.
- Pregnancy History
 - Exposure to teratogens (medications, alcohol, infections) can lead to malformations.
 - Poor fetal movement may suggest neurologic abnormalities.
 - A history of low or absent amniotic fluid (oligohydramnios) or high levels of amniotic fluid (polyhydramnios) may suggest neurologic, pulmonary, or renal problems for the infant.

- Birth History
 - Premature infants have more complications than term infants.
 - The size of the infant—small for gestational age or large for gestational age—has implications for different genetic disorders.
 - Underlying disorders may predispose to a difficult delivery.
 - Resuscitation in the delivery room has implications for growth and development.
- Medical History
 - Children with recurrent hospitalizations for vomiting and dehydration may suggest an inborn error of metabolism.
 - Children with neuromuscular disorders may have a normal period followed by increasing weakness or ataxia.
 - Children with lysosomal storage disorders will have worsening symptoms with increasing age, often having a history of frequent otitis media and may develop sleep apnea.
 - Evaluation of growth may reveal poor prenatal and postnatal growth, good prenatal and poor postnatal growth, or acquired microcephaly or macrocephaly, all of which suggest different underlying genetic disorders.
- Development
 - Many genetic disorders are associated with delays in development.
 - Sometimes development is normal for a period of time, then slows, and is then followed by regression that can suggest a lysosomal storage disorder.
- Physical Exam
 - A careful physical exam is necessary for all patients with signs, symptoms, or suspicion of genetic disease.
 - Anomalous (dysmorphic) features may suggest an underlying genetic syndrome.

Laboratory Evaluation

- Chromosome Analysis
 - Routine chromosome analysis during prophase was the standard way of analyzing chromosome number and large chromosome aberrations.
 - It remains the only way to identify balanced chromosome rearrangements.
 - Chromosomal microarray (array CGH) has supplanted routine cytogenetic techniques for chromosome analysis.
 - Fluorescence in situ hybridization (FISH) uses small DNA probes to identify copy number of common chromosome deletions. It is also helpful to determine complex chromosomal rearrangements.
- DNA Sequencing
 - Sequencing of genes involved in many genetic disorders is now often possible. Several websites offer assistance to find labs that do specific gene tests.
 - Sequencing can assess a single gene, a group of genes related to a patient's phenotype (panel testing), or can assess all of the exons contained in the 20,000–24,000 human genes (exome sequencing [ES]).
 - Whole genome sequencing (WGS) involves sequencing both the exonic and intronic regions of a patient's genome.

- ES and WGS help identify potential causes for undiagnosed genetic disorders; however, analysis and interpretation are complex.

CHAPTER 49

Chromosomal Disorders

- Errors in meiosis lead to abnormalities of chromosome structure or number (aneuploidy).
- Common syndromes caused by abnormalities of chromosome number include the following: Down syndrome, trisomy 13, trisomy 18, Turner syndrome, Klinefelter syndrome.

Down Syndrome

- Most common chromosome abnormality in liveborn infants.
- About 95% are due to nondisjunction, 3% are due to Robertsonian translocations—a fusion of two acrocentric chromosomes (most commonly chromosomes 21 and 14).
- Characteristic facial features, hypotonia, and congenital heart disease (40%) are noted in the neonatal period.

Trisomy 18

- Second most common autosomal trisomy.
- Most trisomy 18 conceptions end in spontaneous abortion. Less than 12% of those born will survive to 1 year of age.

Trisomy 13

- Usually fatal in the first year of life (<20% survive).
- Small for gestational age, midline facial defects, postaxial polydactyly, clubfeet, scalp lesions (cutis aplasia).

Klinefelter

- 1:580 males.
- Most common cause of infertility in men.
- Hypogonadism results in lack of secondary sexual characteristics.

Turner Syndrome

- Turner syndrome is the only monosomy that survives to term.
- Most common chromosomal abnormality in conceptuses.
- Somewhat characteristic facial features, with webbed neck, shieldlike chest, and short stature. Coarctation of the aorta, horseshoe kidney, hypothyroidism, and infertility are also associated.

Cri du chat

- Due to the partial deletion of the short arm of chromosome 5. Larger deletions are more severe.
- Catlike cry.

Williams Syndrome

- Deletion of 7q11.2.
- Distinctive facial appearance, moderate intellectual disability, verbal skills above their deficiencies in other areas. Supravalvar aortic stenosis is associated.

22q11 Deletion Syndrome (DiGeorge, Velocardiofacial Syndrome)

- Cleft palate, velopharyngeal insufficiency.
- Conotruncal cardiac defects (truncus arteriosus, ventricular septal defect [VSD], tetralogy of Fallot).

CHAPTER 50

Approach to the Dysmorphic Child

- Dysmorphology is the study of congenital malformations and the patterns of malformations that occur in syndromes.
- Syndromes are collections of abnormalities (malformations, deformations, dysmorphic features, and abnormal behaviors) that are associated with an identifiable etiology.
- Syndromes may be due to a mutation, a deletion or duplication of a chromosome, or by exposure to a teratogen.
- Congenital **malformations** that are the result of intrinsic defects in morphogenesis are identifiable at birth.
- **Deformations** are due to environmental forces acting on normal structures.
- An **association** is a pattern of anomalies with no clear underlying etiology that occurs more frequently than by chance alone.

History and Physical Examination

- Elements of the history and physical often provide information that leads to a diagnosis.
- Pregnancy
 - Growth of fetus (small or large for gestational age), premature or postmature, fetal movement, amount of amniotic fluid (oligohydramnios or polyhydramnios), exposure to drug and environmental toxins, maternal age.
- Family History
 - Important clues about a pattern of inheritance can be determined from the family history.
- Physical Exam
 - Growth
 - Height, weight, and head circumference should be plotted on age-appropriate growth curves.
 - Craniofacial
 - Assess head shape, asymmetry.
 - Face can be divided into four regions (forehead, mid-face, malar, and mandibular), each of which requires close examination.

- Neck
 - Length, webbing, posterior hairline, thyroid gland should be assessed.
- Trunk
 - Chest shape—shieldlike, pectus deformity.
 - Scoliosis.
- Extremities
 - Joints should be assessed for range of motion, contractures.
 - Number of fingers and toes, their size, and shape (polydactyly, oligodactyly, syndactyly).
- Genitalia
 - Normal male or female, ambiguous.
 - Size, presence of testicles in males, and their size.

Laboratory Evaluation

- Chromosome Analysis
 - Usually done by chromosomal microarray.
- DNA Analysis (Sequencing)
 - For individual genes or sometimes panels of genes related to a family of disorders.
- Exome Sequencing and Whole Genome Sequencing
 - Useful for undiagnosed disorders.
- Radiologic Imaging
 - Individuals with external malformations need a careful evaluation for internal malformations.
 - Ultrasound (head in neonates, abdomen, kidneys).
 - Skeletal radiographs for possible skeletal dysplasias, lysosomal storage disorders.
 - MRI for children with possible neurologic abnormalities or spinal defects.
 - CT of the skull for craniofacial abnormalities.
- A genetic diagnosis is important for the following reasons:
 - Allays guilt of parents.
 - Diagnosis with a particular disorder may permit screening for medical problems.
 - May permit treatment for disorder.
 - Permits genetic counseling for future pregnancies.

METABOLIC DISORDERS

Michael Muriello

CHAPTER 51

Metabolic Assessment

Optimal outcomes for children with inborn errors of metabolism (IEMs) depend upon recognition of the signs and symptoms of metabolic disease and prompt evaluation and referral to a center familiar with their management. Delay in diagnosis may result in end-organ damage including progressive neurologic injury or death.

With the exception of phenylketonuria (PKU) and medium-chain acyl-CoA dehydrogenase (MCAD) deficiency, most metabolic disorders are individually rare with an incidence of less than 1 per 100,000 births in the United States. When considered collectively, the incidence may approach 1 in 800–2,500 births (Table 51.1); the prevalence of a confirmed metabolic disorder detected by newborn screening is 1 in 4,000 live births (about 12,500 diagnoses each year) in the United States. This is comparable with the 1 in 1,000 infants who have early-onset bacterial sepsis and the 1 in 3,000 infants who have invasive group B streptococcal infections.

IEMs are frequent causes of sepsislike presentations, intellectual disability, seizures, sudden infant death, and neurologic impairment. There are at least 89 identified IEMs that are amenable to therapy targeted to the underlying cause, many of which can present with intellectual disability as a prominent feature.

Metabolic disorders can be classified using a variety of schemes based on the clinical presentation, including the age of onset, the tissues or organ systems involved, the defective metabolic pathways, or the subcellular localization of the underlying defect. These classification schemes have differing utility when considering the approach to diagnosis, management, and screening strategies. The clinical presentation and long-term prognosis have the most bearing on management of children with genetic metabolic disorders.

Genetic metabolic disorders result from the deficiency (or overactivity) of an enzyme, its cofactors, or biochemical transporters that lead to the deficiency of a required metabolite, the buildup of a toxic compound, or a combination of both processes (Fig. 51.1; Table 51.2). Understanding which of these mechanisms is involved and if the effects are systemic or restricted to the local tissue enables a rational approach to diagnosis, therapy, and management.

When an IEM is identified or suspected, consultation with a medical geneticist is recommended. Long-term management of patients with IEMs may require frequent surveillance,

diet and medication adjustments, and is best conducted by a center with experience with IEMs.

SIGNS AND SYMPTOMS

The signs and symptoms of an inborn error are diverse and can involve any organ system. The presentation varies among age groups. IEMs often present a few hours to weeks after birth and can mimic late-onset sepsis. Infants who survive the neonatal period without developing recognized symptoms often experience intermittent illness separated by periods of being well. While pursuing the evaluation of the specific clinical presentations (e.g., the approach to the sick newborn, irritable child, or child with liver dysfunction), the hypoglycemic and intoxicating (encephalopathy) metabolic disorders should be considered in all neonates presenting with lethargy, poor tone, poor feeding, hypothermia, irritability, or seizures. In most cases, these should be evaluated by assessment of plasma ammonia, blood glucose, lactate, and anion gap (Fig. 51.2). Assessment of creatinine, transaminases, urine ketones, and blood counts may also be indicated. Significant ketosis in the neonate is unusual and suggests an organic acid disorder. Similarly, specific metabolic disorders predispose to cardiomyopathy, myopathy, liver dysfunction, developmental delay, seizures, sepsis, and developmental regression; appropriate evaluation should be tailored to the clinical presentation. When multiple organ systems are affected with typical complications, an IEM is more likely.

Obtaining a detailed history of events preceding the onset of symptoms is critical to making a diagnosis. Introduction of new foods or metabolic stress associated with fasting, serious infection, or fever may unmask an IEM during infancy or in older children. The introduction of fructose or sucrose in the diet may lead to decompensation in a child with hereditary fructose intolerance. In older children, increased protein intake may unmask disorders of ammonia detoxification (urea cycle disorders).

TYPES OF CLINICAL PRESENTATION OF INBORN ERRORS

Toxic Presentation

The toxic presentation often presents as an **encephalopathy**. Fever, infection, fasting, or other catabolic stresses may precipitate the symptom complex. **Metabolic acidosis**, vomiting, lethargy, and other neurologic findings may be present. Diagnostic testing is most effective when metabolites are present in highest concentration in blood and urine at presentation.

TABLE 51.1 Estimates of Incidence of Various Classes of Disorders Diagnosed or Followed at Specialized Clinics per 100,000 Population

	BRITISH COLUMBIA 1969–1996	WEST MIDLANDS 1999–2003
Amino acid disorders (excluding phenylketonuria)	7.5	19
Lysosomal storage diseases	7.5	19
Phenylketonuria	7.5	8
Organic acidemias	4	12.5
Peroxisomal disorders	3.5	7.5
Mitochondrial diseases	3	20
Glycogen storage diseases	2	7
Urea cycle diseases	2	4.5

*Populations in British Columbia, Canada (a predominantly White population), between 1969 and 1996, and in the West Midlands of the United Kingdom (which has a diverse ethnic breakdown) between 1999 and 2003.

FIGURE 51.1 Depiction of the basic paradigm in inherited disorders of metabolism. Deficiency of an enzyme complex results in accumulation of metabolites proximal to the blocked metabolism and deficiency of the product of the reaction. Sites of genetic control are indicated.

Abnormal metabolism of amino acids, organic acids, ammonia, or carbohydrates may be at fault. **Hyperammonemia** is an important diagnostic possibility if an infant or child presents with features of toxic encephalopathy (see Fig. 51.2). Symptoms and signs depend on the underlying cause of the hyperammonemia, the age at which it develops, and its degree. The severity of hyperammonemia may provide a clue to the etiology (Tables 51.3 and 51.4). In infants and neonates, IEMs can present as a brief resolved unexplained event (BRUE), sudden infant death syndrome (very rare in general, consider if no newborn screening was performed), or fetal hydrops.

Severe Neonatal Hyperammonemia

Infants with genetic defects in urea synthesis, transient neonatal hyperammonemia, and impaired synthesis of urea and glutamine secondary to genetic disorders of organic acid metabolism can have levels of blood ammonia ($>1,000 \mu\text{mol/L}$) more than 10 times normal in the neonatal period. Poor feeding, hypotonia, apnea, hypothermia, and vomiting rapidly give way to **coma** and occasionally to intractable seizures. *Respiratory alkalosis is common.* Death occurs in hours to days

if the condition remains untreated. The duration and severity of untreated hyperammonemia correlate with long-term neurologic outcomes.

Moderate Neonatal Hyperammonemia

Moderate neonatal hyperammonemia (range, 200–400 $\mu\text{mol/L}$) is associated with depression of the central nervous system, poor feeding, and vomiting. Seizures are not characteristic. Respiratory alkalosis may occur. This type of hyperammonemia may be caused by partial or more distal blocks in urea synthesis and, commonly, is caused by disorders of organic acid metabolism (associated with a more prominent metabolic acidosis) that secondarily interfere with the elimination of nitrogen.

Clinical Hyperammonemia in Later Infancy and Childhood

Infants who are affected by defects in the urea cycle may continue to do well while receiving the low-protein intake of breast milk, developing clinical hyperammonemia when dietary protein is increased, or when catabolic stress occurs. Vomiting and lethargy may progress to coma. Seizures are not typical. During a crisis, the plasma ammonia level is usually 200–500 $\mu\text{mol/L}$. However, as the ammonia level decreases with decreased protein intake, the condition may go unrecognized for years, especially in the absence of specific central nervous system symptoms. If a crisis occurs during an epidemic of influenza, the child may be mistakenly thought to have **Reye syndrome**. Older children may have neuropsychiatric or behavioral abnormalities (see Fig. 51.2). Adults may manifest after pregnancy or bariatric surgery.

Specific Organ Presentation

Any organ or system can be injured by toxic accumulation of any of the metabolites involved in inborn errors. Symptoms relate to organ-specific or system-specific toxicity and injury. Examples include the central nervous system (seizures, coma, ataxia), liver (hepatocellular damage, cholestasis), eye (cataracts, optic atrophy, dislocated lenses), kidney (tubular dysfunction, cysts), and heart (cardiomyopathy, pericardial effusion) (Table 51.5).

Energy Deficiency

Disorders whose pathophysiology results in energy deficiency (e.g., disorders of fatty acid oxidation, mitochondrial function/oxidative phosphorylation, or carbohydrate metabolism) may manifest with myopathy; central nervous system dysfunction including intellectual disability, ataxia, movement disorders and seizures; cardiomyopathy; vomiting; hypoglycemia; or renal tubular acidosis.

Ketosis and Ketotic Hypoglycemia

Acidosis is often found in children without metabolic diseases and may be due to fasting associated with anorexia, vomiting, diarrhea, and dehydration in the course of a viral illness. In this normal result of fasting, the blood glucose is relatively low; a mild acidosis and ketonuria may be present. Administration

TABLE 51.2 Primary Underlying Pathophysiologic Mechanisms for Select Metabolic Disorders

DISORDER	DEFICIENCY OF A REQUIRED COMPOUND	ACCUMULATION OF TOXIC COMPOUND	RESULT
HYPOGLYCEMIC DISORDERS			
Medium-chain fatty acid oxidation defects	Fat for energy		Use of glucose with consequent hypoglycemia
Long-chain fatty acid oxidation defects	Fat for energy	Long-chain fats	Use of glucose with consequent hypoglycemia; mitochondrial dysfunction in liver, heart, etc., leading to organ dysfunction
Glycogen storage disease	Glucose to prevent fasting hypoglycemia	Glycogen resulting in storage in liver, muscle, heart	Risk of hypoglycemic brain injury and dysfunction of tissue with storage
Ketone utilization disorders	Fat for energy	Ketones	Risk of hypoglycemic brain injury; profound metabolic acidosis and reversible neurologic dysfunction Cyclic vomiting
Galactosemia		Galactose-1-phosphate Galactitol	Elevated galactose leads to severe hepatic dysfunction, neurologic injury, and impaired immune response
INTOXICATING DISORDERS (ENCEPHALOPATHY)			
Urea cycle defects		Ammonia	Central nervous system dysfunction, probably mediated through glutamine
Propionic acidemia, methylmalonic acidemia, other organic acidemias		Organic acids	Systemic or local impairment of mitochondrial function; impaired neurotransmission; impairment of urea cycle
Phenylketonuria	Tyrosine	Phenylalanine	Impairment of tryptophan metabolism leading to serotonin deficiency; defective neurotransmission and white matter damage
Maple syrup urine disease		Leucine	Leucine toxicity leading to cerebral edema
CELLULAR COMPARTMENT DISORDERS			
Mitochondrial disease	Deficiency of ATP (energy) in affected tissues		Failure of affected tissues to carry out normal functions (e.g., muscle weakness, failure of relaxation of blood vessel muscles); failure of Cori cycle leading to lactate accumulation; cardiomyopathy
Peroxisomal disorders	Defect in peroxisomal β -oxidation Deficiency of steroid hormones necessary for signaling	Accumulation of the saturated very long-chain fatty acids	Aberrant embryonic patterning and hormone deficiency, defects in maintenance of myelin and white matter
Lysosomal storage disorders		Tissue-specific accumulation of compound not metabolized by lysosome	Cell type-specific damage and dysfunction as a result of lysosomal failure and reaction to waste product buildup
OTHER			
Disorders of creatine biosynthesis	Deficiency of cerebral creatine	Accumulation of guanidinoacetate in AGAT deficiency leads to seizures	Global brain energy defect leads to severe cognitive delays and seizures
Cholesterol biosynthesis disorders	Deficiency of steroid hormones		Endocrinopathies; disordered cellular signaling leading to aberrant organogenesis

AGAT, Arginine:glycine amidinotransferase deficiency; ATP, adenosine triphosphate.

of carbohydrate restores balance. Severe ketosis may also be the result of **disorders of ketone utilization** such as ketothiolase deficiency or succinyl-CoA:3 ketoacid CoA transferase (SCOT) deficiency. In these conditions, which frequently present in the context of fasting, infection with fever, or decreased intake secondary to vomiting and diarrhea, hypoglycemia

may be profound; the ketosis resolves slowly. As ketone bodies accumulate, cyclic vomiting may ensue. Permanent ketosis is pathognomonic of SCOT deficiency. These disorders are very rare with fewer than 200 cases reported.

Ketotic hypoglycemia is a common condition in which tolerance for fasting is impaired. Symptomatic hypoglycemia

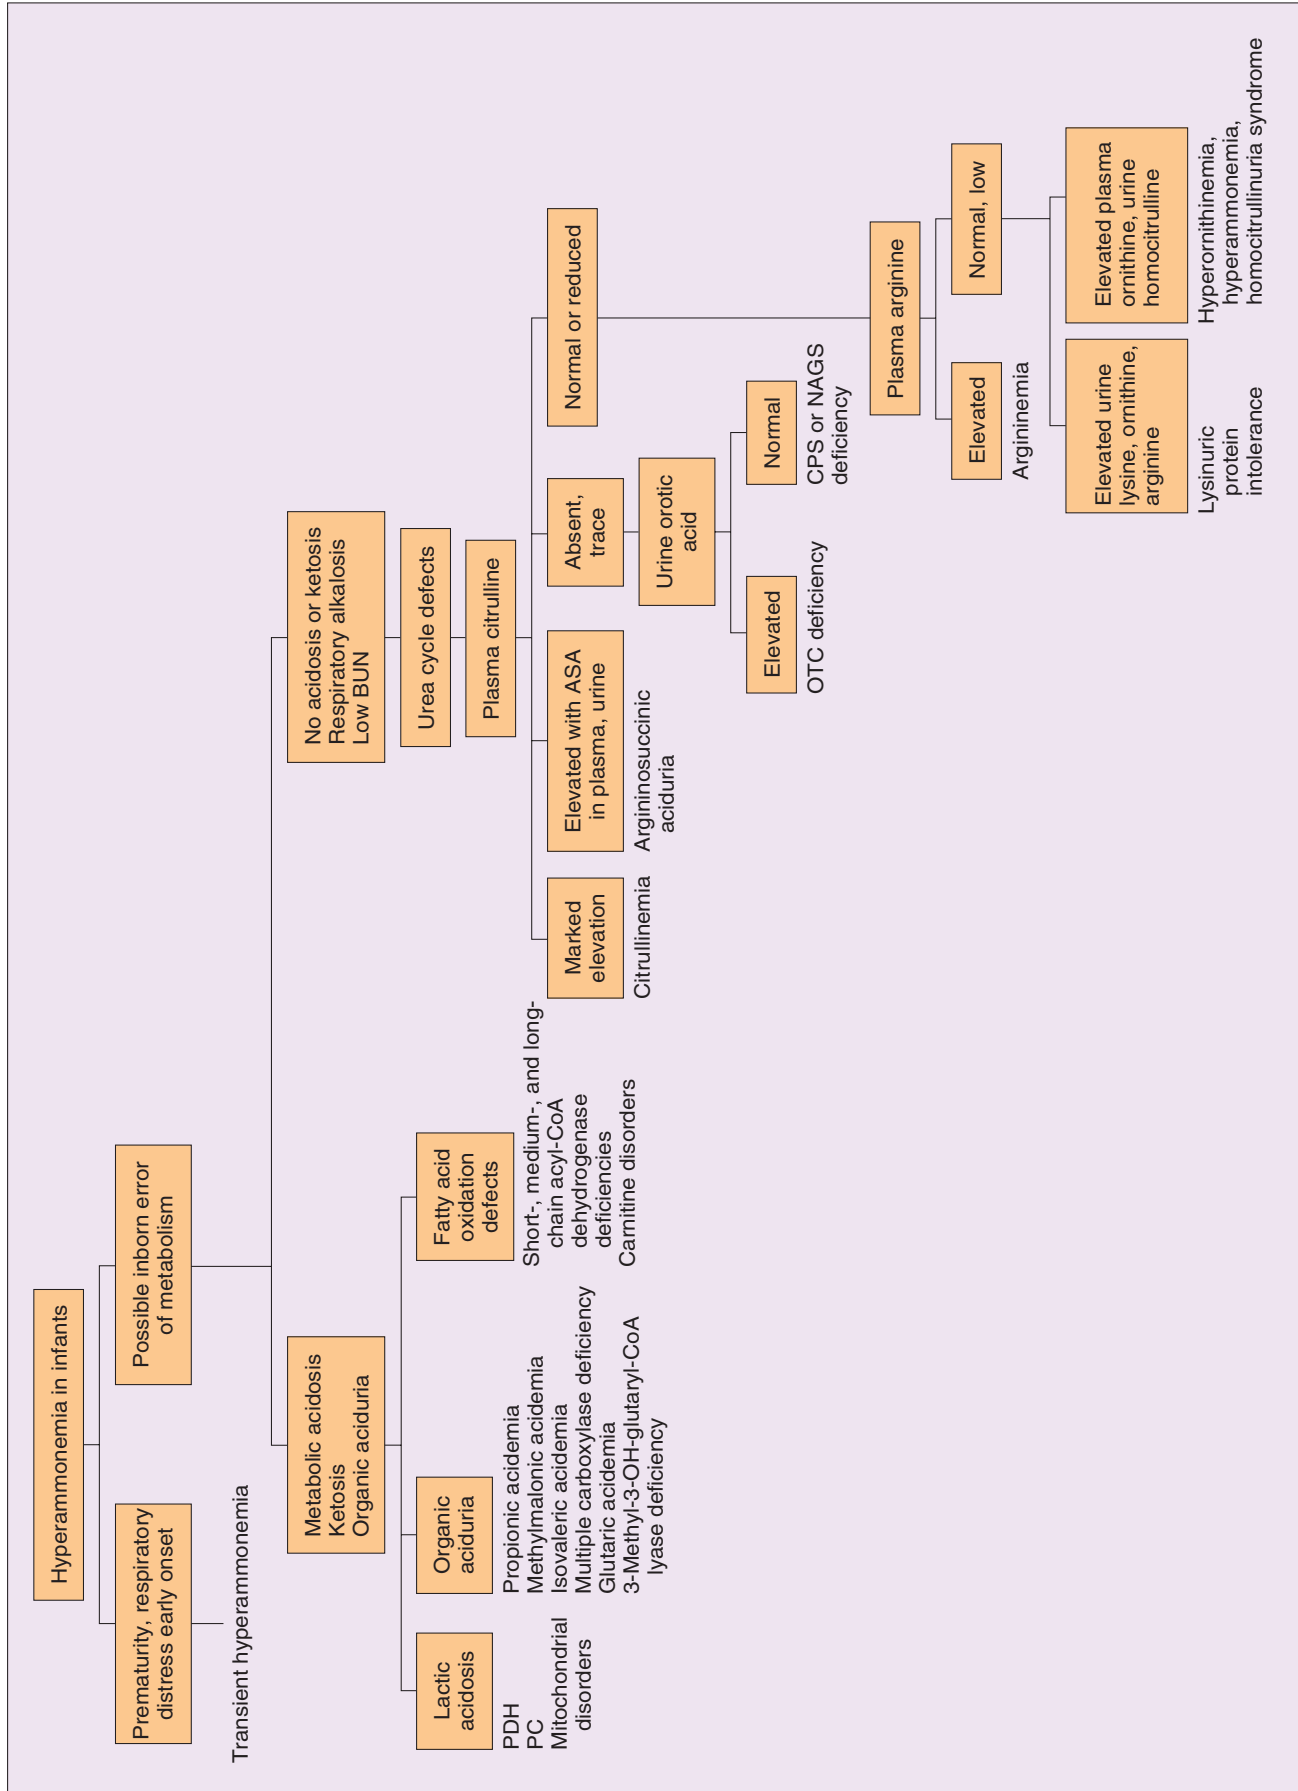

FIGURE 51.2 Algorithm for the approach to hyperammonemia in infants. ASA, Argininosuccinic acid; BUN, blood urea nitrogen; CoA, coenzyme A; CPS, carbamylphosphate synthase; NAGS, N-acetylglutamate synthase; OTC, ornithine transcarbamylase; PC, pyruvate carboxylase deficiency; PDH, pyruvate dehydrogenase deficiency.

with seizures or coma occurs when the child encounters a catabolic stress. The hypoglycemia may occur with significant stress (e.g., viral infection with vomiting) or less commonly after minor stress (e.g., a prolongation by several hours of the normal overnight fast). Ketotic hypoglycemia first appears in the second year of life, occurs in otherwise healthy children, and typically resolves spontaneously by adolescence. It is treated by frequent snacks and the provision of glucose during periods of stress. The pathophysiology is poorly understood (see Chapter 172). Although ketonuria is a normal response to prolonged (not overnight) fasting in older infants and children, it should prompt investigation for metabolic disease in neonates. A *high anion gap metabolic acidosis with or without ketosis* suggests a metabolic disorder (Table 51.6). Although

ketone production may be reduced in some fatty acid oxidation disorders, the presence of ketonuria does not exclude this group of disorders.

Disorders Associated with Dysmorphic Findings

Congenital malformations or dysmorphic features are not intuitively thought of as symptoms and signs of inborn errors. Examples of conditions that cause congenital malformations include congenital disorders of glycosylation, disorders of cholesterol biosynthesis (e.g., Smith-Lemli-Opitz syndrome), disorders of copper transport (e.g., Menkes syndrome, occipital horn syndrome), maternal PKU syndrome, glutaric aciduria II (also called multiple acyl-coenzyme A [CoA] dehydrogenase

TABLE 51.3 Inborn Errors of Metabolism Presenting with Neurologic Signs in Infants Less Than 3 Months of Age

GENERALIZED SEIZURES	ENCEPHALOPATHIC COMA WITH OR WITHOUT SEIZURES
All disorders that cause hypoglycemia: <ul style="list-style-type: none"> • Most hepatic glycogen storage diseases • Galactosemia, hereditary fructose intolerance • Fructose-1,6-bisphosphatase deficiency • Disorders of fatty acid β-oxidation • Glucose transporter deficiency Disorders of the propionate pathway HMG-CoA lyase deficiency Menkes disease Primary mitochondrial disorders Maple syrup urine disease	Primary mitochondrial disorders Maple syrup urine disease Nonketotic hyperglycinemia Diseases producing extreme hyperammonemia: <ul style="list-style-type: none"> • Disorders of the urea cycle • Disorders of the propionate pathway Disorders of β -oxidation Congenital lactic acidosis Lysosomal storage disorders Congenital disorders of glycosylation
SEIZURES AND/OR POSTURING	
Nonketotic hyperglycinemia Maple syrup urine disease

TABLE 51.4 Etiologies of Hyperammonemia in Infants

ETIOLOGY OF HYPERAMMONEMIA	COMMENTS
Disorders of the urea cycle	Lethal hyperammonemia is common
Disorders of the propionate pathway	Severe hyperammonemia may precede acidosis
Disorders of fatty acid catabolism and of ketogenesis	Reye-like syndrome possible
Transient neonatal hyperammonemia	Idiopathic, self-limited
Portal-systemic shunting	Thrombosis of portal vein, cirrhosis, hepatitis
Mitochondrial DNA depletion	Typically associated with elevated lactate level and other organ dysfunction
Drug intoxication: salicylate, valproic acid, acetaminophen	Obtain drug levels
Hyperinsulinism/hyperammonemia syndrome	Clinical hypoglycemia, subclinical hyperammonemia
Nonmetabolic liver disease including infections such as herpes, cytomegalovirus	Ensure evaluation of hepatic function and appropriate infectious disease work-up

TABLE 51.5 Inborn Errors of Metabolism Presenting with Hepatomegaly or Hepatic Dysfunction in Infants

HEPATOMEGALY	HEPATIC FAILURE	JAUNDICE
GSD I	Citrin deficiency Galactosemia	Citrin deficiency Galactosemia
GSD III	Hereditary fructose intolerance	Hereditary fructose intolerance
Mucopolysaccharidosis I and II	Tyrosinemia type 1 (fumarylacetoacetate hydrolase deficiency)	Infantile tyrosinemia (fumarylacetoacetate hydrolase deficiency)
Gaucher and Niemann-Pick diseases Congenital disorders of glycosylation Other lysosomal storage disorders	GSD IV (slowly evolving) Mitochondrial hepatopathies Congenital disorders of glycosylation Hemochromatosis	Crigler-Najjar disease Rotor, Dubin-Johnson syndromes Peroxisomal disorders Alagille syndrome Bile acid synthesis disorders

GSD, Glycogen storage disease.

TABLE 51.6 Etiologies of Metabolic Acidosis Caused by Inborn Errors of Metabolism in Infants

DISORDER	COMMENT
Methylmalonic acidemia (MMA)	Hyperammonemia, ketosis, neutropenia, thrombocytopenia
Propionic acidemia	Similar to MMA plus cardiomyopathy
Isovaleric acidemia	Odor of sweaty feet
Pyruvate dehydrogenase deficiency	Lactic acidosis, hyperammonemia, encephalopathy, seizures
Pyruvate carboxylase deficiency	Lactic acidosis, hypoglycemia, and ketosis
Respiratory chain (mitochondrial) disorders	Lactic acidosis, ketosis occasionally seen, multisystem dysfunction
Medium-chain acyl-CoA dehydrogenase deficiency (MCAD)	Moderate acidosis, hypoglycemia, decreased/absent ketones, possible hyperammonemia
Other fatty acid oxidation defects	Similar to MCAD, with potential hepatic and cardiac disease
Galactosemia	Renal tubular acidosis, <i>Escherichia coli</i> neonatal sepsis, hypoglycemia
3-hydroxy-3-methyl-glutaryl-CoA lyase deficiency	Severe lactic acidosis, hyperammonemia, hypoglycemia
Multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria 2)	Metabolic acidosis, hypoglycemia, lethal renal malformations
Hereditary fructose intolerance	Lactic acidosis, hypoglycemia, central nervous system depression, renal and hepatic failure

deficiency), Aicardi-Goutieres syndrome (mimics congenital infection), peroxisomal disorders (Zellweger syndrome), and several storage diseases.

Storage Disorders

Storage disorders are caused by accumulation of incompletely metabolized macromolecules. This storage often occurs in subcellular organelles, such as lysosomes. The glycogen storage diseases (GSDs), Niemann-Pick disease, and mucopolysaccharidoses are examples of storage disorders.

CLINICAL ASSESSMENT AND LABORATORY TESTING

The assessment begins with a careful history (family and individual) and clinical evaluation. Clinical laboratory testing can define the metabolic derangement (Table 51.7). The results generate a differential diagnosis and a list of more specific laboratory testing to confirm the diagnosis.

The combination of symptoms and abnormal clinical laboratory findings demands urgent metabolic evaluation. A metabolic emergency often presents with vomiting, acidosis, hypoglycemia, ketosis (or *lack of appropriate ketosis*), intercurrent infection, anorexia/failure to feed, lethargy proceeding

[§]When urea cycle disorders are being considered.

to coma, seizures, and hyperventilation or hypoventilation. Clinical evaluation should focus on the cardiac, renal, hepatic, hematologic, neurologic, and developmental assessment specifically looking for changes in mental status, seizures, abnormal tone or movements, visual symptoms or presymptomatic retinal disease, global developmental delay, loss of developmental milestones (regression), short stature, micro- or macrocephaly, cardiomyopathy, cardiac failure, liver failure, bone marrow suppression, hepatosplenomegaly, cystic renal malformation, and renal tubular dysfunction.

Clinical laboratory testing should begin with tests that are available in most hospital clinical laboratories. Care in the collection and handling of laboratory specimens is crucial to obtaining accurate results. Plasma measurements of lactate and ammonia are particularly subject to false elevations if not handled correctly (prolonged tourniquet time, non-free-flowing sample, sample not stored on ice or not processed immediately). Significant ketosis in the neonate is unusual and suggests an organic acid disorder. Ketosis out of proportion to fasting status in an older child occurs in disorders of ketone utilization. Lack of severe ketosis in an older child under conditions of metabolic stress is a feature of fatty acid oxidation disorders or hyperinsulinemic hypoglycemia syndromes. In some disorders, such as urea cycle disorders, ketone utilization disorders, milder forms of fatty acid oxidation defects, and intermittent maple syrup urine disease (MSUD), the laboratory abnormalities may be absent except during an acute presentation. Therefore normal testing in the well state does not rule out a metabolic disorder. In such cases molecular genetic testing may be the best way to make a diagnosis.

GENETIC ASPECTS OF INBORN ERRORS

Mechanisms of Inheritance

Most IEMs are autosomal recessive. Isolation or founder effect may make a specific recessive condition common in some populations (e.g., MSUD in the Old Order Mennonite population

in Pennsylvania, tyrosinemia type 1 in the French-Canadian population in Quebec). X-linked conditions exhibit severe and early presentations in males. In general, carriers of recessive or X-linked diseases are usually asymptomatic. However, in ornithine transcarbamylase (OTC; also known as ornithine carbamoyltransferase) deficiency or Fabry disease, females can be symptomatic if they have a low proportion of unaffected cells (unfavorably skewed X inactivation). Most mitochondrial disorders in children are a result of pathogenic variants in autosomal genes, although there are X-linked forms. Pathogenic variants in the mitochondrial-specific DNA also lead to mitochondrial disease. In this situation, the type and severity of the presentation depend on the specific defects and the tissue-specific ratio of normal to abnormal copies of the mitochondrial DNA (*the degree of heteroplasmy*).

Identification of Molecular Pathology

Molecular genetic testing is a critical component of the evaluation for IEMs. If the molecular basis of an IEM is known (i.e., the gene or genes have been mapped and disease-causing variants defined), clinical genetic testing should be available. If a category of disorders is suspected but no characteristic metabolites are identified, testing a panel of genes may be the best approach. In some disorders, there is a good correlation between specific disease-causing variants and clinical outcome. Genetic testing in other at-risk family members can provide important information, potentially enabling presymptomatic therapy and alternate decision making throughout the rest of the family.

IDENTIFICATION OF INBORN ERRORS BY NEONATAL SCREENING

Disorders Identified by Neonatal Screening

In the United States, the majority of infants diagnosed with a treatable metabolic disorder will be identified as a result of an abnormal newborn screen. Most states use tandem mass spectrometry to screen for a core panel of metabolic disorders (see Chapter 58).

Strategy of Neonatal Screening

The purpose of neonatal screening is the early detection and rapid treatment of disorders before the onset of symptoms, thus preventing morbidity and mortality. In most states, infants are tested at 24–48 hours (see Chapter 58). A positive test demands prompt evaluation. Specific follow-up testing and treatment of an affected child depends on the disorder. Consistent with most screening tests, a significant proportion of infants who have a positive neonatal screening test do not have a metabolic disorder.

Confirmatory Testing Principles

Neonatal screening is designed to maximize detection of affected infants but is not diagnostic. “Cutoff values” for each test are established carefully to identify infants with an elevated concentration of the substance or decreased activity of an enzyme with an acceptable number of false-positive results. A positive screening test must be followed by prompt

clinical assessment as recommended by the screening program and/or metabolic specialist. In many cases, children will also be provided therapy until the completion of definitive testing.

A positive screening test result causes anxiety for new parents; management of such anxiety is essential to minimize the harm of the program. In addition, definitive testing must be carried out promptly and accurately. If an IEM is excluded, parents need a thorough explanation of the results and reassurance that the infant is well. Such explanations will frequently require the expertise of a metabolic specialist or genetic counselor in the newborn period but may require reassessment of parental understanding by the primary care physician in the long term.

Specialized Laboratory and Clinical Testing

Specialized testing for inherited disorders of metabolism is essential in confirming a diagnosis suspected based on an abnormal newborn screening result or clinical suspicion. The tests that are helpful and examples of diagnoses made using these measurements depend on the deficient pathway in the disorder under consideration (Table 51.8). The most common tests ordered for evaluation of IEMs include plasma amino acids, plasma acylcarnitine, and urine organic acid analyses.

Amino acid analysis may be performed in plasma, urine, or cerebrospinal fluid (CSF). The **plasma amino acid profile** is most useful in identifying disorders of amino acid catabolism. Amino acids may also be abnormal in specific disorders of organic acid degradation, but often are normal or not diagnostic. The **urine amino acid profile** is helpful in diagnosing primary disorders of renal tubular function, such as Lowe syndrome and cystinuria, as well as secondary disorders of renal tubular function, such as cystinosis and Fanconi syndrome of any cause. The test may also be useful in screening for several disorders of amino acid transport such as the detection of urinary homocitrulline in hyperornithinemia-hyperammonemia-homocitrullinuria (HHH) syndrome. The urine amino acid profile is **not** the test of choice for diagnosing disorders of amino acid or organic acid metabolism. The **CSF amino acid profile** is most useful in diagnosing errors of amino acid metabolism such as nonketotic hyperglycinemia and serine biosynthesis defects.

Markers of disordered fatty acid oxidation are measured in urine and plasma. Excessive intermediates of fatty acid oxidation and organic acid catabolism are conjugated with glycine and carnitine. The **plasma acylcarnitine profile** and the **urine acylglycine profile** reflect this accumulation. In organic acid disorders and fatty acid oxidation disorders, measurement of free and total plasma carnitine may reveal a secondary deficiency of carnitine and abnormal distribution of free and acylated carnitine. The plasma free fatty acid (nonesterified fatty acid) to 3-OH-butyrate ratio is helpful in the diagnosis of disorders of fatty acid oxidation. Excessive elevation of 3-OH-butyrate may suggest a disorder of ketone metabolism; absence of ketones or decreased 3-OH-butyrate suggests a fatty acid oxidation disorder. Profiling of fatty acid intermediates in cultured skin fibroblasts may be informative but may not be clinically available.

Many IEMs lead to accumulation of diagnostic metabolites detectable by **urine organic acid analysis**, which is done

TABLE 51.8 Specialized Metabolic Testing

TEST	ANALYTES MEASURED	TEST HELPFUL IN IDENTIFYING DISORDERS
Plasma amino acid profile	Amino acids, including alloisoleucine	PKU, urea cycle defects, tyrosinemias, MSUD, homocystinuria
Plasma total homocysteine	Protein-bound and free homocysteine	Homocystinuria, some forms of methylmalonic acidemia
Urine amino acid profile	Amino acids	Disorders of amino acid renal transport
Plasma acylcarnitine profile	Acylcarnitine derivatives of organic and fatty acid catabolism	Organic acid disorders, fatty acid oxidation disorders
Urine acylglycine profile	Acylglycine derivatives of organic and fatty acid catabolism	Organic acid disorders, fatty acid oxidation disorders
Plasma carnitines	Free, total, and acylated carnitine	Primary and secondary carnitine deficiency; abnormal in many organic acid and fatty acid disorders
Urine organic acid profile	Organic acids	Organic acid disorders, mitochondrial and fatty acid disorders
Urine or blood succinylacetone	Succinylacetone	Tyrosinemia I
Plasma very long-chain fatty acid profile	C22 to C26, pipercolid and phytanic acid	Peroxisomal disorders, X-linked adrenoleukodystrophy
Urine oligosaccharide chromatography	Glycosaminoglycans, mucopolysaccharides	Lysosomal storage disorders

MSUD, Maple syrup urine disease; PKU, phenylketonuria.

by tandem mass spectrometry. Disorders of organic acid metabolism, such as propionic acidemia and methylmalonic acidemia, have typical urine organic acid profiles. Although analysis of blood and urine usually suggest the specific diagnosis, more targeted testing by measuring enzymatic activity in the pathway or establishing DNA changes in the gene is typically needed to identify the specific enzymatic defect.

Disorders of creatine biosynthesis are suggested by abnormalities in creatine and guanidinoacetate levels, and/or abnormal ratio of creatine to creatinine in blood, urine, and CSF. Disorders of purine and pyrimidine metabolism are suggested by the presence of an abnormal urinary profile of purines, such as xanthine, hypoxanthine, inosine, guanosine, adenosine, adenine, or succinyladenosine. Similarly, disorders of pyrimidine metabolism are identified by an abnormal profile of pyrimidines, including uracil, uridine, thymine, thymidine, orotic acid, orotidine, dihydrouracil, dihydrothymine, pseudouridine, *N*-carbamoyl- β -alanine, or *N*-carbamoyl- β -aminoisobutyrate, in the urine. Peroxisomal disorders are evaluated by analysis of very long-chain fatty acids, phytanic acid, pristanic acid, and plasmalogens. Congenital disorders of glycosylation are evaluated by isoelectric focusing of carbohydrate-deficient transferrin (detects only N-linked glycosylation defects) or evaluation of both transferrin and N-glycans by tandem mass spectrometry.

Some storage disorders show abnormalities in urine glycosaminoglycans (heparan sulfate, dermatan sulfate, or chondroitin sulfate), oligosaccharides, and sialic acid. In several disorders, CSF is the most helpful specimen, including glycine encephalopathy (CSF amino acid profile when compared to concurrent plasma amino acids), disorders of neurotransmitter synthesis (biogenic amine profile), glucose transporter (GLUT1) deficiency (plasma-to-CSF glucose ratio), and serine synthesis defect (amino acid profile).

The correct tissue for enzymatic confirmation depends on the disorder, and in many cases may be measured on white blood cells or cultured skin fibroblasts. Consequently, such samples should only be collected after review of the testing laboratory's requirements.

In many disorders, an abnormal metabolic profile is consistently present during illness and when the child is well. In some cases, it is only diagnostic during an episode of illness.

OVERVIEW OF TREATMENT

There are several basic principles for treatment of IEMs. Syndromes with toxicity often present with encephalopathy; removal of toxic compounds is the first goal of therapy. Strategies for direct removal of the toxic compound include hemodialysis, hemovenovenous filtration, and administration of alternate pathway scavenger agents (see Chapter 53). A second strategy is to enhance deficient enzyme activity through administration of enzyme cofactors (e.g., pyridoxine in homocystinuria, tetrahydrobiopterin in PKU). If deficiency of a pathway product plays an important role, providing missing products is helpful (e.g., tyrosine in the treatment of PKU). A further principle is to decrease flux through the deficient pathway by restricting precursors in the diet. Examples include the restriction of protein in disorders of ammonia detoxification, phenylalanine in PKU, and of specific amino acid precursors in the organic acid disorders. Preventing and promptly reversing catabolism during times of stress, typically with intravenous glucose, is essential to reducing flux of precursors into deficient pathways for many disorders.

PEARLS FOR PRACTITIONERS

See Metabolic Disorders: Pearls for Practitioners at the end of this section.

CHAPTER 52

Carbohydrate Disorders

GLYCOGEN STORAGE DISEASES

Many glycogen storage diseases are characterized by **hypoglycemia** and **hepatomegaly** (Table 52.1). Glycogen, the storage form of glucose, is found most abundantly in the liver (where

it modulates blood glucose levels) and in muscles (skeletal and cardiac, where it facilitates anaerobic work). Glycogen is synthesized from uridine diphosphoglucose through the concerted action of glycogen synthetase and brancher enzyme (Fig. 52.1). The accumulation of glycogen is stimulated by insulin. Glycogenolysis occurs through a cascade initiated by epinephrine or glucagon. It results in rapid phosphorylation of glycogen to yield glucose-1-phosphate, accompanied by, to a lesser degree, hydrolysis of glucose residues

TABLE 52.1 Glycogen Storage Diseases

DISEASE	AFFECTED ENZYME	ORGANS AFFECTED	CLINICAL SYNDROME	NEONATAL MANIFESTATIONS	PROGNOSIS
Type 0: Glycogen Synthase Deficiency [†]	Glycogen synthase	Liver	Early morning drowsiness and fatigue, fasting hypoglycemia and ketosis	Early morning drowsiness, emesis, fatigue, hypoglycemia, ketosis, and occasionally seizures	Good; resolution of hypoglycemia is typical for patients who survive to adulthood
Type 1a: von Gierke	Glucose-6-phosphatase	Liver, kidney, GI tract, platelets	Hypoglycemia, lactic acidosis, ketosis, hepatomegaly, hypotonia, slow growth, diarrhea, bleeding disorder, gout, hyperlipidemia, hypertriglyceridemia, hyperuricemia, xanthomas	Hypoglycemia, lactic acidemia, liver may not be enlarged	Early death from hypoglycemia, lactic acidosis; do well with early diagnosis and strict adherence to dietary therapy; hepatomas may occur in late childhood
Type 1b	Glucose-6-phosphate translocase	Liver, kidney, GI tract, platelets, white blood cells	As type 1a, but in addition have clinically significant neutropenia, periodontal disease, and inflammatory bowel disease symptoms	As type 1a but also may present with infections	In addition to risks for type 1a, children have significant IBD-like symptoms. Historically, death due to infections has occurred in the second decade
Type II: Pompe	Lysosomal α -glucosidase	All; notably striated muscle, nerve cells	Symmetric profound proximal limb girdle muscle weakness with early involvement of the diaphragm, cardiomegaly, heart failure, shortened P-R interval, hepatomegaly	"Floppy infant" appearance, feeding difficulties, macroglossia, hepatomegaly, hypertrophic cardiomyopathy	Very poor in neonatal form; death in the first year of life is usual; variants exist; therapy with recombinant human α -glucosidase
Type III: Forbes	Debranching enzyme	Liver and muscles (IIIa), liver only (IIIb)	Hypoglycemia, ketonuria, hyperlipidemia, growth retardation, hepatomegaly that resolves with age; may show muscle fatigue	Usually none	Very good for hepatic disorder; if myopathy present, it tends to be like that of types I and V
Type IV: Andersen	Branching enzyme	Liver, other tissues	Hypotonia, hepatomegaly or splenomegaly; hepatic cirrhosis beginning at several months of age; early liver failure	Usually none	Very poor; death from hepatic failure in first decade is typical
Type V: McArdle	Muscle phosphorylase	Muscle	Muscle fatigue beginning in adolescence	None	Good, with sedentary lifestyle
Type VI: Hers	Liver phosphorylase	Liver	Mild hypoglycemia with hepatomegaly, hyperlipidemia, ketonuria	Usually none	Probably good
Type VII: Tarui	Muscle phosphofructokinase	Muscle	Clinical findings similar to type V	None	Similar to that of type V
Type VIII	Phosphorylase kinase	Liver	Clinical findings similar to type III, without myopathy	None	Good

[†]Except for one form of hepatic phosphorylase kinase, which is X linked, these disorders are autosomal recessive.

[†]Not a true glycogen storage disease as it is an enzyme deficiency that leads to decreased glycogen stores.

GI, Gastrointestinal; IBD, inflammatory bowel disease.

from the branch points in glycogen molecules. In the liver and kidneys, glucose-1-phosphate is converted to glucose-6-phosphate through the actions of phosphoglucomutase; glucose-6-phosphatase hydrolyses glucose-6-phosphate to produce glucose. The latter enzyme is not present in muscles. Glycogen storage diseases (GSD) fall into the following four categories:

1. Diseases that predominantly affect the liver and have a direct influence on blood glucose (types 0, I, VI, and VIII)
2. Diseases that predominantly involve muscles and affect the ability to do anaerobic work (types V and VII)
3. Diseases that can affect the liver and muscles, directly influencing both blood glucose and muscle metabolism (type III)
4. Diseases that affect various tissues but have no direct effect on blood glucose or on the ability to do anaerobic work (types II and IV)

The **diagnosis** of type I GSD is suggested by elevated uric acid, lactate, and triglycerides in blood. Neutropenia is typical of type Ib. Hyperlipidemia is also seen with type III GSD, but lactate and uric acid concentrations are typically normal. For all forms, a diagnosis can normally be confirmed by DNA testing. When this is feasible, invasive procedures, such as muscle and liver biopsy, can be avoided. When DNA testing is not available or is inconclusive, enzyme measurements in tissue from the affected organ confirm the diagnosis. If the diagnosis cannot be established, metabolic challenge and exercise testing may be needed. **Treatment** of hepatic GSD is aimed at maintaining satisfactory blood glucose levels or supplying alternative energy sources to muscle. In glucose-6-phosphatase deficiency (type I), the treatment usually requires nocturnal intragastric feedings of glucose during the first 1 or 2 years of life. Thereafter, snacks and uncooked cornstarch every 6 hours may be satisfactory. Hepatic tumors (sometimes malignant) are a threat in adolescence and adult life, and cirrhosis may be a long-term complication. Liver transplantation may be indicated in severe cases for some disorders (types I,

III, and IV). No specific treatment exists for the diseases of muscle that impair skeletal muscle ischemic exercise, aside from avoidance of strenuous exercise and monitoring of cardiac function. Enzyme replacement early in life is effective in Pompe disease (type II), which involves cardiac and skeletal muscle.

GALACTOSEMIA

Galactosemia is an autosomal recessive disease caused by deficiency of galactose-1-phosphate uridylyltransferase (Fig. 52.2). Clinical manifestations are most striking in a neonate who, when fed breast or cow's milk, generally exhibits evidence of **liver failure** (hepatomegaly, hyperbilirubinemia, disorders of coagulation, hypoglycemia), disordered renal tubular function (acidosis, glycosuria, aminoaciduria), food intolerance (vomiting, diarrhea, poor feeding), neurologic changes (lethargy, irritability, seizures), and **cataracts**. The neonatal screening test must have a rapid turnaround time because affected infants may die in the first week of life. Affected infants are at increased risk for severe neonatal *Escherichia coli* sepsis. Major effects on liver and kidney function and the development of cataracts are limited to the first few years of life; older children may have learning disorders despite dietary compliance. Females usually develop premature ovarian failure despite treatment.

Laboratory manifestations of galactosemia depend on dietary galactose intake. When galactose is ingested (as lactose), levels of plasma galactose and erythrocyte galactose-1-phosphate are elevated. Hypoglycemia is frequent, and albuminuria is present. Galactose frequently is present in the urine and can be detected by a positive reaction for reducing substances without a reaction with glucose oxidase on urine strip tests. The absence of urinary reducing substances cannot be relied on to exclude the diagnosis. The diagnosis is made by showing extreme reduction in erythrocyte galactose-1-phosphate uridylyltransferase activity. DNA

FIGURE 52.2 Pathway of galactose metabolism. (1) Lactase (intestinal), (2) galactokinase, (3) galactose-1-phosphate uridylyltransferase, (4) uridine diphosphoglucose-4-epimerase.

testing for pathogenic variants in galactose-1-phosphate uridylyltransferase confirms the diagnosis and may be useful in predicting prognosis. Renal tubular dysfunction may be evidenced by a normal anion-gap hyperchloremic metabolic acidosis. **Treatment** by the elimination of dietary galactose results in rapid correction of abnormalities, but infants who are extremely ill before treatment may die before therapy is effective.

Galactokinase deficiency, an autosomal recessive disorder, also leads to the accumulation of galactose in body fluids (see Fig. 52.2), which results in the formation of galactitol (dulcitol) through the action of aldose reductase. Galactitol, acting as an osmotic agent, can be responsible for cataract formation and, rarely, for increased intracranial pressure. These are the only clinical manifestations. Individuals homozygous for galactokinase deficiency usually develop cataracts after the neonatal period, whereas heterozygous individuals may be at risk for cataracts as adults.

Hereditary fructose intolerance, in many ways, is analogous to galactosemia. When fructose, sucrose, or sorbitol is ingested, deficiency of fructose-1,6-bisphosphate aldolase leads to the intracellular accumulation of fructose-1-phosphate with resultant emesis, hypoglycemia, and severe liver and kidney disease. Elimination of fructose and sucrose from the diet prevents clinical disease. **Fructosuria** is caused by fructokinase deficiency, but its deficiency is not associated with clinical consequences.

PEARLS FOR PRACTITIONERS

See *Metabolic Disorders: Pearls for Practitioners* at the end of this section.

acid accumulates in excess and is toxic to various organs, such as the brain, eyes, skin, or liver. Treatment is directed at the specific pathway and usually involves dietary restriction of the offending amino acid and supplementation with special medical foods (formulas) that provide the other amino acids and other nutrients. Confirmatory testing includes quantitative plasma amino acid profile, specific gene testing, and sometimes enzymology.

PHENYLKETONURIA

Phenylketonuria (PKU), an autosomal recessive disease, primarily affects the brain and occurs in 1 in 10,000 persons. Classic PKU is the result of a defect in the hydroxylation of phenylalanine to form tyrosine (Fig. 53.1); the activity of phenylalanine hydroxylase in the liver is absent or greatly reduced. Affected infants are normal at birth, but if untreated, severe intellectual disability (IQ <35) develops in the first year of life; a musty odor of the breath, skin, or urine may also be noted. A positive newborn screening test must be followed up by performing quantitative plasma amino acid analysis. A plasma phenylalanine value of greater than 360 μM (6 mg/dL) is consistent with the diagnosis of one of the hyperphenylalaninemias and demands prompt evaluation and treatment. Untreated, classic PKU is characterized by blood phenylalanine concentrations higher than 600 μM . Milder forms of hyperphenylalaninemia are indicated by values of plasma phenylalanine lower than this but higher than 360 μM . A significant percentage of premature infants and a few full-term infants have transient elevations in phenylalanine. Short-term follow-up usually identifies these infants promptly. A small percentage of infants diagnosed with PKU ($\leq 2\%$ in the United States) have a defect in the synthesis or metabolism of tetrahydrobiopterin, the cofactor for phenylalanine hydroxylase and for other enzymes involved in the intermediary metabolism of aromatic amino acids. Disorders of biopterin metabolism are diagnosed by measuring dihydrobiopterin reductase in erythrocytes and by analyzing biopterin metabolites in urine. This testing should be carried out in all infants with elevated phenylalanine.

Treatment aims to maintain plasma phenylalanine values in the therapeutic range of 120–360 μM using a diet specifically restricted in phenylalanine but otherwise nutritionally complete. Treatment for life is recommended to reduce the risks of long-term neuropsychiatric problems and reduce the risk of maternal PKU syndrome.

Outcome of treatment in classic PKU is excellent. Most infants with classic PKU who are treated within the first 10 days of life achieve normal intelligence. However, learning problems and problems with executive function are more frequent than in unaffected peers. The safe concentration of phenylalanine in older children and adults with PKU has not been clearly established. Reversible cognitive dysfunction is associated with acute elevations of plasma phenylalanine in adults and children with PKU. If the elevated level has been sustained, the dysfunction may not be reversible. Treatment with modified preparation of tetrahydrobiopterin (sapropterin) shows good response in individuals with mild to moderate PKU and in 10% of individuals with classic PKU. Enzyme replacement therapy has shown effectiveness and is FDA approved for adults with PKU.

Females with PKU and their families must be educated on the risks and prevention of maternal PKU syndrome. **Maternal**

CHAPTER 53

Amino Acid Disorders

DISORDERS OF AMINO ACID METABOLISM

Disorders of amino acid metabolism are the result of the inability to catabolize specific amino acids derived from protein. Usually a single amino acid pathway is involved. This amino

FIGURE 53.1 Metabolism of aromatic amino acids. (1) Phenylalanine hydroxylase, (2) transaminase, (3) *p*-hydroxyphenylpyruvate oxidase, (4) homogentisate oxidase, (5) maleylacetoacetate isomerase, (6) fumarylacetoacetate hydrolase, (7) dihydrobiopterin reductase, (8) tyrosine hydroxylase, (9) tryptophan hydroxylase. SA, Succinylacetone.

hyperphenylalaninemia requires rigorous management before conception and throughout pregnancy to prevent fetal brain damage, congenital heart disease, and microcephaly.

TYROSINEMIAS

Tyrosinemia is identified in neonatal screening programs using tandem mass spectrometry methods to detect elevated tyrosine and/or succinylacetone. Elevated tyrosine levels also occur as a nonspecific consequence of severe liver disease or transient tyrosinemia of the newborn (TTN). TTN is common (1% of live births), more prevalent in premature infants, resolves spontaneously by 2 months of age, is of uncertain clinical significance, and responds to ascorbic acid treatment. The inherited disorders of tyrosine metabolism are a target of neonatal screening. **Tyrosinemia type I**, which is due to fumarylacetoacetate hydrolase deficiency (see Fig. 53.1), is a rare disease in which accumulated metabolites produce severe liver disease associated with bleeding diathesis, hypoglycemia, hypoalbuminemia, elevated transaminases; defects in renal tubular function; and peripheral neuropathy. Hepatocellular carcinoma may eventually occur. Quantitative measurement of plasma tyrosine and blood or urine succinylacetone is performed after a positive neonatal screen. The **diagnosis** of tyrosinemia I is confirmed by an increased concentration of succinylacetone; DNA testing is available. **Treatment** with nitisinone (NTBC; an inhibitor of the oxidation of parahydroxyphenylpyruvic acid) effectively eliminates the production of the toxic succinylacetone. Because nitisinone increases the concentration of tyrosine in the blood, a low-phenylalanine, low-tyrosine diet is important to prevent tyrosine deposition in the cornea. These treatments have reduced the immediate need for liver transplantation in children identified by neonatal screening. Nitisinone therapy, especially if initiated

within 30 days of life, may reduce the risk of hepatocellular carcinoma.

Tyrosinemias II and III are more benign forms of hereditary tyrosinemia. Blocked metabolism of tyrosine at earlier steps in the pathway is responsible, and succinylacetone is not produced. The clinical features include **hyperkeratosis** of palms and soles and **keratitis**, which can cause severe visual disturbance. Significant elevations of tyrosine levels are associated with mild cognitive impairment and specific defects in executive function. Diagnosis is made by elevated tyrosine plasma assays in patients with suggestive exam findings; molecular testing may also be performed. Treatment with a phenylalanine- and tyrosine-restricted diet is effective in preventing these complications.

HOMOCYSTINURIA

Homocystinuria, an autosomal recessive disease (1:200,000 live births) affecting connective tissue, the brain, and the vascular system, is caused by a deficiency of cystathionine β -synthase. In the normal metabolism of the sulfur amino acids, methionine gives rise to cystine; homocysteine is a pivotal intermediate (Fig. 53.2). When cystathionine β -synthase is deficient, homocysteine accumulates in the blood and appears in the urine. Another result is enhanced reconversion of homocysteine to methionine, resulting in an increase in the concentration of methionine in the blood. The most commonly used neonatal screening test evaluates for elevated methionine. An excess of homocysteine produces a slowly evolving **clinical syndrome** that includes dislocated ocular lenses; long, slender extremities; malar flushing; and livedo reticularis. Arachnodactyly, scoliosis, pectus excavatum or carinatum, and genu valgum are skeletal features that mimic Marfan syndrome. Intellectual disability, psychiatric illness, or

both may be present. Major arterial or venous thromboses are a constant threat.

Confirmation of the **diagnosis** requires demonstration of elevated total homocysteine in the blood. A plasma amino acid profile reveals hypermethioninemia. Measurement of cystathionine β -synthase is not clinically available, but numerous pathogenic variants in the gene are known and can be tested.

There are two clinical forms of homocystinuria. In one form, activity of the deficient enzyme can be enhanced by the administration of large doses of pyridoxine (typically 100–500 mg/day). Folate supplementation is added to overcome folate deficiency if folate is trapped in the process of remethylation of homocysteine to methionine. This pyridoxine-responsive form comprises approximately 50% of cases and is the form more likely to be missed by neonatal screening because the methionine concentrations are not always above the screening cutoff. The second form is not responsive to pyridoxine therapy. The use of supplemental betaine (trimethylglycine), a donor of methyl groups for remethylation of homocysteine to methionine, also has a role in the management of pyridoxine-unresponsive

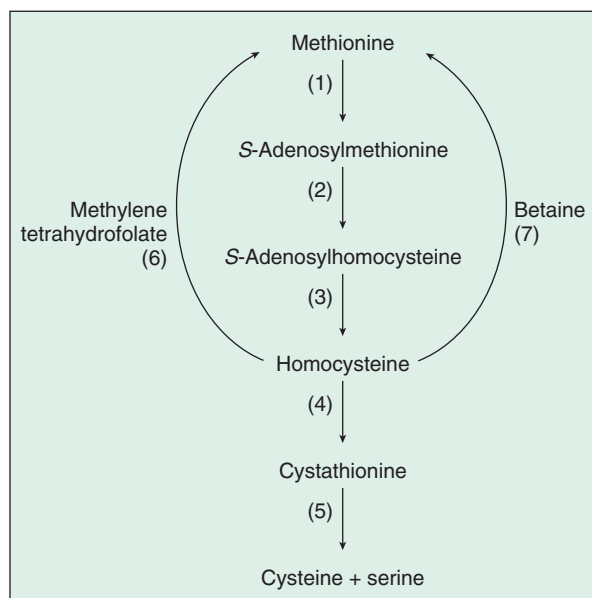

FIGURE 53.2 Metabolism of methionine and homocysteine. (1) Methionine adenosyltransferase, (2) glycine *N*-methyltransferase, (3) *S*-adenosylhomocysteine hydrolase, (4) cystathionine β -synthase, (5) cystathionase, (6) homocysteine methyltransferase, (7) betaine-homocysteine methyltransferase.

patients. A methionine-restricted diet is frequently required. Some cases may benefit from vitamin B₁₂ and folate supplementation. Consequently, diet and betaine are sometimes required to control plasma homocysteine, even in pyridoxine-responsive patients. The prognosis is good for infants whose plasma homocysteine concentration is controlled. Agents and circumstances that raise the risk for thromboembolism (i.e., oral contraceptives) should be avoided.

MAPLE SYRUP URINE DISEASE

Maple syrup urine disease (MSUD) is an autosomal recessive disease, also called **branched chain ketoaciduria**. It is caused by a deficiency of the decarboxylase that initiates the degradation of the ketoacid analogs of the three branched chain amino acids—leucine, isoleucine, and valine (Fig. 53.3). Classic MSUD is rare (1:185,000) in the general population but much more common in some population isolates (Pennsylvania Mennonites 1:380). The recommended uniform screening panel (RUSP) includes MSUD.

Although MSUD has intermittent-onset and late-onset forms, **clinical manifestations** of the classic form typically occur within 1–4 weeks of birth. Poor feeding, vomiting, and tachypnea commonly are noted, but the hallmark of the disease is profound depression of the central nervous system, associated with alternating hypotonia and hypertonia (**extensor spasms, “fencing” or “bicycling”**), opisthotonos, and seizures. Hyperleucinosis is the cause of the central nervous system depression and may cause acute cerebral edema. Decompensation during illness may be rapid and severe. The urine may have the odor of maple syrup.

Laboratory manifestations of MSUD include hypoglycemia and a variable presence of metabolic acidosis, with elevation of the undetermined anions; the acidosis is caused in part by plasma branched chain organic acids. MSUD should be strongly suspected in a child with positive urine ketones on dipstick with no or low β -hydroxybutyrate. A rapid, more specific test demonstrates the rapid formation of copious white precipitate when 2,4-dinitrophenylhydrazine is added to the urine sample. This is because branched chain ketoacids in urine (but not β -hydroxybutyrate or acetoacetate) specifically react with 2,4-dinitrophenylhydrazine.

The **definitive diagnosis** of MSUD generally is made by showing large increases in plasma leucine with fewer increases in isoleucine, and valine concentrations and identification of excess alloisoleucine in the plasma; alloisoleucine above 5 $\mu\text{mol/L}$ is considered pathognomonic. The urinary organic acid profile is usually abnormal and shows the ketoacid

FIGURE 53.3 Metabolism of the branched chain amino acids. (1) Aminotransferases, (2) α -ketoacid dehydrogenase complex.

derivatives of the branched chain amino acids. The diagnosis can be substantiated by detection of pathogenic variants in one of the three genes *BCKDHA*, encoding BCKA decarboxylase (E1) α subunit (MSUD type 1A); *BCKDHB*, encoding BCKA decarboxylase (E1) β subunit (MSUD type 1B); and *DBT*, encoding dihydrolipoyl transacylase (E2) subunit (MSUD type 2).

Provision of adequate calories and protein *with restriction of leucine* is crucial for acute and chronic management. Some patients with disease due to *BCKDHB* variants may be responsive to thiamine supplementation. Ordinary catabolic stresses, such as moderate infections or labor and delivery in a pregnant mother with MSUD, can precipitate clinical crises. The most feared complication of metabolic decompensation is cerebral edema. In critically ill patients, hemodialysis should be instituted to rapidly decrease plasma leucine levels. Liver transplantation effectively treats MSUD but does not reverse preexisting cognitive disability, psychiatric illness, and neurologic injury

DISORDERS OF AMMONIA DISPOSAL

Inherited enzymatic deficiencies have been described for each of the steps of urea synthesis (Fig. 53.4). Collectively, their incidence is estimated to be at least 1:35,000 births. Neonatal screening does not currently detect all disorders in the urea cycle. Clinically, the two most frequent disorders in the United States are ornithine transcarbamylase (OTC) deficiency and argininosuccinate lyase (ASL) deficiency; these disorders should be suspected in neonates with severe hyperammonemia.

OTC deficiency is X linked. Pathogenic variants range from whole gene deletions to single nucleotide substitutions.

If the enzyme is nonfunctional, there is no OTC activity in affected males, who are likely to die in the neonatal period. Affected females are heterozygous and, because of X inactivation, may have a significant degree of enzyme deficiency; they may become clinically affected at any time in life. **Clinical manifestations** range from lethal disease in the male (coma, encephalopathy) to clinical normalcy in a high percentage of females. Late-onset forms in males also occur. Manifestations in clinically affected females include recurrent emesis, lethargy, seizures, developmental delay, psychosis, or episodic confusion, often following ingestion of a high-protein diet or due to a catabolic state (e.g., infection).

Confirmatory testing for OTC deficiency includes a plasma amino acid profile, which may show very low citrulline concentration with increased glutamate and alanine. A urine organic acid profile may show increased excretion of orotic acid after protein loading or with an allopurinol challenge test. Known pathogenic variant testing, deletion testing, and sequencing of the entire coding region of the OTC gene are available as clinical testing. OTC enzyme activity can be assessed in liver.

ASL deficiency is autosomal recessive, and most children in the United States are detected as a result of an elevated citrulline on newborn screening. In addition to hyperammonemia the disorder is characterized by hepatitis, cirrhosis, neurocognitive deficiencies, hypertension, and trichorrhexis nodosa (coarse brittle hair). The diagnosis is confirmed by the detection of elevated argininosuccinic acid in the blood, urine, or cerebrospinal fluid.

The proximal urea cycle disorders *N*-acetylglutamate synthase (NAGS) deficiency and carbamoyl phosphate synthetase 1 (CPS1) deficiency (the most rare disorders of urea disposal) present with hyperammonemia, decreased citrulline,

FIGURE 53.4 The urea cycle. Site of enzymatic defects: (1) *N*-acetylglutamate synthase (NAG), (2) carbamoylphosphate synthetase, (3) ornithine transcarbamylase, (4) argininosuccinate acid synthetase, (5) argininosuccinate acid lyase, (6) arginase. and absent orotic acid. NAGS deficiency may respond to supplementation with carbamylglutamic acid, an analog of *N*-acetylglutamate.

Treatment of Hyperammonemia

During episodes of symptomatic hyperammonemia, protein intake is reduced and intravenous glucose is given in sufficient quantity to suppress catabolism of endogenous protein. Ammonia can be eliminated by use of the **alternate pathway** agents, **sodium benzoate** and **sodium phenylacetate**, which are excreted in the urine as conjugates of glycine and glutamine. Arginine, which is usually deficient, is supplied. When ammonia levels are very high ($>1,000 \mu\text{M}$) or refractory to therapy, direct removal of ammonia using hemodialysis or hemofiltration, but not peritoneal dialysis (clearance of ammonia is substantially lower), is required. The neurologic status must be followed closely and cerebral edema treated promptly. Despite successful management of hyperammonemic crises, the long-term outcome for males with severe neonatal OTC deficiency and all children with severe ASL deficiency is guarded. Early liver transplantation has increased survival, especially in males with severe OTC deficiency.

Restriction of dietary protein intake to daily needs is the mainstay of ongoing treatment for urea cycle defects. Essential amino acids can be supplied in amounts just sufficient to support protein synthesis. Arginine is an essential amino acid when arginine synthesis via the urea cycle is grossly impaired; thus, arginine or citrulline must be supplied except in the case of arginase deficiency. Ongoing maintenance treatment with oral phenylbutyrate (which is metabolized to phenylacetate) prevents accumulation of ammonia.

DISORDERS OF AMINO ACID TRANSPORT THAT AFFECT SPECIFIC TRANSPORT MECHANISMS IN THE KIDNEY AND INTESTINE

Cystinuria is a disorder of renal tubular transport of cystine, lysine, arginine, and ornithine. Although intestinal transport is affected in some genetic forms, the symptoms are largely due to the renal transport abnormality. The concentration of cystine exceeds its solubility product and results in significant renal stones. Evaluation and diagnosis are based on the pattern of amino acid excretion in the urine. DNA testing is likely to be informative. **Treatment** is based on increasing the solubility of cystine by alkalinizing the urine with sodium bicarbonate or sodium citrate and by complexing it with compounds such as penicillamine.

Intestinal transport of tryptophan is impaired in **Hartnup syndrome**; pellagra-like symptoms result from this deficiency as well as psychosis, cerebellar ataxia, and delayed development. Diagnosis is based on elevated excretion of the 10 neutral amino acids in urine. Treatment with niacin or nicotinamide improves outcomes.

PEARLS FOR PRACTITIONERS

See *Metabolic Disorders: Pearls for Practitioners* at the end of this section.

CHAPTER 54

Organic Acid Disorders

DISORDERS OF ORGANIC ACID METABOLISM

Organic acid disorders result from a block in the pathways of amino acid catabolism. Occurring after the amino moiety has been removed, they result in the accumulation of specific organic acids in the blood and urine. Treatment is directed at the specific abnormality, with restriction of precursor substrates and administration of enzyme cofactors, when available. Outcome is generally poor for children with neonatal-onset propionic or methylmalonic acidemia but is influenced by frequency and severity of crises and is optimal when diagnosis is made before the onset of the first episode. Liver transplantation may be used in cases refractory to standard management but is not curative. Confirmatory testing begins with a urine organic acid profile, plasma amino acid profile, and plasma acylcarnitine profile. These disorders are tested for in most newborn screening laboratories. More specific testing often requires enzyme measurements in appropriate tissues. When abnormal results suggest a specific disorder, DNA testing may identify the pathogenic variants involved.

PROPIONIC ACIDEMIA AND METHYLMALONIC ACIDEMIA

Propionic acidemia and methylmalonic acidemia result from defects in the propionate pathway (Fig. 54.1). Defects in these steps produce **metabolic acidosis**, **ketosis**, and **hyperglycinemia**. Propionic acidemia and methylmalonic acidemia are identified by neonatal screening with tandem mass spectrometry methods and confirmed with genetic testing. The **clinical manifestations** of both of these disorders in the neonatal period consist of tachypnea, vomiting, lethargy, coma, intermittent ketoacidosis or lactic acidosis, hyperglycinemia, neutropenia, thrombocytopenia, hyperammonemia, and hypoglycemia. Propionic acidemia causes cardiomyopathy. Methylmalonic acidemia causes secondary intellectual disability, tubulointerstitial nephritis, and renal failure. Both disorders can cause “metabolic stroke” with infarction of the basal ganglia during acute episodes. If these disorders are not identified by neonatal screening, intermittent episodes of metabolic acidosis occur. Crises occur during periods of catabolic stress, such as fever, vomiting, and diarrhea; they also may occur without an apparent precipitating event. During periods of neutropenia, the risk of serious bacterial infection is increased. Failure to thrive and impaired development are common.

Propionic acidemia results from deficiency in propionyl coenzyme A (CoA)-carboxylase, an enzyme that has two pairs of identical subunits. All forms of propionic acidemia are inherited in an autosomal recessive manner and are due to pathogenic variants in one of the subunits. **Methylmalonic acidemia** results from deficiency in methylmalonyl mutase; this may be caused by pathogenic variants in the gene for the mutase protein itself or in one of the steps of the synthesis of the cobalamin (B₁₂) cofactors for the enzyme. A complex set of defects in cobalamin metabolism results in other forms of methylmalonic acidemia, some of which are associated with

FIGURE 54.1 The propionate pathway. (1) β -ketothiolase, (2) propionyl-CoA carboxylase, (3) methylmalonyl-CoA isomerase, (4) methylmalonyl-CoA mutase, (5) cobalamin metabolic pathway. CoA, Coenzyme A.

hyperhomocystinemia. **Treatment** with large doses of parenteral hydroxocobalamin (the active form of vitamin B₁₂) is helpful in some cases of methylmalonic acidemia.

For propionic acidemia and the vitamin B₁₂-unresponsive forms of methylmalonic acidemia, management includes the restriction of dietary protein and addition of a medical food deficient in the specific amino acid precursors of propionyl-CoA (isoleucine, valine, methionine, and threonine). Carnitine supplementation is often needed because it is lost in the urine as acylcarnitines. Intestinal bacteria produce a significant quantity of propionate; thus antibacterial treatment with neomycin or metronidazole to reduce the population of bacteria in the gut has some beneficial effect in propionic acidemia and vitamin B₁₂-unresponsive methylmalonic acidemia. Decompensations must be treated with intravenous glucose to provide adequate calories to prevent catabolism. In severe decompensation, hemodialysis or hemofiltration may be required to treat acidosis or hyperammonemia.

ISOVALERIC ACIDEMIA

Isovaleric acidemia results from a block in the catabolism of leucine. Its clinical manifestations are similar to those of defects in the propionate pathway. The strong odor of isovaleric acid results in **sweaty feet odor** in untreated infants, best appreciated in body sweat or cerumen. Therapy is effective in promoting normal development and involves restricting the intake of leucine and providing glycine as an alternate pathway therapy that conjugates isovaleric acid (Fig. 54.2) and is then excreted in the urine.

GLUTARIC ACIDEMIA I

Glutaric acidemia I results from a deficiency at the end of the lysine catabolic pathway. It is an autosomal recessive disease produced by deficiency of glutaryl-CoA dehydrogenase activity (Fig. 54.3). **Clinical manifestations** include **macrocephaly**

FIGURE 54.2 Metabolism in isovaleric acidemia. (1) Leucine catabolic pathway (transamination and decarboxylation), (2) isovaleryl-CoA dehydrogenase, (3) glycine acyltransferase. CoA, Coenzyme A.

(75% of affected individuals), which may be present at birth. Before the advent of newborn screening, more than 70% of children had *metabolic stroke-like episodes* associated with infarction of the basal ganglia and **dystonia** which characteristically develops after an episode of intercurrent illness or stress but may occur spontaneously. **Treatment** includes a protein-restricted diet accompanied by a medical food deficient in lysine and tryptophan, carnitine supplementation, and aggressive management of intercurrent illness. Despite this treatment, as many as one third of children still develop neurologic symptoms.

BIOTINIDASE DEFICIENCY AND HOLOCARBOXYLASE SYNTHETASE DEFICIENCY

Biotin is a ubiquitous vitamin that is covalently linked to many carboxylases and cannot be recycled from its attachment to the carboxylases. Thus inherited biotinidase deficiency greatly increases the dietary requirement for biotin. Affected individuals become biotin deficient while consuming normal diets.

FIGURE 54.3 Scheme of flavoprotein metabolism with reference to glutaric aciduria types I and II. (1) Glutaryl-CoA dehydrogenase (deficient in glutaric aciduria type I), (2) fatty acyl-CoA dehydrogenases, (3) other flavoprotein dehydrogenases, (4) ETF (deficiency results in glutaric aciduria type II), (5) ETF-ubiquinone oxidoreductase (deficiency results in glutaric aciduria type II). CoA, Coenzyme A; ETF, electron transfer flavoprotein.

Clinical disease can appear in the neonatal period or be delayed until later infancy, depending on the degree of deficiency. Virtually all infants with biotinidase deficiency are detected by newborn screening of biotinidase activity. Newborn screening for holocarboxylase synthetase deficiency can detect elevated C5-OH-carnitine on tandem mass spectrometry, but biotinidase activity is normal in these patients.

Clinical manifestations of biotin deficiency vary greatly (seizures, hypotonia, sensorineural deafness, vision loss, alopecia, skin rash, metabolic acidosis, hyperammonemia, immune deficits, ataxia, developmental delay) and depend on which enzymes in which tissues have the most biotin depletion. Carboxylation is a crucial reaction in the metabolism of organic acids; most patients with biotinidase deficiency excrete abnormal amounts of several organic acids, among which β -methylcrotonylglycine is prominent. In addition to biotinidase deficiency, an inherited deficiency of holocarboxylase synthetase gives rise to severe disease and to similar patterns of organic aciduria. Both conditions respond well to lifelong **treatment** with large doses of biotin (5–10 mg/day). Early treatment is essential as vision and hearing loss are permanent. Confirmatory testing is accomplished with quantitative measurement of the deficient enzyme.

PEARLS FOR PRACTITIONERS

See *Metabolic Disorders: Pearls for Practitioners* at the end of this section.

CHAPTER 55

Fatty Acid Oxidation Disorders

DISORDERS OF FATTY ACID OXIDATION

Fatty acids are derived from hydrolysis of triglycerides and catabolism of fat. The catabolism of fatty acids (Fig. 55.1) proceeds through the serial oxidative removal of two carbons at a time as acetyl groups (each as acetyl-coenzyme A [CoA]). The reactions are catalyzed by a group of enzymes that exhibit specificities related to the chain length and other properties of the fatty acids: very long-chain acyl-CoA dehydrogenase

(VLCAD), long-chain hydroxyacyl-CoA dehydrogenase (LCHAD) or trifunctional protein, medium-chain acyl-CoA dehydrogenase (MCAD), and short-chain acyl-CoA dehydrogenase (SCAD). The pattern of plasma acylcarnitine elevations is diagnostic. The prevalence of these disorders is approximately 1:10,000.

MCAD deficiency is the most common inborn error of β -oxidation. Hypoketotic hypoglycemia is a common manifestation, as is a Reye syndrome–like illness with hypoglycemia and elevated liver enzymes. Fatty infiltration of the liver also occurs. True hepatic failure is rare. Episodes may be recurrent in the patient or the family. **Sudden infant death syndrome** is reported in infants with MCAD deficiency, perhaps related to hypoglycemia.

VLCAD deficiency and LCHAD (trifunctional protein) deficiency result in significant myopathy and cardiomyopathy in addition to hypoglycemia. This cardiomyopathy may be rapidly reversed with appropriate dietary treatment. LCHAD deficiency is accompanied by a retinopathy in later childhood. Female carriers for LCHAD who are carrying affected fetuses are at risk for HELLP syndrome. In all of the disorders of β -oxidation, carnitine depletion can occur through excessive urinary excretion of carnitine esters of the incompletely oxidized fatty acids. Measurement of plasma carnitine is helpful in monitoring for this deficiency, which results in weakness and muscle pain, along with myoglobinuria in some people.

3-Hydroxy-3-methylglutaryl-CoA lyase deficiency, although not a disorder of β -oxidation, interferes profoundly with hepatic adaptation to fasting by impairing ketogenesis (see Fig. 55.1). The clinical manifestations are those of MCAD deficiency, except that carnitine depletion is less prominent.

The diagnosis of disorders involving a deficiency of β -oxidation is suggested by the clinical picture and by **hypoketotic hypoglycemia**. The diagnosis is suggested by abnormal urinary organic acid and acylglycine profiles, along with plasma acylcarnitine and free fatty acid profiles. DNA testing is required to confirm the diagnosis. The profile of acylcarnitines in cultured skin fibroblasts may be helpful if other testing is not conclusive but is not widely available clinically. In MCAD deficiency a single pathogenic variant c.985 A→G accounts for a significant percentage of cases, especially among children of Northern European ancestry. **Treatment** of all disorders of fatty acid oxidation includes avoidance of fasting, as well as fluid and calorie supplementation (either

CoA, Coenzyme A.

intravenous or oral) during periods of metabolic stress, such as fever. In MCAD deficiency, medium-chain triglycerides must be avoided. In the long-chain fatty acid oxidation disorders, provision of medium-chain fatty acids improves muscle energy metabolism.

GLUTARIC ACIDURIA TYPE II

Glutaric aciduria type II (multiple acyl-CoA dehydrogenase deficiency) is an autosomal recessive disorder produced by a defect in the transfer of electrons from flavine adenine nucleotides to the electron transport chain (electron transfer flavo-protein [ETF], or ETF dehydrogenase); this defect results in a deficiency of multiple fatty acyl-CoA dehydrogenases (see Fig. 55.1) from variants in one of three genes. It should not be confused with glutaric acidemia type I (see Chapter 54). When the enzyme essentially is nonfunctional, congenital anomalies are common, including renal cysts, facial abnormalities, rocker-bottom feet, and hypospadias. Severely affected infants have nonketotic hypoglycemia, metabolic acidosis, hepatomegaly, cardiomegaly, and the odor of sweaty feet soon after birth; these infants may die within the neonatal period. Less severely affected infants may have a more episodic, Reye syndrome-like illness. Skeletal and cardiac myopathy with rhabdomyolysis can be prominent in this complex, multisystemic disease. Onset in later childhood may be marked by recurrent hypoglycemia and myopathy. **Treatment** has not been effective in infants with complete deficiency. Milder forms respond to avoidance of fasting and caloric support during metabolic stress. Some patients respond to administration of riboflavin. The diagnosis may be suggested by abnormal urine organic

acid or plasma acylcarnitine profile. It is typically confirmed through DNA testing.

CARNITINE DEFICIENCY

Carnitine is a crucial cofactor in the transport of long-chain fatty acids across the mitochondrial inner membrane (see Fig. 55.1). It is synthesized from lysine by humans and is present in dietary red meat and dairy products. Carnitine deficiency is either primary (caused by failure of intake, synthesis, or transport of carnitine) or secondary (caused by the excretion of excessive amounts of carnitine as carnityl esters in patients with other inborn errors of metabolism, treatment with drugs that complex carnitine such as valproic acid, or as a result of renal replacement therapy). Primary systemic carnitine deficiency is rare and results from inadequate renal reabsorption of carnitine secondary to pathogenic variants in the sodium-dependent carnitine transporter. It is detected by neonatal screening and responds well to high-dose carnitine supplementation. There are numerous examples of secondary carnitine deficiency among the organic acidurias, most prominently in disorders of the propionate pathway and in disorders of the β -oxidation of long-chain and medium-chain fatty acids. Clinical manifestations of carnitine deficiency include hypoketotic hypoglycemia, lethargy, lassitude, muscle weakness, sudden death, and cardiomyopathy.

PEARLS FOR PRACTITIONERS

See *Metabolic Disorders: Pearls for Practitioners* at the end of this section.

CHAPTER 56

Lysosomal and Peroxisomal Disorders

PEROXISOMAL DISORDERS

Peroxisomes are subcellular organelles involved in metabolism and biosynthesis of bile acids, membrane phospholipids, and some β -oxidation of long-chain fatty acids. Disorders include conditions caused by abnormal peroxisomal enzyme function and abnormal peroxisomal biogenesis. **Clinical symptoms** are diverse and frequently include **developmental delay** and **dysmorphic features** that can involve the skeleton and the head. Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease are examples of disorders of peroxisome biogenesis. **Zellweger syndrome (aka Zellweger spectrum disorder)**, an autosomal recessive disease (1:100,000 births), is also called *cerebrohepato-renal syndrome*. Peroxisome structure may be disrupted and function is affected, including the oxidation of very long-chain fatty acids (VLCFAs) and a variety of other metabolic pathways. Affected infants have high foreheads, flat orbital ridges, widely open fontanelles, hepatomegaly, bony stippling of the long bones, and hypotonia. Other anomalies are common. Failure to thrive, seizures, and nystagmus develop early, and death occurs within the first year. Adult Refsum disease, X-linked adrenoleukodystrophy, and malonic aciduria are examples of peroxisomal single-enzyme disorders. Diagnostic testing includes measurement of VLCFAs in plasma and pipercolic acid in urine. Specific molecular testing, particularly for the disorders involving one in the series of *PEX* genes, is available for some disorders. Most of these conditions are untreatable; however, bone marrow transplant can be helpful in X-linked adrenoleukodystrophy (X-ALD) before the onset of severe symptoms.

X-ALD is included in the uniform screening panel (RUSP). This disorder, which affects 1:20,000 males, is caused by a defect in a peroxisomal membrane protein. There are three main ALD phenotypes seen in males with pathogenic variants in the *ABCD1* gene: childhood onset cerebral form, adrenomyeloneuropathy (AMN), and “Addison disease only”; adolescent and asymptomatic forms are also seen in childhood. Impaired adrenocortical function is variably present in all types. Diagnosis is made by analysis of VLCFAs and DNA testing, but the phenotype of affected males cannot be predicted by VLCFA levels or by genotype. The childhood cerebral form is a severe progressive disease that typically presents between age 4 and 8 years with inattentive symptoms and can progress from impaired cognition, vision, hearing, and motor function to total disability within 6 months. AMN presents in adulthood with leg weakness as well as decreased sphincter control and sexual dysfunction. Approximately 20% of carrier females will develop a milder form of the AMN phenotype. Hematopoietic stem cell transplantation (HSCT) should be considered for boys in the early stages of the cerebral form who have evidence of brain involvement on MRI. Because of the significant risks and limited benefit in symptomatic individuals, HSCT is recommended only for individuals with evidence of brain involvement by MRI and minimal neuropsychologic findings (performance IQ >80) with a normal clinical neurologic examination. Corticosteroid replacement therapy can be

lifesaving in individuals with AMN or Addison only presentation. The most sensitive indicators of adrenal dysfunction are elevated plasma adrenocorticotropic hormone (ACTH) and impaired cortisol response to ACTH challenge.

LYSOSOMAL STORAGE DISORDERS

Lysosomes are subcellular organelles that contain degradative enzymes for complex **glycosaminoglycans**, also called **mucopolysaccharides**. Glycosaminoglycans are macromolecules that play a number of roles inside and outside of cells. Genetic disorders result from abnormal formation of the lysosome itself or from deficiency in specific hydrolytic enzymes, in the mechanisms that protect intralysosomal enzymes from hydrolytic destruction, or in the transport of materials into the lysosome and of metabolites out of the lysosome. These materials are stored in cells and ultimately result in their destruction, especially in the nervous system. The clinical disorders are diverse, reflecting tissue specificity of lysosomal function and the intrinsic turnover rates of the compounds whose cycling is affected (Table 56.1). Some disorders are apparent only during adult life. Storage in solid organs results in hepatosplenomegaly and cardiomyopathy. Some disorders affect many tissues but spare the brain, with some having almost exclusive involvement of the musculoskeletal system. In many of these disorders, developmental delay, corneal clouding, and limitation of joint mobility are common features. Storage in tissues of the upper and lower airways may result in respiratory compromise. Nonimmune hydrops fetalis occurs in several lysosomal disorders.

DIAGNOSTIC TESTING

Most cases of Pompe (see Chapter 52) and mucopolysaccharidosis type 1 (MPS1) will be detected on newborn blood spot screening in states that have adopted this testing. However, this testing has a significant false-positive rate. Diagnostic testing includes measurement of glycosaminoglycans in urine and specific assays for lysosomal enzyme activity in white blood cells. If the urine test is positive, it helps direct specific enzyme measurement and gene testing. If it is negative, it does not exclude a lysosomal storage disorder, and other testing modalities are needed if clinical signs are convincing. In disorders in which specific pathogenic variants are known, molecular testing refines the diagnosis and is an important way to resolve disease status in infants with a positive newborn screen. Specific diagnosis, carrier testing, and evaluation of at-risk family members often require a multipronged approach to testing. Making a specific diagnosis is assuming increasing importance because specific treatment for some lysosomal disorders is most effective when started early in the disease course.

TREATMENT STRATEGIES

Specific treatment directed at the metabolic abnormality is available for some lysosomal disorders. In specific disorders (e.g., Gaucher disease), oral medication may be successful in reducing the accumulation of the metabolite that cannot be catabolized. For some disorders, bone marrow (stem cell) transplantation is the most efficacious mechanism to restore lysosomal function. For others, replacement of the missing hydrolytic enzyme by systemic administration of the enzyme allows degradation of stored material. The disorders caused by deficient α -L-iduronidase (MPS1,

TABLE 56.1 Lysosomal Storage Diseases

CNS, Central nervous system; RUSP, recommended uniform screening panel; WBC, white blood cell.

Hurler syndrome, Scheie syndrome, and their variants) respond to treatment with intravenous human recombinant α -L-iduronidase (laronidase). Examples of other disorders for which enzyme therapy is available include MPS6 (Maroteaux-Lamy syndrome), Gaucher disease, Fabry disease, and MPS2 (Hunter syndrome). Stem cell transplantation or ex vivo gene therapy has been helpful or under investigation in the following disorders: MPS type IH (Hurler syndrome), MPS6 (Maroteaux-Lamy syndrome), MPS7 (Sly syndrome), metachromatic leukodystrophy, α -fucosidosis, α -mannosidosis, Gaucher disease, Krabbe disease, and Niemann-Pick disease type B. A discussion of appropriate target therapeutic strategies should be held with patients and their relevant caregivers by an expert in the specific disorder. Nonetheless, treatment for many of these conditions is supportive, with careful attention to respiratory status and physical therapy. As a result of the rapidly changing diagnostic and therapeutic options, providers with a special interest in these disorders should be consulted when a diagnosis is suspected. Treatment decisions should be made by the family in light of the potential therapeutic benefits and burdens of therapy and typically should be resolved before the onset of central nervous system manifestations, which are typically not improved by these approaches.

PEARLS FOR PRACTITIONERS

See Metabolic Disorders: Pearls for Practitioners at the end of this section.

CHAPTER 57

Mitochondrial Disorders

MITOCHONDRIAL FUNCTION

Mitochondria are very complex organelles located in virtually all cells of the body. They perform a variety of functions such as intracellular signaling of oxygen tension and key roles in programmed cell death. From a biochemical perspective, mitochondria are the key site of energy production in the cell. They are the site of β -oxidation (see Chapter 55), the Krebs cycle, and parts of the urea cycle (see Fig. 53.4). This complexity requires more than 1,000 proteins localized specifically to the mitochondrion. Only 13 of these are encoded by the mitochondrial DNA (mtDNA); the remainder are nuclear encoded (on the chromosomes) and require import into the mitochondrion. In addition, the mtDNA needs its own set of proteins to allow for its maintenance, transcription, and translation.

Mitochondrial disorders are typically defined as defects in the ability to generate energy from oxidative phosphorylation to produce adenosine triphosphate (ATP) by transferring electrons formed by glycolysis and the Krebs cycle to a cascade that generates nicotinamide adenine dinucleotide hydrogen (NADH) and flavin adenine dinucleotide hydrogen (FADH_2) (Fig. 57.1) and are also known as phosphorylation disorders or respiratory chain disorders. The more dependent on energy

FIGURE 57.1 The mammalian mitochondrial genome and its protein-coding gene repertoire involved in the oxidative phosphorylation pathway. (A) Schematic representation of genes within mammalian mitochondrial genome (~7,000 bp). Genes on the outer circle are transcribed from the light strand. Location of the tRNAs (red boxes) conforms to the canonical placental mammalian arrangement. (B) Simplified view of the mitochondrial oxidative phosphorylation machinery. Complexes I (NADH dehydrogenase) and II (succinate dehydrogenase) receive electrons from either NADH or FADH_2 . Electrons are then carried between complexes by the carrier molecules coenzyme Q/ubiquinone (UQ) and cytochrome c (CYC). The potential energy of these electron transfer events is used to pump protons against the gradient, from the mitochondrial matrix into the intermembrane space (complexes I and III [cytochrome bc₁] and IV [CYC oxidase]). ATP synthesis by complex V (ATP synthase) is driven by the proton gradient and occurs in the mitochondrial matrix. *HSP*, Putative heavy-strand promoter; *IM*, intermembrane space; *MM*, mitochondrial matrix; *OHR*, origin of heavy-strand replication; *OLR*, origin of light-strand replication. (From da Fonseca RR, Johnson WE, O'Brien SJ, et al. The adaptive evolution of the mammalian mitochondrial genome. *BMC Genomics*. 2008;9:119.)

production an organ is, the more profound the symptoms of deficiency of mitochondrial function in that organ. Certain proteins are only expressed in specific tissues, and defects in these will lead to differing patterns of disease. While individually rare, taken together mitochondrial disorders may affect as many as 1 in 2,500 people.

SIGNS AND SYMPTOMS OF GENETIC DISORDERS OF MITOCHONDRIAL FUNCTION

The signs and symptoms of mitochondrial disorders are varied. Symptoms depend on how an organ is affected by energy deficiency. Muscle function that is compromised will result in muscle fatigue and weakness. Myopathy is common and may show **ragged red fibers** on a muscle biopsy. **Rhabdomyolysis** can occur. Brain dysfunction may be expressed as encephalopathy, seizures, loss of intellectual function, headache, or signs consistent with stroke. Spastic paraplegia and neuropathy may occur. Ataxia and basal ganglia symptoms are features of some disorders. Vision and eye muscle movement may be compromised, with **progressive external ophthalmoplegia** being almost diagnostic of an oxidative phosphorylation defect. Sensorineural hearing loss may occur. **Cardiomyopathy** is frequent, and cardiac rhythm disturbances occur. Liver dysfunction may be expressed as both synthetic deficiencies and frank liver failure. Diabetes may signal pancreatic involvement. Renal tubular abnormalities and renal failure both occur. Gastrointestinal symptoms include both diarrhea and constipation that are difficult to treat. Sideroblastic anemia or bone marrow failure are typical of some disorders. **Alpers disease** (cerebral degeneration and liver disease) and **Leigh disease** (subacute necrotizing encephalomyelopathy) show similar brain lesions but in distinctly different areas of the brain. Because the signs and symptoms may involve multiple organs and may seem nonspecific, physicians may not suspect a mitochondrial disorder until significant progression has occurred. Conversely, because there are no reliable tests to exclude a mitochondrial diagnosis, a high degree of confidence should be required before labeling a child as having a mitochondrial disease. Clinical criteria have been developed to classify patients as “definitive,” “probable,” “possible,” or “unlikely” mitochondrial disorders. The criteria combine data from muscle, central nervous system, multisystem involvement, plus metabolic and imaging studies.

BIOCHEMICAL ABNORMALITIES IN MITOCHONDRIAL FUNCTION

While mitochondrial dysfunction produces many biochemical abnormalities, very few are specific for a hereditary disorder due to the frequency of secondary mitochondrial dysfunction (due to sepsis, renal, cardiac or liver failure, many neurologic disorders). Defects in the mitochondrial respiratory chain may produce **lactic acidosis**. Given the complexity of the respiratory chain, it is not surprising that the described defects are varied as to cause, intensity, and tissues affected. The metabolism of glucose to carbon dioxide and water, with pyruvate as an intermediate (Fig. 57.2), occurs as part of the energy cycle in many tissues. Interference with mitochondrial oxidative metabolism may result in the accumulation of pyruvate. Because lactate dehydrogenase is ubiquitous, and because

FIGURE 57.2 Metabolism of pyruvate and lactate. (1) Alanine aminotransferase, (2) lactate dehydrogenase, (3) pyruvate dehydrogenase, (4) pyruvate carboxylase, (5) Krebs cycle, (6) phosphoenolpyruvate carboxykinase, (7) reverse glycolysis. CoA, Coenzyme A.

the equilibrium catalyzed by this enzyme greatly favors lactate over pyruvate, the accumulation of pyruvate results in lactic acidosis. The most common cause of such lactic acidosis is end-organ oxygen deficiency caused by hypoxia or poor perfusion. Lactic acidosis also occurs when specific reactions of pyruvate are impaired. In the liver, pyruvate undergoes carboxylation to form oxaloacetate using the enzyme pyruvate carboxylase; deficiency in this enzyme causes severe lactic acidosis. In many tissues, lactate is catabolized to form acetyl-coenzyme A (CoA) by the pyruvate dehydrogenase complex; deficiency in pyruvate dehydrogenase also can cause lactic acidosis. Because these reactions also play a role in gluconeogenesis, hypoglycemia can be a feature of these disorders. These disorders comprise forms of **primary lactic acidosis**. They frequently present as intractable, lethal acidosis in the first days or weeks of life and are difficult to treat. Some of the enzymes in this pathway can be measured and specific diagnoses can be made. This may require white blood cells or tissue biopsy. Measurement of growth and differentiation factor 15 (GDF-15) or fibroblast growth factor 21 (FGF-21), cytokines which are elevated when mitochondrial turnover is increased or the respiratory chain is deficient, can be used as a quantitative screening tests for mitochondrial disorders. Urine organic acids may show suggestive elevations.

GENETICS OF MITOCHONDRIAL DISORDERS

Mitochondrial function is carried out by proteins that are coded for by both nuclear and mitochondrial genes. The mitochondrial genome encodes 13 subunits of the enzymes involved in mitochondrial oxidative phosphorylation. More than 85 autosomal genes code for the rest of the subunits of these enzymes. In children, only about 15% of cases of mitochondrial disease are caused by pathogenic variants in mtDNA; the rest are due to pathogenic variants in nuclear genes. The most frequent cases in several large series have been pathogenic variants that lead to a reduction in the ability of the mtDNA to maintain itself. Large population studies show carrier rates of about 2% of the population for pathogenic variants in polymerase (DNA directed), gamma (*POLG*), and

deoxyguanosine kinase (*DGUOK*). Most disorders show autosomal recessive inheritance. A few are autosomal dominant, X linked, or caused by pathogenic variants in the mtDNA inherited from the mother, such as **MELAS** (mitochondrial encephalopathy, lactic acidosis, and strokelike episodes) and **MERRF** (mitochondrial encephalopathy with ragged red fibers), or deletions such as **MIDD** (maternally inherited diabetes and deafness). Diagnosis of primary mitochondrial disorder may require sequencing of mtDNA, nuclear mitochondrial genes, and/or exome sequencing.

TREATMENT OF MITOCHONDRIAL DISORDERS

Repairing the basic energy deficit and getting the appropriate drugs and cofactors to the appropriate location within the mitochondrion are difficult. Nevertheless, a number of strategies are used, including judicious physical therapy and exercise with adequate rest, adequate nutrition, and cofactors for the deficient pathway. Specific treatment is limited for most mitochondrial defects. Providing adequate calories with intravenous dextrose during acute illness is essential. Vitamin cofactors for the respiratory chain, such as riboflavin and pharmaceutical forms of coenzyme Q, are often used, but evidence for their efficacy alone or in combination is poor. Proven therapies exist for some disorders, such as arginine supplementation for preventing strokelike episodes in MELAS and idebenone for vision loss in LHON (Leber hereditary optic neuropathy). When a single organ bears most of the damage, organ transplant may be effective. Long-term surveillance and early treatment for complications are recommended. Identification of family members at risk may allow earlier diagnosis and treatment.

PEARLS FOR PRACTITIONERS

CHAPTER 51

Metabolic Assessment

- Metabolic inborn errors of metabolism (IEMs) disorders are individually uncommon but as a group account for a significant disease burden.
- IEMs are frequent causes of sepsislike presentations, intellectual disability, seizures, sudden infant death, and neurologic impairment.
- Genetic metabolic disorders result from the deficiency of an enzyme, its cofactors, or biochemical transporters that lead to the deficiency of a required metabolite, the buildup of a toxic compound, or a combination of both processes.
- There are at least 89 identified IEMs that are amenable to therapy targeted to the underlying cause and that present with intellectual disability as a prominent feature.
- Hypoglycemic and intoxicating (encephalopathy) metabolic disorders should be considered in all neonates presenting with lethargy, poor tone, poor feeding, hypothermia, irritability, or seizures.
- All children presenting with altered levels of consciousness, irritability, neurologic impairment, or apparent sepsislike episodes should have a plasma ammonia, blood glucose, and anion gap tested.
- Significant ketosis in the neonate is unusual and suggests an organic acid disorder.
- In general, diagnostic testing for disorders of small molecule metabolism is most effective when metabolites are present in highest concentration in blood and urine, typically at times of catabolism such as during intercurrent illness or prolonged starvation.
- Respiratory alkalosis is frequently seen in the early stages of a hyperammonemic crisis, but this may give way to respiratory failure as the ammonia level increases.
- General clinical laboratory testing can define the metabolic derangement and refine the differential diagnosis in a child suspected to have an IEM.
- In the United States, the majority of infants diagnosed with a treatable metabolic disorder will be identified as a result of an abnormal newborn screen.
- The recommended uniform screening panel (RUSP) is defined by the Federal Advisory Committee on Heritable

Disorders in the Newborn and Child (ACHDNC). To be added to the RUSP, conditions must have a proven benefit of identification through newborn screening in terms of reducing mortality or improving long-term neurocognitive outcomes.

- Newborn screening tests have a wide range of specificity, with some tests having close to 90% false-positive rate. Therefore it is essential to perform appropriate confirmatory testing. Counseling of parents throughout the testing process is important due to the potential psychosocial harm of false-positive test results.
- Therapy for metabolic disease may focus on reducing the intake of specific substances that lead to buildup of toxic compounds. In addition, specific medications may prevent the buildup of toxic substances. Therapy may provide supraphysiologic cofactors that enhance residual enzymatic function.
- Catabolism increases the rate of production of these toxic small molecules in many metabolic disorders. Consequently, adequate and, at times, supraphysiologic provision of sources of energy (e.g., parenteral dextrose) is used to create an anabolic state, decreasing production of toxic metabolites.
- In many metabolic disorders, compounds that would otherwise be nonessential need to be provided (e.g., tyrosine in phenylketonuria [PKU], citrulline in ornithine transcarbamylase [OTC]).
- In specific metabolic disorders, the primary pathology is driven by a deficiency of essential compounds. In these disorders ongoing replacement of such factors is essential for prevention of secondary injury.
- Enzyme replacement therapy, organ transplant (e.g., liver transplant in OTC deficiency), or cell-based therapy (e.g., hematopoietic stem cell transplantation [HSCT] in mucopolysaccharidosis type 1 [MPS1]) are methods of providing missing enzymes in some disorders.

CHAPTER 52

Carbohydrate Disorders

- Glycogen storage disease type I manifests with hypoglycemia, hepatomegaly, lactic acidosis, and hypertriglyceridemia.
- Enzyme replacement therapy improves the outcome of Pompe disease (glycogen storage disease type II), which presents with cardiomyopathy.
- Patients with galactosemia present with hepatic failure, renal tubular dysfunction, cataracts, and *Escherichia coli* sepsis.

CHAPTER 53

Amino Acid Disorders

- PKU is an autosomal recessive disorder and will result in severe intellectual disability; patients are normal at birth.

- Tyrosinemia type I manifests with severe hepatic dysfunction, coagulopathy, hypoglycemia, and renal tubular dysfunction.
- Homocystinuria resembles a connective tissue disorder and manifests with dislocated lens, long slender fingers, scoliosis, and arterial or venous thrombosis.
- Maple syrup urine disease (MSUD) presents 1–4 weeks after birth with poor feeding, emesis, coma, and hypotonia alternating with extensor spasms.

CHAPTER 54

Organic Acid Disorders

- Propionic and methylmalonic acidemias may present with tachypnea, emesis, lethargy, coma, neutropenia, thrombocytopenia, ketosis, hypoglycemia, and hyperglycinemia.
- Glutaric acidemia I presents with macrocephaly, dystonia, and metabolic strokes.

CHAPTER 55

Fatty Acid Oxidation Disorders

- Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common disorder of fatty acid oxidation and presents with hypoketotic hypoglycemia, sudden death, and a Reye syndrome–like syndrome.
- Glutaric acidemia II may present with congenital anomalies, nonketotic hypoglycemia, and myopathy.

CHAPTER 56

Lysosomal and Peroxisomal Disorders

- Peroxisomal disorders often present with developmental delay and dysmorphic features affecting the skeleton or skin.
- Lysosomal storage disorders affect many organ systems and typically involve progressive central nervous system disease. Treatments include enzyme replacement therapy and HSCT.

CHAPTER 57

Mitochondrial Disorders

- Most mitochondrial disorders are due to mutations in nuclear genes.
- Mitochondrial DNA mutations are maternally inherited.
- Mitochondrial disorders can produce myopathy, cardiomyopathy, central nervous system dysfunction, or hepatopathy, with or, occasionally, without lactic acidosis.

FETAL AND NEONATAL MEDICINE

Clarence W. Gowen, Jr.

CHAPTER 58

Assessment of the Mother, Fetus, and Newborn

ASSESSMENT OF THE MOTHER

Pregnancies associated with perinatal morbidity or mortality are considered high risk. Identification of high-risk pregnancies is essential as they may be caused by maternal and/or fetal conditions. Conditions include intrauterine growth restriction (IUGR) or excessive fetal growth, congenital anomalies, birth asphyxia and trauma, prematurity (birth at <37 weeks) or postmaturity (birth at ≥ 42 weeks), neonatal disease, or long-term risks of cerebral palsy, intellectual disability, and chronic sequelae of neonatal intensive care. Ten to 20% of women may be high risk at some time during their pregnancy. Although some obstetric complications are first seen during labor and delivery and cannot be predicted, more than 50% of perinatal mortality and morbidity results from problems identified before delivery. After a high-risk pregnancy is identified, measures can be instituted to prevent complications, provide intensive fetal surveillance, and initiate appropriate treatments of the mother and fetus.

A history of previous premature birth, intrauterine fetal death, multiple gestation, IUGR, congenital malformation, explained or unexplained neonatal death (e.g., group B streptococcal sepsis), birth trauma, preeclampsia, gestational diabetes, grand multipara status (five or more pregnancies), or cesarean section is associated with additional risk in subsequent pregnancies.

Pregnancy complications that increase the risk of adverse outcomes can be secondary to maternal or fetal conditions or both (Table 58.1). Neonatal complications include conditions caused by the placenta which tend to cause asphyxia and anemia, while disorders of the mother lead to problems such as electrolyte disorders or growth problems.

Maternal medical complications associated with increased risk of maternal and fetal morbidity and mortality include diabetes, chronic hypertension, congenital heart disease (especially with right-to-left shunting and Eisenmenger complex), glomerulonephritis, autoimmune diseases (especially systemic lupus erythematosus with or without antiphospholipid antibodies), lung disease (cystic fibrosis), severe anemia (sickle cell anemia), hyperthyroidism, myasthenia gravis, idiopathic thrombocytopenic purpura, inborn errors of metabolism

(maternal phenylketonuria), acute infection (COVID-19), and malignancy.

Obstetric complications often are associated with increased fetal or neonatal risk. Vaginal bleeding in the first trimester or early second trimester may be caused by a threatened or actual spontaneous abortion and is associated with increased risk of congenital malformations or chromosomal disorders. Painless vaginal bleeding that is not associated with labor and occurs in the late second or (more likely) third trimester often is the result of **placenta previa**. Bleeding develops when the placental mass overlies the internal cervical os; this may produce maternal hemorrhagic shock, necessitating transfusions. Bleeding also may result in premature delivery. Painful vaginal bleeding is often the result of retroplacental hemorrhage or **placental abruption**. Associated findings include advanced maternal age and parity, maternal chronic hypertension, cocaine use, preterm rupture of membranes, polyhydramnios, twin gestation, and preeclampsia. Fetal asphyxia ensues as the retroplacental hematoma causes placental separation that interferes with fetal oxygenation. Both types of bleeding are associated with fetal blood loss. Neonatal anemia may be more common with placenta previa.

Abnormalities in the volume of amniotic fluid, resulting in oligohydramnios or polyhydramnios, are associated with increased fetal and neonatal risk. **Oligohydramnios** (amniotic ultrasound fluid index ≤ 2 cm) is associated with IUGR and major congenital anomalies (particularly of the fetal kidneys) and with chromosomal syndromes. Bilateral renal agenesis results in diminished production of amniotic fluid and a specific deformation syndrome (**Potter syndrome**), which includes clubfeet, characteristic compressed facies, low-set ears, scaphoid abdomen, and diminished chest wall size accompanied by pulmonary hypoplasia and, often, pneumothorax. Uterine compression in the absence of amniotic fluid retards lung growth; patients with this condition die of respiratory failure rather than renal insufficiency. Twin-to-twin transfusion syndrome (donor) and complications from amniotic fluid leakage also are associated with oligohydramnios. Oligohydramnios increases the risk of fetal distress during labor (meconium-stained fluid and variable decelerations); the risk may be reduced by saline amnioinfusion during labor.

Polyhydramnios may be acute and associated with premature labor, maternal discomfort, and respiratory compromise. More often, polyhydramnios is chronic and is associated with diabetes, immune or nonimmune hydrops fetalis, multiple gestation, trisomy 18 or 21, and major congenital anomalies. Anencephaly, hydrocephaly, and meningomyelocele are

associated with reduced fetal swallowing of amniotic fluid. Esophageal and duodenal atresia as well as cleft palate interfere with swallowing and gastrointestinal fluid dynamics. Additional causes of polyhydramnios include spinal muscular atrophy and Beckwith-Wiedemann syndrome, conjoined twins, chylothorax, congenital pulmonary airway malformation, diaphragmatic hernia, gastroschisis, sacral teratoma, placental chorioangioma, and myotonic dystrophy. **Hydrops fetalis** may be a result of Rh or other blood group incompatibilities and anemia caused by intrauterine hemolysis of fetal erythrocytes by maternal immunoglobulin G (IgG)-sensitized antibodies crossing the placenta. Hydrops is characterized by fetal edema, ascites, hypoalbuminemia, and heart failure. Causes of **nonimmune hydrops** include fetal arrhythmias (supraventricular tachycardia, congenital heart block), fetal anemia (parvovirus infection, bone marrow suppression, nonimmune hemolysis, or twin-to-twin transfusion), severe congenital malformation, intrauterine infections, congenital neuroblastoma, inborn errors of metabolism (storage diseases), fetal hepatitis, nephrotic syndrome, and pulmonary lymphangiectasia. Twin-to-twin transfusion syndrome (recipient) also may be associated with polyhydramnios. Polyhydramnios is often the result of unknown causes. If severe, polyhydramnios may be managed with bed rest, indomethacin, or serial amniocenteses.

Premature rupture of the membranes, which occurs in the absence of labor, and **prolonged rupture of the membranes** (>24 hours) are associated with an increased risk of maternal or fetal infection (chorioamnionitis) and preterm birth. In the immediate newborn period, group B streptococcus and *Escherichia coli* are the two most common pathogens associated with sepsis. *Listeria monocytogenes* is a less common cause. *Mycoplasma hominis*, *Ureaplasma urealyticum*, *Chlamydia trachomatis*, and anaerobic bacteria of the vaginal flora also have been implicated in infection of the amniotic fluid. Infection with community-acquired methicillin-resistant *Staphylococcus aureus* must be considered for infants with skin infections or with known exposures. The risk of serious fetal infection increases as the duration between rupture and labor (latent period) increases, especially if the period is greater than 24 hours. Intrapartum antibiotic therapy decreases the risk of neonatal sepsis.

Multiple gestations are associated with increased risk resulting from polyhydramnios, premature birth, IUGR, abnormal presentation (breech), congenital anomalies (intestinal atresia, porencephaly, and single umbilical artery), intrauterine fetal demise, birth asphyxia, and twin-to-twin transfusion syndrome. **Twin-to-twin transfusion syndrome** is associated with a high mortality and is seen only in monozygotic twins who share a common placenta and have an arteriovenous connection between their circulations. The fetus on the arterial side of the shunt serves as the blood donor, resulting in fetal anemia, growth restriction, and oligohydramnios for this fetus. The recipient, or venous-side twin, is larger or discordant in size, is plethoric and polycythemic, and may show polyhydramnios. Weight differences of 20% and hemoglobin differences of 5 g/dL suggest the diagnosis. Ultrasonography in the second trimester reveals discordant amniotic fluid volume with oliguria/oligohydramnios and hypervolemia/polyuria/polyhydramnios with a distended bladder, with or without hydrops and heart failure. Treatment includes attempts to ablate the arteriovenous connection (using a laser). The birth

order of twins also affects morbidity by increasing the risk of the second-born twin for breech position, birth asphyxia, birth trauma, and respiratory distress syndrome.

Overall, twinning is observed in 1 of 80 pregnancies; 80% of all twin gestations are dizygotic twins. The diagnosis of the type of twins can be determined by placentation, sex, fetal membrane structure, and, if necessary, DNA analysis.

Toxemia of pregnancy, or **preeclampsia/eclampsia**, is a disorder of unknown but probably vascular etiology that may lead to maternal hypertension, uteroplacental insufficiency, IUGR, intrauterine asphyxia, maternal seizures, and maternal death. Toxemia is more common in nulliparous women and in women with twin gestation, chronic hypertension, obesity, renal disease, positive family history of toxemia, or diabetes mellitus. A subcategory of preeclampsia, the **HELLP** syndrome (hemolysis, elevated liver enzyme levels, low platelets), is more severe and is often associated with a fetal inborn error of fatty acid oxidation (long-chain hydroxyacyl-coenzyme A dehydrogenase of the trifunctional protein complex).

FETUS AND NEWBORN

The late fetal-early neonatal period has the highest mortality rate of any age interval. **Perinatal mortality** refers to fetal deaths occurring from the 20th week of gestation until the 28th day after birth and is expressed as number of deaths per 1,000 live births. Intrauterine fetal death accounts for 40–50% of the perinatal mortality rate. Such infants, defined as **stillborn**, are born without a heart rate and are apneic, limp, pale, and cyanotic. Many stillborn infants exhibit evidence of maceration; pale, peeling skin; corneal opacification; and soft cranial contents.

Mortality rates around the time of birth are expressed as number of deaths per 1,000 live births. The **neonatal mortality rate** includes all infants dying during the period from after birth to the first 28 days of life. Modern neonatal intensive care allows many newborns with life-threatening diseases to survive the neonatal period, only to die of their original diseases or of complications of therapy after 28 days of life. This delayed mortality and mortality caused by acquired illnesses occurs during the **postneonatal period**, which begins after 28 days of life and extends to the end of the first year of life.

The **infant mortality rate** encompasses the neonatal and the postneonatal periods. In the United States, it declined to 5.5:1,000 in 2019. The rate for Black infants was approximately 10.9:1,000. The most common causes of perinatal and neonatal death are listed in [Table 58.1](#). Overall, congenital anomalies and diseases of the premature infant are the most significant causes of neonatal mortality.

Low birthweight (LBW) infants, defined as infants having birthweights of less than 2,500 g, represent a disproportionately large component of the neonatal and infant mortality rates. Although LBW infants make up only about 7–8% of all births, they account for more than 70% of neonatal deaths. IUGR is the most common cause of LBW in developing countries, whereas prematurity is the cause in developed countries.

Very low birthweight (VLBW) infants, weighing less than 1,500 g at birth, represent about 1.5% of all births but account for 50% of neonatal deaths. Compared with infants weighing 2,500 g or more, LBW infants are 40 times more likely to die in the neonatal period; VLBW infants have a 200-fold higher risk of neonatal death. The LBW rate has increased in recent years

and is one of the major reasons that the U.S. infant mortality rate is high compared with other large, modern, industrialized countries.

Maternal factors associated with a LBW caused by premature birth or IUGR include a previous LBW birth, low socioeconomic status, low level of maternal education, poor antenatal care, maternal age younger than 16 years or older than 35 years, short interval between pregnancies, cigarette smoking, alcohol and illicit drug use, physical (excessive standing or walking) or psychologic (poor social support) stresses, single parent, low prepregnancy weight (<45 kg), poor weight gain during pregnancy (<10 lb), and being Black. LBW and VLBW rates for Black women are twice the rates for White women. The neonatal and infant mortality rates are nearly twofold higher among Black infants. These racial differences are only partly explained by poverty; racism is an important factor.

ASSESSMENT OF THE FETUS

Fetal growth can be assessed by determining the fundal height of the uterus through bimanual examination of the gravid abdomen. **Fetal size** can be determined accurately by ultrasound techniques. Ultrasound measurements of the fetal biparietal diameter, femur length, and abdominal circumference are used to estimate fetal growth. A combination of these measurements predicts fetal weight. Deviations from the normal fetal growth curve are associated with high-risk conditions.

IUGR is present when fetal growth stops and, over time, declines to less than the 5th percentile of growth for gestational age or when growth proceeds slowly, but absolute size remains less than the 5th percentile. Growth restriction may result from fetal conditions that reduce the innate growth potential, such as fetal rubella infection, primordial dwarfing syndromes, chromosomal abnormalities, and congenital malformation syndromes. Reduced fetal production of insulin and insulin-like growth factor I is associated with fetal growth restriction. Placental causes of IUGR include villitis (congenital infections), placental tumors, chronic abruptio placentae, twin-to-twin transfusion syndrome, and placental insufficiency. Maternal causes include severe peripheral vascular diseases that reduce uterine blood flow (chronic hypertension, diabetic vasculopathy, and preeclampsia/eclampsia), reduced nutritional intake, alcohol or drug use, cigarette smoking, uterine constraint (noted predominantly in mothers of small stature with a low prepregnancy weight), and reduced weight gain during pregnancy. The outcome of IUGR depends on the cause of the reduced fetal growth and the associated complications after birth (Table 58.2). Fetuses subjected to chronic intrauterine hypoxia as a result of uteroplacental insufficiency are at an increased risk for the comorbidities of birth asphyxia, polycythemia, and hypoglycemia. Fetuses with reduced tissue mass due to chromosomal, metabolic, or multiple congenital anomaly syndromes have poor outcomes based on the prognosis for the particular syndrome. Fetuses born to small mothers and fetuses of mothers with poor nutritional intake usually show catch-up growth after birth.

Fetal size does not always correlate with functional or structural maturity. Determining **fetal maturity** is crucial when making a decision to deliver a fetus because of fetal or maternal disease. Fetal gestational age may be determined accurately on the basis of a correct estimate of the last menstrual period. Clinically relevant landmark dates can be used to determine gestational age; the first audible heart tones by fetoscope are detected at 18–20 weeks (12–14 weeks by Doppler methods), and quickening of fetal movements usually is perceived at 18–20 weeks. However, it is not always possible to determine fetal maturity by such dating, especially in a high-risk situation, such as preterm labor or a diabetic pregnancy; fetal ultrasonography before 20 weeks of gestation provides an accurate measure of gestational age.

Methods used to assess **fetal well-being** before the onset of labor are focused on identifying a fetus at risk for asphyxia or a fetus already compromised by uteroplacental insufficiency. The **oxytocin challenge test** simulates uterine contractions through an infusion of oxytocin sufficient to produce three contractions in a 10-minute period. The development of periodic fetal bradycardia out of phase with uterine contractions (late deceleration) is a positive test result and predicts an at-risk fetus.

TABLE 58.2 Problems of Intrauterine Growth Restriction and Small for Gestational Age	
PROBLEM*	PATHOGENESIS
Intrauterine fetal demise	Placental insufficiency, hypoxia, acidosis, infection, lethal anomaly
Temperature instability	Cold stress, ↓ fat stores, hypoxia, hypoglycemia
Perinatal asphyxia	↓ Uteroplacental perfusion during labor with or without chronic fetal hypoxia-acidosis, meconium aspiration syndrome
Hypoglycemia	↓ Tissue glycogen stores; ↓ gluconeogenesis, hyperinsulinism, ↑ glucose needs of hypoxia, hypothermia, relatively large brain
Polycythemia-hyperviscosity	Fetal hypoxia with ↑ erythropoietin production
Reduced oxygen consumption/hypothermia	Hypoxia, hypoglycemia, starvation effect, poor subcutaneous fat stores
Dysmorphology	Syndrome anomalads, chromosomal-genetic disorders, oligohydramnios-induced deformations
Pulmonary hemorrhage	Hypothermia, polycythemia, hypoxia

*Other problems are common to the gestational age–related risks of prematurity if born before 37 weeks.

Modified from Brady JM, Barnes-Davis ME, Poindexter BB. *The high-risk infant*. In Kliegman RM, St. Geme JW, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia: Elsevier; 2020.

The **nonstress test** examines the heart rate response to fetal body movements. Heart rate increases of more than 15 beats/min lasting 15 seconds are reassuring. If two such episodes occur in 30 minutes, the test result is considered reactive (versus nonreactive), and the fetus is not at risk. Additional signs of fetal well-being are fetal breathing movements, gross body movements, fetal tone, and the presence of amniotic fluid pockets more than 2 cm in size, detected by ultrasound. The **biophysical profile** combines the nonstress test with these four parameters and offers the most accurate fetal assessment.

Doppler examination of the fetal aorta or umbilical arteries permits identification of decreased or reversed diastolic blood flow associated with increased peripheral vascular resistance, fetal hypoxia with acidosis, and placental insufficiency. **Cordocentesis** (percutaneous umbilical blood sampling) can provide fetal blood for PaO_2 , pH, lactate, and hemoglobin measurements to identify a hypoxic, acidotic, or anemic fetus that is at risk for intrauterine fetal demise or birth asphyxia. Cordocentesis also can be used to determine fetal blood type, platelet count, microbial testing, antibody titer, and rapid karyotype.

In a high-risk pregnancy, the fetal heart rate should be monitored continuously during labor, as should uterine contractions. Fetal heart rate abnormalities may indicate baseline tachycardia (>160 beats/min as a result of anemia, β -sympathomimetic drugs, maternal fever, hyperthyroidism, arrhythmia, or fetal distress), baseline **bradycardia** (<120 beats/min as a result of fetal distress, complete heart block, or local anesthetics), or reduced beat-to-beat variability

(flattened tracing resulting from fetal sleep, tachycardia, atropine, sedatives, prematurity, or fetal distress). Periodic changes of the heart rate relative to uterine pressure help determine the presence of hypoxia and acidosis caused by uteroplacental insufficiency or maternal hypotension (late or type II decelerations) or by umbilical cord compression (variable decelerations). In the presence of severe decelerations (late or repeated prolonged variable), a fetal scalp blood gas level should be obtained to assess **fetal acidosis**. A scalp pH of less than 7.20 indicates fetal hypoxic compromise. A pH between 7.20 and 7.25 is in a borderline zone and warrants repeat testing.

Fetal anomalies may be detected by ultrasonography. Emphasis should be placed on visualization of the genitourinary tract; the head (for anencephaly or hydrocephaly), neck (for thickened nuchal translucency), and back (for spina bifida); skeleton; gastrointestinal tract; and heart. Four-chamber and great artery views are required for detection of heart anomalies. **Chromosomal anomaly syndromes** are often associated with an abnormal “quadruple test” (low unconjugated estriols, low maternal serum α -fetoprotein levels, high inhibin A, and elevated placental chorionic gonadotropin levels). Fetal genetic and chromosomal disorders can also be detected by analyzing free fetal DNA that is present in the maternal circulation. If a fetal abnormality is detected, fetal therapy or delivery with therapy in the neonatal intensive care unit may be lifesaving.

ASSESSMENT OF THE NEWBORN

The approach to the birth of an infant requires a detailed history (Table 58.3). Knowing the mother’s risk factors enables the delivery room team to anticipate problems that may occur. The history of a woman’s labor and delivery can reveal events that might lead to complications affecting either the mother or the neonate, even when the pregnancy was previously considered low risk. Anticipating the need to resuscitate a newborn as a result of fetal distress increases the likelihood of successful resuscitation.

The **transition from fetal to neonatal physiology** occurs at birth. Oxygen transport across the placenta results in a gradient between the maternal and fetal PaO_2 . Although fetal oxygenated blood has a low PaO_2 level compared with that of adults and infants, the fetus is not anaerobic. Fetal oxygen uptake and consumption are similar to neonatal rates, even though the thermal environments and activity levels of fetuses and neonates differ. The oxygen content of fetal blood is almost equal to the oxygen content in older infants and children because fetal blood has a much higher concentration of hemoglobin.

Fetal hemoglobin (two α and two γ chains) has a higher affinity for oxygen than adult hemoglobin, facilitating oxygen transfer across the placenta. The fetal hemoglobin-oxygen dissociation curve is shifted to the left of the adult curve (Fig. 58.1); at the same PaO_2 level, fetal hemoglobin is more saturated than adult hemoglobin. Because fetal hemoglobin functions on the steep, lower end of the oxygen saturation curve (PaO_2 , 20–30 mm Hg), oxygen unloading to the tissue is not deficient. In contrast, at the higher oxygen concentrations present in the placenta, oxygen loading is enhanced. In the last trimester, fetal hemoglobin production begins to decrease as adult hemoglobin production begins to increase, becoming the only hemoglobin available to the infant by 3–6 months

TABLE 58.3 Components of the Perinatal History

DEMOGRAPHIC SOCIAL INFORMATION	PRESENT PREGNANCY
Age	Current gestational age
Ethnicity	Method of assessing gestational age
Sexually transmitted infections, hepatitis, AIDS	Fetal surveillance (OCT, NST, biophysical profile)
Drugs: cigarettes, ethanol, cocaine, opiates	Ultrasonography (anomalies, hydrops)
Immune status (syphilis, rubella, hepatitis B, HIV, blood group)	Amniotic fluid analysis (L/S ratio)
Occupational exposure	Oligohydramnios-polyhydramnios
PAST MEDICAL DISEASES	Vaginal bleeding
Chronic hypertension	Preterm labor
Heart disease	Premature (prolonged) rupture of membranes (duration)
Diabetes mellitus	Preeclampsia
Thyroid disorders	Urinary tract infection
Hematologic/malignancy	Colonization status (herpes simplex, group B streptococcus)
Collagen-vascular disease (SLE)	Medications/drugs
Genetic history—inborn errors of metabolism, bleeding, jaundice	Acute medical illness/exposure to infectious agents
Drug therapy	Fetal therapy
PRIOR PREGNANCY	LABOR AND DELIVERY
Abortion/stillbirths	Duration of labor
Intrauterine fetal demise	Presentation—vertex, breech
Congenital malformation	Vaginal vs cesarean section
Incompetent cervix	Spontaneous labor vs augmented or induced with oxytocin (Pitocin)
Birthweight	Forceps delivery
Prematurity	Presence of meconium-stained fluid
Twins	Maternal fever/amnionitis
Blood group sensitization/neonatal jaundice	Fetal heart rate patterns (distress)
Hydrops	Scalp pH
Infertility	Maternal analgesia, anesthesia
	Nuchal cord
	Apgar score/methods of resuscitation
	Gestational age assessment
	Growth status (AGA, LGA, SGA)

AGA, Average for gestational age; AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; LGA, large for gestational age; L/S, lecithin-to-sphingomyelin ratio; NST, nonstress test; OCT, oxytocin challenge test; SGA, small for gestational age; SLE, systemic lupus erythematosus.

of life. At this time, the hemoglobin dissociation curve has shifted to the adult position.

A portion of well-oxygenated umbilical venous blood returning to the heart from the placenta partially perfuses the liver. The remainder bypasses the liver through a shunt (the **ductus venosus**) and enters the inferior vena cava. This oxygenated blood in the vena cava constitutes 65–70% of venous return to the right atrium. The crista dividens in the right atrium directs one third of this blood across the patent foramen ovale to the left atrium, where it subsequently is pumped to the coronary, cerebral, and upper extremity circulations by

the left ventricle. Venous return from the upper body combines with the remaining two thirds of the vena caval blood in the right atrium and is directed to the right ventricle. This mixture of venous low-oxygenated blood from the upper and lower body enters the pulmonary artery. Only 8–10% of it is pumped to the pulmonary circuit; the remaining 80–92% of the right ventricular output bypasses the lungs through **ductus arteriosus** and enters the descending aorta. Vasoconstriction produced by medial muscle hypertrophy of the pulmonary arterioles and fluid in the fetal lung increases resistance to pulmonary blood flow. Pulmonary artery tone

FIGURE 58.1 Hemoglobin-oxygen dissociation curves. The position of the adult curve depends on the binding of adult hemoglobin to 2,3-diphosphoglycerate (DPG), temperature, P_{CO_2} , and hydrogen ion concentration (pH).

also responds to hypoxia, hypercapnia, and acidosis with vasoconstriction, a response that may increase pulmonary vascular resistance further. The ductus arteriosus remains patent in the fetus because of low P_{aO_2} levels and dilating prostaglandins. In utero, the right ventricle is the dominant ventricle, pumping 65% of the combined ventricular output, which is a high volume (450 mL/kg/min) compared with that pumped by an older infant's right ventricle (200 mL/kg/min).

The **transition of circulation**, occurring between the fetal and neonatal periods, involves the removal of the low-resistance circulation of the placenta, the onset of breathing, reduction of pulmonary arterial resistance, and closure of in utero shunts. Clamping the umbilical cord eliminates the low-pressure system of the placenta and increases systemic blood pressure. Decreased venous return from the placenta decreases right atrial pressure. As breathing begins, air replaces lung fluid, maintaining the functional residual capacity. Fluid leaves the lung, in part, through the trachea; it is either swallowed or squeezed out during vaginal delivery. The pulmonary lymphatic and venous systems reabsorb the remaining fluid.

Most normal infants require little pressure to spontaneously open the lungs after birth (5–10 cm H_2O). With the onset of breathing, pulmonary vascular resistance decreases, partly a result of the mechanics of breathing and partly a result of the elevated arterial oxygen tensions. The increased blood flow to the lungs increases the volume of pulmonary venous blood returning to the left atrium; left atrial pressure now exceeds right atrial pressure, and the foramen ovale closes. As the flow through the pulmonary circulation increases and arterial oxygen tensions rise, the ductus arteriosus begins to constrict. In a term infant, this constriction functionally closes the ductus arteriosus within 1 day after birth. A permanent closure requires thrombosis and fibrosis, a process that may

take several weeks. In a premature infant, the ductus arteriosus is less sensitive to the effects of oxygen; if circulating levels of vasodilating prostaglandins are elevated, the ductus arteriosus may remain patent. This patency is a common problem in a premature infant with respiratory distress syndrome.

Ventilation, oxygenation, and normal pH and P_{CO_2} levels immediately reduce pulmonary artery vasoconstriction by causing smooth muscle relaxation. Remodeling of the medial muscle hypertrophy begins at birth and continues for the next 3 months, resulting in a further reduction of pulmonary vascular resistance and a further increase of pulmonary blood flow. Persistence or aggravation of pulmonary vasoconstriction caused by acidosis, hypoxia, hypercapnia, hypothermia, polycythemia, asphyxia, shunting of blood from the lungs, or pulmonary parenchymal hypoplasia results in **persistent pulmonary hypertension of the newborn (PPHN)**. Failure to replace pulmonary alveolar fluid completely with air can lead to respiratory distress (**transient tachypnea of the newborn**).

Routine Delivery Room Care and Resuscitation

Silver nitrate (1%) instilled into both eyes without being washed out is an indicated effective therapy for the prevention of neonatal gonococcal ophthalmia, which can result in severe panophthalmitis and subsequent blindness. Silver nitrate may produce a chemical conjunctivitis with a mucopurulent discharge and is not effective against *Chlamydia trachomatis*. Many hospitals use erythromycin drops to prevent neonatal gonococcal and chlamydial eye disease.

Bacterial colonization of a newborn may begin in utero if the fetal membranes have been ruptured. Most infants undergo colonization after birth and acquire the bacteria present in the mother's genitourinary system, such as group B streptococci, staphylococci, *Escherichia coli*, and Clostridia. Antiseptic skin or cord care is routine in many nurseries to prevent the spread of pathologic bacteria from one infant to another and to prevent disease in the individual infant. Staphylococcal bullous impetigo, omphalitis, diarrhea, and systemic disease may result from colonization with virulent *S. aureus*. Antibiotic ointment, topical alcohol, or chlorhexidine may be applied to the umbilical cord to reduce its colonization with gram-positive bacteria. Nonetheless, many newborn units recommend dry cord care. Epidemics of *S. aureus* nursery infections are managed with strict infectious disease control measures (cohorting, handwashing, and monitoring for colonization).

Vitamin K prophylaxis (intramuscular) should be given to all infants to prevent hemorrhagic disease of the newborn. Before discharge, infants should receive the hepatitis B vaccine and be screened for various diseases (Tables 58.4, 58.5, and 58.6). New diseases are being added to newborn screening, including lysosomal storage diseases and spinal muscular atrophy.

The **Apgar examination**, a rapid scoring system based on physiologic responses to the birth process, is a good method for assessing the need to resuscitate a newborn (Table 58.7). At intervals of 1 and 5 minutes after birth, each of the five physiologic parameters is observed or elicited by a qualified examiner. Full-term infants with a normal cardiopulmonary adaptation should score 8–9 at 1 and 5 minutes. Apgar scores of 4–7 warrant close attention to determine whether the infant's status will improve and to ascertain whether any pathologic condition is contributing to the low Apgar score.

An Apgar score of 0–3 represents either a cardiopulmonary arrest or a condition caused by severe bradycardia, hypoventilation, or central nervous system depression. Most low Apgar scores are caused by difficulty in establishing adequate ventilation and not by primary cardiac pathology. In addition to an Apgar score of 0–3, most infants with asphyxia severe

TABLE 58.6 Abnormal Newborn Screening Results: Possible Implications and Initial Action to Be Taken

NEWBORN SCREENING FINDING	DIFFERENTIAL DIAGNOSIS	INITIAL ACTION
↑ Phenylalanine	PKU, non-PKU hyperphenylalaninemia, pterin defect, galactosemia, transient hyperphenylalaninemia	Repeat blood specimen
↓ T ₄ , ↑ TSH	Congenital hypothyroidism, iodine exposure	Repeat blood specimen or thyroid function testing, begin thyroxine treatment
↓ T ₄ , normal TSH	Maternal hyperthyroidism, thyroxine-binding globulin deficiency, secondary hypothyroidism, congenital hypothyroidism with delayed TSH elevation	Repeat blood specimen
↑ Galactose 1-P	Galactosemia, liver disease, reducing substance, repeat deficiency variant (Duarte), transient	Clinical evaluation, urine for blood specimen. If reducing substance positive, begin lactose-free formula
↓ Galactose-1-phosphate uridylyltransferase	Galactosemia, transferase deficiency variant (Duarte), transient	Clinical evaluation, urine for reducing substance, repeat blood specimen. If reducing substance positive, begin lactose-free formula
↑ Methionine	Homocystinuria, isolated liver dysfunction, tyrosinemia type I, transient hypermethioninemia	Repeat blood and urine specimen
↑ Leucine	Maple syrup urine disease, transient elevation	Clinical evaluation including urine for ketones, acid-base status, amino acid studies, immediate neonatal ICU care if urine ketones positive
↑ Tyrosine	Tyrosinemia type I or type II, transient tyrosinemia, liver disease	Repeat blood specimen
↑ 17α-hydroxyprogesterone	Congenital adrenal hyperplasia, prematurity, transient (residual fetal adrenal cortex), stress in neonatal period, early specimen collection	Clinical evaluation including genital examination, serum electrolytes, repeat blood specimen
S-hemoglobin	Sickle cell disease, sickle cell trait	Hemoglobin electrophoresis
↑ Trypsinogen	Cystic fibrosis, transient, intestinal anomalies, perinatal stress, trisomies 13 and 18, renal failure	Repeat blood specimen, possible sweat test and DNA testing
↑ Creatinine phosphokinase	Duchenne muscular dystrophy, other type of muscular dystrophy, birth trauma, invasive procedure	Repeat blood test
↓ Biotinidase	Biotinidase deficiency	Serum biotinidase assay, biotin therapy
↓ G6PD	G6PD deficiency	Complete blood count, bilirubin determination
↓ α ₁ -antitrypsin	α ₁ -antitrypsin deficiency	Confirmatory test
Toxoplasma antibody (IgM)	Congenital toxoplasmosis	Infectious disease consultation
HIV antibody (IgG)	Maternally transmitted HIV, possible AIDS	Infectious disease consultation
↑ Organic acids	Fatty acid oxidation defects (medium-chain acyl-CoA dehydrogenase deficiency)	Perform specific assay (tandem mass spectroscopy); frequent feeds

AIDS, Acquired immunodeficiency syndrome; G6PD, glucose-6-phosphate dehydrogenase; HIV, human immunodeficiency virus; ICU, intensive care unit; PKU, phenylketonuria; T₄, thyroxine; TSH, thyroid-stimulating hormone.

From Kim SZ, Levy HL. Newborn screening. In: Taeusch HW, Ballard RA, eds. Avery's Diseases of the Newborn. 7th ed. Philadelphia: Saunders; 1998.

TABLE 58.7 Apgar Score

SIGNS	POINTS		
	0	1	2
Heart rate	0	<100/min	>100/min
Respiration	None	Weak cry	Vigorous cry
Muscle tone	None	Some extremity flexion	Arms, legs well flexed
Reflex irritability	None	Some motion	Cry, withdrawal
Color of body	Blue	Pink body, blue extremities	Pink all over

enough to cause neurologic injury also manifest fetal acidosis (pH <7); seizures, coma, or hypotonia; and multiorgan dysfunction. Low Apgar scores may be caused by fetal hypoxia or other factors listed in Table 58.8. Most infants with low Apgar scores respond to assisted ventilation by face mask or by endotracheal intubation and usually do not need emergency medication.

About 80–85% of infants born at term will initiate spontaneous breathing by 10 to 30 seconds; another 10% will begin respirations with stimulation. However, about 3% of infants will establish spontaneous breathing only after positive pressure ventilation (PPV) while another 2% will require endotracheal intubation and less than 1% will require chest compressions and medications.

TABLE 58.8 Etiology of Birth Asphyxia

TYPE	EXAMPLE
INTRAUTERINE	
Hypoxia-ischemia	Uteroplacental insufficiency, abruptio placentae, prolapsed cord, maternal hypotension, unknown
Anemia-shock	Vasa previa, placenta previa, fetomaternal hemorrhage, erythroblastosis
INTRAPARTUM	
Birth trauma	Cephalopelvic disproportion, shoulder dystocia, breech presentation, spinal cord transection
Hypoxia-ischemia	Umbilical cord compression, tetanic uterine contraction, abruptio placentae
POSTPARTUM	
Central nervous system	Maternal medication, trauma, previous episodes of fetal hypoxia-acidosis
Congenital neuromuscular disease	Congenital myasthenia gravis, myopathy, myotonic dystrophy
Infection	Consolidated pneumonia, shock
Airway disorder	Choanal atresia, severe obstructing goiter or tumor, laryngeal webs
Pulmonary disorder	Severe immaturity, pneumothorax, pleural effusion, diaphragmatic hernia, pulmonary hypoplasia
Renal disorder	Pulmonary hypoplasia, pneumothorax

Resuscitation of the newborn is a process of assessment, intervention, and reassessment. It begins with the initial steps of providing warmth ensuring that the airway is patent and open, clearing the airway of secretions (as needed), drying, and providing gentle tactile stimulation. Observation of the infant drives the resuscitation. The baby should be observed for vigor and muscle tone, along with heart rate, and respirations, including use of a pulse oximeter. If the baby is vigorous with good muscle tone, heart rate is above 100 beats/minute, and breathing (unlabored), no further resuscitation is needed. Alternatively, if the neonate is apneic or hypoventilating and remains cyanotic, artificial ventilation should be initiated. Ventilation should be performed with a well-fitted mask attached to an anesthesia bag and a manometer to prevent extremely high pressures from being given to the newborn; initially 21% oxygen (for infants >35 weeks gestational age) should be administered through the mask. If the infant does not revive, an endotracheal tube should be placed, attached to the anesthesia bag and manometer, and 21% oxygen should be administered. If 21% (room air) is ineffective, the F_{iO_2} may be increased to 100% oxygen; continuous pulse oximetry monitors oxygenation. The pressure generated should begin at 20–25 cm H_2O , with a rate of 40–60 breaths/minute. An adequate response to ventilation includes good chest rise, return of breath sounds, well-oxygenated color, heart rate returning to the normal range (120–160 beats/minute), normal end-tidal carbon dioxide, and, later, increased muscle activity and wakefulness. The usual recovery after a cardiac arrest first involves a return to a normal heart rate, followed by disappearance of cyanosis and noticeably improved perfusion. An infant may remain limp and be apneic for a prolonged time after return of cardiac output and correction of acidosis.

Resuscitation of a newborn with low Apgar score follows the same systematic sequence as that for resuscitation of older patients, but in the newborn period this simplified

ABCD approach requires some qualification (Fig. 58.2). In the ABCD approach, **A** stands for securing a patent **airway** by clearing amniotic fluid or meconium by suctioning; **A** is also a reminder of *anticipation* and the need for knowing the events of pregnancy, labor, and delivery. Evidence of a diaphragmatic hernia and a low Apgar score indicate that immediate endotracheal intubation is required. If a mask and bag are used, gas enters the lung and the stomach, and the latter may act as an expanding mass in the chest that compromises respiration. If fetal hydrops has occurred with pleural effusions, bilateral thoracentesis to evacuate the pleural effusions may be needed to establish adequate ventilation.

B represents **breathing**. If the neonate is apneic or hypoventilating and remains cyanotic, artificial ventilation should be initiated. Ventilation should be performed with a well-fitted mask attached to an anesthesia bag and a manometer to prevent extremely high pressures from being given to the newborn; 100% oxygen should be administered through the mask. If the infant does not revive, an endotracheal tube should be placed, attached to the anesthesia bag and manometer, and 100% oxygen should be administered. The pressure generated should begin at 20–25 cm H_2O , with a rate of 40–60 breaths/minute. An adequate response to ventilation includes good chest rise, return of breath sounds, well-oxygenated color, heart rate returning to the normal range (120–160 beats/minute), normal end-tidal carbon dioxide, and, later, increased muscle activity and wakefulness.

C represents **circulation**. Concurrently, while assessing the pulmonary status of the infant, heart rate is critical to assess. If artificial ventilation does not improve bradycardia, if asystole is present, or if peripheral pulses cannot be palpated, external cardiac massage should be performed at a rate of 120 compressions/minute with compressions and breaths given at a ratio of 3:1 (3 compressions followed by 1 breath). External cardiac massage usually is not needed because most infants in the delivery room respond to ventilation.

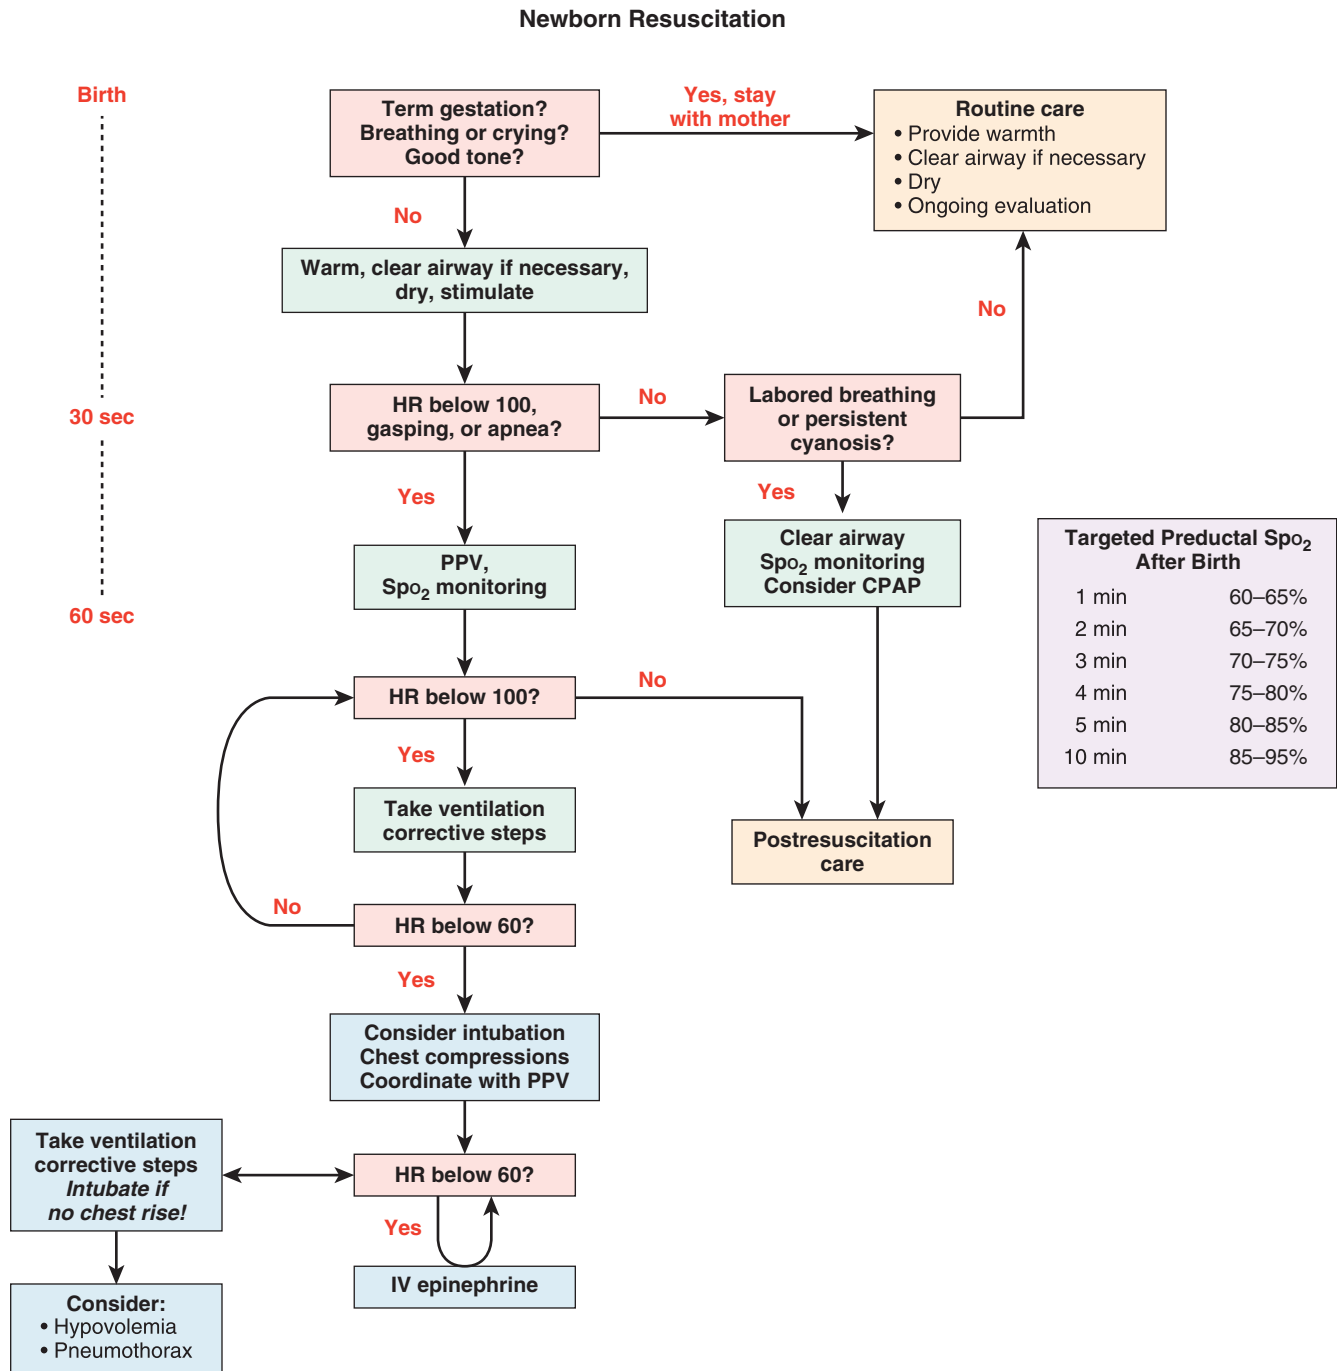

FIGURE 58.2 New guidelines and algorithm for neonatal resuscitation. CPAP, Continuous positive airway pressure; IV, intravenous; HR, heart rate; PPV, positive pressure ventilation; Sp_o₂, blood oxygen saturation. (From Kattwinkel J, Perlman JM, Aziz K, et al. Special report—neonatal resuscitation: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. *Pediatrics*. 2010;126[5]:e1400–e1413. Erratum in *Neoreviews* 2011;128[1]:176.)

D represents the administration of **drugs**. If bradycardia is unresponsive to ventilation or if asystole is present, epinephrine should be administered. Intravenous (IV) epinephrine (1:10,000), 0.1–0.3 mL/kg, should be given through an umbilical venous line or injected into the endotracheal tube. However, when epinephrine is administered through the endotracheal tube, the result is unpredictable. Before medications are administered in the presence of electrical

cardiac activity with poor pulses, it is important to determine whether there is a pneumothorax. Transillumination of the thorax, involving the use of a bright light through each side of the thorax and over the sternum, may suggest pneumothorax if one side transmits more light than the other. Breath sounds may be decreased over a pneumothorax, and there may be a shift of the heart tones away from the side of a tension pneumothorax.

TABLE 58.9 Life-Threatening Congenital Anomalies

NAME	MANIFESTATIONS
Choanal atresia (stenosis)	Respiratory distress in delivery room, apnea, unable to pass nasogastric tube through nares
Pierre Robin (Stickler) syndrome	Micrognathia, cleft palate, airway obstruction
Diaphragmatic hernia	Scaphoid abdomen, bowel sounds present in left chest, heart shifted to right, respiratory distress, polyhydramnios
Tracheoesophageal fistula	Polyhydramnios, aspiration pneumonia, excessive salivation, unable to place nasogastric tube in stomach
Intestinal obstruction: volvulus, duodenal atresia, ileal atresia	Polyhydramnios, bile-stained emesis, abdominal distention
Gastroschisis/omphalocele	Polyhydramnios; intestinal obstruction
Renal agenesis/Potter syndrome	Oligohydramnios, anuria, pulmonary hypoplasia, pneumothorax
Hydronephrosis	Bilateral abdominal masses
Neural tube defects: anencephaly, meningomyelocele	Polyhydramnios, elevated α -fetoprotein; decreased fetal activity
Down syndrome (trisomy 21)	Hypotonia, congenital heart disease, duodenal atresia
Ductal-dependent congenital heart disease	Cyanosis, murmur, shock

If central nervous system depression in the infant may be due to a narcotic medication given to or taken by the mother acutely, 0.1 mg/kg of naloxone (Narcan) can be given to the infant intravenously or endotracheally. Before this drug is administered, resuscitation should be followed carefully. Naloxone should not be given to a newborn of a mother who is suspected of being addicted to narcotics or is on methadone maintenance because the newborn may experience severe withdrawal seizures.

In babies of more than 35 weeks of gestation suffering moderate to severe hypoxic-ischemic injury at birth, induced therapeutic **hypothermia** (33.0–34.0°C) for 72 hours has been shown in clinical studies to be efficacious in reducing the severity of brain injury. Brain hypothermia, whether induced by whole body or selective head cooling, provides neuroprotection against encephalopathy presumably due to hypoxic ischemia.

Physical Examination and Gestational Age Assessment

The first physical examination of a newborn may be a general physical examination of a well infant or an examination to confirm fetal diagnoses or to determine the cause of various manifestations of neonatal diseases. Problems in the transition from fetal to neonatal life may be detectable immediately in the delivery room or during the first day of life. Physical examination also may reveal effects of the labor and delivery resulting from asphyxia, drugs, or birth trauma. The first newborn examination is an important way to detect congenital malformations or deformations (Table 58.9). Significant congenital malformations may be present in 1–3% of all births.

Appearance

Signs such as cyanosis, nasal flaring, intercostal retractions, and grunting suggest pulmonary disease. Meconium staining

of the umbilical cord, nails, and skin suggest fetal distress and the possibility of aspiration pneumonia. The level of spontaneous activity, passive muscle tone, quality of the cry, and apnea are useful screening signs to evaluate the state of the nervous system.

Vital Signs

The examination should proceed with an assessment of vital signs, particularly heart rate (normal rate, 120–160 beats/minute), respiratory rate (normal rate, 30–60 breaths/minute), temperature (usually done per rectum and later as an axillary measurement), and blood pressure (often reserved for sick infants). Length, weight, and head circumference should be measured and plotted on growth curves to determine whether growth is normal, accelerated, or retarded for the specific gestational age.

Gestational Age

Gestational age is determined by an assessment of various physical signs (Fig. 58.3) and neuromuscular characteristics (Fig. 58.4) that vary according to fetal age and maturity. **Physical criteria** mature with advancing fetal age, including increasing firmness of the pinna of the ear; increasing size of the breast tissue; decreasing fine, immature lanugo hair over the back; and decreasing opacity of the skin. **Neurologic criteria** mature with gestational age, including increasing flexion of the legs, hips, and arms; increasing tone of the flexor muscles of the neck; and decreasing laxity of the joints. These signs are determined during the first day of life and are assigned scores. The cumulative score is correlated with a gestational age, which is usually accurate to within 2 weeks (Fig. 58.5).

Gestational age assessment permits the detection of abnormal fetal growth patterns, aiding in predicting the neonatal complications for large or small for gestational age infants (Fig. 58.6). Infants born at a weight greater than the 90th percentile for age are considered **large for gestational age**. Among

Physical maturity	-1	0	1	2	3	4	5
Skin	Sticky, friable, transparent	Gelatinous, red, translucent	Smooth, pink, visible veins	Superficial peeling or rash, few veins	Cracking, pale areas, rare veins	Parchment, deep cracking, no vessels	Leathery, cracked, wrinkled
Lanugo	None	Sparse	Abundant	Thinning	Bald areas	Mostly bald	
Plantar surface	Heel-toe 40-50 mm: -1 Less than 40 mm: -2	<50 mm, no crease	Faint red marks	Anterior transverse crease only	Creases on anterior ² / ₃	Creases over entire sole	
Breast	Imperceptible	Barely perceptible	Flat areola-no bud	Stripped areola, 1-2 mm bud	Raised areola, 3-4 mm bud	Full areola, 5-10 mm bud	
Eye/ear	Lids fused, loosely (-1), tightly (-2)	Lids open, pinna flat, stays folded	Slightly curved pinna; soft, slow recoil	Well-curved pinna, soft but ready recoil	Formed and firm; instant recoil	Thick cartilage, ear stiff	
Genitals male	Scrotum flat, smooth	Scrotum empty, faint rugae	Testes in upper canal, rare rugae	Testes descending, few rugae	Testes down, good rugae	Testes pendulous, deep rugae	
Genitals female	Clitoris prominent, labia flat	Prominent clitoris, small labia minora	Prominent clitoris, enlarging minora	Majora and minora equally prominent	Majora large, minora small	Majora cover clitoris and minora

the risks associated with being large for gestational age are all the risks of the infant of a diabetic mother and risks associated with postmaturity. Infants born at a weight less than 10th percentile for age (some growth curves use <2 standard deviations or the 5th percentile) are **small for gestational age** and have IUGR. Problems associated with small for gestational age infants include congenital malformations, in addition to the problems listed in [Table 58.2](#).

Skin

The skin should be evaluated for pallor, plethora, jaundice, cyanosis, meconium staining, petechiae, ecchymoses, congenital nevi, and neonatal rashes. Vasomotor instability with cutis marmorata, telangiectasia, phlebectasia (intermittent mottling with venous prominence), and acrocyanosis (feet and hands) is normal in a premature infant. Acrocyanosis also may be noted in a healthy term infant in the first days after birth.

The skin is covered with lanugo hair, which disappears by term gestation. **Hair tufts** over the lumbosacral spine suggest a spinal cord defect. **Vernix caseosa**, a soft, white, creamy layer covering the skin in preterm infants, disappears by term. Post-term infants often have peeling, parchmentlike skin. **Mongolian spots** are transient, dark blue to black pigmented macules seen over the lower back and buttocks in 90% of Black, Indian, and Asian infants. **Nevus simplex** (*salmon patch*), or pink macular hemangioma, is common, usually transient, and noted on the back of the neck, eyelids, and forehead. **Nevus flammeus**, or **port-wine stain**, is seen on the face and should cause the examiner to consider Sturge-Weber syndrome (trigeminal angiomatosis, convulsions, and ipsilateral intracranial *tram-line* calcifications).

Congenital melanocytic nevi are pigmented lesions of varying size noted in 1% of neonates. **Giant pigmented nevi** are uncommon but have malignant potential. **Capillary hemangiomas** are raised, red lesions, whereas **cavernous hemangiomas** are deeper, blue masses. Both lesions increase in size after birth then resolve over 1–4 years. When enlarged, these hemangiomas may produce high-output heart failure or platelet trapping and hemorrhage. **Erythema toxicum** is an erythematous, papular-vesicular rash common in neonates that develops after birth and involves eosinophils in the vesicular fluid. **Pustular melanosis**, more common in Black infants, may be seen at birth and consists of small, dry vesicles on a pigmented brown macular base. Erythema toxicum and pustular melanosis are benign lesions but may mimic more serious conditions, such as the vesicular rash of disseminated herpes simplex or the bullous eruption of *S. aureus* impetigo. Tzanck smear, Gram stain, Wright stain, direct fluorescent antibody stain, polymerase chain reaction for herpes DNA, and appropriate cultures may be needed to distinguish these rashes. Other common characteristic rashes are **milia** (yellow-white epidermal cysts of the pilosebaceous follicles that are noted on the nose) and **miliaria** (prickly heat), which is caused by obstructed sweat glands. **Edema** may be present in preterm infants but also suggests hypodermis fetalis, sepsis, hypoalbuminemia, or lymphatic disorders.

Skull

The skull may be elongated and molded after a prolonged labor; this resolves 2–3 days after birth. The sutures should be palpated to determine the width and the presence of premature fusion or cranial synostosis. The anterior and posterior fontanelles should be soft and nonbulging, with the anterior larger than the posterior. A large fontanel is associated with hydrocephalus, hypothyroidism, rickets, and other disorders. Soft areas away from the fontanel are **craniotabes**; these lesions feel like a Ping-Pong ball when they are palpated. They may be a result of in utero compression. The skull should be examined carefully for signs of trauma or lacerations from internal fetal electrode sites or fetal scalp pH sampling; abscesses may develop in these areas.

Vaginal delivery or prolonged labor prior to a cesarean section may result in a **caput succedaneum**, a soft edematous subcutaneous scalp swelling that crosses suture lines, or a **cephalohematoma**, a subperiosteal hematoma confined within suture lines.

Face, Eyes, and Mouth

The face should be inspected for dysmorphic features, such as epicanthal folds, hypertelorism, preauricular tags or sinuses, low-set ears, long philtrum, and cleft lip or palate. Facial asymmetry may be a result of seventh nerve palsy; head tilt may be caused by torticollis.

The eyes should open spontaneously, especially in an upright position. Before 28 weeks gestational age, the eyelids may be fused. Coloboma, megalocornea, and microphthalmia suggest other malformations or intrauterine infections. A cloudy cornea greater than 1 cm in diameter also may be seen in congenital glaucoma, uveal tract dysgenesis, and storage diseases. Conjunctival and retinal hemorrhages are common and usually of no significance. The pupillary response to light is present at 28 weeks of gestation. The **red reflex** of the retina is shown easily. A white reflex, or **leukokoria**, is abnormal and may be the result

of cataracts, ocular tumor, severe chorioretinitis, persistent hyperplastic primary vitreous, or retinopathy of prematurity.

The mouth should be inspected for the presence of natal teeth, clefts of the soft and hard palate and uvula, and micrognathia. A bifid uvula suggests a submucosal cleft. White, shiny, multiple transient epidermal inclusion cysts (Epstein pearls) on the hard palate are normal. Hard, marble-sized masses in the buccal mucosa are usually transient idiopathic fat necrosis. The **tympanic membranes** are dull, gray, opaque, and immobile in the first 1–4 weeks. These findings should not be confused with otitis media.

Neck and Chest

The neck appears short and symmetric. Abnormalities include midline clefts or masses caused by thyroglossal duct cysts or by goiter and lateral neck masses (or sinuses), which are the result of branchial clefts. Cystic hygromas (lymphangiomas) and hemangiomas may be present. Shortening of the sternocleidomastoid muscle with a fibrous tumor over the muscle produces head tilt and asymmetric facies (neonatal torticollis). Arnold-Chiari malformation and cervical spine lesions also produce torticollis. Edema and webbing of the neck suggest Turner syndrome. Both clavicles should be palpated for fractures.

Examination of the **chest** includes inspection of the chest wall to identify asymmetry resulting from absence of the pectoralis muscle and inspection of the breast tissue to determine gestational age and detect a breast abscess. Boys and girls may have breast engorgement and produce milk; milk expression should not be attempted. **Supernumerary nipples** may be bilateral and may be associated with renal anomalies.

Lungs

Examination of the lungs includes observations of the rate, depth, and nature of intercostal or sternal retractions. Breath sounds should be equal on both sides of the chest, and rales should not be heard after the first 1–2 hours of life. Diminished or absent breath sounds on one side suggest pneumothorax, collapsed lung, pleural effusion, or diaphragmatic hernia. Shift of the cardiac impulse away from a tension pneumothorax and diaphragmatic hernia and toward the collapsed lung is a helpful physical finding for differentiating these disorders. Subcutaneous emphysema of the neck or chest also suggests a pneumothorax or pneumomediastinum, whereas bowel sounds auscultated in the chest in the presence of a scaphoid abdomen suggest a diaphragmatic hernia.

Heart

The position of the heart in infants is more midline than in older children. The first heart sound is normal, whereas the second heart sound may not be split in the first day of life. Decreased splitting of the second heart sound is noted in PPHN, transposition of the great vessels, and pulmonary atresia. Heart murmurs in newborns are common in the delivery room and during the first day of life. Most of these murmurs are transient and are due to closure of the ductus arteriosus, peripheral pulmonary artery stenosis, or a small ventricular septal defect. Pulses should be palpated in the upper and lower extremities (over the brachial and femoral arteries). Blood pressure in the upper and lower extremities should be measured in all patients with a murmur or heart failure. An upper-to-lower extremity gradient of more than 10–20 mm Hg suggests coarctation of the aorta.

Abdomen

A normal liver may be palpable up to 2 cm below the right costal margin. The spleen tip is less likely to be palpable. A left-sided liver suggests situs inversus and asplenia syndrome. Both kidneys should be palpable in the first day of life with gentle, deep palpation. The first urination occurs during the first day of life in more than 95% of normal term infants.

Abdominal masses usually represent hydronephrosis or dysplastic-multicystic kidney disease. Less often, masses indicate ovarian cysts, intestinal duplication, neuroblastoma, or mesoblastic nephroma. Masses should be evaluated immediately with ultrasound. Abdominal distention may be caused by intestinal obstructions, such as ileal atresia, meconium ileus, midgut volvulus, imperforate anus, or Hirschsprung disease. Meconium stool is passed normally within 48 hours of birth in 99% of term infants. The anus should be patent. An imperforate anus is not always visible; the first temperature taken with a rectal thermometer should be taken carefully. The abdominal wall musculature may be absent, as in prune-belly syndrome, or weak, resulting in diastasis recti. **Umbilical hernias** are common in Black infants. The umbilical cord should be inspected to determine the presence of two arteries and one vein and the absence of an urachus or a herniation of abdominal contents, as occurs with an **omphalocele**. The latter is associated with extraintestinal problems, such as genetic trisomies and hypoglycemia (Beckwith-Wiedemann syndrome). Bleeding from the cord suggests a coagulation disorder, and a chronic discharge may be a granuloma of the umbilical stump or, less frequently, a draining omphalomesenteric cyst or urachus. Erythema around the umbilicus is **omphalitis** and may cause portal vein thrombophlebitis and subsequent extrahepatic portal hypertension. The herniation of bowel through the abdominal wall 2–3 cm lateral to the umbilicus is a **gastroschisis**.

Genitalia

At term, the testes should be descended into a well-formed pigmented and rugated scrotum. The testes occasionally are in the inguinal canal; this is more common among preterm infants, as is cryptorchidism. Scrotal swelling may represent a hernia, transient hydrocele, in utero torsion of the testes, or, rarely, dissected meconium from meconium ileus and peritonitis. Hydroceles are clear and readily seen by transillumination, whereas testicular torsion in the newborn may present as a painless, dark swelling. The urethral opening should be at the end of the penis. Epispadias or hypospadias alone should not raise concern about pseudohermaphroditism. However, if no testes are present in the scrotum and hypospadias is present, problems of sexual development should be suspected. Circumcision should be deferred with hypospadias because the foreskin is often needed for the repair. The normal prepuce is often too tight to retract in the neonatal period.

The female genitalia normally may reveal a milky white or blood-streaked vaginal discharge as a result of maternal hormone withdrawal. Mucosal tags of the labia majora are common. Distention of an imperforate hymen may produce hydrometrocolpos and a lower midline abdominal mass as a result of an enlarged uterus. Clitoral enlargement with fusion of the labial-scrotal folds (labia majora) suggests adrenogenital syndrome or exposure to masculinizing maternal hormones.

Extremities

Examination of the extremities should involve assessment of length, symmetry, and presence of hemihypertrophy, atrophy, polydactyly, syndactyly, simian creases, absent fingers, overlapping fingers, rocker-bottom feet, clubfoot, congenital bands, fractures, and amputations.

Spine

The spine should be examined for evidence of sacral hair tufts, a dermal sinus tract above the gluteal folds, congenital scoliosis (a result of hemivertebra), and soft tissue masses such as lipomas or meningomyeloceles.

Hips

The hips should be examined for congenital dysplasia (dislocation). Gluteal fold asymmetry or leg length discrepancy is suggestive of dysplasia, but the examiner should perform the Barlow test and the Ortolani maneuver to evaluate the stability of the hip joint. These tests determine whether the femoral head can be displaced from the acetabulum (**Barlow test**) and then replaced (**Ortolani maneuver**).

NEUROLOGIC ASSESSMENT

The neurologic examination should include assessment of active and passive tone, level of alertness, primary neonatal (primitive) reflexes, deep tendon reflexes, spontaneous motor activity, and cranial nerves (involving retinal examination, extraocular muscle movement, masseter power as in sucking, facial motility, hearing, and tongue function). The Moro reflex, present at birth and gone in 3–6 months, is one of the primary newborn reflexes. It is elicited by sudden, slight dropping of the supported head from a slightly raised supine position, which should elicit opening of the hands and extension and abduction of the arms, followed by upper extremity flexion and a cry. The palmar grasp is present by 28 weeks of gestation and gone by 4 months of age. Deep tendon reflexes may be brisk in a normal newborn; 5–10 beats of ankle clonus are normal. The Babinski sign is extensor (upgoing). The sensory examination can be evaluated by withdrawal of an extremity, grimace, and cry in response to painful stimuli. The rooting reflex (turning of the head toward light tactile stimulation of the perioral area) is present by 32 weeks of gestation.

Special Conditions Requiring Resuscitation in the Delivery Room

Cyanosis

Acrocyanosis (blue color of the hands and feet with pink color of the rest of the body) is common in the delivery room and is usually normal. **Central cyanosis** of the trunk, mucosal membranes, and tongue can occur at any time after birth and is always a manifestation of a serious underlying condition. Cyanosis is noted with 4–5 g/dL of deoxygenated hemoglobin. Central cyanosis can be caused by problems in many different organ systems, although cardiopulmonary diseases are the most common (Table 58.10). Respiratory distress syndrome, sepsis, and cyanotic heart disease are the three most common causes of cyanosis in infants admitted to a neonatal intensive care unit. A systematic evaluation of these and other causes of cyanosis is required for every cyanotic infant after prompt administration of oxygen, with or without assisted ventilation.

TABLE 58.10 Differential Diagnosis of Neonatal Cyanosis	
SYSTEM/DISEASE	MECHANISM
PULMONARY	
Respiratory distress syndrome	Surfactant deficiency
Sepsis, pneumonia	Inflammation, pulmonary hypertension, ARDS
Meconium aspiration pneumonia	Mechanical obstruction, inflammation, pulmonary hypertension
Persistent pulmonary hypertension of the newborn	Pulmonary hypertension
Diaphragmatic hernia	Pulmonary hypoplasia, pulmonary hypertension
Transient tachypnea	Retained lung fluid
CARDIOVASCULAR	
Cyanotic heart disease with decreased pulmonary blood flow	Right-to-left shunt as in pulmonary atresia, tetralogy of Fallot
Cyanotic heart disease with increased pulmonary blood flow	Mixing lesion as in single ventricle or truncus arteriosus
Cyanotic heart disease with congestive heart failure	Pulmonary edema and poor cardiac output as in hypoplastic left heart and coarctation of aorta
Heart failure alone	Pulmonary edema and poor cardiac contractility as in sepsis, myocarditis, supraventricular tachycardia, or complete heart block; high-output failure as in PDA or vein of Galen or other arteriovenous malformations
CENTRAL NERVOUS SYSTEM (CNS)	
Maternal sedative drugs	Hypoventilation, apnea
Asphyxia	CNS depression
Intracranial hemorrhage	CNS depression, seizure
Neuromuscular disease	Hypotonia, hypoventilation, pulmonary hypoplasia
HEMATOLOGIC	
Acute blood loss	Shock
Chronic blood loss	Heart failure
Polycythemia	Pulmonary hypertension
Methemoglobinemia	Low-affinity hemoglobin or red blood cell enzyme defect
METABOLIC	
Hypoglycemia	CNS depression, congestive heart failure
Adrenogenital syndrome	Shock (salt-losing)

ARDS, Acute respiratory distress syndrome; CNS, central nervous system; PDA, patent ductus arteriosus.

Life-Threatening Congenital Malformations

Various congenital anomalies can interfere with vital organ function after birth (see Table 58.10). Some malformations, such as choanal atresia and other lesions obstructing the airway, may complicate ventilation. Intrathoracic lesions, such as cysts or diaphragmatic hernia, interfere with respiration. Other malformations that obstruct the gastrointestinal system at the level of the esophagus, duodenum, ileum, or colon may lead to aspiration pneumonia, intestinal perforation, or gangrene. Gastroschisis and omphalocele are associated with exposed bowel on the abdominal wall. Omphalocele is often associated with other malformations, whereas intestinal necrosis is more common in gastroschisis.

Perinatal Hypoxia and Asphyxia

Whether in utero or after birth, asphyxia-caused **hypoxic-ischemic brain injury** (encephalopathy) is the result of reduced gaseous exchange through the placenta or through the lungs. Asphyxia associated with severe bradycardia or cardiac insufficiency reduces or eliminates tissue blood flow, resulting in ischemia. The fetal and neonatal circulatory systems respond to reduced oxygen availability by shunting the blood preferentially to the brain, heart, and adrenal glands and away from the intestine, kidneys, lungs, and skin.

Metabolic acidosis during asphyxia is caused by the combined effects of poor cardiac output secondary to hypoxic depression of myocardial function, systemic hypoxia, and

TABLE 58.11 Effects of Asphyxia

SYSTEM	EFFECT
Central nervous system	Hypoxic-ischemic encephalopathy, IVH, PVL, cerebral edema, seizures, hypotonia, hypertonia
Cardiovascular	Myocardial ischemia, poor contractility, tricuspid insufficiency, hypotension
Pulmonary	Persistent pulmonary hypertension, respiratory distress syndrome
Renal	Acute tubular or cortical necrosis
Adrenal	Adrenal haemorrhage
Gastrointestinal	Perforation, ulceration, necrosis
Metabolic	Inappropriate ADH, hyponatremia, hypoglycemia, hypocalcemia, myoglobinuria
Integument	Subcutaneous fat necrosis
Hematology	Disseminated intravascular coagulation

ADH, Antidiuretic hormone; IVH, intraventricular hemorrhage; PVL, periventricular leukomalacia.

tissue anaerobic metabolism. With severe or prolonged intrauterine or neonatal asphyxia, multiple vital organs are affected (Table 58.11).

Many conditions that contribute to **fetal or neonatal asphyxia** are the same medical or obstetric problems associated with high-risk pregnancy (see Table 58.8). Maternal diseases that interfere with uteroplacental perfusion (chronic hypertension, preeclampsia, and diabetes mellitus) place the fetus at risk for intrauterine asphyxia. Maternal epidural anesthesia and the development of the vena caval compression syndrome may produce maternal hypotension, which decreases uterine perfusion. Maternal medications given to relieve pain during labor may cross the placenta and depress the infant's respiratory center, resulting in apnea at the time of birth.

Fetal conditions associated with asphyxia usually do not become manifested until delivery, when the infant must initiate and sustain ventilation. In addition, the upper and lower airways must be patent and unobstructed. Alveoli must be free from foreign material (meconium, amniotic fluid debris, and infectious exudates), which increases airway resistance, reduces lung compliance, and leads to respiratory distress and hypoxia. Some extremely immature infants weighing less than 1,000 g at birth may be unable to expand their lungs, even in the absence of other pathology. Their compliant chest walls and surfactant deficiency may result in poor air exchange, retractions, hypoxia, and apnea.

The newborn (particularly a preterm infant) responds paradoxically to hypoxia with apnea rather than tachypnea as occurs in adults. Episodes of intrauterine asphyxia also may depress the neonatal central nervous system. If recovery of the fetal heart rate occurs as a result of improved uteroplacental perfusion, fetal hypoxia and acidosis may resolve. Nonetheless, if the effect on the respiratory center is more severe, a newborn may not initiate an adequate ventilatory response at birth and may undergo another episode of asphyxia.

Shock

Shock in the delivery room is manifested by pallor, poor capillary refill time, lack of palpable pulses, hypotonia, cyanosis, and eventually cardiopulmonary arrest. Blood loss before or during labor and delivery is a common cause of shock in the delivery room. Blood loss may be caused by fetal-maternal hemorrhage, placenta previa, vasa previa, twin-to-twin transfusion syndrome, or displacement of blood from the fetus to the placenta as during asphyxia (*asphyxia pallida*). Hemorrhage into a viscus, such as the liver or spleen, may be noted in macrosomic infants, and hemorrhage into the cerebral ventricles may produce shock and apnea in preterm infants. Anemia, hypoalbuminemia, hypovolemia, and shock at birth are common manifestations of Rh immune hydrops.

Severe intrauterine bacterial sepsis may present with shock in the delivery room or immediately after the infant is transferred to the nursery. Typically, these infants are mottled, hypotonic, and cyanotic and have diminished peripheral pulses. They have a normal hemoglobin concentration but may manifest neutropenia, thrombocytopenia, and disseminated intravascular coagulation. Peripheral symmetric gangrene (purpuric rash) often is a sign of hypotensive shock in infants with severe congenital bacterial infections. Congenital left ventricular cardiac obstruction (critical aortic stenosis or hypoplastic left heart syndrome) also produces shock, although not usually in the delivery room.

Treatment of newborn infants with shock should involve the management approaches used for the sick infant. Problems may be anticipated through knowledge of the infant's immune status, evidence of hydrops, or suspicion of intrauterine infection or anomalies. Stabilization of the airway and institution of respiratory support are essential. Hypovolemic shock should be managed with repeated boluses of 10–15 mL/kg of normal saline or lactated Ringer solution. If severe immune hemolysis is predicted, blood typed against the mother's blood should be available in the delivery room and should be given to the newborn if signs of anemia and shock are present. Thereafter, all blood should be cross-matched with the infant's and mother's blood before transfusion. Drugs such as dopamine, epinephrine, or cortisol may improve cardiac output and tissue perfusion.

Birth Injury

Birth injury refers to avoidable and unavoidable injury to the fetus during the birth process. **Caput succedaneum** is a diffuse, edematous, often dark swelling of the soft tissue of the scalp that extends across the midline and suture lines. In infants delivered from a face presentation, soft tissue edema of the eyelids and face is an equivalent phenomenon. Caput succedaneum may be seen after prolonged labor in full-term and preterm infants. Molding of the head often is associated with caput succedaneum and is the result of pressure that is induced from overriding the parietal and frontal bones against their respective sutures.

A **cephalhematoma** is a subperiosteal hemorrhage that does not cross the suture lines surrounding the respective bones. A linear skull fracture rarely may be seen underlying a cephalhematoma. With time, the cephalhematoma may organize, calcify, and form a central depression.

Infants with cephalhematoma and caput succedaneum require no specific treatment. Occasionally a premature infant

may develop a massive scalp hemorrhage. This **subgaleal bleeding** and the blood within a cephalhematoma may cause indirect hyperbilirubinemia requiring phototherapy. **Retinal and subconjunctival hemorrhages** are common but usually are small and insignificant; no treatment is necessary.

Spinal cord or spine injuries may occur in the fetus as a result of the hyperextended *star gazing* posture. Injuries also may occur in infants after excessive rotational (at C3–4) or longitudinal (at C7–T1) force is transmitted to the neck during vertex or breech delivery. Fractures of vertebrae are rare; trauma may cause direct damage to the spinal cord, leading to transection and permanent sequelae, hemorrhage, edema, and neurologic signs. Rarely, a snapping sound indicating cord transection rather than vertebral displacement is heard at the time of delivery. Neurologic dysfunction usually involves complete flaccid paralysis, absence of deep tendon reflexes, and absence of responses to painful stimuli below the lesion. Painful stimuli may elicit reflex flexion of the legs. Infants with spinal cord injury often are flaccid, apneic, and asphyxiated, all of which may mask the underlying spinal cord transection.

Injury to the nerves of the **brachial plexus** may result from excessive traction on the neck, producing paresis or complete paralysis. The mildest injury (neurapraxia) is edema; axonotmesis is more severe and consists of disrupted nerve fibers with an intact myelin sheath; neurotmesis, or complete nerve disruption or root avulsion, is most severe. **Erb-Duchenne paralysis** involves the fifth and sixth cervical nerves and is the most common and usually mildest injury. The infant cannot abduct the arm at the shoulder, externally rotate the arm, or supinate the forearm. The usual picture is one of painless adduction, internal rotation of the arm, and pronation of the forearm. The **Moro reflex** is absent on the involved side; the hand grasp is intact. **Phrenic nerve palsy** (C3, C4, and C5) may lead to diaphragmatic paralysis and respiratory distress. Elevation of the diaphragm caused by nerve injury must be differentiated from elevation caused by eventration resulting from congenital weakness or absence of diaphragm muscle. **Klumpke paralysis** is caused by injury to the seventh and eighth cervical nerves and the first thoracic nerve, resulting in a paralyzed hand and, if the sympathetic nerves are injured, an ipsilateral **Horner syndrome** (ptosis, miosis). Complete arm and hand paralysis are noted with the most severe form of damage to C5, C6, C7, C8, and T1. **Treatment** of brachial plexus injury is supportive and includes positioning to avoid contractures. Active and passive range of motion exercises also may be beneficial. If the deficit persists, nerve grafting may be beneficial.

Facial nerve injury may be the result of compression of the seventh nerve between the facial bone and the mother's pelvic bones or the physician's forceps. This peripheral nerve injury is characterized by an asymmetric crying face whose normal side, including the forehead, moves in a regular manner. The affected side is flaccid, the eye does not close, the nasolabial fold is absent, and the side of the mouth droops at rest. If there is a central injury to the facial nerve, only the lower two thirds of the face (not the forehead) are involved. Complete agenesis of the facial nucleus results in a central facial paralysis; when this is bilateral, as in **Möbius syndrome**, the face appears expressionless.

Skull fractures are rare, are usually linear, and require no treatment other than observation for very rare, delayed

(1–3 months) complications (e.g., leptomeningeal cyst). Depressed skull fractures are unusual but may be seen with complicated forceps delivery and may need surgical elevation. Fractures of the **clavicle** usually are unilateral and are noted in macrosomic infants after shoulder dystocia. Often a snap is heard after a difficult delivery, and the infant exhibits an asymmetric Moro response and decreased movement of the affected side. The prognosis is excellent; many infants require no treatment or a simple figure-of-eight bandage to immobilize the bone.

Extremity fractures are less common than fractures of the clavicle and involve the humerus more often than the femur. **Treatment** involves immobilization and a triangular splint bandage for the humerus and traction suspension of the legs for femoral fractures. The prognosis is excellent.

Fractures of the **facial bones** are rare, but dislocation of the cartilaginous part of the nasal septum out of the vomeral groove and columella is common. Clinical manifestations include feeding difficulty, respiratory distress, asymmetric nares, and a flattened, laterally displaced nose. Treatment reduces the dislocation by elevating the cartilage back into the vomeral groove.

Visceral trauma to the liver, spleen, or adrenal gland occurs in macrosomic infants and in extremely premature infants, with or without breech or vaginal delivery. Rupture of the liver with subcapsular hematoma formation may lead to anemia, hypovolemia, shock, hemoperitoneum, and disseminated intravascular coagulation. Infants with anemia and shock who are suspected to have an intraventricular hemorrhage but with a normal head ultrasound examination should be evaluated for hepatic or splenic rupture. Adrenal hemorrhage may be asymptomatic, detected only by finding calcified adrenal glands in normal infants. Infants with severe adrenal hemorrhage may exhibit a flank mass, jaundice, and hematuria, with or without shock.

Temperature Regulation

After birth, a newborn remains covered by amniotic fluid and situated in a cold environment (20–25°C). An infant's skin temperature may decrease 0.3°C/minute, and the core temperature may decrease 0.1°C/minute in the delivery room. In the absence of an external heat source, the infant must increase metabolism substantially to maintain body temperature.

Heat loss occurs through four basic mechanisms. In the cold delivery room, the wet infant loses heat predominantly by **evaporation** (cutaneous and respiratory loss when wet or in low humidity), **radiation** (loss to nearby cold, solid surfaces), and **convection** (loss to air current). When the infant is dry, radiation, convection, and **conduction** (loss to object in direct contact with infant) are important causes of heat loss. After birth, all high-risk infants should be dried immediately to eliminate evaporative heat losses. A radiant or convective heat source should be provided for high-risk infants. Normal term infants should be dried and wrapped in a blanket.

The ideal environmental temperature is the **neutral thermal environment**, the ambient temperature that results in the lowest rate of heat being produced by the infant and maintains normal body temperature. The neutral thermal environmental temperature decreases with increasing gestational and postnatal age. Ambient temperatures less than the neutral thermal environment result in increasing rates of oxygen consumption

for heat production. If the ambient temperature decreases further or if oxygen consumption cannot increase sufficiently (due to hypoxia, hypoglycemia, or drugs), the core body temperature decreases.

Heat production by a newborn is created predominantly by nonshivering thermogenesis in specialized areas of tissue containing brown adipose tissue. Brown fat is highly vascular, contains many mitochondria per cell, and is situated around large blood vessels, resulting in rapid heat transfer to the circulation. The vessels of the neck, thorax, and interscapular region are common locations of brown fat. These tissues also are innervated by the sympathetic nervous system, which serves as a primary stimulus for heat production by brown adipose cells. Shivering does not occur in newborns.

Severe **cold injury** in an infant is manifested by acidosis, hypoxia, hypoglycemia, apnea, bradycardia, pulmonary hemorrhage, and a pink skin color. The color is caused by trapping of oxygenated hemoglobin in the cutaneous capillaries. Many of these infants appear dead, but most respond to treatment and recover. Milder degrees of cold injury in the delivery room may contribute to metabolic acidosis and hypoxia after birth. Conversely, hypoxia delays heat generation in cold-stressed infants.

Treatment of severe hypothermia should involve resuscitation and rapid warming of core (e.g., lung and stomach) and external surfaces. Fluid resuscitation also is needed to treat hypovolemia seen in many of these infants. Reduced core temperature (32–35°C) in the immediate newborn period often requires only external warming with a radiant warmer, incubator, or both.

Elevated Temperature

Exposure to ambient temperatures above the neutral thermal environment results in *heat stress* and an elevated core temperature. Sweating is uncommon in newborns and may be noted only on the forehead. In response to moderate heat stress, infants may increase their respiratory rate to dissipate heat. Excessive environmental temperatures may result in heat stroke or in hemorrhagic shock encephalopathy syndrome.

MISCELLANEOUS DISORDERS

Hypocalcemia

Hypocalcemia is common in sick and premature newborns. Calcium levels are higher in cord blood than in maternal blood because of active placental transfer of calcium to the fetus. Fetal calcium accretion in the third trimester approaches 150 mg/kg/24 hours; fetal bone mineral content doubles between 30 and 40 weeks of gestation. All infants show a slight decline of serum calcium levels after birth, reaching a trough level at 24–48 hours, the point at which hypocalcemia usually occurs. Total serum calcium levels of less than 7 mg/dL and ionized calcium levels of less than 3–3.5 mg/dL are considered hypocalcemia.

The etiology of hypocalcemia varies with the time of onset and the associated illnesses of the child. **Early neonatal hypocalcemia** occurs in the first 3 days of life and is often asymptomatic. Transient hypoparathyroidism and a reduced parathyroid response to the usual postnatal decline of serum calcium levels may be responsible for hypocalcemia in premature infants and infants of diabetic mothers. Congenital

absences of the parathyroid gland with DiGeorge syndrome is a cause of hypocalcemia. **Hypomagnesemia** (<1.5 mg/dL) may be seen simultaneously with hypocalcemia, especially in infants of diabetic mothers. Treatment with calcium alone does not relieve symptoms or increase serum calcium levels until hypomagnesemia is also treated. Sodium bicarbonate therapy, phosphate release from cell necrosis, transient hypoparathyroidism, and hypercalcitoninemia may be responsible for early neonatal hypocalcemia associated with asphyxia. Early-onset hypocalcemia associated with asphyxia often occurs with seizures as a result of hypoxic-ischemic encephalopathy.

Late neonatal hypocalcemia, or **neonatal tetany**, often is the result of ingestion of high phosphate-containing milk or the inability to excrete the usual phosphorus in commercial infant formula. Hyperphosphatemia (>8 mg/dL) usually occurs in infants with hypocalcemia after the first week of life. Vitamin D deficiency states and malabsorption also have been associated with late-onset hypocalcemia.

The clinical manifestations of hypocalcemia and hypomagnesemia include apnea, muscle twitching, seizures, and laryngospasm. The **Chvostek sign** (facial muscle spasm when the side of the face over the seventh nerve is tapped) and **Trousseau sign** (carpedal spasm induced by partial inflation of a blood pressure cuff) are rare in the immediate newborn period.

Neonatal hypocalcemia may be prevented in high-risk neonates by administration of IV or oral calcium supplementation at a rate of 25–75 mg/kg/24 hours. Early asymptomatic hypocalcemia of preterm infants and infants of diabetic mothers often resolves spontaneously. Symptomatic hypocalcemia should be treated with 2–4 mL/kg of 10% calcium gluconate given intravenously slowly over 10–15 minutes, followed by a continuous infusion of 75 mg/kg/24 hours of elemental calcium. If hypomagnesemia is associated with hypocalcemia, 50% magnesium sulfate, 0.1 mL/kg, should be given by intramuscular injection and repeated every 8–12 hours.

The **treatment** of late hypocalcemia includes immediate management plus the initiation of feedings with low-phosphate formula. Subcutaneous infiltration of IV calcium salts can cause tissue necrosis; oral supplements are hypertonic and may irritate the intestinal mucosa.

Neonatal Drug Withdrawal

Infants may become passively and physiologically addicted to medications or to drugs of abuse (heroin, methadone, barbiturates, tranquilizers, amphetamines) taken chronically by the mother during pregnancy; these infants may subsequently have signs and symptoms of drug withdrawal. Many of these pregnancies are at high risk for other complications related to IV drug abuse, such as hepatitis, AIDS, and syphilis. In addition, the LBW rate and the long-term risk for sudden infant death syndrome are higher in the infants of these high-risk women.

Opiates

Neonatal withdrawal signs and symptoms of neonatal abstinence syndrome (NAS) usually begin at 1–5 days of life with maternal heroin use and at 1–4 weeks with maternal

methadone use. Clinical manifestations of withdrawal include sneezing, yawning, ravenous appetite, emesis, diarrhea, fever, diaphoresis, tachypnea, high-pitched cry, tremors, jitteriness, poor sleep, poor feeding, and seizures. Symptoms tend to be more severe during methadone withdrawal. The initial treatment includes swaddling in blankets in a quiet, dark room. When hyperactivity is constant, and irritability interferes with sleeping and feeding, or when diarrhea or seizures are present, pharmacologic treatment is indicated. Opioids are the first-line pharmacotherapy for NAS; weaning from narcotics may be prolonged over 1–2 months. Phenobarbital is often the first drug of choice for nonopiate withdrawal or seizures associated with opiate withdrawal.

Cocaine

Cocaine use during pregnancy is associated with preterm labor, abruptio placentae, neonatal irritability, and decreased attentiveness. Infants may be small for gestational age and have small head circumferences. Usually no treatment is needed.

PEARLS FOR PRACTITIONERS

See *Fetal and Neonatal Medicine: Pearls for Practitioners* at the end of this section.

CHAPTER 59

Maternal Diseases Affecting the Newborn

Maternal diseases during pregnancy can affect the fetus directly or indirectly (Table 59.1). Autoantibody-mediated diseases can have direct consequences on the fetus and neonate because the antibodies are usually of the immunoglobulin G (IgG) type and can cross the placenta to the fetal circulation.

ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid syndrome is associated with thrombophilia and recurrent pregnancy loss. Antiphospholipid antibodies are found in 2–5% of the general healthy population, but they also may be associated with systemic lupus erythematosus (SLE) and other rheumatic diseases. Obstetric complications arise from the prothrombotic effects of the antiphospholipid antibodies on placental function. Vasculopathy, infarction, and thrombosis have been identified in mothers with antiphospholipid syndrome. Antiphospholipid syndrome can include fetal growth impairment, placental insufficiency, maternal preeclampsia, premature birth, and possible fetal thrombosis.

IDIOPATHIC (IMMUNE) THROMBOCYTOPENIA

Idiopathic thrombocytopenic purpura (ITP) is seen in approximately 1–2 per 1,000 live births and is an immune process in which platelet-associated IgG antibodies directed against platelets cross the placenta and cause thrombocytopenia in the fetus and newborn. The severely thrombocytopenic fetus is at increased risk for intracranial hemorrhage. ITP during pregnancy requires close maternal and fetal management to reduce the risks of life-threatening maternal hemorrhage and trauma to the fetus at delivery. Postnatal management involves observation of the infant's platelet count. For infants who have evidence of hemorrhage, single-donor irradiated platelets may be administered to control the bleeding. The infant may benefit from an infusion of intravenous immunoglobulin. Neonatal thrombocytopenia usually resolves within 4–6 weeks.

SYSTEMIC LUPUS ERYTHEMATOSUS

Immune abnormalities in SLE can lead to the production of anti-Ro (SS-A) and anti-La (SS-B) antibodies that can cross the placenta and injure fetal tissue. The most serious complication is damage to the cardiac conducting system, which results in **congenital heart block**. This heart block tends to be complete (third degree), although less advanced blocks have been observed. The mortality rate is approximately 20%; most surviving infants require pacing. Neonatal lupus may occur and is characterized by skin lesions (sharply demarcated erythematous plaques or central atrophic macules with peripheral scaling with predilection for the eyes, face, and scalp), thrombocytopenia, autoimmune hemolysis, and hepatic involvement.

NEONATAL HYPERTHYROIDISM

Graves disease is associated with thyroid-stimulating antibodies. The prevalence of clinical hyperthyroidism in pregnancy has been reported to be about 0.1–0.4%; it is the second most common endocrine disorder during pregnancy (after diabetes). Neonatal hyperthyroidism is due to the transplacental passage of thyroid-stimulating antibodies; hyperthyroidism can appear rapidly within the first 12–48 hours. Symptoms may include intrauterine growth restriction, prematurity, goiter (may cause tracheal obstruction), exophthalmos, stare, craniosynostosis (usually coronal), flushing, heart failure, tachycardia, arrhythmias, hypertension, hypoglycemia, thrombocytopenia, and hepatosplenomegaly. Treatment includes propylthiouracil, iodine drops, and propranolol. Autoimmune induced neonatal hyperthyroidism usually resolves in 2–4 months.

DIABETES MELLITUS

Both diabetes mellitus that develops during pregnancy (*gestational diabetes*, noted in about 5% of women) and diabetes that

TABLE 59.1 Maternal Conditions Affecting the Fetus or Neonate		
DISORDER	EFFECT(S)	MECHANISM(S)
Assisted reproductive technology	Beckwith-Wiedemann, Silver-Russel, Angelman syndromes	Altered imprinting
Autoantibody against folate receptors	Neural tube defects	Blockage of cellular uptake of folate
Cervical neoplasia	Preterm premature rupture of membranes, preterm birth	Associated with loop electrosurgical excision procedure or cone therapy
Cholestasis	Preterm delivery, intrauterine fetal demise	Unknown, possibly bile acid–induced fetal arrhythmia
Cyanotic heart disease	IUGR	Low fetal oxygen delivery
Diabetes mellitus:		
Mild	LGA, hypoglycemia	Fetal hyperglycemia: produces hyperinsulinemia; insulin promotes growth
Severe	Growth restriction	Vascular disease, placental insufficiency
Drug addiction	IUGR, neonatal withdrawal	Direct drug effect plus poor nutrition
Endemic goiter	Hypothyroidism	Iodine deficiency
Graves disease	Transient neonatal thyrotoxicosis	Transplacental passage of IgG thyroid-stimulating antibody
Herpes gestationis (noninfectious)	Bullous rash, intrauterine fetal demise	Autoantibody similar to that in bullous pemphigoid
Hyperparathyroidism	Neonatal hypocalcemia	Maternal calcium crosses to fetus and suppresses fetal parathyroid gland
Hypertension	IUGR, intrauterine fetal demise	Placental insufficiency, fetal hypoxia
Idiopathic thrombocytopenic purpura	Thrombocytopenia	Nonspecific maternal platelet antibodies cross placenta
Isoimmune neutropenia or thrombocytopenia	Neutropenia or thrombocytopenia	Specific antifetus neutrophil or platelet antibody crosses placenta after sensitization of mother
Malignant melanoma	Placental or fetal tumor	Placental metastasis
Myasthenia gravis	Transient neonatal myasthenia	IgG antibody to acetylcholine receptor crosses placenta
Myotonic dystrophy	Neonatal myotonic dystrophy, congenital contractures, respiratory insufficiency	Genetic anticipation
NMDAR antibody encephalitis	Cortical dysplasia	Transplacental antibody
Obesity	LGA or IUGR, hypoglycemia	Unknown, similarities to diabetes
Phenylketonuria	Microcephaly, retardation	Elevated fetal phenylalanine values
Poor nutrition	IUGR, adult insulin resistance	Reduced fetal nutrients, nutritional programming
Preeclampsia, eclampsia	IUGR, thrombocytopenia, neutropenia, fetal demise	Uteroplacental insufficiency, fetal hypoxia, vasoconstriction
Renal transplantation	IUGR	Uteroplacental insufficiency
Rhesus or other blood group sensitization	Fetal anemia, hypoalbuminemia, hydrops, neonatal jaundice	IgG crosses placenta and is directed to fetal cells with antigen
Sickle cell anemia	Preterm birth, IUGR, stillbirth	Placental insufficiency via maternal sickling, producing fetal hypoxia
Systemic lupus erythematosus	Congenital heart block, rash, anemia, thrombocytopenia, neutropenia	Antibody directed to fetal heart, red and white blood cells, and platelets

IgG, Immunoglobulin G; LGA, large for gestational age; NMDAR, antibody to N-methyl-D-aspartate receptor; IUGR, intrauterine growth restriction. From Suhrie KR, Tabbah SM. High-risk pregnancies. In Kliegman RM, St. Geme J, eds. Nelson Textbook of Pediatrics. 21st ed. Philadelphia: Elsevier, 2020 [table 114.2].

is present before pregnancy adversely influence fetal and neonatal well-being. The effect of diabetes on the fetus depends, in part, on the severity of the diabetic state: age of onset of diabetes, duration of treatment with insulin, and presence of vascular disease. Poorly controlled maternal diabetes leads to maternal and fetal hyperglycemia that stimulates the fetal pancreas, resulting in hyperplasia of the islets of Langerhans. Fetal hyperinsulinemia results in increased fat and protein synthesis, producing a fetus that is large for gestational age. After birth, hyperinsulinemia persists, resulting in fasting neonatal hypoglycemia. Strictly controlling maternal diabetes during pregnancy and preventing hyperglycemia during labor and delivery prevent macrosomic fetal growth and neonatal hypoglycemia. Additional problems of the diabetic mother and her fetus and newborn are summarized in Table 59.2.

OTHER CONDITIONS

Other maternal illnesses, such as severe pulmonary disease (cystic fibrosis), cyanotic heart disease, and sickle cell anemia, may reduce oxygen availability to the fetus. Severe hypertensive or diabetic vasculopathy can result in uteroplacental insufficiency. The fetus and the newborn may also be adversely affected by the medications used to treat maternal illnesses. These effects may appear as teratogenesis or as an adverse metabolic, neurologic, or cardiopulmonary adaptation to extrauterine life (Table 59.3). Acquired infectious diseases of the mother also may affect the fetus or newborn adversely.

PEARLS FOR PRACTITIONERS

See *Fetal and Neonatal Medicine: Pearls for Practitioners* at the end of this section.

TABLE 59.2 Problems of Diabetic Pregnancy

MATERNAL
Ketoacidosis
Hyperglycemia/hypoglycemia
Nephritis
Preeclampsia
Polyhydramnios
Retinopathy
NEONATAL
Birth asphyxia
Birth injury (macrosomia, shoulder dystocia)
Congenital anomalies (lumbosacral dysgenesis—caudal regression)
Congenital heart disease (ventricular and atrial septal defects, transposition of the great arteries, truncus arteriosus, double-outlet right ventricle, coarctation of the aorta)
Hyperbilirubinemia (unconjugated)
Hypocalcemia
Hypoglycemia
Hypomagnesemia
Neurologic disorders (neural tube defects, holoprosencephaly)
Organomegaly
Polycythemia (hyperviscosity)
Renal disorders (double ureter, renal vein thrombosis, hydronephrosis, renal agenesis)
Respiratory distress syndrome
Small left colon syndrome
Transient tachypnea of the newborn

TABLE 59.3 Maternal Medications and Toxins: Possible Effects on the Fetus and Newborn

MEDICATION	EFFECT ON FETUS AND NEWBORN
ANALGESICS AND ANTIINFLAMMATORIES	
Acetaminophen	Generally safe except with maternal overdose
Aspirin	Hemorrhage, premature closure of ductus arteriosus, pulmonary artery hypertension (effects not seen at ≤ 100 mg/day)
Opiates	Neonatal abstinence syndrome with chronic use
Ibuprofen	Reduced amniotic fluid volume when used in tocolysis; risk for premature ductus arteriosus closure and pulmonary hypertension
Indomethacin	Closure of fetal ductus arteriosus and pulmonary artery hypertension
Meperidine	Respiratory depression peaks 2 to 3 hours after maternal dose
ANESTHETICS	
General anesthesia	Respiratory depression of infant at delivery with prolonged anesthesia just before delivery
Lidocaine	High serum levels cause central nervous system (CNS) depression; accidental direct injection into the fetal head causes seizures

Continued

TABLE 59.3 Maternal Medications and Toxins: Possible Effects on the Fetus and Newborn—cont'd

MEDICATION	EFFECT ON FETUS AND NEWBORN
ANTIBIOTICS	
Aminoglycosides	Ototoxicity reported after use of kanamycin and streptomycin
Cephalosporins	Some drugs in this group displace bilirubin from albumin
Isoniazid	Risk for folate deficiency
Metronidazole	Potential teratogen and carcinogen, but not proven in humans
Penicillins	Generally no adverse effect
Tetracyclines	Yellow-brown staining of infant's teeth (when given at ≥ 5 months of gestation); stillbirth and prematurity due to maternal hepatotoxicity
Sulfonamides	Some drugs in this group displace bilirubin from albumin; can cause kernicterus
Trimethoprim	Folate antagonism
Vancomycin	Potential for ototoxicity
ANTICONVULSANTS	
Carbamazepine	Neural tube defects; midfacial hypoplasia
Phenobarbital	Withdrawal symptoms, hemorrhagic disease; midfacial hypoplasia
Phenytoin	Hemorrhagic disease; fetal hydantoin syndrome: growth and mental deficiency, midfacial hypoplasia, hypoplasia of distal phalanges
Trimethadione	Fetal trimethadione syndrome: growth and mental deficiency, abnormal facies (including synophrys with upslanting eyebrows), cleft lip and palate, cardiac and genital anomalies
Valproic acid	Neural tube defects, midfacial hypoplasia
ANTICOAGULANTS	
Warfarin (Coumadin)	Warfarin embryopathy: stippled epiphyses, growth and mental deficiencies, seizures, hypoplastic nose, eye defects, CNS anomalies including Dandy-Walker syndrome
Heparin	No direct adverse effects on the fetus
ANTINEOPLASTICS	
Aminopterin	Cleft palate, hydrocephalus, meningomyelocele, intrauterine growth restriction
Cyclophosphamide	Intrauterine growth restriction, cardiovascular and digital anomalies
Methotrexate	Absent digits, CNS malformation
ANTITHYROID DRUGS	
Iodide-containing drugs	Hypothyroidism
Methimazole	Hypothyroidism, cutis aplasia
Potassium iodide	Hypothyroidism and goiter, especially with chronic use
Propylthiouracil	Hypothyroidism
Iodine 131	Hypothyroidism, partial to complete ablation of thyroid gland
ANTIVIRALS	
Acyclovir	No definite adverse effects
Ribavirin	Teratogenic and embryolethal in animals
Zidovudine	Potential for fetal bone marrow suppression; combined maternal and neonatal treatment reduces perinatal transmission of human immunodeficiency virus
CARDIOVASCULAR DRUGS AND ANTIHYPERTENSIVES	
Angiotensin-converting enzyme inhibitors	Fetal hypocalvaria, oligohydramnios and fetal compression, oliguria, renal failure
β -blockers (propranolol)	Neonatal bradycardia, hypoglycemia

Continued

TABLE 59.3 Maternal Medications and Toxins: Possible Effects on the Fetus and Newborn—cont'd	
MEDICATION	EFFECT ON FETUS AND NEWBORN
Calcium channel blockers	If maternal hypotension occurs, this could affect placental blood flow
Diazoxide	Hyperglycemia; decreased placental perfusion with maternal hypotension
Digoxin	Fetal toxicity with maternal overdose
Hydralazine	If maternal hypotension occurs, this could affect placental blood flow
Methyldopa	Mild, clinically insignificant decrease in neonatal blood pressure
DIURETICS	
Furosemide	Increases fetal urinary sodium and potassium levels
Thiazides	Thrombocytopenia, hypoglycemia, hyponatremia, hypokalemia
HORMONES AND RELATED DRUGS	
Androgens (danazol)	Masculinization of female fetuses
Corticosteroids	Cleft lip/palate
Diethylstilbestrol (DES)	DES daughters: vaginal adenosis, genital tract anomalies, increased incidence of clear cell adenocarcinoma, increased rate of premature delivery in future pregnancy DES sons: possible increase in genitourinary anomalies
Estrogens, progestins	Risk for virilization of female fetuses reported with progestins; small, if any, risk for other anomalies
Insulin	No apparent direct adverse effects, uncertain risk related to maternal hypoglycemia
Tamoxifen	Animal studies suggest potential for DES-like effect
SEDATIVES, TRANQUILIZERS, AND PSYCHIATRIC DRUGS	
Barbiturates	Risk for hemorrhage and drug withdrawal
Benzodiazepines	Drug withdrawal; possible increase in cleft lip/palate
Selective serotonin reuptake inhibitors (SSRIs)	Pulmonary artery hypertension, jitteriness, irritability, poor delivery room transition
Lithium	Ebstein anomaly, diabetes insipidus, thyroid depression, cardiovascular dysfunction
Thalidomide	Limb deficiency, cardiac defects, ear malformations
Tricyclic antidepressants	Jitteriness, irritability
SOCIAL AND ILLICIT DRUGS	
Alcohol	Fetal alcohol syndrome, renal and cardiac anomalies
Amphetamines	Withdrawal, prematurity, decreased birthweight and head circumference, cerebral injury
Cocaine	Decreased birthweight, microcephaly, prematurity, abruptio placentae, stillbirth, cerebral hemorrhage; possible teratogen: genitourinary, cardiac, facial, limb, intestinal atresia/infarction
Heroin	Increased incidence of low birthweight and small for gestational age, drug withdrawal, postnatal growth and behavioral disturbances; decreased incidence of respiratory distress syndrome
Marijuana	Elevated blood carboxyhemoglobin; possible cause of shorter gestation, dysfunctional labor, intrauterine growth restriction, and anomalies
Methadone	Increased birthweight as compared to heroin, drug withdrawal (worse than with heroin alone)
Phencyclidine (PCP)	Irritability, jitteriness, hypertonia, poor feeding
Tobacco smoking	Elevated blood carboxyhemoglobin; decreased birthweight, increased prematurity rate, increased premature rupture of membranes, placental abruption and previa, increased fetal death, possible oral clefts
TOCOLYTICS	
Magnesium sulfate	Respiratory depression, hypotonia, bone demineralization with prolonged (weeks) use for tocolysis
Ritodrine	Neonatal hypoglycemia
Terbutaline	Neonatal hypoglycemia

Continued

TABLE 59.3 Maternal Medications and Toxins: Possible Effects on the Fetus and Newborn—cont'd

MEDICATION	EFFECT ON FETUS AND NEWBORN
VITAMINS AND RELATED DRUGS	
A (preformed, not carotene)	Excessive doses ($\geq 50,000$ IU/day) may be teratogenic
Acitretin	Activated form of etretinate (see later)
D	Megadoses may cause hypercalcemia, craniosynostosis
Etretinate	Limb deficiency, neural tube defect; ear, cardiac, and CNS anomalies
Folate deficiency	Neural tube defects
Isotretinoin (13- <i>cis</i> -retinoic acid)	Ear, cardiac, CNS, and thymic anomalies
Menadione (vitamin K ₃)	Hyperbilirubinemia and kernicterus
Phytonadione (vitamin K ₁)	No adverse effect
MISCELLANEOUS	
Anticholinergics	Neonatal meconium ileus
Antiemetics	Doxylamine succinate and/or dicyclomine HCl with pyridoxine reported to be teratogens, but bulk of evidence is clearly negative
Aspartame	Contains phenylalanine; potential risk to fetus of a mother with phenylketonuria
Chorionic villus sampling (CVS)	Limb deficiency with early CVS
Irradiation	Adverse effects primarily associated with therapeutic, not diagnostic doses, and is dose dependent: fetal death, microcephaly, intrauterine growth restriction
Lead	Decreased IQ (dose related)
Methylene blue	Hemolytic anemia, hyperbilirubinemia, methemoglobinemia; intraamniotic injection in early pregnancy associated with intestinal atresia
Methylmercury	CNS injury, neurodevelopmental abnormalities, microcephaly
Misoprostol	Möebius sequence
Oral hypoglycemics	Neonatal hypoglycemia
Polychlorinated biphenyls	Cola skin coloration, minor skeletal anomalies, neurodevelopmental deficits

CHAPTER 60

Diseases of the Fetus

The principal determinants of fetal disease include the fetal genotype and the environment in utero. Variation in environmental factors plays a more significant role in determining overall fetal well-being than fetal genetics, although a genetically abnormal fetus may not thrive as well or survive. The ability to assess a fetus genetically, biochemically, and physically is greatly enhanced through the development of amniocentesis, fetoscopy, chorionic villus sampling, fetal blood sampling, genetic testing of circulating fetal DNA in the mother's blood, and real-time ultrasonography.

INTRAUTERINE GROWTH RESTRICTION AND SMALL FOR GESTATIONAL AGE

Fetuses subjected to abnormal maternal, placental, or fetal conditions that restrain growth are a high-risk group and traditionally classified as having intrauterine growth restriction (IUGR). The terms *IUGR* and *small for gestational age*

(*SGA*) are not synonymous. IUGR represents a deviation from expected growth patterns. The decreased fetal growth associated with IUGR is usually an adaptation to unfavorable intrauterine conditions that result in permanent alterations in metabolism, growth, and development. IUGR most frequently occurs with a variety of maternal conditions that are also associated with preterm delivery. SGA describes an infant whose birth weight is statistically less than the 10th percentile or two standard deviations below the mean birthweight for gestational age. The cause of SGA may be pathologic, as in an infant with IUGR, or nonpathologic, as in an infant who is small but otherwise healthy (Table 60.1).

Only about 50% of IUGR infants are identified before delivery. Measurement and recording of maternal fundal height in conjunction with serial ultrasound assessment of the fetus (growth rate, amniotic fluid volume, malformations, anomalies, and Doppler velocimetry of uterine, placental, and fetal blood flow) can aid detection. When suspected and identified, IUGR and SGA fetuses must be monitored for fetal well-being, and appropriate maternal care should be instituted (see Chapter 58).

At birth, infants who are mildly to moderately SGA appear smaller than normal with decreased subcutaneous fat. More

TABLE 60.1 Etiologies for Intrauterine Growth Restriction and Small for Gestational Age at Birth

TABLE 60.1 Etiologies for Intrauterine Growth Restriction and Small for Gestational Age at Birth	
MATERNAL FACTORS	
Age (young and advanced)	
Cigarette smoking	
Genetics (short stature, weight)	
Illnesses during pregnancy (preeclampsia, severe diabetes, chronic hypertension, connective tissue disease)	
Infections (intrauterine)	
Lack of good prenatal care	
Oligohydramnios	
Poor nutrition	
FETAL FACTORS	
Chromosomal abnormality and nonchromosomal syndromes	
Congenital infections	
Inborn errors of metabolism	
Multiple gestations	
Insulin resistance or reduced insulin or insulin-like growth factor-1 production	
MATERNAL MEDICATIONS	
Antimetabolites (methotrexate)	
Heavy metals (mercury, lead)	
Hydantoin	
Narcotics (morphine, methadone)	
Steroids (prednisone)	
Substance and illicit drug use (alcohol, cocaine)	
Warfarin	
PLACENTAL AND UTERINE ABNORMALITIES	
Abruptio placentae	
Abnormal implantation	
Abnormal placental vessels	
Chorioangioma	
Circumvallate placenta	
Fetal vessel thrombosis	
Ischemic villus necrosis	
Multiple gestations	
True knots in umbilical cord	
Villitis (congenital infection)	

severely affected infants may present with a *wasted appearance* with asymmetric findings, including larger heads for the size of the body (central nervous system sparing), widened anterior fontanels, small abdomen, thin arms and legs, decreased subcutaneous fat, dry and redundant skin, decreased muscle mass, and thin (often meconium-stained) umbilical cord.

Gestational age is often difficult to assess when based on physical appearance and perceived advanced neurologic maturity. Physical examination should detail the presence of dysmorphic features, abnormal extremities, or gross anomalies that might suggest underlying congenital malformations, chromosomal defects, or exposure to teratogens. Hepatosplenomegaly, jaundice, and skin rashes in addition to ocular disorders, such as chorioretinitis, cataracts, glaucoma, and cloudy cornea, suggest the presence of a congenital infection or inborn error of metabolism. Infants with severe IUGR or SGA, particularly in conjunction with fetal distress, may have problems at birth that include metabolic acidosis, asphyxia, hypoxemia, hypotension, hypoglycemia, polycythemia, meconium aspiration syndrome, and persistent pulmonary hypertension of the newborn.

Management of IUGR and SGA infants is usually symptomatic and supportive. The diagnostic evaluation at birth should be directed at identifying the cause of the IUGR and SGA, if possible. The consequences of IUGR and SGA depend on the etiology, severity, and duration of growth retardation. The mortality rates of infants who are severely affected are 5–20 times those of infants who are appropriate for gestational age. Postnatal growth and development depend in part on the etiology, the postnatal nutritional intake, and the social environment. Infants who have IUGR and SGA secondary to congenital infection, chromosomal abnormalities, or congenital anomaly syndromes remain small throughout life. Infants who have growth inhibited late in gestation because of uterine constraints, placental insufficiency, or poor maternal nutrition have catch-up growth and, under optimal environmental conditions, approach their inherited growth and development potential.

HYDROPS FETALIS

Hydrops fetalis is caused by immune and nonimmune conditions. Hydrops fetalis is a fetal clinical condition of excessive fluid accumulation in the skin plus one or more other body compartments, including the pleural space, peritoneal cavity, pericardium, or placenta with resultant high morbidity and mortality. There is often polyhydramnios. Hydrops initially was described in association with Rhesus blood group isoimmunization. The use of Rho (D) immune globulin has reduced the incidence of isoimmune fetal hydrops. Concurrently, the proportion of **nonimmune hydrops** has increased as a cause of this severe clinical condition.

Fetal hydrops results from an imbalance of interstitial fluid accumulation and decreased removal of fluid by the capillaries and lymphatic system. Fluid accumulation can be secondary to congestive heart failure, obstructed lymphatic flow, or decreased plasma oncotic pressure (hypoproteinemic states). Edema formation is the final common pathway for many disease processes that affect the fetus, including fetal cardiac (congenital anomaly, arrhythmia, tumor), genetic, hematologic, lymphatic, metabolic, infection, or malformation syndromes.

The diagnostic work-up of the hydropic fetus should focus on discovering the underlying cause. Maternal findings may include hypertension, anemia, multiple gestation, thickened placenta, polyhydramnios, and edema, whereas fetal findings may include tachycardia, ascites, scalp and body wall edema, and pleural and pericardial effusion. Invasive fetal testing may be indicated. Amniocentesis provides amniotic fluid samples for karyotype, culture, α -fetoprotein, and metabolic and enzyme analysis. Percutaneous umbilical cord blood sampling can provide fetal blood for chromosomal analysis and

hematologic and metabolic studies and provide a source for intervention (fetal transfusion for profound anemia).

Management depends on the underlying cause and the gestational age of the fetus. Resuscitative efforts at delivery are often required. It is often necessary to remove ascitic fluid from the abdomen or pleural fluid to improve ventilation. Profound anemia necessitates immediate transfusion with packed red blood cells.

The overall mortality for infants with nonimmune hydrops is approximately 50%. If the diagnosis is made before 24 weeks of gestation with subsequent premature delivery, the survival rate is approximately 4–6%.

PEARLS FOR PRACTITIONERS

See Fetal and Neonatal Medicine: Pearls for Practitioners at the end of this section.

CHAPTER 61

Respiratory Diseases of the Newborn

Respiratory distress that becomes manifested by tachypnea, intercostal retractions, reduced air exchange, cyanosis, expiratory grunting, and nasal flaring is a nonspecific response to serious illness. The differential diagnosis of respiratory

distress includes pulmonary, cardiac, hematologic, infectious, anatomic, and metabolic disorders that may involve the lungs directly or indirectly (Fig. 61.1). Surfactant deficiency causes **respiratory distress syndrome (RDS)**, resulting in cyanosis and tachypnea; **infection** produces pneumonia, shown by interstitial or lobar infiltrates; **meconium aspiration** results in a chemical pneumonitis with hypoxia and pulmonary hypertension; **hydrops fetalis** causes anemia and hypoalbuminemia with high-output heart failure and pulmonary edema; and congenital or acquired **pulmonary hypoplasia** causes pulmonary hypertension and pulmonary insufficiency. It also is clinically useful to differentiate the common causes of respiratory distress according to gestational age (Table 61.1).

In addition to the specific therapy for the individual disorder, supportive care and evaluation of the infant with respiratory distress can be applied to all the problems mentioned earlier (Table 61.2). Blood gas monitoring and interpretation are key components of general respiratory care.

Treatment of hypoxemia requires knowledge of normal values. In term infants, the arterial P_{aO_2} level is 55–60 mm Hg at 30 minutes of life, 75 mm Hg at 4 hours, and 90 mm Hg at 24 hours. Preterm infants may have lower values. P_{aCO_2} levels should be 35–40 mm Hg, and the pH should be 7.35–7.40. It is imperative that arterial blood gas analysis be performed in all infants with *significant* respiratory distress whether or not cyanosis is perceived. Cyanosis becomes evident when there is ~5 g of unsaturated hemoglobin; anemia may interfere with the perception of cyanosis. Jaundice also may interfere with the appearance of cyanosis. Capillary blood gas determinations are useful in determining blood pH and the P_{aCO_2} level

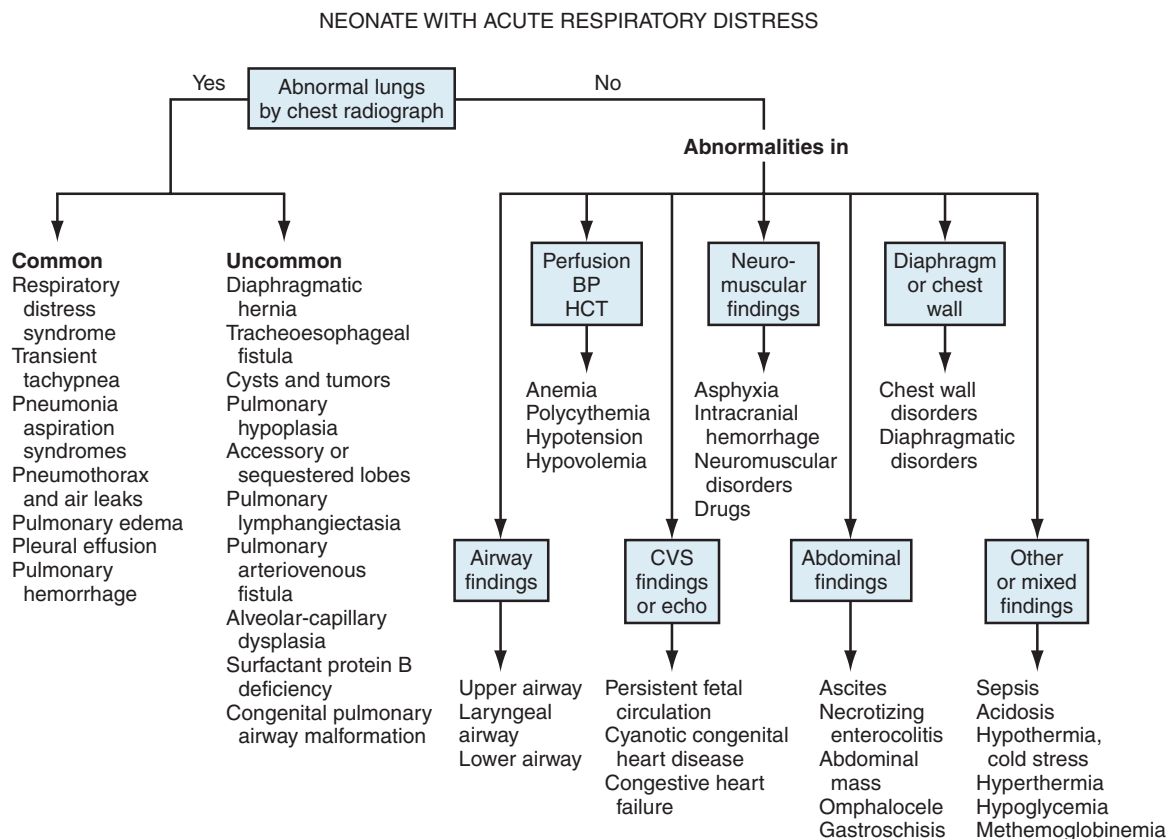

FIGURE 61.1 Diagram of causes of respiratory distress in neonates. BP, Blood pressure; CVS, cardiovascular system; echo, echocardiogram; HCT, hematocrit. TABLE 61.2 Initial Laboratory Evaluation of Respiratory Distress

TEST	RATIONALE
Chest radiograph	To determine reticular granular pattern of RDS; to determine presence of pneumothorax, cardiomegaly, life-threatening congenital anomalies
Arterial blood gas	To determine severity of respiratory compromise, hypoxemia, and hypercapnia and type of acidosis; severity determines treatment strategy
Complete blood count	Hemoglobin/hematocrit to determine anemia and polycythemia; white blood cell count to determine neutropenia/sepsis; platelet count and smear to determine DIC
Blood culture	To recover potential pathogen
Blood glucose	To determine presence of hypoglycemia, which may produce or occur simultaneously with respiratory distress; to determine stress hyperglycemia
Echocardiogram, ECG	In the presence of a murmur, cardiomegaly, or refractory hypoxia; to determine structural heart disease or PPHN

DIC, Disseminated intravascular coagulation; ECG, electrocardiogram; PPHN, persistent pulmonary hypertension of the newborn; RDS, respiratory distress syndrome.

but result in falsely low blood P_{aO_2} readings. Serial blood gas levels may be monitored by an indwelling arterial catheter placed in the radial artery or through the umbilical artery. Another method for monitoring blood gas levels is to combine capillary blood gas techniques with noninvasive methods used to monitor oxygen (pulse oximetry).

Metabolic acidosis, defined as a reduced pH (<7.25) and bicarbonate concentration (<18 mEq/L) accompanied by a normal or low P_{aCO_2} level, may be caused by hypoxia or by insufficient tissue perfusion. The origin of the disorder may be pulmonary, cardiac, infectious, renal, hematologic, nutritional, metabolic, or iatrogenic. The initial approach to metabolic acidosis is to determine the cause and treat the pathophysiologic problem. This approach may include, as in the sequence of therapy for hypoxia, increasing the inspired oxygen concentration; applying continuous positive airway pressure (CPAP) nasally; or initiating mechanical ventilation using positive end-expiratory pressure. Patients with hypotension produced by hypovolemia require fluids and may need inotropic or vasoactive drug support. Rarely, if metabolic acidosis persists despite specific therapy, sodium bicarbonate (1 mEq/kg/dose) may be given by slow intravenous infusion. Near-normal or low PCO_2 levels should be documented before sodium bicarbonate infusion. The buffering effect of sodium bicarbonate results in increased PCO_2 levels unless adequate ventilation is maintained.

Respiratory acidosis, defined as an elevated PCO_2 level and reduced pH without a reduction in the bicarbonate concentration, may be caused by pulmonary insufficiency or central hypoventilation. Many disorders producing respiratory distress can lead to hypercapnia. Treatment involves assisted ventilation but not sodium bicarbonate. If central nervous system depression of respirations is caused by placental passage of narcotic analgesics, assisted ventilation is instituted first, then the central nervous system depression is reversed by naloxone.

RESPIRATORY DISTRESS SYNDROME (HYALINE MEMBRANE DISEASE)

RDS occurs after the onset of breathing and is associated with an insufficiency of pulmonary surfactant.

Lung Development

The lining of the alveolus consists of 90% type I cells and 10% type II cells. After 20 weeks of gestation, the type II cells contain vacuolated, osmophilic, lamellar inclusion bodies, which are packages of surface-active material (Fig. 61.2). This lipoprotein surfactant is 90% lipid and is composed predominantly of saturated phosphatidylcholine (lecithin), but also contains phosphatidylglycerol, other phospholipids, and neutral lipids. The surfactant proteins, SP-A, SP-B, SP-C, and SP-D, are packaged into the lamellar body and contribute to surface-active properties and recycling of surfactant. Surfactant prevents atelectasis by reducing surface tension at low lung volumes when it is concentrated at end expiration as the alveolar radius decreases; surfactant contributes to lung recoil by increasing surface tension at larger lung volumes when it is diluted during inspiration as the alveolar radius increases. Without surfactant, surface tension forces are not reduced, and atelectasis develops during end expiration as the alveolus collapses.

The timing of surfactant production in quantities sufficient to prevent atelectasis depends on an increase in fetal cortisol

FIGURE 61.2 Proposed pathway of synthesis, transport, secretion, and reuptake of surfactant in the type II alveolar cell. Phospholipids are synthesized in the smooth endoplasmic reticulum (ER). The glucose/glycerol precursor may be derived from lung glycogen or circulating glucose. Phospholipids and surfactant proteins are packaged in the Golgi apparatus (GZ), emerge as small lamellar bodies (SLB), coalesce to mature lamellar bodies (MLB), migrate to the apical membrane, and released by exocytosis into the liquid hypophase below the air-liquid interface. The tightly coiled lamellar body unravels to form the lattice (tubular) myelin figure (LMF), the immediate precursor to the phospholipid monolayer at the alveolar surface. Reuptake by endocytosis forms multivesicular bodies (MVB) that recycle surfactant. The enzymes, receptors, transporters, and surfactant proteins are controlled by regulatory processes at the transcriptional level in the nucleus (N). Corticosteroid and thyroid hormones are regulatory ligands that may accelerate surfactant synthesis. (From Hansen T, Corbet A. Lung development and function. In: Taeusch HW, Ballard R, Avery ME, eds. *Diseases of the Newborn*. 6th ed. Philadelphia: Saunders; 1991:465.)

levels that begins between 32 and 34 weeks of gestation. By 34–36 weeks, sufficient surface-active material is produced by the type II cells in the lung, is secreted into the alveolar lumen, and is excreted into the amniotic fluid. Lecithin concentration increases with increasing gestational age, beginning at 32–34 weeks, and indicates fetal pulmonary maturity. Because the amount of lecithin is difficult to quantify, the ratio of lecithin (which increases with maturity) to sphingomyelin (which remains constant during gestation; L/S ratio) is determined. An L/S ratio of 2:1 usually indicates pulmonary maturity. The presence of minor phospholipids, such as phosphatidylglycerol, also is indicative of fetal lung maturity and may be useful in situations in which the L/S ratio is borderline or possibly affected by maternal diabetes, which reduces lung maturity. The absence of phosphatidylglycerol suggests that surfactant might not be mature.

Clinical Manifestations

A deficiency of pulmonary surfactant (most often due to prematurity) results in atelectasis, decreased functional residual capacity, arterial hypoxemia, and respiratory distress. Surfactant synthesis may also be reduced because of

FIGURE 61.3 Air pressure volume curves of normal and abnormal lung. Volume is expressed as milliliters of air per gram of lung. Lung of infant with respiratory distress syndrome (RDS) accepts smaller volume of air at all pressures. Note that deflation pressure volume curve closely follows inflation curve for the RDS lung. (From Fanaroff AA, Fanaroff JM. *Klaus & Fanaroff's Care of the High-Risk Neonate*. 6th ed. Philadelphia: Elsevier; 2013:249 [fig. 10-3].)

hypovolemia, hypothermia, acidosis, hypoxemia, and rare genetic disorders of surfactant synthesis. These factors also produce pulmonary artery vasospasm, which may contribute to RDS in larger premature infants who have developed sufficient pulmonary arteriole smooth muscle to produce vasoconstriction. Surfactant deficiency-induced atelectasis causes alveoli to be perfused but not ventilated, which results in a pulmonary shunt and hypoxemia. As atelectasis increases, the lungs become increasingly difficult to expand, and lung compliance decreases (Fig. 61.3). Because the chest wall of the premature infant is very compliant, the infant attempts to overcome decreased lung compliance with increasing inspiratory pressures, resulting in retractions of the chest wall. The sequence of decreased lung compliance and chest wall retractions leads to poor air exchange, an increased physiologic dead space, alveolar hypoventilation, and hypercapnia. A cycle of hypoxia, hypercapnia, and acidosis acts on type II cells to reduce surfactant synthesis and, in some infants, on the pulmonary arterioles to produce pulmonary hypertension.

Infants at greatest risk for RDS are premature and have an immature L/S ratio. The incidence of RDS increases with decreasing gestational age. RDS develops in 30–60% of infants between 28 and 32 weeks of gestation. Other risk factors include delivery of a previous preterm infant with RDS, maternal diabetes, hypothermia, fetal distress, asphyxia, males, being the second-born of twins, and delivery by cesarean section without labor.

RDS may develop immediately in the delivery room in extremely immature infants at 26–30 weeks of gestation. Some more mature infants (34 weeks of gestation) may not show signs of RDS until 3–4 hours after birth, correlating with the initial release of stored surfactant at the onset of breathing accompanied by the ongoing inability to replace the surfactant owing to inadequate stores. **Manifestations** of RDS include cyanosis, tachypnea, nasal flaring, intercostal and sternal retractions, and grunting. Grunting is caused by closure of the glottis during expiration, the effect of which is to maintain lung volume (decreasing atelectasis) and gas exchange during exhalation. Atelectasis is well documented by radiographic examination of the chest, which shows a ground-glass haze

FIGURE 61.4 Respiratory distress syndrome. The infant is intubated, and the lungs show a dense reticulonodular pattern with air bronchograms (A). To evaluate rotation on the frontal chest, the lengths of the posterior ribs are compared from left to right (arrows). Because the infant is supine, the side of the longer ribs indicates to which side the thorax is rotated. In this case, the left ribs are longer, and this radiograph is a left posterior oblique view. Surfactant was administered, resulting in significant improvement in the density of the lung (B). The right lung is slightly better aerated than the left. Uneven distribution of clearing is common. (From Hilton S, Edwards D. *Practical Pediatric Radiology*. 2nd ed. Philadelphia: Saunders; 1994.)

in the lung surrounding air-filled bronchi (the air bronchogram) (Fig. 61.4). Severe RDS may show an airless lung field (*whiteout*) on a radiograph, even obliterating the distinction between the atelectatic lungs and the heart.

During the first 72 hours, infants with untreated RDS have increasing distress and hypoxemia. In infants with severe RDS, the development of edema, apnea, and respiratory failure necessitates assisted ventilation. Thereafter, uncomplicated cases show a spontaneous improvement that often is heralded by diuresis and a marked resolution of edema. Complications include the development of a pneumothorax, a patent ductus arteriosus (PDA), and bronchopulmonary dysplasia (BPD). The differential diagnosis of RDS includes diseases associated with cyanosis and respiratory distress (see Fig. 61.1 and Table 58.11).

Prevention and Treatment

Strategies to prevent preterm birth include maternal cervical cerclage, bed rest, treatment of infections, and administration of tocolytic medications. In addition, prevention of neonatal cold stress, birth asphyxia, and hypovolemia reduces the risk of RDS. If premature delivery is unavoidable, the antenatal administration of corticosteroids (e.g., betamethasone) to the mother (and thus to the fetus) stimulates fetal lung production

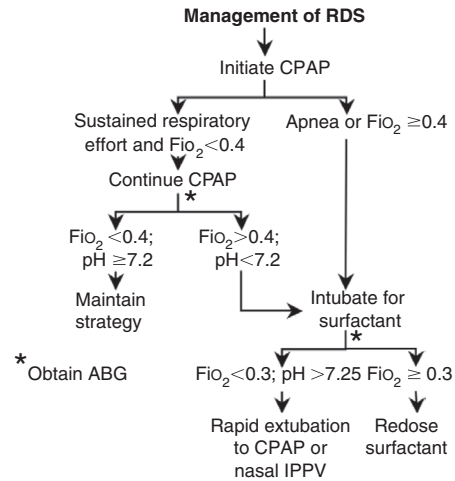

FIGURE 61.5 Algorithm suggesting management strategy of respiratory distress syndrome (RDS). ABG, Arterial blood gas; CPAP, continuous positive airway pressure; FiO_2 , fraction of inspired oxygen; IPPV, intermittent positive-pressure ventilation. (From Fanaroff AA, Fanaroff JM. *Klaus & Fanaroff's Care of the High-Risk Neonate*. 6th ed. Philadelphia: Elsevier; 2013:253 [fig. 10-5].)

of surfactant; this approach requires multiple doses for at least 48 hours.

After birth, RDS may be prevented or its severity reduced by intratracheal administration of exogenous surfactant immediately after birth in the delivery room or within a few hours of birth. Exogenous surfactant can be administered repeatedly during the course of RDS in patients receiving endotracheal intubation, mechanical ventilation, and oxygen therapy. Early application of nasal CPAP also reduces the severity of RDS (Fig. 61.5). Additional management includes the general supportive and ventilation care presented in Table 61.2.

The Pao_2 level should be maintained between 60 and 70 mm Hg (oxygen saturation 90%), and the pH should be maintained above 7.25. An increased concentration of warm and humidified inspired oxygen administered by CPAP or a nasal cannula may be all that is needed. If respiratory failure ensues ($PCO_2 > 60$ mm Hg, $pH < 7.20$, and $Pao_2 < 50$ mm Hg with 100% oxygen), assisted ventilation using a ventilator is indicated.

In response to persistent hypercapnia, alveolar ventilation ($[\text{tidal volume} - \text{dead space}] \times \text{rate}$) must be increased. Ventilation can be increased by an increase in the ventilator's rate or an increase in the tidal volume. In response to hypoxia, the inspired oxygen content may be increased. Alternatively, the degree of oxygenation depends on the mean airway pressure. Mean airway pressure is directly related to positive end-expiratory pressure, flow, and inspiratory time. Increased mean airway pressure may improve oxygenation by improving lung volume, enhancing ventilation-perfusion matching. Because of the difficulty in distinguishing sepsis and pneumonia from RDS, broad-spectrum parenteral antibiotics (ampicillin and gentamicin) are administered for 48–72 hours, pending the recovery of an organism from a previously obtained blood culture.

COMPLICATIONS OF RESPIRATORY DISTRESS SYNDROME

Patent Ductus Arteriosus

PDA is a common complication that occurs in many low birthweight infants who have RDS. The incidence of PDA is inversely related to the gestational age of the infant. In term

newborns, the ductus closes within 24–48 hours after birth. However, in preterm newborns, especially those with RDS, the ductus frequently fails to close, requiring medical or surgical closure. The ductus arteriosus in a preterm infant is less responsive to vasoconstrictive stimuli, which, when complicated with hypoxemia during RDS, may lead to a persistent PDA that creates a shunt between the pulmonary and systemic circulations.

During the acute phase of RDS, hypoxia, hypercapnia, and acidosis lead to pulmonary arterial vasoconstriction. The pulmonary and systemic pressures may be equal, and flow through the ductus may be small or bidirectional. When RDS improves and pulmonary vascular resistance declines, flow through the ductus arteriosus increases in a left-to-right direction. Significant systemic-to-pulmonary shunting may lead to heart failure and pulmonary edema. Excessive intravenous fluid administration may increase the incidence of symptomatic PDA. The infant's respiratory status deteriorates because of increased lung fluid, hypercapnia, and hypoxemia.

Clinical manifestations of a PDA usually become apparent on day 2–4 of life. Because the left-to-right shunt directs flow to a low-pressure circulation from one of high pressure, the pulse pressure widens; a previously inactive precordium shows an extremely active precordial impulse, and peripheral pulses become easily palpable and bounding. The murmur of a PDA may be continuous in systole and diastole, but usually only the systolic component is auscultated. Heart failure and pulmonary edema result in rales and hepatomegaly. A chest radiograph shows cardiomegaly and pulmonary edema, a two-dimensional echocardiogram shows ductal patency, and Doppler studies show markedly increased left-to-right flow through the ductus.

Treatment of a PDA during RDS involves initial fluid restriction and diuretic administration. If there is no improvement after 24–48 hours, a prostaglandin synthetase inhibitor, ibuprofen, indomethacin, or acetaminophen is administered. Contraindications to using indomethacin include thrombocytopenia (platelets $<50,000/\text{mm}^3$), bleeding, serum creatinine measuring more than 1.8 mg/dL, and oliguria. Because 20–30% of infants do not respond initially to medical therapy and because the PDA reopens in 10–20% of infants, a repeat course of medications or surgical ligation, or catheter-based occlusion may be required.

Pulmonary Air Leaks

Assisted ventilation with high peak inspiratory pressures and positive end-expiratory pressures may cause overdistention of alveoli in localized areas of the lung. Rupture of the alveolar epithelial lining may produce pulmonary interstitial emphysema as gas dissects along the interstitial space and the peribronchial lymphatics. Extravasation of gas into the parenchyma reduces lung compliance and worsens respiratory failure. Gas dissection into the mediastinal space produces a pneumomediastinum, occasionally dissecting into the subcutaneous tissues around the neck, causing subcutaneous emphysema.

Alveolar rupture adjacent to the pleural space produces a **pneumothorax** (Fig. 61.6). If the gas is under tension, the pneumothorax shifts the mediastinum to the opposite side of the chest, producing hypotension, hypoxia, and hypercapnia. The diagnosis of a pneumothorax may be based on unequal transillumination of the chest and may be confirmed by chest

FIGURE 61.6 Pneumothorax. Right-sided hyperlucent pleural air is obvious. The findings of linear interstitial air and the resultant non-compliant but collapsed lung are noted. (From Heller RM, Kirchner SG. *Advanced Exercises in Diagnostic Radiology: The Newborn*. Philadelphia: WB Saunders; 1979.)

radiograph. Treatment of a symptomatic pneumothorax requires insertion of a pleural chest tube connected to negative pressure or to an underwater drain. Prophylactic or therapeutic use of exogenous surfactant has reduced the incidence of pulmonary air leaks.

Pneumothorax also is observed after vigorous resuscitation, meconium aspiration pneumonia, pulmonary hypoplasia, and diaphragmatic hernia. Spontaneous pneumothorax is seen in fewer than 1% of deliveries and may be associated with renal malformations.

Bronchopulmonary Dysplasia (Chronic Lung Disease)

BPD is a clinical diagnosis defined by oxygen dependence at 36 weeks of postconceptual age and accompanied by characteristic clinical and radiographic findings that correspond to anatomic abnormalities. Oxygen concentrations greater than 40% are toxic to the neonatal lung. Oxygen-mediated lung injury results from the generation of superoxides, hydrogen peroxide, and oxygen free radicals, which disrupt membrane lipids. Assisted ventilation with high peak pressures produces barotrauma, compounding the damaging effects of highly inspired oxygen levels. In most patients, BPD develops after ventilation for RDS that may have been complicated by PDA or pulmonary interstitial emphysema. Inflammation from prolonged assisted ventilation and repeated systemic and pulmonary infections may play a major role. Failure of RDS to improve after 2 weeks, the need for prolonged mechanical ventilation, and oxygen therapy required at 36 weeks of postconceptual age are characteristic of patients with RDS in whom BPD develops. BPD also may develop in infants weighing less than 1,000 g who require mechanical ventilation for poor respiratory drive in the absence of RDS. Fifty percent of infants born at 24–26 weeks of gestational age require oxygen at 36 weeks of corrected age.

The **radiographic appearance** of BPD is characterized initially by lung opacification and subsequently by development of cysts accompanied by areas of overdistention and atelectasis, giving the lung a spongelike appearance. The histopathology of BPD reveals interstitial edema, atelectasis, mucosal metaplasia, interstitial fibrosis, necrotizing obliterative bronchiolitis, and overdistended alveoli.

The **clinical manifestations** of BPD are oxygen dependence, hypercapnia with a compensatory metabolic alkalosis, pulmonary hypertension, poor growth, and development of right-sided heart failure. Increased airway resistance with reactive airway bronchoconstriction also is noted and is treated with bronchodilating agents. Severe chest retractions produce negative interstitial pressure that draws fluid into the interstitial space. Together with cor pulmonale, these chest retractions cause fluid retention, necessitating fluid restriction and the administration of diuretics.

Infants with severe BPD may need treatment with mechanical ventilation for many months. To reduce the risk of subglottic stenosis, a tracheotomy may be indicated. To reduce oxygen toxicity and barotrauma, ventilator settings are reduced to maintain blood gases with slightly lower P_{aO_2} (50 mm Hg) and higher P_{aCO_2} (50–75 mm Hg) levels than for infants during the acute phase of RDS. Dexamethasone therapy may reduce inflammation, improve pulmonary function, and enhance weaning of patients from assisted ventilation. However, dexamethasone may increase the risk of cerebral palsy or abnormal neuromotor developmental outcome. Older survivors of BPD may have hyperinflation, reactive airways, and developmental delay. They are at risk for severe respiratory syncytial virus pneumonia and as infants should receive prophylaxis against respiratory syncytial virus.

Retinopathy of Prematurity (Retrolental Fibroplasia)

Retinopathy of prematurity (ROP) is caused by the acute and chronic effects of oxygen toxicity on the developing blood vessels of the premature infant's retina. The completely vascularized retina of the term infant is not susceptible to ROP. ROP is a leading cause of blindness in very low birthweight infants (<1,500 g). Excessive arterial oxygen tensions produce vasoconstriction of immature retinal vasculature in the first stage of this disease. Vaso-oblivation follows if the duration and extent of hyperoxia are prolonged beyond the time when vasoconstriction is reversible. Hypercarbia and hypoxia may contribute to ROP. The subsequent proliferative stages are characterized by extraretinal fibrovascular proliferation, forming a ridge between the vascular and avascular portions of the retina, and by the development of neovascular tufts. In mild cases, vasoproliferation is noted at the periphery of the retina. Severe cases may have neovascularization involving the entire retina, retinal detachment resulting from traction on vessels as they leave the optic disc, fibrous proliferation behind the lens producing leukokoria, and synechiae displacing the lens forward, leading to glaucoma. Both eyes usually are involved, but severity may be asymmetric.

The incidence of ROP may be reduced by careful monitoring of arterial blood gas levels in all patients receiving oxygen. Although there is no absolutely safe P_{aO_2} level, it is wise to keep the arterial oxygen level between 50 and 70 mm Hg in premature infants. Infants who weigh less than 1,500 g or who

are born before 28 weeks of gestational age (some authors say 32 weeks) should be screened when they are 4 weeks of age or more than 34 weeks of corrected gestational age, whichever comes first. Laser therapy or (less often) cryotherapy may be used for vitreous hemorrhage or for severe, progressive vasoproliferation. Surgery is indicated for retinal detachment. Less severe stages of ROP resolve spontaneously and without visual impairment in most patients.

TRANSIENT TACHYPNEA OF THE NEWBORN

Transient tachypnea of the newborn is a self-limited condition characterized by tachypnea, mild retractions, hypoxia, and occasional grunting, usually without signs of severe respiratory distress. Cyanosis, when present, usually requires treatment with supplemental oxygen in the range of 30–40%. Transient tachypnea of the newborn usually is noted in larger premature infants and in term infants born by precipitous delivery or cesarean section without prior labor. Infants of diabetic mothers and infants with poor respiratory drive as a result of placental passage of analgesic drugs are at risk. Transient tachypnea of the newborn may be caused by retained lung fluid or slow resorption of lung fluid. Chest radiographs show prominent central vascular markings, fluid in the lung fissures, overaeration, and occasionally a small pleural effusion. Air bronchograms and a reticulogranular pattern are not seen; their presence suggests another pulmonary process, such as RDS or pneumonia.

MECONIUM ASPIRATION SYNDROME

Meconium-stained amniotic fluid is seen in 15% of predominantly term and post-term deliveries. Although the passage of meconium into amniotic fluid is common in infants born in the breech presentation, meconium-stained fluid should be considered clinically as a sign of fetal distress in all infants. The presence of meconium in the amniotic fluid suggests in utero distress with asphyxia, hypoxia, and acidosis.

Aspiration of amniotic fluid contaminated with particulate meconium may occur in utero in a distressed, gasping fetus; more often, meconium is aspirated into the lung immediately after delivery. Affected infants have abnormal chest radiographs, showing a high incidence of pneumonia and pneumothoraces.

Meconium aspiration pneumonia is characterized by tachypnea, hypoxia, hypercapnia, and small airway obstruction causing a ball-valve effect, leading to air trapping, overdistention, and extra-alveolar air leaks. Complete small-airway obstruction produces atelectasis. Within 24–48 hours, a chemical pneumonitis develops in addition to the mechanical effects of airway obstruction. Abnormal pulmonary function may be caused by the meconium, in part, through inactivation of surfactant. Pulmonary hypertension frequently accompanies meconium aspiration, with right-to-left shunting caused by increased pulmonary vascular resistance. The chest radiograph reveals patchy infiltrates, overdistention, flattening of the diaphragm, increased anteroposterior diameter, and a high incidence of pneumomediastinum and pneumothoraces. Comorbid diseases include those associated with in utero asphyxia that initiated the passage of meconium.

Treatment of meconium aspiration includes general supportive care and assisted ventilation. Newborns with a persistent pulmonary hypertension (PPHN)-like presentation should be treated for PPHN (see next section). If severe hypoxia does not subside with conventional or high-frequency ventilation, surfactant therapy, and inhaled nitric oxide, extracorporeal membrane oxygenation (ECMO) may be beneficial.

Prevention of meconium aspiration syndrome involves careful in utero monitoring to prevent asphyxia. When meconium-stained fluid is observed, the obstetrician should suction the infant's oropharynx before delivering the rest of the infant's body.

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

PPHN occurs in post-term, term, or near-term infants. PPHN is characterized by severe hypoxemia, without evidence of parenchymal lung or structural heart disease. PPHN is often seen with asphyxia or meconium-stained fluid. The chest radiograph usually reveals normal lung fields rather than the expected infiltrates and hyperinflation that may accompany meconium aspiration. Additional problems that may lead to PPHN are congenital pneumonia, hyperviscosity-polycythemia, congenital diaphragmatic hernia, pulmonary hypoplasia, congenital cyanotic heart disease, hypoglycemia, and hypothermia. Total anomalous venous return associated with obstruction of blood flow may produce a clinical picture that involves severe hypoxia and that is initially indistinguishable from PPHN; however, a chest radiograph reveals severe pulmonary venous engorgement and a small heart. Echocardiography or cardiac catheterization confirms the diagnosis.

Significant right-to-left shunting through a patent foramen ovale, through a PDA, and through intrapulmonary channels is characteristic of PPHN. The pulmonary vasculature often shows hypertrophied arterial wall smooth muscle, suggesting that the process of or predisposition to PPHN began in utero as a result of previous periods of fetal hypoxia. After birth, hypoxia, hypercapnia, and acidosis exacerbate pulmonary artery vasoconstriction, leading to further hypoxia and acidosis. Some infants with PPHN have extrapulmonary manifestations as a result of asphyxia. Myocardial injuries include heart failure, transient mitral insufficiency, and papillary muscle or myocardial infarction. Thrombocytopenia, right atrial thrombi, and pulmonary embolism also may be noted.

The **diagnosis** is confirmed by echocardiographic examination, which shows elevated pulmonary artery pressures and sites of right-to-left shunting. Echocardiography also rules out structural congenital heart disease and transient myocardial dysfunction.

Treatment involves general supportive care; correction of hypotension, anemia, and acidosis; and management of complications associated with asphyxia. If myocardial dysfunction is present, dopamine or dobutamine is needed. The most important therapy for PPHN is assisted ventilation. Reversible mild pulmonary hypertension may respond to conventional assisted ventilation. Patients with severe PPHN do not always respond to conventional therapy. Paralysis with a muscle relaxant may be needed to assist ventilation. Surfactant replacement seems to have no effect when PPHN is the primary diagnosis. If mechanical ventilation and supportive care

TABLE 61.3 Potential Causes of Neonatal Apnea

Central nervous system	IVH, drugs, seizures, hypoxic injury
Respiratory	Pneumonia, obstructive airway lesions, atelectasis, extreme prematurity (<1,000 g), laryngeal reflex, phrenic nerve paralysis, severe RDS, pneumothorax
Infectious	Sepsis, necrotizing enterocolitis, meningitis (bacterial, fungal, viral)
Gastrointestinal	Oral feeding, bowel movement, gastroesophageal reflux, esophagitis, intestinal perforation
Metabolic	↓ Glucose, ↓ calcium, ↓ PO ₂ , ↓↑ sodium, ↑ ammonia, ↑ organic acids, ↑ ambient temperature, hypothermia

Idiopathic	Immaturity of respiratory center, sleep state, upper airway collapse

IVH, Intraventricular hemorrhage; RDS, respiratory distress syndrome.

are unsuccessful in improving oxygenation, inhaled nitric oxide, a selective pulmonary artery vasodilating agent, should be administered. If hypoxia persists, the patient may be a candidate for ECMO. Infants who require extremely high ventilator settings, marked by an alveolar-to-arterial oxygen gradient greater than 620 mm Hg, have a high mortality rate and benefit from ECMO if they do not respond to nitric oxide. In addition, the oxygenation index (OI) is used to assess the severity of hypoxemia and to guide the timing of interventions such as inhaled nitric oxide and ECMO. The OI is calculated using the equation $OI = [(mean\ airway\ pressure \times \text{fraction of inspired oxygen}) / PaO_2] \times 100$. A high OI indicates severe hypoxemic respiratory failure.

APNEA OF PREMATURITY

Although apnea typically is associated with immaturity of the respiratory control system, it also may be the presenting sign of other diseases or pathophysiologic states that affect preterm infants (Table 61.3). A thorough consideration of possible causes is always warranted, especially with the onset or unexpected increase in the frequency of episodes of apnea (or bradycardia).

Apnea is defined as the cessation of pulmonary airflow for a specific time interval, usually longer than 10–20 seconds. Bradycardia often accompanies prolonged apnea. **Central apnea** refers to a complete cessation of airflow and respiratory efforts with no chest wall movement. **Obstructive apnea** refers to the absence of noticeable airflow but with the continuation of chest wall movements. **Mixed apnea**, a combination of these two events, is the most frequent type. It may begin as a brief episode of obstruction followed by a central apnea. Alternatively, central apnea may produce upper airway closure (passive pharyngeal hypotonia), resulting in mixed apnea.

A careful evaluation to determine the cause of apnea should be performed immediately in any infant with apnea. The incidence of apnea increases as gestational age decreases.

Idiopathic apnea, a disease of premature infants, appears in the absence of any other identifiable disease states during the first week of life and usually resolves by 36–40 weeks of post-conceptual age (gestational age at birth + postnatal age). The premature infant's process of regulating respiration is especially vulnerable to apnea. Preterm infants respond paradoxically to hypoxia by developing apnea rather than by increasing respirations as in mature infants. Poor tone of the laryngeal muscles also may lead to collapse of the upper airway, causing obstruction. Isolated obstructive apnea also may occur as a result of flexion or extreme lateral positioning of the premature infant's head, which obstructs the soft trachea.

Treatment of apnea of prematurity involves administration of oxygen to hypoxic infants, transfusion of anemic infants, and physical cutaneous stimulation for infants with mild apnea. Methylxanthines (caffeine or theophylline) are the mainstay of pharmacologic treatment of apnea. Xanthine therapy increases minute ventilation, improves the carbon dioxide sensitivity, decreases hypoxic depression of breathing, enhances diaphragmatic activity, and decreases periodic breathing. Treatment usually is initiated with a loading dose followed by maintenance therapy. High-flow nasal cannula therapy and nasal CPAP of 4–6 cm H₂O also are effective and relatively safe methods of treating obstructive or mixed apneas; they may work by stimulating the infant and splinting the upper airway. CPAP also probably increases functional residual capacity, improving oxygenation.

PEARLS FOR PRACTITIONERS

See *Fetal and Neonatal Medicine: Pearls for Practitioners* at the end of this section.

CHAPTER 62

Anemia and Hyperbilirubinemia

ANEMIA

Embryonic hematopoiesis begins by the 20th day of gestation and is evidenced as blood islands in the yolk sac. In mid-gestation, erythropoiesis occurs in the liver and spleen; the bone marrow becomes the predominant site in the last trimester. Hemoglobin concentration increases from 8–10 g/dL at 12 weeks to 16.5–18 g/dL at 40 weeks. Fetal red blood cell (RBC) production is responsive to erythropoietin; the concentration of this hormone increases with fetal hypoxia and anemia.

After birth, hemoglobin levels increase transiently at 6–12 hours, then decline to 11–12 g/dL at 3–6 months. A premature infant (<32 weeks of gestational age) has a lower hemoglobin concentration and a more rapid postnatal decline of hemoglobin level, which achieves a nadir 1–2 months after birth. Fetal and neonatal RBCs have a shorter life span (70–90 days) and a higher mean corpuscular volume (110–120 fL) than adult cells. In the fetus, hemoglobin synthesis in the last two trimesters of pregnancy produces fetal hemoglobin (hemoglobin F), composed of two α chains and two γ chains. Before term, the infant begins to synthesize β -hemoglobin chains; the term infant should have some adult hemoglobin

(two α chains and two β chains). Fetal hemoglobin represents 60–90% of hemoglobin at term birth. The levels decline to adult levels of less than 5% by 4 months of age.

For a term infant, blood volume is 72–93 mL/kg, and for a preterm infant, blood volume is 90–100 mL/kg. The placenta and umbilical vessels contain approximately 20–30 mL/kg of additional blood that can increase neonatal blood volume and hemoglobin levels transiently for the first 3 days of life if clamping or milking (*stripping*) of the umbilical cord is delayed at birth. Delayed clamping usually has no adverse effects but may increase the risk of polycythemia and jaundice. Early clamping may lead to anemia, a cardiac murmur, poor peripheral perfusion, and less tachypnea. Hydrostatic pressure affects blood transfer between the placenta and the infant at birth. An undesired fetal-to-placental transfusion occurs if the infant is situated above the level of the placenta.

The physiologic anemia noted at 2–3 months of age in term infants and at 1–2 months of age in preterm infants is a normal process that does not result in signs of illness and does not require any treatment. It is a physiologic condition believed to be related to several factors, including increased tissue oxygenation experienced at birth, shortened RBC life span, and low erythropoietin levels.

Etiology

Symptomatic anemia in the newborn period (Fig. 62.1) may be caused by decreased RBC production, increased RBC destruction, or blood loss.

Decreased Red Blood Cell Production

Anemia caused by decreased production of RBCs appears at birth with pallor, a low reticulocyte count, and absence of erythroid precursors in the bone marrow. Potential causes of neonatal decreased RBC production include bone marrow failure syndromes (congenital RBC aplasia [Blackfan-Diamond anemia]), infection (congenital viral infections [parvovirus, rubella], acquired bacterial or viral sepsis), and congenital leukemia.

Increased Red Blood Cell Destruction

Immunologically mediated hemolysis in utero may lead to **erythroblastosis fetalis**, or the fetus may be spared, and **hemolytic disease** may appear in the newborn. Hemolysis of fetal erythrocytes is a result of blood group differences between the sensitized mother and fetus, which causes production of maternal immunoglobulin G (IgG) antibodies directed against an antigen on fetal cells.

ABO blood group incompatibility with neonatal hemolysis develops only if the mother has IgG antibodies from a previous exposure to A or B antigens. These IgG antibodies cross the placenta by active transport and affect the fetus or newborn. Sensitization of the mother to fetal antigens may have occurred by previous transfusions or by conditions of pregnancy that result in transfer of fetal erythrocytes into the maternal circulation, such as first-trimester abortion, ectopic pregnancy, amniocentesis, manual extraction of the placenta, version (external or internal) procedures, or normal pregnancy.

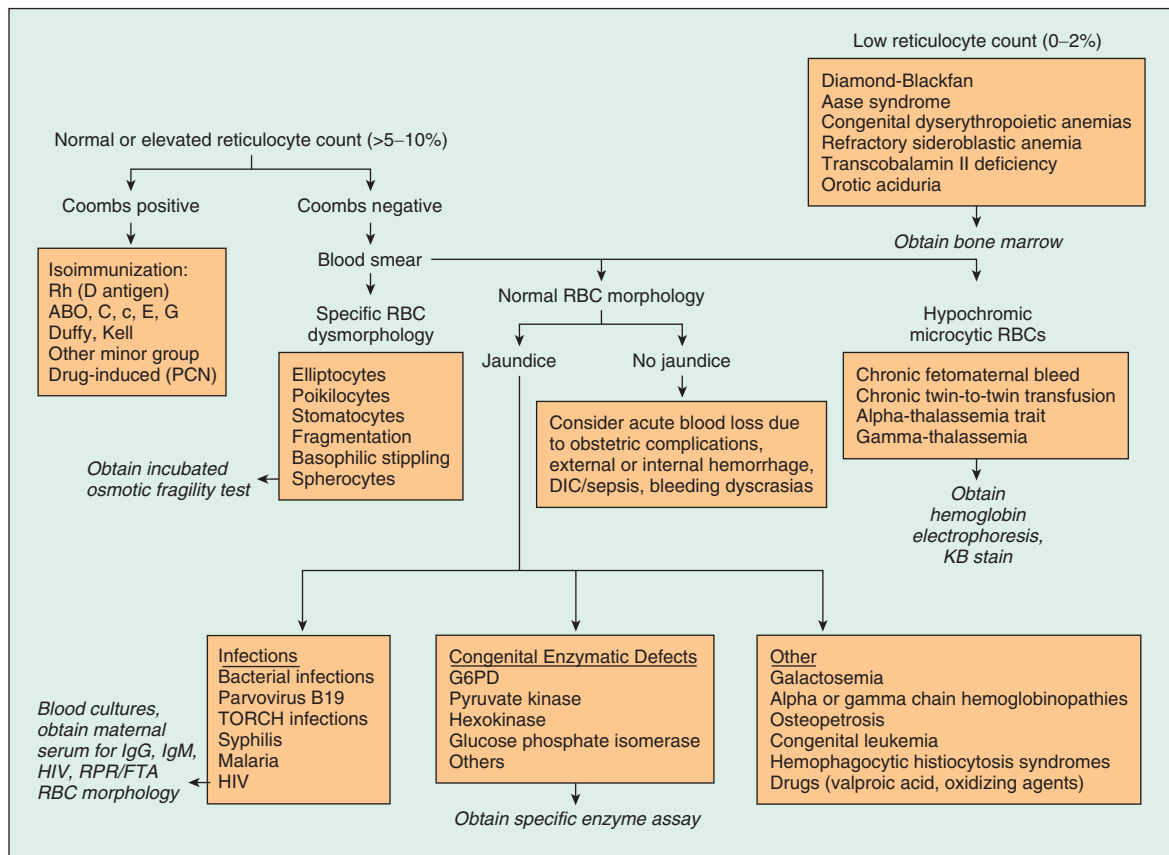

FIGURE 62.1 Differential diagnosis of neonatal anemia. The physician obtains information from the family, maternal and labor and delivery histories, and laboratory tests, including hemoglobin, reticulocyte count, blood type, direct Coombs test, peripheral smear, red blood cell (RBC) indices, and bilirubin concentration. *DIC*, Disseminated intravascular coagulation; *FTA*, fluorescent treponemal antibody test; *G6PD*, glucose-6-phosphate dehydrogenase; *HIV*, human immunodeficiency virus; *KB*, Kleihauer-Betke; *PCN*, penicillin; *RPR*, rapid plasma reagin tests; *TORCH*, toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex. (From Ohls RK. Anemia in the neonate. In: Christensen RD, ed. *Hematologic Problems of the Neonate*. Philadelphia: Saunders; 2000:162.)

ABO incompatibility with sensitization usually does not cause fetal disease other than a mild anemia. It may produce **hemolytic disease of the newborn**, which is manifested as significant anemia and hyperbilirubinemia. Because many mothers who have blood group O have IgG antibodies to A and B before pregnancy, the firstborn infant of A or B blood type may be affected. In contrast to Rh disease, ABO hemolytic disease does not become more severe with subsequent pregnancies. Hemolysis with ABO incompatibility is less severe than hemolysis in Rh-sensitized pregnancy, either because the anti-A or anti-B antibody may bind to nonerythrocytic cells that contain A or B antigen or because fetal erythrocytes have fewer A or B antigenic determinants than they have Rh sites. With the declining incidence of Rh hemolytic disease, ABO incompatibility has become the most common cause of neonatal hyperbilirubinemia requiring therapy, currently accounting for approximately 20% of clinically significant jaundice in the newborn.

Erythroblastosis fetalis classically is caused by Rh blood group incompatibility. Most Rh-negative women have no anti-Rh antibodies at the time of their first pregnancy. The Rh antigen system consists of five antigens: C, D, E, c, and e; the d type is not antigenic. In most Rh-sensitized cases, the D antigen of the fetus sensitizes the Rh-negative (d) mother, resulting in

IgG antibody production during the first pregnancy. Because most mothers are not sensitized to Rh antigens at the start of pregnancy, Rh erythroblastosis fetalis is usually a disease of the second and subsequent pregnancies. The first affected pregnancy results in an antibody response in the mother, which may be detected during antenatal screening with the Coombs test and determined to be anti-D antibody. The first affected newborn may show no serious fetal disease and may manifest hemolytic disease of the newborn only by the development of anemia and hyperbilirubinemia. Subsequent pregnancies result in an increasing severity of response because of an earlier onset of hemolysis in utero. Fetal anemia, heart failure, elevated venous pressure, portal vein obstruction, and hypoalbuminemia result in **fetal hydrops**, which is characterized by ascites, pleural and pericardial effusions, and anasarca (see Chapter 60). The risk of fetal death is high.

The **management** of a pregnancy complicated by Rh sensitization depends on the severity of hemolysis, its effects on the fetus, and the maturity of the fetus at the time it becomes affected. The severity of the hemolysis can be assessed by the quantity of bilirubin transferred from the fetus to the amniotic fluid, quantified by spectrophotometric analysis of the optical density (at 450 nm) of amniotic fluid.

In an affected fetus, the lungs are immature and the fetus is between 22 and 33 weeks of gestational age, an ultrasound-guided intrauterine transfusion with O-negative blood into the umbilical vein is indicated and may have to be repeated until pulmonary maturity is reached or fetal distress is detected. Indications for fetal intravascular transfusion in sensitized fetuses between 22 and 32 weeks of gestational age include a fetal hematocrit of less than 25–30%, fetal hydrops, and fetal distress too early in gestation for delivery. Intravascular intrauterine transfusion corrects fetal anemia, improves the outcome of severe hydrops, and reduces the need for postnatal exchange transfusion, but is associated with neonatal anemia as a result of continued hemolysis plus suppressed erythropoiesis.

Prevention of sensitization of the mother carrying an Rh-positive fetus is possible by treating the mother during gestation (>28 weeks of gestational age) and within 72 hours after birth with anti-Rh-positive immune globulin (RhoGAM). The dose of RhoGAM (300 µg) is based on the ability of this amount of anti-Rh-positive antibody to bind all the possible fetal Rh-positive erythrocytes entering the maternal circulation during the fetal-to-maternal transfusion at birth (~30 mL). RhoGAM may bind Rh-positive fetal erythrocytes or interfere with maternal anti-Rh-positive antibody production by another, unknown mechanism. RhoGAM is effective only in preventing sensitization to the D antigen. Other blood group antigens that can cause immune hydrops and erythroblastosis include Rh C, E, Kell, and Duffy. Anti-Kell alloimmunity produces lower amniotic bilirubin levels and a lower reticulocyte count because, in addition to hemolysis, it inhibits erythropoiesis.

Nonimmune causes of hemolysis in the newborn include RBC enzyme deficiencies of the Embden-Meyerhof pathway, such as pyruvate kinase or glucose-6-phosphate dehydrogenase deficiency. RBC membrane disorders are another cause of nonimmune hemolysis. Hereditary spherocytosis is inherited as a severe autosomal recessive form or less severe autosomal dominant form and is the result of a deficiency of spectrin, a protein of the RBC membrane. Hemoglobinopathies, such as thalassemia, are another cause of nonimmunologically mediated hemolysis.

Blood Loss

Anemia from blood loss at birth is manifested by two patterns of presentation, depending on the rapidity of blood loss. **Acute blood loss** after fetal-maternal hemorrhage, rupture of the umbilical cord, placenta previa, or internal hemorrhage (hepatic or splenic hematoma; retroperitoneal) is characterized by pallor, diminished peripheral pulses, and shock. There are no signs of extramedullary hematopoiesis and no hepatosplenomegaly. The hemoglobin content and serum iron levels initially are normal, but the hemoglobin levels decline during the subsequent 24 hours. Newborns with **chronic blood loss** caused by chronic fetal-maternal hemorrhage or a twin-to-twin transfusion present with marked pallor, heart failure, hepatosplenomegaly with or without hydrops, a low hemoglobin level at birth, a hypochromic microcytic blood smear, and decreased serum iron stores. Fetal to maternal bleeding occurs in 50–75% of all pregnancies, with fetal blood losses ranging from 1–100 mL; most blood losses are 1 mL or less, 1 in 400 are approximately 30 mL, and 1 in 2,000 are approximately 100 mL.

The diagnosis of fetal-maternal hemorrhage is confirmed by the Kleihauer-Betke acid elution test. Pink fetal RBCs are observed and counted in the mother's peripheral blood smear because fetal hemoglobin is resistant to acid elution; adult hemoglobin is eluted, leaving discolored maternal cells (patients with sickle cell anemia or hereditary persistence of fetal hemoglobin may have a false-positive result, and ABO incompatibility may produce a false-negative result).

Diagnosis and Management

Hemolysis in utero resulting from any cause may produce a spectrum of clinical manifestations at birth. Severe hydrops with anasarca, heart failure, and pulmonary edema may prevent adequate ventilation at birth, resulting in asphyxia. Infants affected with hemolysis in utero have hepatosplenomegaly and pallor and become jaundiced within the first 24 hours after birth. Less severely affected infants manifest pallor and hepatosplenomegaly at birth and become rapidly jaundiced subsequently. Patients with ABO incompatibility are often asymptomatic and show no physical signs at birth; mild anemia with jaundice develops during the first 24–72 hours of life.

Because hydrops, anemia, or jaundice is secondary to many diverse causes of hemolysis, a laboratory evaluation is needed in all patients with suspected hemolysis. A complete blood count, blood smear, reticulocyte count, blood type, and direct Coombs test (to determine the presence of antibody-coated RBCs) should be performed in the initial evaluation of all infants with hemolysis. Reduced hemoglobin levels, reticulocytosis, and a blood smear characterized by polychromasia and anisocytosis are expected with isoimmune hemolysis. Spherocytes commonly are observed in ABO incompatibility. The determination of the blood type and the Coombs test identify the responsible antigen and antibody in immunologically mediated hemolysis.

In the absence of a positive Coombs test and blood group differences between the mother and fetus, causes of nonimmune hemolysis must be considered. RBC enzyme assays, hemoglobin electrophoresis, or RBC membrane tests (osmotic fragility, spectrin assay) should be performed. Internal hemorrhage also may be associated with anemia, reticulocytosis, and jaundice when the hemorrhage reabsorbs; ultrasound evaluation of the brain, liver, spleen, or adrenal gland may be indicated when nonimmune hemolysis is suspected. Shock is more typical in patients with internal hemorrhage, whereas in hemolytic diseases, heart failure may be seen with severe anemia. Evaluation of a possible fetal-maternal hemorrhage should include the Kleihauer-Betke test.

The **treatment** of *symptomatic* neonatal anemia is transfusion of cross-matched packed RBCs. If immune hemolysis is present, the cells to be transfused must be cross-matched against maternal and neonatal plasma. Acute volume loss may necessitate resuscitation with nonblood products, such as saline if blood is not available; packed RBCs can be given subsequently. To correct anemia and any remaining blood volume deficit, 10–15 mL/kg of packed RBCs should be sufficient. Cytomegalovirus-seronegative blood should be given and all blood products should be irradiated to reduce the risk of graft-versus-host disease; blood should be screened for HIV, hepatitis B and C, and syphilis. Recombinant erythropoietin may improve the hematocrit in infants with a hyporegenerative anemia after in utero transfusion.

HYPERBILIRUBINEMIA

Hemolytic disease of the newborn is a common cause of neonatal jaundice. Nonetheless, because of the immaturity of the pathways of bilirubin metabolism, many newborn infants without evidence of hemolysis become jaundiced.

Bilirubin is produced by the catabolism of hemoglobin in the reticuloendothelial system. The tetrapyrrole ring of heme is cleaved by heme oxygenase to form equivalent quantities of biliverdin and carbon monoxide. Because no other biologic source of carbon monoxide exists, the excretion of this gas is stoichiometrically identical to the production of bilirubin. Biliverdin is converted to bilirubin by biliverdin reductase. One gram of hemoglobin produces 35 mg of bilirubin. Sources of bilirubin other than circulating hemoglobin represent 20% of bilirubin production; these sources include inefficient (shunt) hemoglobin production and lysis of precursor cells in bone marrow. Compared with adults, newborns have a two- to threefold greater rate of bilirubin production (6–10 mg/kg/24 hours vs. 3 mg/kg/24 hours). This increased production is caused, in part, by an increased RBC mass (higher hematocrit) and a shortened erythrocyte life span of 70–90 days compared with the 120-day erythrocyte life span in adults.

Bilirubin produced after hemoglobin catabolism is lipid soluble and unconjugated and reacts as an indirect reagent in the van den Bergh test. Indirect-reacting, unconjugated bilirubin is toxic to the central nervous system and is insoluble in water, limiting its excretion. Unconjugated bilirubin binds to albumin on specific bilirubin binding sites; 1 g of albumin binds 8.5 mg of bilirubin in a newborn. If the binding sites become saturated or if a competitive compound binds at the site, displacing bound bilirubin, free bilirubin becomes available to enter the central nervous system. Organic acids such as free fatty acids and drugs such as sulfisoxazole can displace bilirubin from its binding site on albumin.

Bilirubin dissociates from albumin at the hepatocyte and becomes bound to a cytoplasmic liver protein Y (ligandin). Hepatic conjugation results in the production of bilirubin diglucuronide, which is water soluble and capable of biliary and renal excretion. The enzyme glucuronosyltransferase represents the rate-limiting step of bilirubin conjugation. The concentrations of ligandin and glucuronosyltransferase are lower in newborns, particularly in premature infants, than in older children.

Conjugated bilirubin gives a direct reaction in the van den Bergh test. Most conjugated bilirubin is excreted through the bile into the small intestine and eliminated in the stool. Some bilirubin may undergo hydrolysis back to the unconjugated fraction by intestinal glucuronidase, however, and may be reabsorbed (enterohepatic recirculation). In addition, bacteria in the neonatal intestine convert bilirubin to urobilinogen and stercobilinogen, which are excreted in urine and stool and usually limit bilirubin reabsorption. Delayed passage of meconium, which contains bilirubin, also may contribute to the enterohepatic recirculation of bilirubin.

Bilirubin is produced in utero by the normal fetus and by the fetus affected by erythroblastosis fetalis. Indirect, unconjugated, lipid-soluble fetal bilirubin is transferred across the placenta and becomes conjugated by maternal hepatic enzymes. The placenta is impermeable to conjugated water-soluble bilirubin. Fetal bilirubin levels become only mildly elevated in the presence of severe hemolysis but may increase when hemolysis produces fetal hepatic inspissated bile stasis and conjugated

hyperbilirubinemia. Maternal indirect (but not direct) hyperbilirubinemia also may increase fetal bilirubin levels.

Etiology of Indirect Unconjugated Hyperbilirubinemia

Physiologic jaundice is a common cause of hyperbilirubinemia among newborns. It is a diagnosis of exclusion, made after careful evaluation has ruled out more serious causes of jaundice, such as hemolysis, infection, and metabolic diseases. Physiologic jaundice is the result of many factors that are normal physiologic characteristics of newborns: increased bilirubin production resulting from an increased RBC mass, shortened RBC life span, and hepatic immaturity of ligandin and glucuronosyltransferase. Physiologic jaundice may be exaggerated among infants of Greek and Asian ancestry.

The clinical pattern of physiologic jaundice in term infants includes a peak indirect-reacting bilirubin level of no more than 12 mg/dL on day 3 of life. In premature infants, the peak is higher (15 mg/dL) and occurs later (day 5). The peak level of indirect bilirubin during physiologic jaundice may be higher in breast milk–fed infants than in formula-fed infants (15–17 mg/dL vs. 12 mg/dL). This higher level may be partly a result of the decreased fluid intake of infants fed breast milk. Jaundice is unphysiologic or pathologic if it is clinically evident on the first day of life, if the bilirubin level increases more than 0.5 mg/dL/hour, if the peak bilirubin is greater than 13 mg/dL in term infants, if the direct bilirubin fraction is greater than 1.5 mg/dL, or if hepatosplenomegaly and anemia are present.

Crigler-Najjar syndrome is a serious, rare, autosomal recessive, permanent deficiency of glucuronosyltransferase that results in severe indirect hyperbilirubinemia. Type II responds to enzyme induction by phenobarbital, producing an increase in enzyme activity and a reduction of bilirubin levels. Type I does not respond to phenobarbital and manifests as persistent indirect hyperbilirubinemia, often leading to kernicterus. **Gilbert disease** is caused by a mutation of the promoter region of glucuronosyltransferase and results in a mild indirect hyperbilirubinemia. In the presence of another icterogenic factor (hemolysis), more severe jaundice may develop.

Breast milk jaundice may be associated with unconjugated hyperbilirubinemia without evidence of hemolysis during the first to second week of life. Bilirubin levels rarely increase to more than 20 mg/dL. Interruption of breast-feeding for 1–2 days results in a rapid decline of bilirubin levels, which do not increase significantly after breast-feeding resumes. Breast milk may contain an inhibitor of bilirubin conjugation or may increase enterohepatic recirculation of bilirubin because of breast milk glucuronidase.

Jaundice on the first day of life is always pathologic and may be unconjugated or conjugated; immediate attention is needed to establish the cause. Early onset often is a result of hemolysis, internal hemorrhage (cephalhematoma, hepatic or splenic hematoma), or infection (Table 62.1). Infection also is often associated with direct-reacting bilirubin resulting from perinatal congenital infections or from bacterial sepsis.

Physical evidence of jaundice is observed in infants when bilirubin levels reach 5–10 mg/dL (versus 2–3 mg/dL in adults). When jaundice is observed, the laboratory evaluation for hyperbilirubinemia should include a total bilirubin measurement to determine the magnitude of hyperbilirubinemia. Bilirubin levels greater than 5 mg/dL on the first day

	HEMOLYSIS PRESENT	HEMOLYSIS ABSENT
Common	<i>Blood group incompatibility:</i> ABO, Rh, Kell, Duffy infection	Physiologic jaundice, breast milk jaundice, internal hemorrhage, polycythemia, infant of diabetic mother
Rare	<i>Red blood cell enzyme defects:</i> glucose-6-phosphate dehydrogenase, pyruvate kinase <i>Red blood cell membrane disorders:</i> spherocytosis, ovalocytosis <i>Hemoglobinopathy:</i> thalassemia	Mutations of glucuronyl transferase enzyme (Crigler-Najjar syndrome, Gilbert disease), pyloric stenosis, hypothyroidism, immune thrombocytopenia

of life or greater than 13 mg/dL thereafter in term infants should be evaluated further with measurement of indirect and direct bilirubin levels, blood typing, Coombs test, complete blood count, blood smear, and reticulocyte count. These tests must be performed before treatment of hyperbilirubinemia with phototherapy or exchange transfusion. In the absence of hemolysis or evidence for either the common or the rare causes of nonhemolytic indirect hyperbilirubinemia, the diagnosis is either physiologic or breast milk jaundice. Jaundice appearing or increasing after 2 weeks of age is pathologic and suggests a direct-reacting hyperbilirubinemia.

Etiology of Direct Conjugated Hyperbilirubinemia

Direct-reacting hyperbilirubinemia (defined as a direct bilirubin level >2 mg/dL or >20% of the total bilirubin) is never physiologic and should always be evaluated thoroughly according to the diagnostic categories (Table 62.2). Direct-reacting bilirubin (composed mostly of conjugated bilirubin) is not neurotoxic to the infant but signifies a serious underlying disorder involving cholestasis or hepatocellular injury. The diagnostic evaluation of patients with direct-reacting hyperbilirubinemia involves the determination of the levels of liver enzymes (aspartate aminotransferase, alkaline phosphatase, alanine aminotransferase, and γ -glutamyl transpeptidase), bacterial and viral cultures, metabolic screening tests, hepatic ultrasound, sweat chloride test, and occasionally liver biopsy. In addition, the presence of dark urine and gray-white (acholic) stools with jaundice after the second week of life strongly suggests biliary atresia. The treatment of disorders manifested by direct bilirubinemia is specific for the diseases that are listed in Table 62.2. These diseases do not respond to phototherapy or exchange transfusion.

Kernicterus Spectrum Disorder (Bilirubin Encephalopathy)

Lipid-soluble, unconjugated, indirect bilirubin fraction is toxic to the developing central nervous system, especially

COMMON
Hyperalimentation cholestasis
CMV infection
Other perinatal congenital infections (TORCH)
Inspissated bile from prolonged hemolysis
Neonatal hepatitis
Sepsis, urinary tract infection
UNCOMMON
Hepatic infarction
Inborn errors of metabolism (galactosemia, tyrosinemia)
Cystic fibrosis
Biliary atresia
Pan hypopituitarism
Choledochal cyst
α_1 -antitrypsin deficiency
Gestational alloimmune liver disease (neonatal hemochromatosis)
Alagille syndrome (arteriohepatic dysplasia)
Byler disease, progressive familial intrahepatic cholestasis types 1, 2, 3

CMV, Cytomegalovirus; TORCH, toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex.

when indirect bilirubin concentrations are high and exceed the binding capacity of albumin. Kernicterus results when indirect bilirubin is deposited in brain cells and disrupts neuronal metabolism and function, especially in the basal ganglia. Indirect bilirubin may cross the blood-brain barrier because of its lipid solubility. Other theories propose that a disruption of the blood-brain barrier permits entry of a bilirubin-albumin or free bilirubin–fatty acid complex.

Kernicterus usually is noted when the bilirubin level is excessively high for gestational age. It usually does not develop in term infants when bilirubin levels are less than 20–25 mg/dL, but the incidence increases as serum bilirubin levels exceed 25 mg/dL. Kernicterus may be noted at bilirubin levels less than 20 mg/dL in the presence of sepsis, meningitis, hemolysis, asphyxia, hypoxia, hypothermia, hypoglycemia, bilirubin-displacing drugs (sulfa drugs), and prematurity. Other risks for kernicterus in term infants are hemolysis, jaundice noted within 24 hours of birth, and delayed diagnosis of hyperbilirubinemia. Kernicterus has developed in extremely immature infants weighing less than 1,000 g when bilirubin levels are less than 10 mg/dL because of a more permeable blood-brain barrier associated with prematurity.

The earliest clinical manifestations of kernicterus are lethargy, hypotonia, irritability, poor Moro response, and poor feeding. A high-pitched cry and emesis also may be present. Early signs are noted after day 4 of life. Later signs include bulging fontanel, opisthotonic posturing, pulmonary hemorrhage, fever, hypertonicity, paralysis of upward gaze, and seizures. Infants with severe cases of kernicterus die in the neonatal period. Spasticity resolves in surviving infants, who

may manifest later nerve deafness, choreoathetoid cerebral palsy, mental retardation, enamel dysplasia, and discoloration of teeth as permanent sequelae. Kernicterus may be prevented by avoiding excessively high indirect bilirubin levels and by avoiding conditions or drugs that may displace bilirubin from albumin. Early signs of kernicterus occasionally may be reversed by immediately instituting an exchange transfusion (see later).

Therapy of Indirect Hyperbilirubinemia

Phototherapy is an effective and safe method for reducing indirect bilirubin levels, particularly when initiated before serum bilirubin increases to levels associated with kernicterus. In term infants, phototherapy is begun depending on the post-natal age. Lower thresholds for phototherapy may be applied during the first and second days of life, if indirect bilirubin levels are between 16 and 18 mg/dL. Phototherapy is initiated in premature infants when bilirubin is at lower levels, to prevent bilirubin from reaching the high concentrations necessitating exchange transfusion. Blue lights and white lights are effective in reducing bilirubin levels.

Under the effects of phototherapy light with maximal irradiance in the 425–475 nm wavelength band, bilirubin is transformed into isomers that are water soluble and easily excreted. Unconjugated bilirubin (IX) is in the 4Z, 15Z configuration. Phototherapy causes a photochemical reaction producing the reversible, more water-soluble isomer 4Z, 15E bilirubin IX. This isomer can be excreted easily, bypassing the liver's conjugation system. Another photochemical reaction results in the rapid production of lumirubin, a more water-soluble isomer than the isomer, which does not spontaneously revert to unconjugated native bilirubin and can be excreted in urine.

Complications of phototherapy include an increased insensible water loss, diarrhea, and dehydration. Additional problems are macular-papular red skin rash, lethargy, masking of cyanosis, nasal obstruction by eye pads, and potential for retinal damage. Skin bronzing may be noted in infants with direct-reacting hyperbilirubinemia. Infants with mild hemolytic disease of the newborn occasionally may be managed successfully with phototherapy for hyperbilirubinemia, but care must be taken to follow these infants for the late occurrence of anemia from continued hemolysis.

Exchange transfusion usually is reserved for infants with dangerously high indirect bilirubin levels who are at risk for kernicterus. As a rule of thumb, a level of 20 mg/dL for indirect-reacting bilirubin is the *exchange number* for infants *with hemolysis* who weigh more than 2,000 g. Asymptomatic infants with physiologic or breast milk jaundice may not require exchange transfusion, unless the indirect bilirubin level exceeds 25 mg/dL. The exchangeable level of indirect bilirubin for other infants may be estimated by calculating 10% of the birthweight in grams: the level in an infant weighing 1,500 g would be 15 mg/dL. Infants weighing less than 1,000 g usually do not require an exchange transfusion until the bilirubin level exceeds 10 mg/dL.

The exchange transfusion is usually performed through an umbilical venous catheter placed in the inferior vena cava or, if free flow is obtained, at the confluence of the umbilical vein and the portal system. The level of serum bilirubin immediately after the exchange transfusion declines to levels that are about half of those before the exchange; levels rebound

6–8 hours later as a result of continued hemolysis and redistribution of bilirubin from tissue stores.

Complications of exchange transfusion include problems related to the blood (transfusion reaction, metabolic instability, or infection), the catheter (vessel perforation or hemorrhage), or the procedure (hypotension or necrotizing enterocolitis [NEC]). Unusual complications include thrombocytopenia and graft-versus-host disease. Continuation of phototherapy may reduce the necessity for subsequent exchange transfusions.

Polycythemia (Hyperviscosity Syndrome)

Polycythemia is an excessively high hematocrit ($\geq 65\%$), which may lead to hyperviscosity that produces symptoms related to vascular stasis, hypoperfusion, and ischemia. As the hematocrit increases from 40% to 60%, there is a small increase in blood viscosity. When the *central* hematocrit increases to greater than 65%, the blood viscosity begins to increase markedly, and symptoms may appear. Neonatal erythrocytes are less filterable or deformable than adult erythrocytes, which further contributes to hyperviscosity. A central venous hematocrit of 65% or greater is noted in 3–5% of infants. Infants at special risk for polycythemia are term and post-term small for gestational age infants, infants of diabetic mothers, infants with delayed cord clamping, and infants with neonatal hyperthyroidism, adrenogenital syndrome, trisomy 13, trisomy 18, trisomy 21, twin-to-twin transfusion syndrome (recipient), or Beckwith-Wiedemann syndrome. In some infants, polycythemia may reflect a compensation for prolonged periods of fetal hypoxia caused by placental insufficiency; these infants have increased erythropoietin levels at birth.

Polycythemic patients appear plethoric or ruddy and may develop acrocyanosis. Symptoms, if present, are a result of the increased RBC mass and of vascular compromise. Seizures, lethargy, and irritability reflect abnormalities of microcirculation of the brain, whereas hyperbilirubinemia may reflect the poor hepatic circulation or the increased amount of hemoglobin that is being broken down into bilirubin. Additional problems include respiratory distress and persistent pulmonary hypertension of the newborn (PPHN) that result in part from elevated pulmonary vascular resistance. The chest radiograph often reveals cardiomegaly, increased vascular markings, pleural effusions, and interstitial edema. Other problems are NEC, hypoglycemia, thrombocytopenia, priapism, testicular infarction, hemiplegic stroke, and feeding intolerance. Many of these complications also are related to the primary condition associated with polycythemia (small for gestational age infants are at risk for hypoglycemia and PPHN after periods of hypoxia in utero).

Long-term sequelae of neonatal polycythemia relate to neurodevelopmental abnormalities that may be prevented by treatment of symptomatic infants with partial exchange transfusion after birth. A partial exchange transfusion removes whole blood and replaces it with normal saline.

Coagulation Disorders

Disorders of coagulation are common in the neonatal period. Hemorrhage during this time may be a result of trauma, inherited permanent deficiency of coagulation factors, transient deficiencies of vitamin K-dependent factors, disorders

of platelets, and disseminated intravascular coagulation (DIC) seen in sick newborns with shock or hypoxia. Thrombosis also is a potential problem in the newborn because of developmentally lower circulating levels of antithrombin III, protein C (a vitamin K–dependent protein that inhibits factors VIII and V), and the fibrinolytic system.

Coagulation factors do not pass through the placenta to the fetus, and newborn infants have relatively low levels of the vitamin K–dependent factors II, VII, IX, and X. Contact factors XI and XII, prekallikrein, and kininogen also are lower in newborns than in adults. Fibrinogen (factor I); plasma levels of factors V, VIII, and XIII; and platelet counts are within the adult normal range.

Because of the transient, relative deficiencies of the contact and vitamin K–dependent factors, the *partial thromboplastin time* (PTT), which is dependent on factors XII, IX, VIII, X, V, II, and I, is prolonged in the newborn period. Preterm infants have the most marked prolongation of the PTT (50–80 seconds) compared with term infants (35–50 seconds) and older, more mature infants (25–35 seconds). The administration of heparin and the presence of DIC, hemophilia, and severe vitamin K deficiency prolong the PTT.

The *prothrombin time* (PT), which is dependent on factors X, VII, V, II, and I, is a more sensitive test for vitamin K deficiency. The PT is only slightly prolonged in term infants (13–20 seconds) compared with preterm infants (13–21 seconds) and more mature patients (12–14 seconds). Abnormal prolongations of the PT occur with vitamin K deficiency, hepatic injury, and DIC. Levels of *fibrinogen* and *fibrin degradation products* are similar in infants and adults. The *bleeding time*, which reflects platelet function and number, is normal during the newborn period in the absence of maternal salicylate therapy.

Vitamin K is a necessary cofactor for the carboxylation of glutamate on precursor proteins, converting them into the more active coagulation factors II, VII, IX, and X; γ -carboxyglutamic acid binds calcium, which is required for the immediate activation of factors during hemorrhage. There is no congenital deficiency of hepatic synthesis of these precursor proteins, but in the absence of vitamin K their conversion to the active factor is not possible. Levels of *protein induced by vitamin K absence* increase in vitamin K deficiency and are helpful diagnostic markers; vitamin K administration rapidly corrects the coagulation defects, reducing protein induced by vitamin K absence to undetectable levels.

Although most newborns are born with reduced levels of vitamin K–dependent factors, hemorrhagic complications develop only rarely. Infants at risk for **hemorrhagic disease of the newborn** have the most profound deficiency of vitamin K–dependent factors, and these factors decline further after birth. Because breast milk is a poor source of vitamin K, breast-fed infants are at increased risk for hemorrhage that usually occurs between days 3 and 7 of life. Bleeding usually ensues from the umbilical cord, circumcision site, intestines, scalp, mucosa, and skin, but internal hemorrhage places the infant at risk for fatal complications, such as intracranial bleeding.

Hemorrhage on the first day of life resulting from a deficiency of the vitamin K–dependent factors often is associated with administration to the mother of drugs that affect vitamin K metabolism in the infant. This early pattern of hemorrhage

has been seen with maternal warfarin or antibiotic (e.g., isoniazid or rifampin) therapy and in infants of mothers receiving phenobarbital and phenytoin. Bleeding also may occur 1–3 months after birth, particularly among breast-fed infants. Vitamin K deficiency in breast-fed infants also should raise suspicion about the possibility of vitamin K malabsorption resulting from cystic fibrosis, biliary atresia, hepatitis, or antibiotic suppression of the colonic bacteria that produce vitamin K.

Bleeding associated with vitamin K deficiency may be **prevented** by administration of vitamin K to all infants at birth. Before routine administration of vitamin K, 1–2% of all newborns had hemorrhagic disease of the newborn. One intramuscular dose (1 mg) of vitamin K prevents vitamin K–deficiency bleeding. **Treatment** of bleeding resulting from vitamin K deficiency involves intravenous administration of 1 mg of vitamin K. If severe, life-threatening hemorrhage is present, fresh frozen plasma also should be given. Unusually higher doses of vitamin K may be needed for hepatic disease and for maternal warfarin or anticonvulsant therapy.

Clinical Manifestations and Differential Diagnoses of Bleeding Disorders

Bleeding disorders in a newborn may be associated with cutaneous bleeding, such as cephalhematoma, subgaleal hemorrhage, ecchymosis, and petechiae. Facial petechiae are common in infants born by vertex presentation, with or without a nuchal cord, and usually are insignificant. Mucosal bleeding may appear as hematemesis, melena, or epistaxis. Internal hemorrhage results in organ-specific dysfunction, such as seizures associated with intracranial hemorrhage. Bleeding from venipuncture or heel stick sites, circumcision sites, or the umbilical cord also is common with bleeding disorders.

The differential diagnosis depends partly on the clinical circumstances associated with the hemorrhage. In a **sick newborn**, the differential diagnosis should include DIC, hepatic failure, and thrombocytopenia. Thrombocytopenia in an ill neonate may be secondary to consumption by trapping of platelets in a hemangioma (**Kasabach-Merritt syndrome**) or may be associated with perinatal, congenital, or bacterial infections; NEC; thrombotic endocarditis; PPHN; organic acidemia; maternal preeclampsia; or asphyxia. Thrombocytopenia also may be due to peripheral washout of platelets after an exchange transfusion. Treatment of a sick infant with thrombocytopenia should be directed at the underlying disorder, supplemented by infusions of platelets, blood, or both.

The etiology of DIC in a newborn includes hypoxia, hypotension, asphyxia, bacterial or viral sepsis, NEC, death of a twin while in utero, cavernous hemangioma, nonimmune hydrops, neonatal cold injury, neonatal neoplasm, and hepatic disease. The treatment of DIC should be focused primarily on therapy for the initiating or underlying disorder. Supportive management of consumptive coagulopathy involves platelet transfusions and factor replacement with fresh frozen plasma. Heparin and factor C concentrate should be reserved for infants with DIC who also have thrombosis.

Disorders of hemostasis in a *well child* are not associated with systemic disease in a newborn but reflect coagulation factor or platelet deficiency. Hemophilia initially is associated

with cutaneous, scalp, or mucosal bleeding and no systemic illness. If bleeding continues, hypovolemic shock may develop. Bleeding into the brain, liver, or spleen may result in organ-specific signs and shock.

In a *well child*, thrombocytopenia may be part of a syndrome such as Fanconi anemia syndrome (involving hypoplasia and aplasia of the thumb), radial aplasia-thrombocytopenia syndrome (thumbs present), or Wiskott-Aldrich syndrome. Various maternal drugs also may reduce the neonatal platelet count without producing other adverse effects. These drugs include sulfonamides, quinidine, quinine, and thiazide diuretics.

The most common causes of thrombocytopenia in well newborns are transient isoimmune thrombocytopenia and transient neonatal thrombocytopenia. **Isoimmune thrombocytopenia** is caused by antiplatelet antibodies produced by the PLA-1–negative mother after her sensitization to specific paternal platelet antigen (PA-1a and PA-5b represent 85% and 10% of cases, respectively) expressed on the fetal platelet. The incidence is 1 in 1,000–2,000 births. This response to maternal-sensitized antibodies that produce isoimmune thrombocytopenia is analogous to the response that produces erythroblastosis fetalis. The maternal antiplatelet antibody does not produce maternal thrombocytopenia, but after crossing the placenta this IgG antibody binds to fetal platelets that are trapped by the reticuloendothelial tissue, resulting in thrombocytopenia. Infants with thrombocytopenia produced in this manner are at risk for development of petechiae, purpura, and intracranial hemorrhage (an incidence of 10–15%) before or after birth. Vaginal delivery may increase the risk of neonatal bleeding; cesarean section may be indicated.

Specific **treatment** for severe thrombocytopenia ($<20,000$ platelets/ mm^3) or significant bleeding is transfusion of ABO-compatible and RhD-compatible, PA-1a–negative and PA-5b–negative maternal platelets. Because the antibody in isoimmune thrombocytopenia is directed against the fetal rather than the maternal platelet, thrombocytapheresis of the mother yields sufficient platelets to treat the affected infant. After one platelet transfusion, the infant's platelet count dramatically increases and usually remains in a safe range. Without treatment, thrombocytopenia resolves during the first month of life as the maternal antibody level declines. *Treatment* of the mother with intravenous immunoglobulin or the thrombocytopenic fetus with intravascular platelet transfusion (cordocentesis) is also effective. Cesarean section reduces the risk of intracranial hemorrhage.

Neonatal thrombocytopenia in infants born to women with idiopathic thrombocytopenic purpura (ITP) also is a result of placental transfer of maternal IgG antibodies. In ITP, these autoantibodies are directed against all platelet antigens; mother and newborn may have low platelet counts. The risks of hemorrhage in an infant born to a mother with ITP may be lessened by cesarean section and by treatment of the mother with corticosteroids.

Treatment of an affected infant born to a mother with ITP may involve prednisone and intravenous immunoglobulin. In an emergency, random donor platelets may be used and may produce a transient increase in the infant's platelet count. Thrombocytopenia resolves spontaneously during the first month of life as maternal-derived antibody levels decline.

Elevated levels of platelet-associated antibodies also have been noted in thrombocytopenic infants with sepsis and thrombocytopenia of unknown cause who were born to mothers without demonstrable platelet antibodies.

The laboratory evaluation of an infant (well or sick) with bleeding must include a platelet count, blood smear, and evaluation of PTT and PT. Isolated thrombocytopenia in a well infant suggests immune thrombocytopenia. Laboratory evidence of DIC includes a markedly prolonged PTT and PT (minutes rather than seconds), thrombocytopenia, and a blood smear suggesting a microangiopathic hemolytic anemia (burr or fragmented blood cells). Further evaluation reveals low levels of fibrinogen (<100 mg/dL) and elevated levels of fibrin degradation products. Vitamin K deficiency prolongs the PT more than the PTT, whereas hemophilia resulting from factors VIII and IX deficiency prolongs only the PTT. Specific factor levels confirm the diagnosis of hemophilia.

CHAPTER 63

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is a syndrome of intestinal injury and is the most common intestinal emergency occurring in preterm infants admitted to the neonatal intensive care unit. NEC occurs in 1–3 per 1,000 live births and 1–8% of admissions to the neonatal intensive care unit. Prematurity is the most consistent and significant factor associated with neonatal NEC. The disease occurs in 4–13% of infants who weigh less than 1,500 g at birth. NEC is infrequent in term infants (<10% of affected infants).

Most cases of NEC occur in premature infants born before 34 weeks of gestation who have been fed enterally. Prematurity is associated with immaturity of the gastrointestinal tract, including decreased integrity of the intestinal mucosal barrier, depressed mucosal enzymes, suppressed gastrointestinal hormones, suppressed intestinal host defense system, decreased coordination of intestinal motility, and differences in blood flow autoregulation, which is thought to play a significant role in the pathogenesis of NEC. More than 90% of infants diagnosed with NEC have been fed enterally, but NEC has been reported in infants who have never been fed. Feeding with human milk has shown a beneficial role in reducing the incidence of NEC. In addition, probiotics may offer potential benefits for the preterm infant by increasing mucosal barrier function, upregulating the immune system, and reducing mucosal colonization by potential pathogens. It is also theorized that compromised intestinal blood flow contributes to NEC.

Early clinical signs of NEC include abdominal distention, feeding intolerance/increased gastric residuals, emesis, rectal bleeding, and occasional diarrhea. As the disease progresses, patients may develop marked abdominal distention, bilious

emesis, ascites, abdominal wall erythema, lethargy, temperature instability, increased episodes of apnea/bradycardia, disseminated intravascular coagulation, and shock. With abdominal perforation, the abdomen may develop a bluish discoloration.

The white blood cell count can be elevated, but often it is depressed. Thrombocytopenia is common. In addition, infants may develop coagulation abnormalities along with metabolic derangements, including metabolic acidosis, electrolyte imbalance, and hypoglycemia and hyperglycemia. No unique infectious agent has been associated with NEC; bacteriologic and fungal cultures may prove helpful but not conclusive.

Radiographic imaging is essential to the diagnosis of NEC. The earliest radiographic finding is intestinal ileus, often associated with thickening of the bowel loops and air-fluid levels. The pathognomonic radiographic finding is **pneumatosis intestinalis** caused by hydrogen gas production from pathogenic bacteria present between the subserosal and muscularis layers of the bowel wall. Radiographic findings also may include a fixed or persistent dilated loop of bowel, intrahepatic venous gas, and *pneumoperitoneum* seen with bowel perforation.

The **differential diagnosis** of NEC includes sepsis with intestinal ileus or a volvulus. Both conditions can present with systemic signs of sepsis and abdominal distention. The absence of pneumatosis on abdominal radiographs does not rule out the diagnosis of NEC; other causes of abdominal distention and perforation (gastric or ileal perforation) should be considered and investigated. Patients diagnosed with Hirschsprung enterocolitis or severe gastroenteritis may present with pneumatosis intestinalis.

The **management** of NEC includes the discontinuation of enteral feedings, gastrointestinal decompression with nasogastric suction, fluid and electrolyte replacement, total parenteral nutrition, and systemic broad-spectrum antibiotics. When the diagnosis of NEC is made, consultation with a pediatric surgeon should be obtained. Even with aggressive and appropriate medical management, 25–50% of infants with NEC require surgical intervention. The decision to perform surgery is obvious when the presence of a pneumoperitoneum is observed on abdominal radiograph. Other, not so obvious indications for surgical intervention include rapid clinical deterioration despite medical therapy, an abdominal mass, and intestinal obstruction. The surgical procedure of choice is laparotomy with removal of the frankly necrotic and nonviable bowel. Many extremely small infants are managed initially with primary peritoneal drainage followed by surgical intervention as needed later, when the infant is stable, and a laparotomy can be performed safely. The long-term outcome includes intestinal strictures requiring further surgical intervention, short bowel syndrome with poor absorption of enteral fluids and nutrients, associated cholestasis with resultant cirrhosis and liver failure from prolonged parenteral nutrition, and neurodevelopmental delay from prolonged hospitalization.

PEARLS FOR PRACTITIONERS

See *Fetal and Neonatal Medicine: Pearls for Practitioners* at the end of this section.

CHAPTER 64

Hypoxic-Ischemic Encephalopathy, Intracranial Hemorrhage, and Seizures

The human newborn spends more time asleep (predominantly in rapid eye movement or active sleep) than in a wakeful state and is totally dependent on adults. Primitive reflexes, such as the Moro, grasp, stepping, rooting, sucking, and crossed extensor reflexes, are readily elicited and are normal for this age. In addition, the newborn has a wealth of cortical functions that are less easily shown (e.g., the ability to extinguish repetitive or painful stimuli). The newborn also has the capacity for attentive eye fixation and differential responses to the mother's voice. During the perinatal period, many pathophysiologic mechanisms can adversely and permanently affect the developing brain, including prenatal events, such as hypoxia, ischemia, infections, inflammation, malformations, maternal drugs, and coagulation disorders, as well as postnatal events, such as birth trauma, hypoxia-ischemia, inborn errors of metabolism, hypoglycemia, hypothyroidism, hyperthyroidism, polycythemia, hemorrhage, and meningitis.

NEONATAL SEIZURES

Seizures during the neonatal period may be the result of multiple causes, with characteristic **historical and clinical manifestations**. Seizures caused by **hypoxic-ischemic encephalopathy** (postasphyxial seizures), a common cause of seizures in the full-term infant, usually occur 12–24 hours after a history of birth asphyxia and often are refractory to conventional doses of anticonvulsant medications. Postasphyxial seizures also may be caused by metabolic disorders associated with neonatal asphyxia, such as hypoglycemia and hypocalcemia. **Intraventricular hemorrhage (IVH)** is a common cause of seizures in premature infants and often occurs between 1 and 3 days of age. Seizures with IVH are associated with a bulging fontanel, hemorrhagic spinal fluid, anemia, lethargy, and coma. Seizures caused by **hypoglycemia** often occur when blood glucose levels decline to the lowest postnatal value (at 1–2 hours of age or after 24–48 hours of poor nutritional intake). Seizures caused by **hypocalcemia** and **hypomagnesemia** develop in high-risk infants and respond well to therapy with calcium, magnesium, or both.

Seizures noted in the delivery room often are caused by direct *injection of local anesthetic agents* into the fetal scalp (associated with transient bradycardia and fixed dilated pupils), severe *anoxia*, or *congenital brain malformation*. Seizures after the first 5 days of life may be the result of *infection* or *drug withdrawal*. Seizures associated with lethargy, acidosis, and a family history of infant deaths may be the result of an *inborn error of metabolism*. An infant whose parent has a history of a neonatal seizure also is at risk for *benign familial neonatal seizures*; these seizures have onset on days 3–7 and resolve by 1–4 months, and are due to mutations in *KCNQ2* and *KCNQ3* potassium channel genes. In an infant who appears well, a sudden onset on days 1–3 of life of seizures that are of short

TABLE 64.1 Clinical Characteristics of Neonatal Seizures

DESIGNATION	CHARACTERIZATION
Focal clonic	<p>Repetitive, rhythmic contractions of muscle groups of the limbs, face, or trunk</p> <p>May be unilateral or multifocal</p> <p>May appear synchronously or asynchronously in various body regions</p> <p>Cannot be suppressed by restraint</p>
Focal tonic	<p>Sustained posturing of single limbs</p> <p>Sustained asymmetric posturing of the trunk</p> <p>Sustained eye deviation</p> <p>Cannot be provoked by stimulation or suppressed by restraint</p>
Myoclonic	<p>Arrhythmic contractions of muscle groups of the limbs, face, or trunk</p> <p>Typically not repetitive or may recur at a slow rate</p> <p>May be generalized, focal, or fragmentary</p> <p>May be provoked by stimulation</p>
Generalized tonic	<p>Sustained symmetric posturing of limbs, trunk, and neck</p> <p>May be flexor, extensor, or mixed extensor/flexor</p> <p>May be provoked by stimulation</p> <p>May be suppressed by restraint or repositioning</p>
Ocular signs	<p>Random and roving eye movements or nystagmus</p> <p>Distinct from tonic eye deviation</p>
Orobuccolingual movements	<p>Sucking, chewing, tongue protrusions</p> <p>May be provoked by stimulation</p>
Progression movements	<p>Rowing or swimming movements of the arms</p> <p>Pedaling or bicycling movements of the legs</p> <p>May be provoked by stimulation</p> <p>May be suppressed by restraint or repositioning</p>

From Mizrahi EM. Neonatal seizures. In: Shinnar S, Branski D, eds. Pediatric and Adolescent Medicine. Basel: S. Karger; 1995 [vol 6].

duration and that do not recur may be the result of a *subarachnoid hemorrhage*. Focal seizures often are the result of local cerebral infarction.

Seizures may be difficult to differentiate from benign jitteriness or from tremulousness in infants of diabetic mothers, in infants with narcotic withdrawal syndrome, and in any infants after an episode of asphyxia. In contrast to seizures, jitteriness and tremors are sensory dependent, elicited by stimuli, and interrupted by holding the extremity. Seizure activity becomes manifested as coarse, fast and slow clonic activity, whereas jitteriness is characterized by fine, rapid movement. Seizures may be associated with abnormal eye movements, such as tonic deviation to one side. The electroencephalogram often shows seizure activity when the clinical diagnosis is uncertain. Identifying seizures in the newborn period is often difficult because the infant, especially the low birthweight infant, usually does not show the tonic-clonic major motor activity typical of the older child (Table 64.1). Subtle seizures are a common manifestation

in newborns. The subtle signs of seizure activity include apnea, eye deviation, tongue thrusting, eye blinking, fluctuation of vital signs, and staring. Continuous bedside electroencephalographic monitoring can help identify subtle seizures.

The **diagnostic evaluation** of infants with seizures should involve an immediate determination of capillary blood glucose levels with a Chemstrip. In addition, blood concentrations of sodium, calcium, glucose, and bilirubin should be determined. When infection is suspected, cerebrospinal fluid and blood specimens should be obtained for culture. After the seizure has stopped, a careful examination should be done to identify signs of increased intracranial pressure, congenital malformations, and systemic illness. If signs of elevated intracranial pressure are absent, a lumbar puncture should be performed. If the diagnosis is not apparent at this point, further evaluation should involve MRI, CT, or cerebral ultrasound and tests to determine the presence of an inborn error of metabolism. Determinations of inborn errors of metabolism are especially

important in infants with unexplained lethargy, coma, acidosis, ketonuria, or respiratory alkalosis.

The **treatment** of neonatal seizures may be specific, such as treatment of meningitis or the correction of **hypoglycemia, hypocalcemia, hypomagnesemia, hyponatremia, or vitamin B₆ deficiency or dependency**. In the absence of an identifiable cause, therapy should involve an anticonvulsant agent, such as 20–40 mg/kg of phenobarbital, 10–20 mg/kg of phenytoin, or 0.1–0.3 mg/kg of diazepam. Levetiracetam (Keppra) is an alternative anticonvulsant drug. Treatment of status epilepticus requires repeated doses of phenobarbital and may require diazepam or midazolam, titrated to clinical signs. The long-term outcome for neonatal seizures usually is related to the underlying cause and to the primary pathology, such as hypoxic-ischemic encephalopathy, meningitis, drug withdrawal, stroke, or hemorrhage.

INTRACRANIAL HEMORRHAGE

Intracranial hemorrhage may be confined to one anatomic area of the brain, such as the subdural, subarachnoid, periventricular, intraventricular, intraparenchymal, or cerebellar region. **Subdural hemorrhages** are seen in association with birth trauma, cephalopelvic disproportion, forceps delivery, large for gestational age infants, skull fractures, and postnatal head trauma. The subdural hematoma does not always cause symptoms immediately after birth; with time, however, the red blood cells (RBCs) undergo hemolysis and water is drawn into the hemorrhage because of the high oncotic pressure of protein, resulting in an expanding symptomatic lesion. Anemia, vomiting, seizures, and macrocephaly may occur in an infant who is 1–2 months of age and has a subdural hematoma. **Child abuse** should be suspected in this situation and appropriate diagnostic evaluation undertaken to identify other possible signs of skeletal, ocular, or soft tissue injury. Occasionally, a massive subdural hemorrhage in the neonatal period is caused by rupture of the vein of Galen or by an inherited coagulation disorder, such as hemophilia. Infants with these conditions exhibit shock, seizures, and coma. The **treatment** of all symptomatic subdural hematomas is surgical evacuation.

Subarachnoid hemorrhages may be spontaneous, associated with hypoxia, or caused by bleeding from a cerebral arteriovenous malformation. Seizures are a common presenting manifestation, and the *prognosis* depends on the underlying injury. Treatment is directed at the seizure and the rare occurrence of posthemorrhagic hydrocephalus.

Periventricular hemorrhage and IVH are common in very low birthweight infants; the risk decreases with increasing gestational age. Fifty percent of infants weighing less than 1,500 g have evidence of intracranial bleeding. The pathogenesis for these hemorrhages is unknown (they usually are not caused by coagulation disorders), but the initial site of bleeding may be the weak blood vessels in the periventricular germinal matrix. The vessels in this area have poor structural support. These vessels may rupture and hemorrhage because of passive changes in cerebral blood flow occurring with the variations of blood pressure that sick premature infants often exhibit (failure of autoregulation). In some sick infants, these blood pressure variations are the only identifiable etiologic factors. In others, the disorders that may cause the elevation or depression of blood pressure or that interfere with venous return from the head (venous stasis) increase the risk of IVH;

these disorders include asphyxia, pneumothorax, mechanical ventilation, hypercapnia, hypoxemia, prolonged labor, breech delivery, patent ductus arteriosus, heart failure, and therapy with hypertonic solutions such as sodium bicarbonate.

Most periventricular hemorrhages and IVHs occur in the first 3 days of life. It is unusual for IVH to occur after day 5 of life. The clinical manifestations of IVH include seizures, apnea, bradycardia, lethargy, coma, hypotension, metabolic acidosis, anemia not corrected by blood transfusion, bulging fontanel, and cutaneous mottling. Many infants with small hemorrhages (grade 1 or 2) are asymptomatic; infants with larger hemorrhages (grade 4) often have a catastrophic event that rapidly progresses to shock and coma.

The diagnosis of IVH is confirmed and the severity graded by ultrasound through the anterior fontanel or CT examination. Grade 1 IVH is confined to the germinal matrix; grade 2 is an extension of grade 1, with blood noted in the ventricle without ventricular enlargement; grade 3 is an extension of grade 2 with ventricular dilation; and grade 4 has blood in dilated ventricles and in the cerebral cortex, either contiguous with or distant from the ventricle. Grade 4 hemorrhage has a poor prognosis, as does the development of periventricular, small, echolucent cystic lesions, with or without porencephalic cysts and posthemorrhagic hydrocephalus. Periventricular cysts often are noted after the resolution of echodense areas in the periventricular white matter. The cysts may correspond to the development of **periventricular leukomalacia**, which may be a precursor to cerebral palsy. Extensive intraparenchymal echodensities represent hemorrhagic necrosis. They are associated with a high mortality rate and have a poor neurodevelopmental prognosis for survivors.

Treatment of an acute hemorrhage involves standard supportive care, including ventilation for apnea and blood transfusion for hemorrhagic shock. Posthemorrhagic hydrocephalus may be managed with serial daily lumbar punctures, an external ventriculostomy tube, or a permanent ventricular-peritoneal shunt. Implementation of the shunt often is delayed because of the high protein content of the hemorrhagic ventricular fluid. Holding the infant's head in a straight, upright position for the first 96 hours of life and minimizing stimulation has shown some benefit in the prevention of severity of IVH.

HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Conditions known to reduce uteroplacental blood flow or to interfere with spontaneous respiration lead to perinatal hypoxia, lactic acidosis, and, if severe enough to reduce cardiac output or cause cardiac arrest, ischemia. The combination of the reduced availability of oxygen for the brain resulting from hypoxia and the diminished or absent blood flow to the brain resulting from ischemia leads to reduced glucose for metabolism and to an accumulation of lactate that produces local tissue acidosis. After reperfusion, hypoxic-ischemic injury also may be complicated by cell necrosis and vascular endothelial edema, reducing blood flow distal to the involved vessel. Typically, hypoxic-ischemic encephalopathy in the term infant is characterized by cerebral edema, cortical necrosis, and involvement of the basal ganglia, whereas in the preterm infant it is characterized by periventricular leukomalacia. Both lesions may result in cortical atrophy, mental retardation, and spastic quadriplegia or diplegia.

TABLE 64.2 Hypoxic-Ischemic Encephalopathy in Term Infants

SIGNS	STAGE 1	STAGE 2	STAGE 3
Level of consciousness	Hyperalert	Lethargic	Stuporous
Muscle tone	Normal	Hypotonic	Flaccid
Tendon reflexes/clonus	Hyperactive	Hyperactive	Absent
Moro reflex	Strong	Weak	Absent
Pupils	Mydriasis	Miosis	Unequal, poor light reflex
Seizures	None	Common	Decerebration
Electroencephalography	Normal	Low voltage changing to seizure activity	Burst suppression to isoelectric
Duration	>24 hr if progresses, otherwise may remain normal	24 hr to 14 days	Days to weeks

Modified from Sarnat HB, Sarnat MS. Neonatal encephalopathy following fetal distress. *Arch Neurol.* 1976;33:696.

The clinical manifestations and characteristic course of hypoxic-ischemic encephalopathy vary according to the severity of the injury (Table 64.2). Infants with severe stage 3 hypoxic-ischemic encephalopathy are usually hypotonic, although occasionally they initially appear hypertonic and hyperalert at birth. As cerebral edema develops, brain functions are affected in a descending order; cortical depression produces coma, and brainstem depression results in apnea. As cerebral edema progresses, refractory seizures begin 12–24 hours after birth. Concurrently the infant has no signs of spontaneous respirations, is hypotonic, and has diminished or absent deep tendon reflexes. Hypoxic-ischemic encephalopathy in term infants is often managed with induced hypothermia.

Survivors of stage 3 hypoxic-ischemic encephalopathy have a high incidence of seizures and serious neurodevelopmental handicaps. The prognosis of severe asphyxia also depends on other organ system injury (see Table 58.6). Another indicator of poor prognosis is time of onset of spontaneous respiration as estimated by Apgar score. Infants with Apgar scores of 0–3 at 10 minutes have a 20% mortality and a 5% incidence of cerebral palsy; if the score remains this low by 20 minutes, the mortality increases to 60%, and the incidence of cerebral palsy increases to 57%.

PEARLS FOR PRACTITIONERS

See *Fetal and Neonatal Medicine: Pearls for Practitioners at the end of this section.*

CHAPTER 65

Sepsis and Meningitis

Systemic and local infections (lung, cutaneous, ocular, umbilical, kidney, bone-joint, and meningeal) are common in the newborn period. Infection may be acquired in utero through the transplacental or transcervical routes and during or after birth. Ascending infection through the cervix, with or without

rupture of the amniotic fluid membranes, may result in amnionitis, funisitis (infection of the umbilical cord), congenital pneumonia, and sepsis. The bacteria responsible for ascending infection of the fetus are common bacterial organisms of the maternal genitourinary tract, such as group B streptococci, *Escherichia coli*, *Haemophilus influenzae*, and *Klebsiella*. Herpes simplex virus (HSV)-1 or, more often, HSV-2 also causes ascending infection that at times may be indistinguishable from bacterial sepsis. Syphilis and *Listeria monocytogenes* are acquired by transplacental infection.

Maternal humoral immunity may protect the fetus against some neonatal pathogens, such as group B streptococci and HSV. Nonetheless, various deficiencies of the neonatal antimicrobial defense mechanism probably are more important than maternal immune status as a contributing factor for neonatal infection, especially in the low birthweight infant. The incidence of sepsis is approximately 1:1,500 in full-term infants and 1:250 in preterm infants. The sixfold-higher rate of sepsis in preterm infants relates to the more immature immunologic systems of preterm infants and to their prolonged periods of hospitalization, which increase risk of nosocomially acquired infectious diseases.

Preterm infants before 32 weeks of gestational age have not received the full complement of maternal antibodies (immunoglobulin G [IgG]), which cross the placenta by active transport predominantly in the latter half of the third trimester. In addition, although low birthweight infants may generate IgM antibodies, their own IgG response to infection is reduced. These infants also have deficiencies of the alternate and, to a smaller degree, the classic complement activation pathways, which results in diminished complement-mediated opsonization. Newborn infants also show a deficit in phagocytic migration to the site of infection (to the lung) and in the bone marrow reserve pool of leukocytes. In addition, in the presence of suboptimal activation of complement, neonatal neutrophils ingest and kill bacteria less effectively than adult neutrophils do. Neutrophils from sick infants seem to have an even greater deficit in bacterial killing capacity compared with phagocytic cells from normal neonates.

Defense mechanisms against viral pathogens also may be deficient in a newborn. Neonatal antibody-dependent,

cell-mediated immunity by the natural killer lymphocytes is deficient in the absence of maternal antibodies and in the presence of reduced interferon production; reduced antibody levels occur in premature infants and in infants born during a primary viral infection of the mother, such as with enteroviruses, HSV-2, or cytomegalovirus. In addition, antibody-independent cytotoxicity may be reduced in lymphocytes of newborns.

Bacterial sepsis and meningitis often are linked closely in neonates. Despite this association, the incidence of meningitis relative to neonatal sepsis has been on a steady decline. The incidence of meningitis is approximately 1 in 20 cases of sepsis. The causative organisms isolated most frequently are the same as for neonatal sepsis: group B streptococci, *E. coli*, and *L. monocytogenes*. Gram-negative organisms, such as *Klebsiella*, *Salmonella*, and *Serratia marcescens*, are more common in less developed countries, and coagulase-negative staphylococcus needs to be considered in very low birthweight infants. Male infants seem to be more susceptible to neonatal infection than female infants. Neonates in the neonatal intensive care unit live in a high-risk environment, with exposure to endotracheal tubes, central arterial and venous catheters, and blood draws, all predisposing to bacteremia and meningitis. Genetic factors have been implicated in the ability of bacteria to cross the blood-brain barrier. This penetration has been noted for group B streptococci, *E. coli*, *Listeria*, *Citrobacter*, and *Streptococcus pneumoniae*.

Neonatal sepsis presents during three periods. **Early-onset sepsis** often begins in utero and usually is a result of infection caused by the bacteria in the mother's genitourinary tract. Organisms related to this sepsis include group B streptococci, *E. coli*, *Klebsiella*, *L. monocytogenes*, and nontypeable *H. influenzae*. Most infected infants are premature and show nonspecific cardiorespiratory signs, such as grunting, tachypnea, and cyanosis at birth. Risk factors for early-onset sepsis include vaginal colonization with group B streptococci, prolonged rupture of the membranes (>24 hours), amnionitis, maternal fever or leukocytosis, fetal tachycardia, and preterm birth. Black race and male sex are unexplained additional risk factors for neonatal sepsis.

Early-onset sepsis (birth–7 days) is an overwhelming multiorgan system disease frequently manifested as respiratory failure, shock, meningitis (in 30% of cases), disseminated intravascular coagulation, acute kidney injury, and less often symmetric peripheral gangrene. Early manifestations—grunting, poor feeding, pallor, apnea, lethargy, hypothermia, or an abnormal cry—may be nonspecific. Profound neutropenia, hypoxia, and hypotension may be refractory to treatment with broad-spectrum antibiotics, mechanical ventilation, and vasopressors. In the initial stages of early-onset septicemia in a preterm infant, it is often difficult to differentiate sepsis from respiratory distress syndrome. Because of this difficulty, premature infants with respiratory distress syndrome receive broad-spectrum antibiotics.

Infants with early-onset sepsis should be evaluated by blood and cerebrospinal fluid (CSF) cultures, CSF Gram stain, cell count, and protein and glucose levels. Normal newborns generally have an elevated CSF protein content (100–150 mg/dL) and may have 25–30/mm³ white blood cells (mean, 9/mm³), which are 75% lymphocytes in the absence of infection. Some infants with neonatal meningitis caused by group B streptococci do not have an elevated CSF leukocyte count but are seen

to have microorganisms in the CSF on Gram stain. In addition to culture, other methods of identifying the pathogenic bacteria are the determination of bacterial DNA in samples of CSF. In cases of neonatal meningitis, the ratio of CSF glucose to blood glucose usually is less than 50%. The polymerase chain reaction test primarily is used to identify viral infections. Serial complete blood counts should be performed to identify neutropenia, an increased number of immature neutrophils (bands), and thrombocytopenia. C-reactive protein levels are often elevated in neonatal patients with bacterial sepsis.

A chest radiograph also should be obtained to determine the presence of pneumonia. In addition to the traditional neonatal pathogens, pneumonia in very low birthweight infants may be the result of acquisition of maternal genital mycoplasmal agent (e.g., *Ureaplasma urealyticum* or *Mycoplasma hominis*). Arterial blood gases should be monitored to detect hypoxemia and metabolic acidosis that may be caused by hypoxia, shock, or both. Blood pressure, urine output, and peripheral perfusion should be monitored to determine the need to treat septic shock with fluids and vasopressor agents.

The mainstay of treatment for sepsis and meningitis is immediate antibiotic therapy. Antibiotics are used to suppress bacterial growth, allowing the infant's defense mechanisms time to respond. In addition, support measures, such as assisted ventilation and cardiovascular support, are equally important to the management of the infant. A combination of ampicillin and an aminoglycoside (usually gentamicin) for 10–14 days is effective treatment against most organisms responsible for early-onset sepsis. The combination of ampicillin and cefepime also is proposed as an alternative method of treatment. If meningitis is present, the treatment should be extended to 21 days or 14 days after a negative result from a CSF culture. Persistently positive results from CSF cultures are common with neonatal meningitis caused by gram-negative organisms, even with appropriate antibiotic treatment, and may be present for 2–3 days after antibiotic therapy. If gram-negative meningitis is present, some authorities continue to treat with an effective penicillin derivative combined with an aminoglycoside, whereas most change to a third-generation cephalosporin. High-dose penicillin (300,000–450,000 U/kg/24 hours divided every 8 hours if ≤7 days of age; 375,000 U/kg/24 hours divided every 6 hours if >7 days of age) is appropriate for group B streptococcal meningitis. Extracorporeal membrane oxygenation (in term infants) may improve the outcome of sepsis-related pulmonary hypertension or systemic hypotension. Intrapartum penicillin empirical prophylaxis for group B streptococcal colonized mothers or mothers with risk factors (fever, preterm labor, previous infant with group B streptococci, known colonization, and amnionitis) has reduced the rate of early-onset infection.

Late-onset sepsis (8–28 days) usually occurs in a healthy full-term infant who was discharged in good health from the normal newborn nursery. Clinical manifestations may include lethargy, poor feeding, hypotonia, apathy, seizures, bulging fontanel, fever, and direct-reacting hyperbilirubinemia. In addition to bacteremia, hematogenous seeding may result in focal infections, such as meningitis (in 75% of cases), osteomyelitis (group B streptococci, *Staphylococcus aureus*), arthritis (gonococcus, *S. aureus*, *Candida albicans*, gram-negative bacteria), and urinary tract infection (gram-negative bacteria).

The evaluation of infants with late-onset sepsis is similar to that for infants with early-onset sepsis, with special

attention given to a careful physical examination of the bones (infants with osteomyelitis may exhibit pseudoparalysis) and to the laboratory examination and culture of urine obtained by sterile suprapubic aspiration or urethral catheterization. Late-onset sepsis may be caused by the same pathogens as early-onset sepsis, but infants exhibiting sepsis late in the neonatal period also may have infections caused by the pathogens usually found in older infants (*H. influenzae*, *S. pneumoniae*, and *Neisseria meningitidis*). In addition, viral agents (HSV, cytomegalovirus, or enteroviruses) may manifest with a late-onset, sepsislike picture.

Because of the increased rate of resistance of *H. influenzae* and pneumococcus to ampicillin, some centers begin treatment with ampicillin and a third-generation cephalosporin (and vancomycin if meningitis is present) when sepsis occurs in the last week of the first month of life. The treatment of late-onset neonatal sepsis and meningitis is the same as that for early-onset sepsis.

PEARLS FOR PRACTITIONERS

See *Fetal and Neonatal Medicine: Pearls for Practitioners* at the end of this section.

CHAPTER 66

Congenital Infections

An infection acquired transplacentally during gestation is a congenital infection. Numerous pathogens that produce mild or subclinical disease in older infants and children can cause severe disease in neonates who acquire such infections prenatally or perinatally. Sepsis, meningitis, pneumonia, and other infections caused by numerous perinatally acquired pathogens are the cause of significant neonatal morbidity and mortality. Congenital infections include a well-known group of fungal, bacterial, and viral pathogens: toxoplasmosis, rubella, cytomegalovirus (CMV), herpes simplex virus (HSV), varicella-zoster virus, congenital syphilis, parvovirus, HIV, hepatitis B, Zika virus, *Neisseria gonorrhoeae*, *Chlamydia*, and *Mycobacterium tuberculosis*.

Many of the clinical manifestations of congenital infections are similar, including intrauterine growth restriction, nonimmune hydrops, anemia, thrombocytopenia, jaundice, hepatosplenomegaly, chorioretinitis, and congenital malformations. Some unique manifestations and epidemiologic characteristics of these infections are listed in Table 66.1. Evaluation of patients thought to have a congenital infection should include attempts to isolate the organism by culture (for rubella, CMV, HSV, gonorrhea, and *M. tuberculosis*) to identify the antigen of the pathogen (for hepatitis B and *Chlamydia trachomatis*), to identify the pathogen's genome with polymerase chain reaction (PCR), and to identify specific fetal production of antibodies (immunoglobulin M [IgM] or increasing titer of IgG for *Toxoplasma*, syphilis, parvovirus, HIV, or *Borrelia*).

Treatment is not always available, specific, or effective. Nonetheless, some encouraging results have been reported for preventing the disease and for specifically treating the infant when the correct diagnosis is made (see Table 66.1).

TOXOPLASMOSIS

Vertical transmission of *Toxoplasma gondii* occurs by transplacental transfer of the organism from the mother to the fetus after an acute maternal infection. Fetal infection rarely can occur after reactivation of disease in an immunocompromised pregnant mother. Transmission from an acutely infected mother to her fetus occurs in about 30–40% of cases, but the rate varies directly with gestational age. Transmission rates and the timing of fetal infection correlate directly with placental blood flow; the risk of infection increases throughout gestation to 90% or greater near term, and the time interval between maternal and fetal infection decreases.

The severity of fetal disease varies inversely with the gestational age at which maternal infection occurs. Most infants have subclinical infection with no overt disease at birth; however, specific ophthalmologic and central nervous system (CNS) evaluations may reveal abnormalities. The classic findings of hydrocephalus, chorioretinitis, and intracerebral calcifications suggest the diagnosis of congenital toxoplasmosis. Affected infants tend to be small for gestational age, develop early-onset jaundice, have hepatosplenomegaly, and present with a generalized maculopapular rash. Seizures are common, and skull films may reveal diffuse cortical calcifications in contrast to the periventricular pattern observed with CMV. These infants are at increased risk for long-term neurologic and neurodevelopmental complications.

Serologic tests are the primary means of diagnosis. IgG-specific antibodies achieve a peak concentration 1–2 months after infection and remain positive indefinitely. For infants with seroconversion or a fourfold increase in IgG titers, specific IgM antibody determinations should be performed to confirm disease. Especially for congenital infections, measurement of IgA and IgE antibodies can be useful to confirm the disease. Thorough ophthalmologic, auditory, and neurologic evaluations (head CT and cerebrospinal fluid [CSF] examination) are indicated.

For symptomatic and asymptomatic congenital infections, initial therapy should include pyrimethamine (supplemented with folic acid) combined with sulfadiazine. Duration of therapy is often prolonged, even up to 1 year. Optimal dosages of medications and duration of therapy should be determined in consultation with appropriate specialists.

RUBELLA

With the widespread use of vaccination, congenital rubella is rare in developed countries. Acquired in utero during early gestation, rubella can cause severe neonatal consequences. The occurrence of congenital defects approaches 85% if infection is acquired during the first 4 weeks of gestation; close to 40% spontaneously abort or are stillborn. If infection occurs during weeks 13–16, 35% of infants can have abnormalities. Infection after 4 months of gestation does not seem to cause disease.

The most common characteristic abnormalities associated with congenital rubella include ophthalmologic (cataracts, retinopathy, and glaucoma), cardiac (patent ductus arteriosus and peripheral pulmonary artery stenosis), auditory (sensorineural hearing loss), and neurologic (behavioral disorders, meningoencephalitis, and developmental delay) conditions. In addition, infants can present with growth retardation, hepatosplenomegaly, early-onset jaundice, thrombocytopenia,

radiolucent bone disease, and purpuric skin lesions (“blueberry muffin” appearance from dermal erythroplasia).

Detection of rubella-specific IgM antibody usually indicates recent infection. Measurement of rubella-specific IgG over several months can be confirmatory. Rubella virus can be isolated from blood, urine, CSF, and throat swab specimens. Infants with congenital rubella are chronically and persistently infected and tend to shed live virus in urine, stools, and respiratory secretions for 1 year. Infants should be isolated while in the hospital and kept away from susceptible pregnant women when sent home.

CYTOMEGALOVIRUS

CMV is the most common congenital infection and the leading cause of sensorineural hearing loss, intellectual disability, retinal disease, and cerebral palsy. Congenital CMV occurs in about 0.5–1.5% of births. When primary infection occurs in mothers during a pregnancy, the virus is transmitted to the fetus in approximately 35% of cases. Rates of CMV infection are three to seven times greater in infants born to adolescent mothers compared to others. The risk of transmission of CMV to the fetus is independent of gestational age at the time of maternal infection. The earlier in gestation that the primary maternal infection occurs, the more symptomatic the infant will be at birth. The most common sources of CMV for primary infections occurring in mothers during pregnancy are sexual contacts and contact with young children. It is well known that CMV can be transmitted to the fetus even when maternal infection occurred long before conception. This transmission can occur as the result of virus reactivation, chronic infection, or reinfection with a new strain.

More than 90% of infants who have congenital CMV infection exhibit no clinical evidence of disease at birth. Approximately 10% of infected infants are small for gestational age and have symptoms at birth. Findings include microcephaly, thrombocytopenia, hepatosplenomegaly, hepatitis, intracranial calcifications, chorioretinitis, and hearing abnormalities. Some infants can present with a blueberry muffin appearance as the result of dermal erythroplasia. Skull films may reveal periventricular calcifications. An additional 10% of infected infants may not present until later in infancy or early childhood, when they are found to have sensorineural hearing loss and developmental delays. Mortality is 10–15% in symptomatic newborns. Perinatal CMV infection acquired during birth or from mother’s milk is not associated with newborn illness or CNS sequelae.

Congenital CMV infection is diagnosed by detection of virus in the urine or saliva. PCR can be used to detect small amounts of CMV DNA in the urine. Detection of CMV within the first 3 weeks after birth is considered proof of congenital CMV infection.

Postnatal studies in severely symptomatic newborns using the antiviral agent ganciclovir have shown a positive effect on the severity of hearing loss.

HERPES SIMPLEX VIRUS

HSV-2 accounts for 90% of primary genital herpes. About 70–85% of neonatal herpes simplex infections are caused by HSV-2. Most commonly, neonatal infections are acquired from the mother shortly before (ascending infection) or

during passage through the birth canal at delivery. The incidence of neonatal HSV is estimated to range from 1 in 3,000–20,000 live births. Infants with HSV infections are more likely to be born prematurely (40% of affected infants are <36 weeks of gestation). The risk of infection at delivery in an infant born vaginally to a mother with primary genital herpes is about 33–50%. The risk to an infant born to a mother with a reactivated infection is less than 5%. More than 75% of infants who acquire HSV infection are born to mothers who have no previous history or clinical findings consistent with HSV infection.

Most infants are normal at birth, and symptoms of infection develop at 5–10 days of life. Symptoms of neonatal HSV infection include disseminated disease involving multiple organ systems, most notably the liver and lungs; localized infection to the CNS; or localized infection to the skin, eyes, and mouth. Symptoms may overlap, and in many cases of disseminated disease, skin lesions are a late finding. Disseminated infection should be considered in any infant with symptoms of sepsis, liver dysfunction, and negative bacteriologic cultures. HSV infection also should be suspected in any neonate who presents with fever, irritability, abnormal CSF findings, and seizures. Initial symptoms can occur anytime between birth and 4 weeks of age, although disseminated disease usually occurs during the first week of life. HSV infections are often severe, and a delay in treatment can result in significant morbidity and mortality.

For the diagnosis of neonatal HSV infection, specimens for culture should be obtained from any skin vesicle, nasopharynx, eyes, urine, blood, CSF, stool, or rectum. Positive cultures obtained from these sites more than 48 hours after birth indicate intrapartum exposure. PCR is a sensitive method for detecting HSV DNA in blood, skin lesions, and CSF.

Parenteral acyclovir is the treatment of choice for neonatal HSV infections. Acyclovir should be administered to all infants suspected to have infection or diagnosed with HSV. The most benign outcome with regard to morbidity and mortality is observed in infants with disease limited to the skin, eyes, and mouth.

CONGENITAL SYPHILIS

Congenital syphilis most commonly results from transplacental infection of the fetus, although the fetus can acquire infection by contact with a chancre at birth. In addition, hematogenous infection can occur throughout pregnancy. The longer the time elapsed between the mother’s infection and pregnancy, the less likely she is to transmit the disease to the fetus.

Intrauterine infection can result in stillbirth, hydrops fetalis, or prematurity. Clinical symptoms vary but include hepatosplenomegaly, snuffles, lymphadenopathy, mucocutaneous lesions, osteochondritis, rash, hemolytic anemia, and thrombocytopenia. Untreated infants, regardless of whether they manifest symptoms at birth, may develop late symptoms, which usually appear after 2 years of age and involve the CNS, bones, joints, teeth, eyes, and skin. Some manifestations of disease may not become apparent until many years after birth, such as interstitial keratitis, eighth cranial nerve deafness, Hutchinson teeth, bowing of the shins, frontal bossing, mulberry molars, saddle nose, rhagades, and Clutton joints. The combination of interstitial keratitis, eighth cranial nerve deafness, and Hutchinson teeth is commonly referred to as the *Hutchinson triad* (see [Table 66.1](#)).

TABLE 66.1 Perinatal Congenital Infections (TORCH)

AGENT	MATERNAL EPIDEMIOLOGY	NEONATAL FEATURES
<i>Toxoplasma gondii</i>	Heterophil-negative mononucleosis Exposure to cats or raw meat or immunosuppression High-risk exposure at 10–24 wk of gestation	Hydrocephalus, abnormal spinal fluid, intracranial calcifications, chorioretinitis, jaundice, hepatosplenomegaly, fever Many infants asymptomatic at birth Treatment: pyrimethamine plus sulfadiazine
Rubella virus	Unimmunized seronegative mother; fever ± rash Detectable defects with infection: by 8 wk, 85%; 9–12 wk, 50%; 13–20 wk, 16% Virus may be present in infant's throat for 1 yr Prevention: vaccine	Intrauterine growth restriction, microcephaly, microphthalmia, cataracts, glaucoma, "salt and pepper" chorioretinitis, hepatosplenomegaly, jaundice, PDA, deafness, blueberry muffin rash, anemia, thrombocytopenia, leukopenia, metaphyseal lucencies, B-cell and T-cell deficiency Infant may be asymptomatic at birth
CMV	Sexually transmitted disease: primary genital infection may be asymptomatic Heterophil-negative mononucleosis; infant may have viruria for 1–6 yr	Sepsis, intrauterine growth restriction, chorioretinitis, microcephaly, periventricular calcifications, blueberry muffin rash, anemia, thrombocytopenia, neutropenia, hepatosplenomegaly, jaundice, deafness, pneumonia Many asymptomatic at birth Prevention: CMV-negative blood products Possible treatment: ganciclovir
Herpes simplex type 2 or 1 virus	Sexually transmitted disease: primary genital infection may be asymptomatic; intrauterine infection rare, acquisition at time of birth more common	Intrauterine infection: chorioretinitis, skin lesions, microcephaly Postnatal: encephalitis, localized or disseminated disease, skin vesicles, keratoconjunctivitis Treatment: acyclovir
Varicella-zoster virus	Intrauterine infection with chickenpox Infant develops severe neonatal varicella with maternal illness 5 days before or 2 days after delivery	Microphthalmia, cataracts, chorioretinitis, cutaneous and bony aplasia/hypoplasia/atrophy, cutaneous scars Zoster as in older child Prevention of neonatal condition with VZIG Treatment of ill neonate: acyclovir
<i>Treponema pallidum</i> (syphilis)	Sexually transmitted infection Maternal primary asymptomatic: painless "hidden" chancre Penicillin, not erythromycin, prevents fetal infection	Presentation at birth as nonimmune hydrops, prematurity, anemia, neutropenia, thrombocytopenia, pneumonia, hepatosplenomegaly Late neonatal as snuffles (rhinitis), rash, hepatosplenomegaly, condylomata lata, metaphysitis, cerebrospinal fluid pleocytosis, keratitis, periosteal new bone, lymphocytosis, hepatitis Late onset: teeth, eye, bone, skin, central nervous system, ear Treatment: penicillin
Parvovirus	Etiology of fifth disease; fever, rash, arthralgia in adults	Nonimmune hydrops, fetal anemia Treatment: in utero transfusion
HIV	AIDS; most mothers are asymptomatic and HIV positive; high-risk history; prostitute, drug abuse, married to bisexual, or hemophilic	AIDS symptoms develop between 3 and 6 mo of age in 10–25%; failure to thrive, recurrent infection, hepatosplenomegaly, neurologic abnormalities Management: trimethoprim/sulfamethoxazole, AZT, other antiretroviral agents Prevention: prenatal, intrapartum, postpartum AZT; avoid breast-feeding
Hepatitis B virus	Vertical transmission common; may result in cirrhosis, hepatocellular carcinoma	Acute neonatal hepatitis; many become asymptomatic carriers Prevention: HBIG, vaccine
<i>Neisseria gonorrhoeae</i>	Sexually transmitted infection, infant acquires at birth Treatment: cefotaxime, ceftriaxone	Gonococcal ophthalmia, sepsis, meningitis Prevention: silver nitrate, erythromycin eye drops Treatment: ceftriaxone
<i>Chlamydia trachomatis</i>	Sexually transmitted infection, infant acquires at birth Treatment: oral erythromycin	Conjunctivitis, pneumonia Prevention: erythromycin eye drops Treatment: oral erythromycin
<i>Mycobacterium tuberculosis</i>	Positive PPD skin test, recent converter, positive chest radiograph, positive family member Treatment: INH and rifampin ± ethambutol	Congenital rare septic pneumonia; acquired primary pulmonary TB; asymptomatic, follow PPD Prevention: INH, BCG, separation Treatment: INH, rifampin, pyrazinamide
<i>Trypanosoma cruzi</i> (Chagas disease)	Central South American native, immigrant, travel Chronic disease in mother	Failure to thrive, heart failure, achalasia Treatment: nifurtimox
Zika virus	See Chapter 122 and text	See Chapter 122 and text

AZT, Zidovudine (azidothymidine); BCG, bacille Calmette-Guerin; CMV, cytomegalovirus; HBIG, hepatitis B immune globulin; INH, isoniazid; PDA, patent ductus arteriosus; PPD, purified protein derivative; TB, tuberculosis; VZIG, varicella-zoster immune globulin.

Many infants are asymptomatic at the time of diagnosis. If untreated, most infants develop symptoms within the first 5 weeks of life. The most striking lesions affect the mucocutaneous tissues and bones. Early signs of infection may be poor feeding and snuffles (syphilitic rhinitis). Snuffles are more severe and persistent than the common cold and are often bloody. A maculopapular desquamative rash develops over the palms and soles and around the mouth and anus. The rash may progress to become vesicular with bullae. Severely ill infants may be born with hydrops and have profound anemia. Severe consolidated pneumonia may be present at birth, and there may be laboratory findings consistent with a glomerulonephritis. CSF evaluation may reveal a pleocytosis and elevated protein. More than 90% of symptomatic infants exhibit radiographic abnormalities of the long bones consistent with osteochondritis and perichondritis.

No newborn should be discharged from the hospital without knowledge or determination of the mother's serologic status for syphilis. All infants born to seropositive mothers require a careful examination and a quantitative nontreponemal syphilis test. Dark-field examination of direct fluorescent antibody staining of organisms obtained by scraping a skin or mucous membrane lesion is the quickest and most direct method of diagnosis. More commonly, serologic testing is used. The nontreponemal reaginic antibody assays—the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR)—are helpful as indicators of disease. The test performed on the infant should be the same as that performed on the mother to enable comparison of results. An infant should be evaluated further if the maternal titer has increased fourfold, if the infant's titer is fourfold greater than the mother's titer, if the infant is symptomatic, or if the mother has inadequately treated syphilis. A mother infected later in pregnancy may deliver an infant who is incubating active disease. The mother and infant may have negative serologic testing at birth. When clinical or serologic tests suggest congenital syphilis, CSF should be examined microscopically, and a CSF VDRL test should be performed. An increased CSF white blood cell count and protein concentration suggest neurosyphilis; a positive CSF VDRL is diagnostic.

Parenteral penicillin is the preferred drug of choice for treatment of syphilis. Penicillin G for 10–14 days is the only documented effective therapy for infants who have congenital syphilis and neurosyphilis. Infants should have repeat nontreponemal antibody titers repeated at 3, 6, and 12 months to document falling titers. Infants with neurosyphilis must be followed carefully with serologic testing and CSF determinations every 6 months for at least 3 years or until CSF findings are normal.

HUMAN IMMUNODEFICIENCY VIRUS

See Chapter 125.

HEPATITIS B

See Chapter 113.

NEISSERIA GONORRHOEAE

N. gonorrhoeae infection in a newborn usually involves the eyes (ophthalmia neonatorum). Other sites of infection

include scalp abscesses (often associated with fetal monitoring with scalp electrodes), vaginitis, and disseminated disease with bacteremia, arthritis, or meningitis. Transmission to the infant usually occurs during passage through the birth canal when mucous membranes come in contact with infected secretions.

Infection usually is present within the first 5 days of life and is characterized initially by a clear, watery discharge, which rapidly becomes purulent. There is marked conjunctival hyperemia and chemosis. Infection tends to be bilateral; however, one eye may be clinically worse than the other. Untreated infections can spread to the cornea (keratitis) and anterior chamber of the eye. This extension can result in corneal perforation and blindness.

Recommended treatment for isolated infection, such as ophthalmia neonatorum, is one intramuscular dose of ceftriaxone. Infants with gonococcal ophthalmia should receive eye irrigations with saline solution at frequent intervals before discharge. Topical antibiotic therapy alone is inadequate and is unnecessary when recommended systemic antimicrobial therapy is given. Infants with gonococcal ophthalmia should be hospitalized and evaluated for disseminated disease (sepsis, arthritis, meningitis). Disseminated disease should be treated with antimicrobial therapy (ceftriaxone) for 7 days. Cefepime can be used in infants with hyperbilirubinemia. If documented, infants with meningitis should be treated for 10–14 days.

Tests for concomitant infection with *C. trachomatis*, congenital syphilis, and HIV should be performed. Results of the maternal test for hepatitis B surface antigen should be confirmed. Topical prophylaxis with silver nitrate, erythromycin, or tetracycline is recommended for all newborns for the prevention of gonococcal ophthalmia.

CHLAMYDIA

C. trachomatis is the most common reportable sexually transmitted infection, with a high rate of infection among sexually active adolescents and young adults. Prevalence of the organism in pregnant women ranges from 6–12% and can be 40% in adolescents. *Chlamydia* can be transmitted from the genital tract of an infected mother to her newborn. Acquisition occurs in about 50% of infants born vaginally to infected mothers. Transmission also has been reported in some infants delivered by cesarean section with intact membranes. In infected infants, the risk of conjunctivitis is 25–50%, and the risk of pneumonia is 5–20%. The nasopharynx is the most commonly infected anatomic site.

Neonatal chlamydial conjunctivitis is characterized by ocular congestion, edema, and discharge developing 5–14 days to several weeks after birth and lasting 1–2 weeks. Clinical manifestations vary from mild conjunctivitis to intense inflammation and swelling. Both eyes are almost always involved; however, one eye may appear to be more swollen and infected than the other. The cornea is rarely involved, and preauricular adenopathy is rare.

Pneumonia in a young infant can occur between 2 and 19 weeks of age and is characterized by an afebrile illness with a repetitive staccato cough, tachypnea, and rales. Wheezing is uncommon. Hyperinflation with diffuse infiltrates can be seen on chest radiograph. Nasal stuffiness and otitis media can occur.

Diagnosis can be made by scraping the conjunctiva and culturing the material. Giemsa staining of the conjunctival

scrapings revealing the presence of blue-stained intracytoplasmic inclusions within the epithelial cells is diagnostic. PCR is also available. Infants with conjunctivitis and pneumonia are treated with oral azithromycin for 3 days or erythromycin for 14 days. Topical treatment of conjunctivitis is ineffective and unnecessary. The recommended topical prophylaxis with silver nitrate, erythromycin, or tetracycline for all newborns for the prevention of gonococcal ophthalmia does not prevent neonatal chlamydial conjunctivitis.

MYCOBACTERIUM TUBERCULOSIS

See Chapter 124.

ZIKA VIRUS

Zika virus is an arthropod-borne flavivirus carried and transmitted by mosquitoes and is associated with severe congenital anomalies. Zika virus is a neurotropic virus that particularly targets progenitor cells. Zika virus causes a maternal infection leading to a placental infection and injury to the fetus. The infection is transmitted to the fetal brain where it kills neuronal progenitor cells disrupting neuronal proliferation, migration, and differentiation. In utero infections can be transmitted to the fetus at any time during the pregnancy and result in severe brain abnormalities (i.e., microcephaly, cerebellar hypoplasia, ventriculomegaly, lissencephaly) and craniofacial malformations. Additionally, the virus can result in pulmonary hypoplasia and multiple congenital contractures.

COVID-19

SARS-CoV-2 infection in the neonate is uncommon. Neonatal infection is usually acquired and may be mild or asymptomatic. Maternal COVID-19 disease may result in premature birth and result in neonatal respiratory distress syndrome (RDS) and other problems associated with prematurity. Premature infants and neonates with other conditions may develop severe COVID-19 symptoms. The diagnosis of COVID-19 infection in infants should meet the following criteria: (1) at least one clinical symptom, including unstable body temperature, low activity, poor feeding, diarrhea or other mild gastrointestinal

symptom, or shortness of breath; (2) chest radiograph showing abnormalities (opacities or ground glass appearance); (3) infection diagnosed in the infant's family or caregivers; and (4) close contact with people who may have or have confirmed infection with COVID-19.

The diagnosis of COVID-19 in neonates is made by using reverse transcriptase polymerase chain reaction (RT-PCR) on nasopharyngeal, nasal, or endotracheal samples to detect the presence of SARS-CoV-2. Testing should be performed (~24 hours of life and repeated ~48 hours) on asymptomatic and symptomatic neonates born to mothers with suspected or confirmed COVID-19. Suspected or confirmed mothers and infants should be isolated from other unaffected mothers and newborns.

PEARLS FOR PRACTITIONERS

CHAPTER 58

Assessment of the Mother, Fetus, and Newborn

- High-risk pregnancies include those with intrauterine growth restriction (IUGR), maternal hypertension, diabetes, autoimmune diseases (systemic lupus erythematosus), and those with prior intrauterine fetal demise or neonatal deaths. Additional high-risk pregnancies include those with oligo- or polyhydramnios, multiple gestation, or macrosomic fetuses.
- Polyhydramnios is associated with fetal central nervous system (CNS) anomalies as well as high gastrointestinal obstruction.
- The biophysical profile, which includes fetal movement, fetal breathing, fetal tone, amniotic fluid volume, and fetal heart rate reactivity, is often used to assess fetal well-being. A score of less than 6 of 10 indicates possible fetal compromise and may necessitate delivery of the infant.
- Low birthweight is defined by birthweight less than 2,500 g.

- The Apgar examination performed at 1 and 5 minutes assesses fetal to neonatal transition and identifies infants in need of resuscitation.
- About 10% of neonates will require some form of intervention and/or resuscitation in the delivery room.
- Vitamin K must be given to all newborns to prevent hemorrhagic disease of the newborn.
- Hair tufts over the lumbosacral area suggest a neural tube anomaly.
- Leukokoria may be due to cataracts, ocular tumor, chorioretinitis, retinopathy of prematurity, or persistent hyperplastic primary vitreous.
- Shock in the delivery room is often due to blood loss such as fetal-maternal hemorrhage or internal bleeding (liver, spleen).
- Erb-Duchenne palsy involves the fifth and sixth cervical nerves.
- Early neonatal hypocalcemia may be due to maternal hyperparathyroidism or neonatal DiGeorge syndrome; it is also seen in infants of diabetic mothers, preterm infants, or following birth asphyxia.
- Since most medical centers now use erythromycin eye ointment following delivery, any eye redness or purulent discharge needs immediate attention and potential treatment.
- Pulse oximetry screening (preductal and postductal) should be performed on all infants before discharge from the hospital. A difference of greater than 3% is suggestive of cyanotic heart disease.
- Hearing loss is a most common congenital condition in the United States; each infant should be screened for hearing loss prior to being discharged from the hospital.
- Failure of a term infant to pass urine in the first 24 hours or meconium in the first 48 hours warrants further evaluation.
- Rule of 2s and congenital heart failure: Heart failure at 2 days is most likely caused by transposition of the great arteries (as the patent ductus arteriosus [PDA] closes); at 2 weeks, coarctation of the aorta; and at 2 months, ventricular septal defect.

CHAPTER 59

Maternal Diseases Affecting the Newborn

- Maternal diabetes mellitus represents a high risk for teratogenic changes in the fetus (i.e., congenital heart disease, caudal regression).
- For the fetus, insulin is the primary growth hormone; in situations where fetal insulin levels are increased, the fetus can be overgrown (macrosomic, large for gestational age).
- Infants of diabetic mothers are at risk for birth trauma, hypoglycemia, hypocalcemia, hyperbilirubinemia (increased red cell mass), cardiac disease, and caudal regression.
- All pregnant mothers should be screened for HIV. In addition, serologies for the following should be known at the time of birth: complete blood type; immunity for rubella, syphilis, and chlamydia status; gonorrhea and group B streptococcus cultures (usually obtained at ~35 weeks of gestation); and hepatitis B titers.
- Autoimmune diseases of the mother may affect the fetus by placental transfer of IgG autoantibodies such as seen in maternal immune thrombocytopenia, systemic lupus erythematosus (SLE), hyperthyroidism, or myasthenia gravis.

CHAPTER 60

Diseases of the Fetus

- Causes of intrauterine growth restriction (IUGR) include poor maternal nutrition, maternal hypertension, fetal anomalies or infection, and twin-twin transfusion syndrome.
- Hepatosplenomegaly, jaundice, dermatitis, chorioretinitis, and micro- or hydrocephaly in an infant with IUGR suggests an intrauterine infection.
- Organ anomalies such as congenital heart disease, oral clefts, and limb anomalies suggest a congenital malformation syndrome.
- Hydrops fetalis is often due to fetal anemia secondary to immune hemolysis or decreased red cell production.
- Nonimmune hydrops has many etiologies including infection, malignancy, autoinflammatory diseases, and complex congenital anomalies.

CHAPTER 61

Respiratory Diseases of the Newborn

- Respiratory distress may manifest by cyanosis, sternal and intercostal retractions, nasal flaring, and expiratory grunting.
- Common causes of respiratory distress include infection, respiratory distress syndrome (RDS; hyaline membrane disease), and congenital anomalies of the airway, lung, or diaphragm.
- Maternal betamethasone therapy reduces the risk of RDS in at-risk premature infants.
- A patent ductus arteriosus may present with a widened pulse pressure, worsening hypoxia and hypercarbia, and signs of heart failure with a new cardiac murmur.
- Bronchopulmonary dysplasia may develop in infants with severe ventilator treated RDS and manifests as persistent ventilator and oxygen requirements and chronic changes on chest x-ray.
- Persistent pulmonary hypertension of the newborn (PPHN) often accompanies birth asphyxia, meconium aspiration syndrome, pulmonary hypoplasia, and a congenital diaphragmatic hernia.
- PPHN is managed by oxygen and ventilation therapy; if these are unsuccessful, patients may be treated with inhaled nitric oxide and then extracorporeal membrane oxygenation (ECMO).

CHAPTER 62

Anemia and Hyperbilirubinemia

- Neonatal anemia is often due to immune mediated hemolysis, red cell membrane defects, or red cell enzyme deficiencies. Rarely, it is due to decreased production as seen in Blackfan-Diamond syndrome.
- Prevention of hemolytic disease of the newborn due to Rh factor incompatibility is possible by administering RhoGAM to the Rh-negative mother during gestation and within 3 days after the delivery of the Rh-positive infant.
- Fetal-maternal hemorrhage may produce fetal anemia and may be detected by the Kleihauer-Betke test.

- Physiologic jaundice is an indirect hyperbilirubinemia peaking on day 3 of life in term babies; the peak may be later in premature infants.
- Breast milk jaundice is an indirect hyperbilirubinemia that occurs 1–2 weeks after birth; its cause is unknown.
- Visible jaundice in the first day of life and any direct hyperbilirubinemia are due to potentially serious pathologic processes and require immediate evaluation.

CHAPTER 63

Necrotizing Enterocolitis

- Necrotizing enterocolitis (NEC) manifests with a sepsislike presentation and with abdominal distention and tenderness.
- Abdominal x-rays in NEC demonstrate pneumatosis intestinalis, portal-hepatic gas, pneumoperitoneum, or intestinal distention.
- Significant bilious emesis is considered a neonatal emergency and deserves further evaluation with an upper gastrointestinal tract series to rule out malrotation and midgut volvulus.

CHAPTER 64

Hypoxic-Ischemic Encephalopathy, Intracranial Hemorrhage, and Seizures

- Seizures in a neonate within the first 24 hours of birth are most likely secondary to birth asphyxia or hypoxia during labor and delivery.

- Therapeutic hypothermia has been shown to reduce the risk of neurodevelopmental disability following moderate to severe in utero hypoxia or ischemia; the outcome is best if hypothermia can be started before 6 hours of age.

CHAPTER 65

Sepsis and Meningitis

- Maternal chorioamnionitis puts the fetus at the greatest risk for a poor pregnancy and delivery outcome.
- Fever in the neonatal period should be considered as caused by significant bacterial infections and herpes virus infection.
- The most common organisms causing early onset neonatal sepsis include group B streptococcus and *Escherichia coli*; a synergistic combination of ampicillin and an aminoglycoside (usually gentamicin) is appropriate initial therapy for early-onset sepsis.

CHAPTER 66

Congenital Infections

- “Blueberry muffin” appearance is most commonly seen in neonates with congenital rubella or cytomegalovirus infection. A biopsy of a blueberry muffin lesion will reveal dermal hematopoiesis. The “skin” is the first organ system to produce red cells.

ADOLESCENT MEDICINE

Kim Blake | Nancy Van Eyk

CHAPTER 67

Overview and Assessment of Adolescents

Adolescents have unique concerns and health issues compared to children and adults, many of which can center around puberty and psychosocial development. The leading causes of mortality (Table 67.1) and morbidity (Table 67.2) in adolescents in the United States are behaviorally mediated. Motor vehicle injuries and other injuries account for more than 75% of all deaths. Unhealthy dietary behaviors and inadequate physical activity result in adolescent obesity, with associated health complications (e.g., diabetes, hypertension).

It is the physician's responsibility to use every opportunity to inquire about risk-taking and protective behaviors, regardless of the presenting issue. Physical symptoms in adolescents can be related to psychosocial problems so it is important to fully explore these issues using a HEADDSSS (home, education, activities, alcohol, drugs, diet, sex, suicide, self) format as found in the Structured Communication Adolescent Guide (SCAG) (Fig. 67.1).

INTERVIEWING ADOLESCENTS

The adolescent interview shifts information gathering from the parent to the adolescent. Interviewing an adolescent alone and discussing confidentiality are the cornerstones of obtaining an accurate history of risk-taking behaviors, anticipatory guidance, and protective factors (see Chapters 7 and 9).

The nature of the questions should take into account the developmental age of the adolescent (Table 67.3). Conversations about sports, friends, videogames, and activities

outside of school can be useful for all ages and help build rapport (Fig. 67.2).

Confidentiality is a key element in interviewing an adolescent (Table 67.4). An open discussion about risk-taking and protective behaviors is more likely to happen when the adolescent is alone (Table 67.5). Certain issues cannot be kept confidential, such as suicidal intent, serious harm to others, and disclosure of sexual or physical abuse. This needs to be explained to the parent and adolescent. In caring for a young adolescent, the health care provider should encourage open discussions with a parent, guardian, or other adult.

The law confers certain rights on adolescents, depending on their health condition and personal characteristics; this allows

TABLE 67.2 Prevalence of Common Chronic Illnesses in Children and Adolescents

ILLNESS	PREVALENCE
PULMONARY	
• Asthma	8–12%
• Cystic fibrosis	1:2,500 White; 1:17,000 Black
NEUROMUSCULAR	
• Cerebral palsy	2–3:1,000
• Mental retardation	1–2%
• Seizure disorder	3.5:1,000
• Any seizure	3–5%
• Auditory/visual defects	2–3%
• Traumatic paralysis	2:1,000
• Scoliosis	3% males, 5% females
• Migraine	6–27% (↑ with increasing age)
ENDOCRINE/NUTRITION	
• Diabetes mellitus	1.8:1,000
• Obesity	25–30%
• Anorexia nervosa	0.5–1%
• Bulimia	1% (early adolescence), 5–10% (19–20yr)
• Dysmenorrhea	20%
• Acne	65%

TABLE 67.1 Leading Causes of Death in Adolescents

RANK	CAUSE	RATE (PER 100,000)
1	Unintentional injuries	26.9
2	Suicide	11.5
3	Assault (homicide)	9.4
4	Malignant neoplasms (cancer)	3.6
5	Diseases of the heart	2.2

them to receive health services without parental permission (Table 67.6). Usually adolescents can seek health care without parental consent for reproductive, mental, and emergency health services. Emancipated adolescents and *mature minors* may be treated without parental consent; this status should be documented in the record. The key characteristics of mature

minors are their competence and capacity to understand, not their chronological age. There must be a reasonable judgment that the health intervention is in the best interests of the minor.

During the physical examination, the adolescent must be offered a choice between having a parent or a chaperone present.

			Future
			Planning
			Partner
			Separation

Prepare the preadolescent and parent for confidentiality and being interviewed alone.
Discuss confidentiality at the start of the interview.
Conversations with parents/guardians/adolescent are confidential (with exceptions*).
Reaffirm confidentiality when you are alone with your adolescent patient.

*Exceptions to confidentiality include major or impending harm to any person (i.e., abuse, suicide, homicide).

HOME/FRIENDS	Family, relationships, and activities. "What do you do for fun?" "What social media do you use?" "How much screen time in a day?"
EDUCATION	"What do you like best at school?" "How's school going?" "Any bullying?"
ALCOHOL	"Are any of your friends drinking?" "Are you drinking?"
DRUGS	Cigarettes, marijuana, street drugs. "Have you ever smoked or tried e-cigarettes?" "Many adolescents experiment with different drugs and substances. Have you tried anything?"
DIET*	Weight, diet/eating habits. "Many adolescents worry about their weight and try dieting. Have you ever done this?"
SEX	Sexual activity, contraception. "Are you going out with anybody?" "Have you dated in the past?"
SUICIDE/DEPRESSION	Mood swings, depression, suicide attempts or thoughts, self-image. "Feeling down or depressed is common for everyone. Have you ever felt so bad that you wanted to harm yourself?"

*The acronym HEADDSSS can represent other terms, that is, A, Activities; D, Depression. Also see Fig. 67.1.

Age of majority (≥18 yr of age in most states)
Exceptions in which health care services can be provided to a minor*
Emergency care (e.g., life-threatening condition or condition in which a delay in treatment would increase significantly the likelihood of morbidity)
Diagnosis and treatment of sexuality-related health care
Diagnosis and treatment of drug-related health care
Emancipated minors (physically and financially independent of family; Armed Forces, married, childbirth)
Mature minors (able to comprehend the risks and benefits of evaluation and treatment)
All exceptions <i>should be documented clearly in the patient's health record.</i>

*Determined by individual state laws.

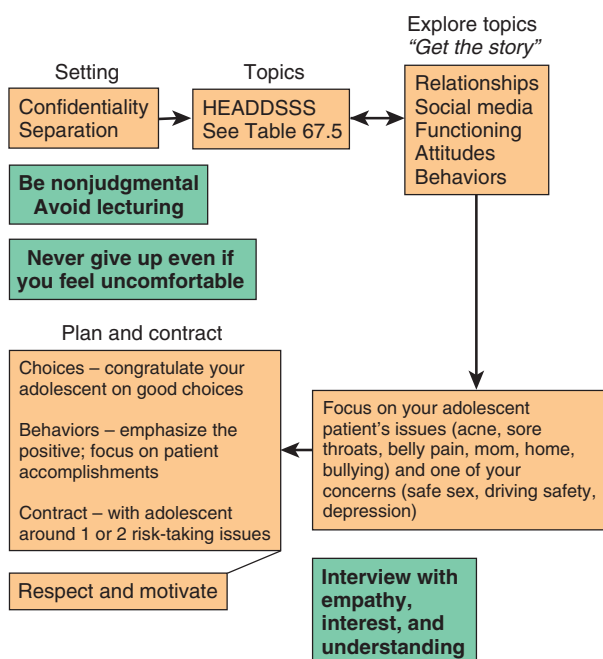

FIGURE 67.2 STEP guide for adolescent interviewing.

PHYSICAL GROWTH AND DEVELOPMENT OF ADOLESCENTS

Girls

Adrenarche, the increased production of androgens by the adrenal glands, is the first physiologic change associated with puberty. Breast development (**thelarche**) is the first external manifestation of puberty (secondary sexual characteristic) in White girls, occurring at 10 years of age, while growth of pubic hair (**pubarche**) occurs a year later at 11 (Table 67.7). Thelarche and pubarche typically both occur around the same time in Black girls, at an average age of 8 years and 9 months. Obesity

TABLE 67.7 Normal Female Puberty: PROS Study

PUBERTAL EVENT	AGE (YR): BLACK	AGE (YR): WHITE
Thelarche	8.9	10.0
Pubarche	8.8	10.5
Axillary	10.1	11.8
Menarche	12.2	12.9

Adapted from Hermann-Giddens ME, Slora EJ, Wasserman RC, et al. Secondary sexual characteristics and menses in young girls seen in office practice: a study from the Pediatric Research in Office Settings (PROS) network. *Pediatrics*. 1997;99(4):505–512.

is associated with earlier onset of puberty. Progression through puberty is denoted by Tanner staging (Fig. 67.3) for each of breast and pubic hair growth, stages 1 (no growth/prepubertal) through 5 (complete development). Not all girls achieve Tanner 5 pubic hair.

An increase in height velocity occurs at the onset of puberty. However, the peak height velocity or “growth spurt” usually occurs approximately 1 year after thelarche, at Tanner stage 3 breast development. Females only grow an additional 2–5 cm in height after menarche.

Onset of menstruation (**menarche**) occurs at stage 4 breast development. The mean ages of menarche are 12.2 and 12.9 years for Black and White girls, respectively. However, the

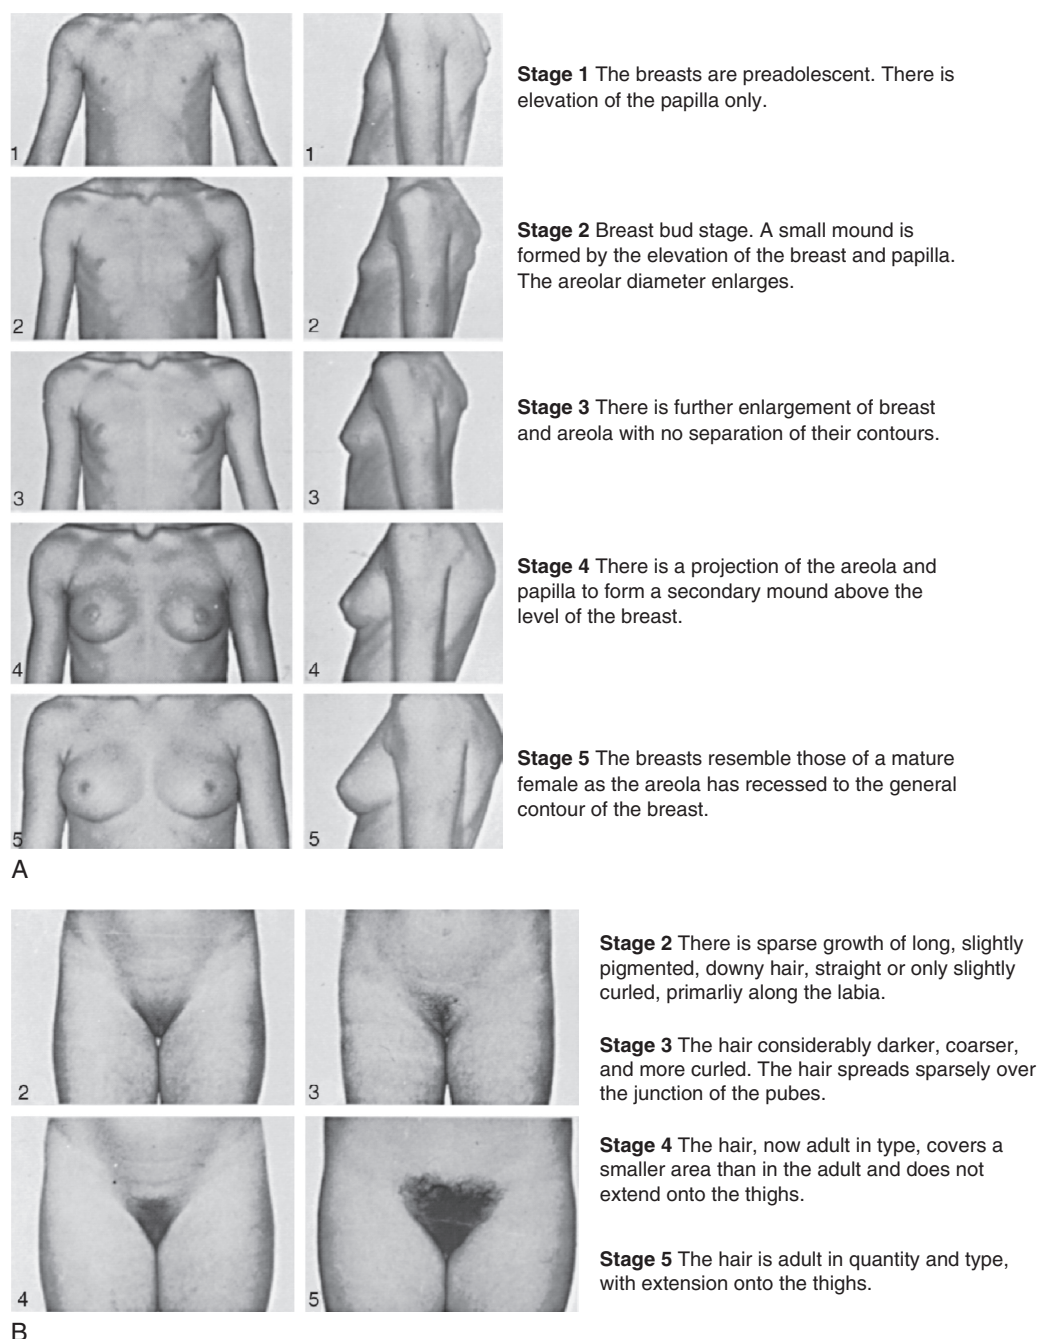

FIGURE 67.3 Typical progression of female pubertal development, stages 1–5. (A) Pubertal development in the size of female breasts. (B) Pubertal development of female pubic hair. Note that at stage 1 (not shown) there is no pubic hair. (Courtesy Tanner JM. Institute of Child Health, Department of Growth and Development. London, England: University of London.)

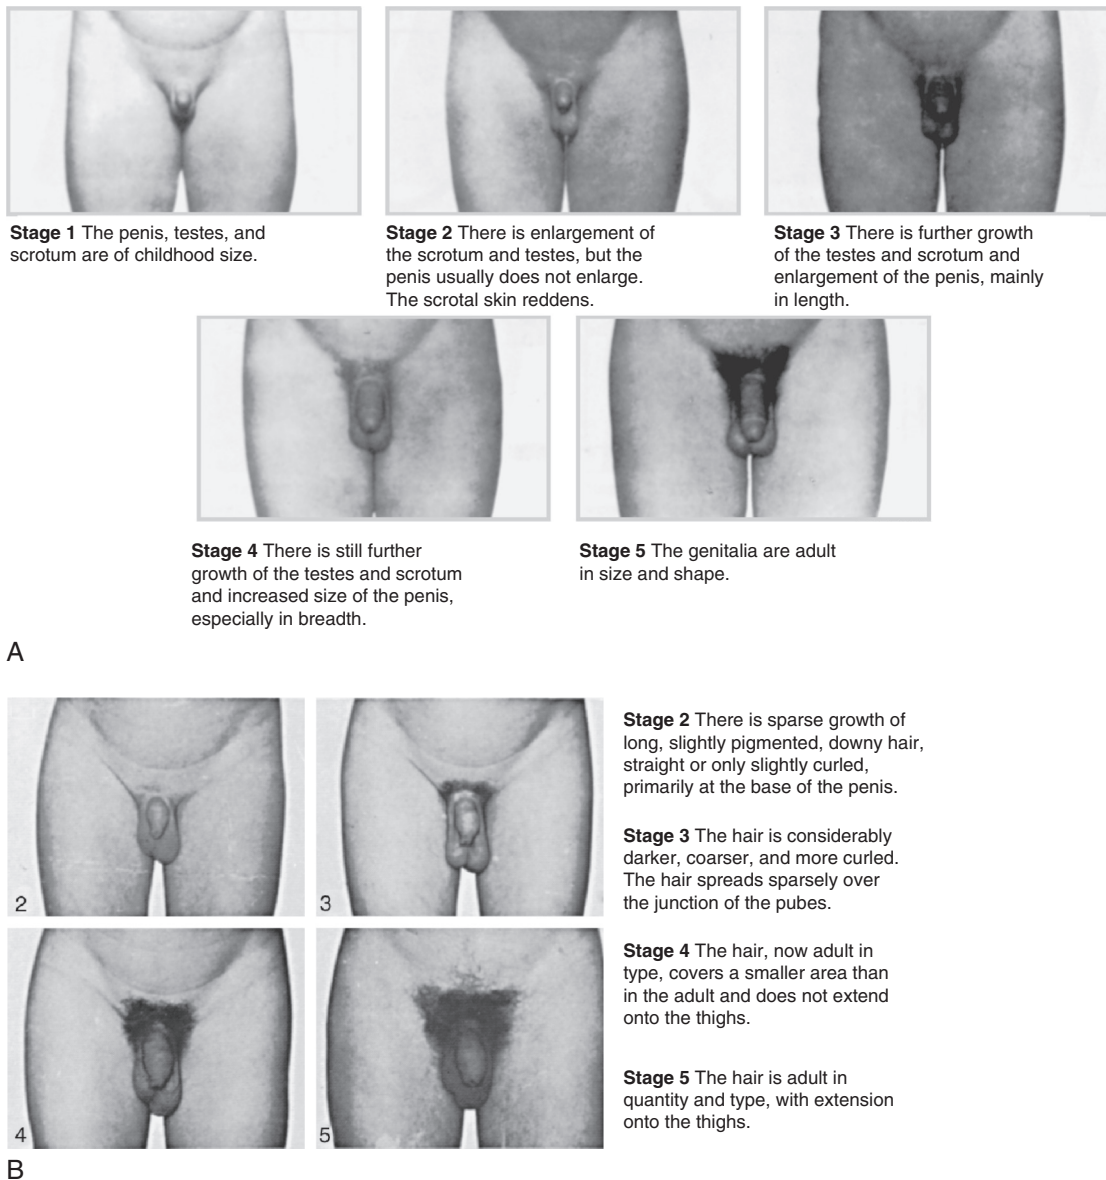

FIGURE 67.4 Typical progression of male pubertal development. (A) Pubertal development in the size of male genitalia. (B) Pubertal development of male pubic hair. Note that at stage 1 there is no pubic hair. (Courtesy Tanner JM. Institute of Child Health, Department of Growth and Development. London, England: University of London.)

most important predictor for each individual girl is when her mother had menarche. The interval from the initiation of thelarche to the onset of menses (menarche) is 2.3 years plus or minus 1 year.

Boys

Testicular enlargement (≥ 2.5 cm) corresponds to Tanner stages 1 to 2 for boys (Fig. 67.4; Table 67.8). Testicular enlargement is followed by pubic hair development at the base of the penis (**adrenarche**) and then axillary hair within the year. The growth spurt is a relatively late event; it can occur from 10½ to 16 years of age. Deepening of the voice, the appearance of facial hair, and acne indicate the early stages of puberty. See Chapter 174 for discussion of disorders of puberty.

TABLE 67.8 Normal Male Puberty: PROS Study

PUBERTAL EVENT	AGE (YR): BLACK	AGE (YR): HISPANIC WHITE
Genital development	9.1	10
Testicular volume >3 mL	9.7	9.5
Pubic hair	10.2	11.4
Testicular volume >4 mL	11.7	11.3

Adapted from Hermann-Giddens ME, Steffes J, Harris D, et al. Secondary sexual characteristics in boys: data from the Pediatric Research in Office Setting Network (PROS). *Pediatrics*. 2012;130(5):1058–1068.

Changes Associated with Physical Maturation

Tanner stages mark biologic maturation, which can be related to specific changes in laboratory values and certain physical conditions. The higher hematocrit values in adolescent boys than in adolescent girls are the result of greater androgenic stimulation of the bone marrow and not loss through menstruation. Alkaline phosphatase levels in boys and girls increase during puberty because of rapid bone turnover, especially during the growth spurt. Worsening of mild scoliosis can occur in adolescents during the growth spurt.

PSYCHOLOGIC GROWTH AND DEVELOPMENT OF ADOLESCENTS

See Table 67.3 and Chapters 7 and 9.

PEARLS FOR PRACTITIONERS

See *Adolescent Medicine: Pearls for Practitioners* at the end of this section.

CHAPTER 68

Well-Adolescent Care

When interviewing adolescents, use a nonjudgmental approach and find some common ground to engage the adolescents to talk about themselves. Try to focus on the positive actions these adolescents are taking to ensure their physical and mental well-being (protective factors). The HEADDSSS (home, education, alcohol, activities, drugs, diet, sex, suicide/depression, self) mnemonic addresses important risk-taking elements of the history (see Table 67.5). Adolescents who experiment in one area of risk taking often have contemplated or tried multiple other risk-taking behaviors. When all of the protective factors and risk-taking information have been gathered, choose one or two health care issues to discuss, making it clear that the information is confidential and that you are there to help the adolescent in a partnership way. Although the focus in adolescent care is on psychosocial issues, a general examination must also be performed (Table 68.1). General pediatric issues, such as immunization (see Chapter 94) and health screening, should be included (see Table 9.5).

EARLY ADOLESCENCE (AGES 10–14 YEARS)

Rapid changes in physical appearance and behavior are the major characteristics of early adolescence, leading to a great deal of self-consciousness and need for privacy. The history focuses on the early adolescent's physical and psychosocial health.

MIDDLE ADOLESCENCE (AGES 15–17 YEARS)

Autonomy and a global sense of identity are the major characteristics of middle adolescence. The history focuses on

TABLE 68.1 Examination of the Adolescent

PHYSICAL EXAMINATION—CHECKLIST

- Explain to your patient what you are going to do.
- Explain how you are going to do it.
- Ask whether your adolescent wants a parent in the room.*
- Be sensitive to the adolescent's needs.
- Always use a sheet or blanket to provide privacy.
- Let the adolescent remain dressed and work around the clothing.
- Ask some questions as you go through the physical to keep the adolescent at ease. Give reassurance that elements of the physical are normal for this age.

ASSESSMENT

- Examination can be used to offer reassurance about normalcy.†
- Assess the following:
 - Height/weight/body mass index and plot on percentile charts
 - Skin for acne, cutting, picking
 - Mouth for periodontal disease
 - Tanner staging
 - Breasts and testicles
 - Thyroid (palpation)
 - Skeletal: scoliosis, Osgood-Schlatter disease, slipped capital femoral epiphysis
 - Mental status for depression and anxiety; use screening tools
 - Signs of substance abuse, risk-taking behaviors, and trauma

*If not, you will need a chaperone.

†For example, 70% of boys can have breast enlargement (gynecomastia), and girls often have one breast larger than the other.

the middle adolescent's interactions with family, school, and peers. High-risk behaviors as a result of experimentation are common.

LATE ADOLESCENCE (AGES 18–21 YEARS)

Individuality and planning for the future are the major characteristics of late adolescence. Greater emphasis is placed on late adolescents' responsibility for their own health care.

GYNECOLOGIC EXAMINATION

A pelvic exam is rarely required in an adolescent female who has never been sexually active, unless there are gynecologic concerns. Routine Papanicolaou (Pap) smears are not required for normal-risk adolescents; current screening guidelines vary between initiating Pap smears in sexually active women at age 21 or 25. Screening for sexually transmitted infections (STIs) can be performed by the patient doing a vaginal self-swab or a urine specimen.

If a pelvic examination is required, the patient should be informed about the importance of the assessment and exactly what will occur, including any potential discomfort. The patient should be encouraged to ask questions and know that they can request to stop at any time. A chaperone should

TABLE 68.2 Etiology of Breast Masses in Adolescents

Classic or juvenile fibroadenoma (70%)
Fibrocystic disease
Breast cyst
Abscess/mastitis
Intraductal papilloma
Fat necrosis/lipoma
Cystosarcoma phyllodes (low-grade malignancy)
Adenomatous hyperplasia
Hemangioma, lymphangioma, lymphoma (rare)
Carcinoma (<1%)

be offered if a caregiver is not present. The examiner should maintain eye contact during the exam and explain what is happening during each step.

A padded examination table with the patient in a frog-leg position improves comfort during a pelvic examination. Stirrups can be used if a speculum exam is required. The examination room, lubricants, and instruments should be warm. The examination should be unhurried but efficient.

Inspection of the external genitalia includes evaluation of the pubic hair, labia majora and minora, clitoris, urethra, and hymenal ring. When a speculum exam is required, it should be performed before bimanual palpation of internal genitalia because lubricants can interfere with the evaluation of microscopic and microbiologic samples. The speculum allows visualization of the vagina, assessing for any discharge or signs of infection, and the cervix if a Pap smear is required. In the rare circumstance that a speculum examination is necessary in a virginal girl, a Huffman (pediatric) or small Pederson (narrow) speculum should be used.

BREAST CHANGES IN GIRLS AND BOYS

Breast Asymmetry and Masses in Girls

The breast bud is a pea-sized mass below the nipple that is often tender. It is not unusual for one breast to begin growth before the other, or to grow more rapidly, with resulting asymmetry. Reassure that after full maturation, the asymmetry will be less obvious and that all women have some degree of asymmetry. Occasionally young women present with a breast mass; usually these are benign fibroadenomas or cysts (Table 68.2). An ultrasound is superior to mammography in young women.

Gynecomastia in Boys

Breast enlargement (gynecomastia) in boys is common (50–60%) and usually benign and self-limiting. However, it may be noted in various conditions including morbid obesity (Table 68.3). Typical findings include the appearance of a round (1–3 cm), freely mobile, often tender, and firm mass immediately beneath the areola during sexual maturity rating stage 3. Large, hard, or fixed enlargements and masses associated with any nipple discharge warrant further investigation.

TABLE 68.3 Etiology of Gynecomastia

Idiopathic
Hypogonadism (primary or secondary)
Liver disease
Renal disease
Hyperthyroidism
Neoplasms
Adrenal
Ectopic human chorionic gonadotropin secretion
Testicular
Drugs
Antiandrogens
Antibiotics (isoniazid, ketoconazole, metronidazole)
Antacids (H ₂ blockers)
Cancer chemotherapy (especially alkylating agents)
Cardiovascular drugs
Drugs of abuse
Alcohol
Amphetamines
Heroin
Marijuana
Hormones (for female sex)
Psychoactive agents (e.g., diazepam, phenothiazines, tricyclics)

Reassurance is usually the only treatment required for benign gynecomastia. If the condition worsens and is associated with psychologic morbidity, it may be treated with surgery or medication.

PEARLS FOR PRACTITIONERS

See *Adolescent Medicine: Pearls for Practitioners* at the end of this section.

CHAPTER 69

Adolescent Gynecology

VAGINAL DISCHARGE

Physiologic leukorrhea is due to estrogen effect on the cervix and vagina following puberty and is clear or white, without symptoms. Yeast is most commonly associated with pruritus, and bacterial vaginosis may have a stereotypical “fishy” odor. Many sexually transmitted infections (STIs) may be asymptomatic. A focused history should be obtained, particularly enquiring if the patient is sexually active. Swabs can be obtained for STIs, yeast, and bacterial vaginosis. Teens can be instructed to do their own vaginal swab (most labs no longer require cervical specimens), so a speculum exam is not required. If sexually

active, this opportunity also allows the discussion of condom use for STI protection and contraceptive options. Up-to-date treatment options for vaginal infections and STIs are available on the Centers for Disease Control and Prevention website (cdc.gov).

MENSTRUAL DISORDERS

Amenorrhea

Primary amenorrhea is defined as the absence of menstruation by 15 years of age in the *presence* of secondary sexual characteristics, 13 years of age in the *absence* of secondary sexual characteristics, or no onset of menses within 3–4 years of thelarche. Features that should prompt earlier evaluation include signs of hirsutism, a history of excessive exercise or an eating disorder, or absence of menses at any age with symptoms suggestive of an outflow tract obstruction (e.g., cyclic abdominal pain).

Primary amenorrhea may be a result of functional or anatomic abnormalities of the hypothalamus, pituitary gland, ovaries, uterus, cervix, or vagina. The most common etiologies are ovarian failure (e.g., primary ovarian insufficiency, Turner syndrome) and müllerian agenesis. The history and physical examination should guide the investigation.

An outflow tract obstruction should be suspected in adolescents with primary amenorrhea, cyclic abdominal pain, and normal secondary sexual characteristics. An imperforate hymen is easily evident on exam, with a characteristic blue, bulging membrane. Higher outflow tract anomalies require imaging to confirm the diagnosis and should be strongly suspected with a history of renal anomalies. A single-digit vaginal/bimanual examination or rectoabdominal exam may allow palpation of a hematocolpos or hematometra (blood accumulated in the vagina or uterus).

An endocrine evaluation is indicated for girls with primary amenorrhea without secondary sexual characteristics (see Chapter 174). An elevated follicle-stimulating hormone (FSH) over 25 IU/L on two occasions 4 weeks apart indicates hypergonadotropic hypogonadism, which may reflect ovarian dysgenesis/agenesis and warrants a karyotype looking for **Turner syndrome**. Other etiologies include autoimmune diseases and fragile X premutation carriers. Low levels of FSH indicate hypogonadotropic hypogonadism, which may be due to constitutional delay (more common in boys than girls), isolated gonadotropin deficiency (e.g., Kallmann or CHARGE syndrome), a central nervous system (CNS) lesion, or hypothalamic dysfunction (chronic illness, low body weight/anorexia, stress). Additional hormone evaluation may include thyroid-stimulating hormone and prolactin. Hypothyroidism is a common cause of menstrual dysfunction. A prolactinoma, although rare, must be ruled out.

Secondary amenorrhea refers to the cessation of menses for more than 3 consecutive months in girls who previously had regular menses, or greater than 6 months in girls who had irregular menses.

The most common causes of secondary amenorrhea are pregnancy, anorexia/stress (low luteinizing hormone [LH], FSH, and estradiol), and **polycystic ovary syndrome (PCOS)**. In PCOS, there may be symptoms of androgen excess, such as acne and hirsutism, weight gain, and, with insulin resistance, acanthosis. If hirsutism or virilization is present, free

and total testosterone, androstenedione, and didehydroepiandrosterone sulfate (DHEAS) should be measured to rule out ovarian or adrenal tumors. A normal 17-hydroxyprogesterone level rules out late-onset **congenital adrenal hyperplasia**. The diagnosis of PCOS may be difficult in adolescence as there is considerable overlap between normal pubertal development and PCOS. After excluding other etiologies of irregular menses and hyperandrogenism, PCOS may be diagnosed with infrequent menstrual bleeding (or amenorrhea) that has persisted for more than 2 years after menarche in conjunction with clinical or biochemical evidence of hyperandrogenism. Hyperandrogenism in adolescents is defined as moderate or severe hirsutism, persistent acne/poorly responsive to treatment, or persistent elevation of total and/or free testosterone. There are no compelling criteria for polycystic ovarian morphology on imaging in adolescents; therefore, at present, ovarian ultrasound imaging can be deferred during the evaluation of PCOS in this age group. Patients may have impaired glucose tolerance or hypercholesterolemia even in adolescence.

Therapy for the amenorrhea should be directed at the cause. Anovulation can be managed with either cyclic progesterone withdrawal or combined hormonal contraceptives (CHCs). For ovarian failure, therapy is directed at replacing estrogen and progesterone, either with a combined hormone replacement regimen or a CHC. With reversible etiologies of hypothalamic amenorrhea, therapy is directed at modifying the contributing factors (e.g., stress, exercise, or dietary changes). For PCOS, conservative measures include weight loss and exercise, which can restore ovulatory cycles in some. However, many will require cyclic progesterone or CHC. If there is evidence of androgen excess, CHCs reduce androgen production from the ovaries and increase sex hormone-binding globulin to reduce the amount of bioavailable testosterone. The need for contraception would also make a CHC a good choice. Other options include spironolactone, which improves hirsutism, or metformin, which can restore ovulatory cycles.

Abnormal Uterine Bleeding

The International Federation of Gynecology and Obstetrics (FIGO) nomenclature and classification of **abnormal uterine bleeding (AUB)** define menstrual disorders (Table 69.1).

Normal menses occur at intervals of 21–35 days. The average duration of flow is 3–7 days. More than 8 well-soaked pads or 12 tampons per day may be considered heavy menstrual bleeding (HMB). Charting on a menstrual calendar and use of a pictorial bleeding assessment chart (PBAC) can more accurately quantify the volume of blood loss (Fig. 69.1). A PBAC score above 100 is consistent with greater than 80 mL of menstrual loss and HMB.

The differential diagnosis of AUB uses the PALM COEIN classification system (Table 69.2). The PALM categories include anatomic abnormalities (polyp, adenomyosis, leiomyoma, and malignancy) and are rare causes of AUB in adolescents. Far more common are the categories of AUB-C (coagulopathy) and AUB-O (ovulatory).

Anovulation is the most common etiology of AUB in adolescents, resulting in irregular cycles. Without progesterone, produced by the corpus luteum following ovulation, unopposed estrogen causes endometrial thickening and irregular endometrial shedding, which can be prolonged and heavy. Progesterone induces a secretory endometrium (“luteinizes”);

when it is withdrawn, the endometrium sheds in a synchronous fashion with myometrial and vascular contractions (causing dysmenorrhea but limiting blood loss). This typically resolves within 2 years post-menarche as the hypothalamic-pituitary-ovarian (HPO) axis matures but can persist up to 4 years, particularly if menarche was late. If concerning symptoms occur at any time (e.g., hirsutism, symptoms of anemia) or if they persist beyond 4 years, investigation is warranted. When irregular bleeding occurs after regular cycles were established, this usually indicates an organic abnormality. The differential diagnosis of anovulatory bleeding at that

time would include thyroid dysfunction, PCOS, and adrenal and pituitary disorders.

Approximately 20% of adolescents with heavy or prolonged menses have a coagulation disorder (even higher if presenting at/soon after menarche) and 10% have other pathology. Clues on history to suspect a coagulopathy are onset of heavy menses with menarche, severity requiring admission or blood transfusion, failure of initial medical therapy, a family history of a bleeding disorder, or a personal history of bleeding, easy bruising, or epistaxis. If an underlying pathology is discovered, treatment should be directed at the primary disorder and the secondary menstrual dysfunction. It is important to remember that AUB in sexually active adolescents can be due to pregnancy, sexually transmitted infections (STIs), or as a side effect of contraception (AUB-I [iatrogenic]).

Physical examination should assess for signs of anemia, bruising, or petechiae, and signs of hyperandrogenism or thyroid disease. A pelvic examination should be performed in sexually active adolescents and swabs sent for STIs. A complete blood count, pregnancy test, thyroid-stimulating hormone (TSH), and coagulation screen should be performed if appropriate. With a suspicion of PCOS or in the setting of clinical hyperandrogenism, androgens should be included.

TABLE 69.1 Definition of Menstrual Disorders		
CLINICAL DIMENSION	DESCRIPTIVE TERM	DEFINITION
Frequency	Frequent menstrual bleeding	<21 days/cycle
	Infrequent menstrual bleeding	>35 days/cycle
Regularity	Amenorrhea	Absent for ≥6 mo
	Irregular menstrual bleeding	>20-day variation in cycle length
Duration	Prolonged menstrual bleeding	>8 days of flow
	Shortened menstrual bleeding	<2 days of flow
Flow	Heavy menstrual bleeding	>80 mL loss
	Light menstrual bleeding	<5 mL loss
Intermenstrual bleeding		Bleeding between normally timed periods

FIGURE 69.1 Pictorial bleeding assessment chart (PBAC). (Modified from Higham JM, O'Brien PM, Shaw RW. Assessment of menstrual blood loss using a pictorial chart. *Br J Obstet Gynaecol.* 1990;97(8):734-739.)

Due to the infrequency of structural etiologies of AUB at this age, pelvic ultrasound has no role in the initial investigations of AUB. Unpredictable, heavy, and prolonged menses may impair school attendance and social functioning; iron-deficiency anemia is associated with lower academic scores.

Treatment for AUB should be initiated if there are detrimental effects on health (e.g., anemia) or on quality of life. Menstrual irregularity and HMB can be managed with CHCs, which can be prescribed either cyclically or in an extended fashion (e.g., 84 days of active CHC followed by a 5- to 7-day hormone-free interval). Extended use is a good strategy to consider for girls with a recognized **bleeding disorder**, such as von Willebrand disease or thrombocytopenia. For acute heavy bleeding, multiple daily doses of CHC may be required until blood loss is controlled and occasionally requires hospitalization for more intensive management. If estrogen is contraindicated, progestin-only methods can be prescribed. The progesterone-only pill can improve HMB and provide contraception but must be taken within 3 hours of the same time each day and does not consistently block ovulation or allow for extended menstrual suppression. The levonorgestrel-releasing intrauterine system has high rates of amenorrhea, provides over 70% reduction in blood loss, and is the most effective contraceptive. Parents are often concerned that using contraceptives will encourage their daughter to become sexually active, but literature and experience do not support this. Tranexamic acid is an antifibrinolytic taken only on the heavy days of flow, which can decrease blood loss by up to 50% but does not provide cycle regulation or contraceptive benefits.

Dysmenorrhea

The most common gynecologic complaint of young women is painful menstruation, or dysmenorrhea. **Primary dysmenorrhea** is defined as pelvic pain during menstruation in the absence of pelvic pathology. It develops once ovulation is established. Pain occurs as a result of prostaglandins and leukotrienes being released from the degenerating endometrium, causing increased uterine tone and contractions.

Secondary dysmenorrhea is menstrual pain associated with pelvic pathology; it accounts for 10% of dysmenorrhea in adolescents and is caused most frequently by **endometriosis** or **pelvic inflammatory disease**. Severe dysmenorrhea within a few months of menarche should raise the consideration of an asymmetrically obstructed müllerian anomaly, such as an OHVIRA syndrome (obstructed hemivagina and ipsilateral renal agenesis) or a functional noncommunicating uterine horn. Secondary dysmenorrhea is often more severe, fails initial medical therapy, and is more commonly associated with atypical features (e.g., pain outside of menstrual cycle, dyschezia, dyspareunia). Ultrasound is preferred as the initial screen for obstructing genital tract lesions. Magnetic resonance imaging is the gold standard for diagnosing complex reproductive tract anomalies in this age group.

Treatment of primary dysmenorrhea should start with nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen, naproxen, or mefenamic acid. To maximize efficacy, they should be taken prior to or immediately at onset of bleeding, closely following the dosing schedule. If NSAIDs fail to provide adequate relief, if contraception is needed, or if features of AUB are also present, then hormonal treatment can be initiated. CHCs (cyclical or extended) or long-acting reversible

contraceptives (LARCs), such as the levonorgestrel-releasing intrauterine system, can be used. If dysmenorrhea persists despite an adequate trial of hormonal therapy, an alternative diagnosis should be considered, such as endometriosis. The patient should be referred to gynecology to consider laparoscopy or alternative treatments for endometriosis, such as dienogest or gonadotropin-releasing hormone agonists.

PREGNANCY

In 2015–2017, 42% of American never-married female teenagers aged 15–19 and 38% of never-married male teenagers reported sexual intercourse. Risk factors for adolescent pregnancy include lower socioeconomic status, lower educational attainment, low self-esteem, lack of access to contraception, alcohol and drug use, and adverse early life experiences in the home.

The birth rate in this group in 2018 was 17.4 births per 1,000, with 179,871 births; this rate has declined 58% since 2007 (41.5), and 72% since the 1991 high (61.8). The abortion rate in this group in 2016 was 6.2 per 1,000; this rate has declined 56% since 2007.

Diagnosis

Pregnancy should be considered and ruled out in any adolescent presenting with secondary amenorrhea. Frequently, pregnant adolescents delay seeking a diagnosis until several periods have been missed and initially may not disclose having had intercourse. Young adolescents may present with other symptoms, such as vomiting, vague pains, or deteriorating behavior and may report normal periods. Because of the varied presentations of adolescent pregnancy, a thorough menstrual history should be obtained from all menstruating adolescents. Urine pregnancy tests are sensitive approximately 7–10 days after conception. Sexual assault or coercion should be screened for in all cases of adolescent pregnancy. It is important to recognize that adolescent pregnancies are not all unwanted or unplanned. Sensitivity to that awareness and to culture is important in the approach to the pregnant adolescent.

When pregnancy is confirmed, an ultrasound for dating is recommended. Options to continue or terminate the pregnancy should be discussed. Pregnant adolescents should be encouraged to involve their families in decision making, but if competent, these adolescents should be encouraged to make the decision that is right for them.

Continuation of the Pregnancy

Pregnancy risks are influenced by behavior and socioeconomic status as well as inherent biologic risks, particularly in those younger than age 15 years. Adolescents have an increased incidence of preterm and very preterm births, low birthweight infants, infant neonatal admission, postneonatal mortality, child abuse, subsequent maternal unemployment, and poor maternal educational achievement. Children of adolescent parents compared with their peers are more likely to have lower educational achievements, be involved with drugs and alcohol, and become adolescent parents.

Prenatal care for these adolescents should be multidisciplinary, easily accessible, and focus on both social

support and nutritional counseling, which has been shown to improve pregnancy outcomes. Pregnant adolescents should be screened frequently for mood disorders, alcohol and/or drug use, STIs, and interpersonal violence, as reported rates are higher in this age group than in adults. Pregnancy is the most common cause for young women to drop out of school, so special attention should be given to continuing education. Contraceptive planning should be initiated in the antenatal care period with continued focus postpartum. Most teens choose to parent the child, but the option of adoption should also be discussed.

Termination

If a pregnant adolescent chooses to terminate her pregnancy, she should be referred immediately to a nonjudgmental abortion service. The options for pregnancy termination depend on the gestational age, including medical (mifepristone [RU-486]) if less than 8 weeks, or surgical (manual vacuum aspiration or suction curettage). Psychosocial support and subsequent contraceptive counseling should be provided.

CONTRACEPTION

While the proportion of adolescents using contraception the first time they have sex has increased, 20% still initiate intercourse with no contraception, with higher rates in younger adolescents. The best form of contraception is the one an individual will use, thus counseling adolescents about all methods and supporting their choice is important. A history and physical should be performed to determine if any contraindications exist to specific methods; the U.S. Medical Eligibility Criteria (U.S. MEC website or app) provides recommendations for using specific contraceptive methods by women who have certain characteristics or medical conditions. Contraceptives can be divided into user-based methods and long-acting reversible contraceptives (LARCs). Although LARCs are recommended as first-line options, only the minority of adolescents choose these methods. Focused education around LARCs and removing the barriers of cost and access have been shown to improve uptake. It is important to remind young women any hormonal method requires concomitant use of condoms for STI protection.

Steroidal Contraception

Long-Acting Reversible Contraceptives

Implants

The subdermal etonogestrel (progestin) implant is a single rod inserted subcutaneously in the upper inner arm. Effective for 3 years, it has the lowest failure rate of any contraceptive method (0.05% of 100 women during the first year of typical use). The primary mechanism of action is suppression of ovulation; there may be additional efficacy from thickening cervical mucus and endometrial atrophy. Quick starts are possible, with insertion on the day of presentation once pregnancy has been excluded. The implant does not need to be inserted at any particular time in the menstrual cycle. Patients should be counseled that the most common side effect is irregular bleeding, particularly in the first 3 months of use. The continuation rate in adolescents is over 80% at 1 year.

Intrauterine Devices

Intrauterine devices (IUDs) are inserted into the uterus, where they release either copper ions or levonorgestrel. Either IUD method is safe for adolescents. A sterile foreign-body reaction in the uterine cavity is a common mechanism of action of both IUD methods. In addition, the copper IUD impairs sperm function and fertilization, while the levonorgestrel IUDs induce an atrophic endometrium as well as thickening cervical mucus. The copper IUD has the longest approval for duration of use at 10 years; however, it may increase the amount and duration of bleeding as well as dysmenorrhea. The levonorgestrel-releasing intrauterine systems (L-IUS) contain differing amounts of levonorgestrel, with durations of use of 3 years (for the 13.5-mg IUS) and 5 years (for 19.5- and 52-mg IUS). The 52-mg product decreases menstrual flow by up to 70%, and complete amenorrhea is noted in approximately 20% of users at 1 year. They are therefore prescribed frequently for heavy menstrual bleeding and dysmenorrhea. The two lower dose L-IUSs also decrease menstrual flow but to a lesser extent, rarely achieving amenorrhea. All IUDs are highly effective (failure rates of 8/1,000 for copper and 2/1,000 for L-IUS) and have high continuation rates (>85% at 1 year). There is a small increased risk of pelvic inflammatory disease for 21 days after insertion, hence adolescents should be screened for STIs prior to or at the time of IUD insertion. Insertion in nulliparous women can be aided by the use of a paracervical block, but this is not routinely necessary.

Hormonal Injections

Depo-medroxyprogesterone acetate (DMPA) is available in two formulations: intramuscular injection of 150 mg every 12–14 weeks or 104 mg/0.65 mL for subcutaneous use every 12–14 weeks. The primary mechanism of action is suppression of ovulation with a secondary effect on cervical mucus and the endometrium. It is associated with very high rates of amenorrhea (70%); some may experience frequent or irregular menstrual bleeding. The average weight gain on DMPA is 5 lb in the first year; however, some continue to gain weight following that. A decrease in bone mineral density is reversible after cessation, but teens in particular should be counseled about adequate calcium and vitamin D intake, and not smoking. Continuation rates of DMPA in adolescents at 1 year is less than with other LARCs.

Combined Hormonal Contraceptives

CHCs are available in oral, transdermal, and vaginal routes of administration. All contain synthetic estrogen and progesterone that suppress gonadotropin secretion and ovulation. CHCs also induce endometrial atrophy (inhospitable for blastocyst implantation) and thicken cervical mucus to inhibit sperm penetration. Absolute and relative contraindications to CHCs are listed in Table 69.3. CHCs are 99% effective with perfect use and have numerous noncontraceptive benefits including improved acne, dysmenorrhea, and menstrual flow. Any CHC can be used in an extended fashion by limiting hormone-free days to extend intervals between withdrawal bleeds.

Oral contraceptive pills need to be taken at approximately the same time daily. Due to poor compliance, oral CHCs tend to have higher failure rates (~8%/year) and continuation rates at 1 year are low. There are many formulations of oral CHCs available that vary in the type, dose, and duration of estrogen and progestin, as well as variation in the number

TABLE 69.3 Absolute and Relative Contraindications to Combined Hormonal Contraceptives

ABSOLUTE CONTRAINDICATIONS (CATEGORY 4)	RELATIVE CONTRAINDICATIONS (CATEGORY 3)
Smoker age >35yr and >15 cigarettes/day	Smoker age >35yr and <15 cigarettes/day
Hypertension: >160 systolic or >100 diastolic	Hypertension: controlled or 140–159 systolic or 90–99 diastolic
Cardiac: ischemic heart disease, complicated valvular heart disease, atrial fibrillation, peripartum cardiomyopathy <6mo	Cardiac: multiple risk factors for arterial cardiovascular disease, peripartum cardiomyopathy >6mo with no/mild impaired function
Vascular: vascular disease, venous thromboembolic (VTE) disease: acute or high recurrence risk (e.g., thrombophilia), systemic lupus with antiphospholipid antibodies, complicated solid organ transplant	Vascular: VTE on treatment or past history and low recurrence risk, diabetes with end-organ damage (nephropathy, retinopathy, neuropathy)
Neurologic: migraines with focal neurologic symptoms, stroke history	Neurologic: migraine without neurologic symptoms and age >35yr
Breast: current cancer, postpartum <4wk + breast-feeding (BF), postpartum <3wk no BF	Breast: cancer disease-free history >5yr, postpartum 4–6wk + BF + other VTE risks, postpartum 3–6wk + no BF + other VTE risks
Gastrointestinal (GI): liver failure, hepatocellular adenoma, malignant hepatoma, severe cirrhosis	GI: acute viral hepatitis (oral contraceptive pill [OCP] only), symptomatic gallbladder disease, history of combined hormonal contraceptive (CHC)-related cholestasis, malabsorptive bariatric procedures (OCP only)
Immobilization (prolonged): major surgery	Immobilization (prolonged): multiple sclerosis
	Drug interactions: certain anticonvulsants, rifampicin, rifabutin, certain antiretroviral therapies

Modified from Centers for Disease Control and Prevention. Classifications for combined hormonal contraceptives. <https://www.cdc.gov/reproductivehealth/contraception/mmwr/mec/appendixd.html>. Accessed July 26, 2021.

of placebo pills. The contraceptive patch is a 25-cm² pink patch containing ethinyl estradiol and norelgestromin that is applied to the skin of the torso, buttocks, or arm. A new patch is applied each week for 3 weeks, then no patch is worn the fourth week to allow for a withdrawal bleed. It is less efficacious in women weighing more than 90 kg. The contraceptive vaginal ring is a flexible, silastic ring that releases 15 mg of ethinyl estradiol and 0.120 mg of etonogestrel per day. Each ring is placed in the vagina for 3 weeks, and a new ring is inserted 7 days later.

After a history, physical examination (including blood pressure), and ruling out pregnancy, CHCs can be started on the first day of the next menstrual period or as a “quick start.” The quick start method refers to starting on any day of the cycle, as soon as the teen has the medication available. A backup method should be used for 7 days. The adolescent should be seen again within a few months to reinforce good contraceptive use and safer sex.

Initial **side effects**, such as nausea, breast tenderness, and breakthrough bleeding, are common and usually transient. CHCs do not generally cause weight gain. Usually 3–4 months on one CHC are needed to determine acceptability. If there is breakthrough bleeding, the physician should determine compliance with the method before prescribing something new. Adolescents should be taught the appropriate response to missed doses.

Progestogen-Only Pill

The progestin-only pill is an effective form of contraception when used consistently, and is safe with very few contraindications. It is supplied in packages of 28 tablets, each containing norethindrone with no hormone-free interval. The primary mechanism of action is by thickening the cervical mucus, thereby inhibiting penetration by sperm, but also decreases

implantation as a result of endometrial atrophy. Ovulation is inconsistently suppressed with approximately 40% of cycles still being ovulatory. It is frequently considered for women with contraindications to estrogen, but is chosen less often than CHCs due to the stringent compliance needed (must take within 3 hours of the same time every day, due to a short half-life of only 22 hours) and therefore may not be the best first choice for adolescents.

Barrier Methods

Condoms

Condoms are readily accessible without a prescription and provide excellent protection against STIs; however, due to incorrect use and breakage (higher with non-latex), the contraceptive failure rates are quite high (~15%). Condoms may be chosen by individuals who have infrequent intercourse, but a more reliable method of regular contraception should be encouraged for adolescents long term. The female condom is an additional barrier method made of polyurethane that affords females more control, but adolescents usually do not consider it aesthetically pleasing. Any adolescent using barrier methods should be counseled regarding emergency contraceptive (EC) options.

Sponge, Caps, and Diaphragm

The vaginal sponge is a single-use “one size fits all” spermicide-impregnated synthetic sponge. Both the cervical cap and diaphragm come in various sizes so must be fitted by a health care professional and used with a spermicidal gel. Each of these methods can be difficult to source/get fitted, require placement in advance of intercourse and left in place for 6 hours following, and have significantly higher failure rates than hormonal methods. For all these reasons, they are a less favorable choice for adolescents.

TABLE 69.4 Emergency Contraception

INDICATIONS
• No method of contraception being used
• Condom breaks, slips, or leaks
• Diaphragm or cervical cap dislodged/removed <6 hr
• Missed hormonal contraceptive
• Error in using withdrawal (ejaculation on external genitalia or in vagina)
• Sexual assault on no reliable contraceptive
CONTRAINDICATIONS
• Known pregnancy
• If strong contraindications to estrogens, use progestin
• If uterine anomaly—contraindication to intrauterine device

Emergency Postcoital Contraception

Emergency postcoital contraception should be discussed at every visit and a prescription given in advance when over-the-counter access is unavailable. EC reduces the risk of pregnancy after unprotected intercourse or in the case of condom breakage. Indications and contraindications are listed in Table 69.4. There are several forms of EC. The copper IUD can be inserted up to 7 days after unprotected intercourse; it is the most effective EC method with an efficacy of greater than 99%, but access can be a barrier.

A single dose of levonorgestrel 1.5 mg (two 0.75-mg tablets) or ulipristal acetate (UPA) 30 mg can be taken up to 5 days after unprotected intercourse. Effectiveness is higher the earlier the method is used. Both hormonal methods are equally effective if taken within 72 hours, but studies have shown that UPA is superior to levonorgestrel if treatment is delayed more than 72 hours and in young women with a body mass index (BMI) greater than 25 kg/m². Another hormonal contraceptive can be started immediately after levonorgestrel use; however, it should be delayed for 5 days after UPA use. Multiple CHC pills may be taken to deliver the equivalent of 100 mg of ethinyl estradiol and 500 µg of levonorgestrel 12 hours apart (Yuzpe regimen). This method is associated with significantly more nausea and vomiting (take with an antiemetic) and is less effective. Following EC use, a pregnancy test should be completed if normal menstrual bleeding does not occur within 21 days. Young women who use EC should be counseled on alternative contraceptive methods.

Coitus Interruptus and Rhythm Method (Periodic Coital Abstinence)

Neither coitus interruptus nor rhythm method are reliable methods of pregnancy prevention. Withdrawal is ineffective because sperm are released into the vagina before ejaculation, and withdrawal may occur after ejaculation has begun. The rhythm method attempts to avoid intercourse around the time of ovulation, which cannot be accurately predicted with any degree of certainty, particularly in adolescents who are more likely to have irregular cycles.

Oral and Anal Sex

Some adolescents engage in oral or anal sex because they believe that it eliminates the need for contraception. Many do not

consider this activity as “having sex.” Condoms generally are not used during oral or anal sex, but the risk of acquiring an STI is still present. Adolescents should be asked specifically about non-vaginal forms of sexual activity. Adolescents who engage in oral and anal sex require STI and HIV counseling and screening.

SEXUAL VIOLENCE

One in 9 girls and 1 in 53 boys under the age of 18 experience sexual abuse or assault at the hands of an adult. The perpetrator is known in 93% of cases, 34% are family members; 15% of all sexual assaults occur in adolescents aged 12–17, and the vast majority are female. Although gathering historical and physical evidence for a criminal investigation is important, the physician’s primary responsibility is to perform these functions in a supportive, nonjudgmental manner. The history should include details of the sexual assault, time from the assault until presentation, whether the victim cleaned herself, date of last menstrual period, and previous sexual activity, if any.

For optimal results, forensic material should be collected within 72 hours of the assault. Clothes, especially undergarments, need to be placed in a paper bag for drying (plastic holds humidity, which allows organisms to grow, destroying forensic evidence). The patient should be inspected for bruising and bites as well as oral, genital, and anal trauma. Photographs are the best record to document injuries. Specimens should be obtained from the fingernails, mouth, vagina, pubic hair, and anus. The sexual assault kit provides materials to obtain DNA from semen, saliva, blood, fingernail scrapings, and pubic hair. A wet mount of vaginal fluids shows the presence or absence of sperm under the microscope. STI testing should occur but is usually negative (unless the patient was previously infected) because 72 hours are needed for the bacterial load to be sufficient for a positive result. Blood should be drawn for baseline HIV and syphilis. All materials must be maintained in a “chain of evidence” that cannot be called into question in court.

Therapy after a rape includes prophylaxis for EC and STI and, if indicated, hepatitis immune globulin and hepatitis vaccine. A single oral dose of cefixime 800 mg plus azithromycin 1 g, treats *Chlamydia*, gonorrhea, and syphilis. An alternative regimen is a single intramuscular dose of ceftriaxone 250 mg, with a single oral dose of azithromycin 1 g. For prophylaxis against *Trichomonas*, a single oral dose of metronidazole 2 g is recommended. If the HIV status of the perpetrator is known to be positive, and the victim has been exposure to bodily secretions within the last 72 hours, a 28-day course of highly active antiretroviral therapy should be considered. If the assailant’s HIV status is unknown, an individualized approach to prophylaxis should be taken, assessing for risk of infection (trauma, regional prevalence of HIV, nature of exposure) and the patient’s wishes. Consider consulting an HIV specialist for advice. Repeat STI testing and a pregnancy test should be performed 3 weeks after the assault, followed by serology for syphilis, hepatitis, and HIV at 12 weeks. Long-term sequelae are common; as adults, they are more likely to experience post-traumatic stress disorder, major depression, and drug abuse. Patients should be offered immediate and ongoing psychologic support, such as that offered by local rape crisis services.

PEARLS FOR PRACTITIONERS

See *Adolescent Medicine: Pearls for Practitioners* at the end of this section.

CHAPTER 70

Eating Disorders

Eating disorders are common chronic diseases in adolescents, especially in females. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-V) classifies these as psychiatric illnesses. The diagnosis in young adolescents (pre-growth spurt, premenstrual) may not follow the typical diagnostic criteria for anorexia nervosa (Table 70.1). Avoidant/restrictive food intake disorder (ARFID) is a new diagnosis in the DSM-V that was previously referred to as selective eating disorder.

ANOREXIA NERVOSA

The prevalence of anorexia nervosa is 1.5% in teenage girls. The female:male ratio is approximately 20:1, and the condition shows a familial pattern. The cause of anorexia nervosa is unknown but involves a complex interaction between social, environmental, psychologic, and biologic events (Figs. 70.1 and 70.2).

Clinical Manifestations and Diagnosis

Screening for eating disorders is important and is best done as part of the larger psychosocial screen for risk-taking behaviors (see Fig. 67.1). Although it is recommended to interview alone, the adolescent may minimize the problem; thus it is also important to interview the parent(s) alone. The first event

usually described by an affected patient is a behavioral change in eating or exercise (i.e., food obsession, food-related ruminations over exercise, mood changes). The patient often has an unrealistic body image and feels too fat, despite appearing excessively thin. The parents' response to this situation can be

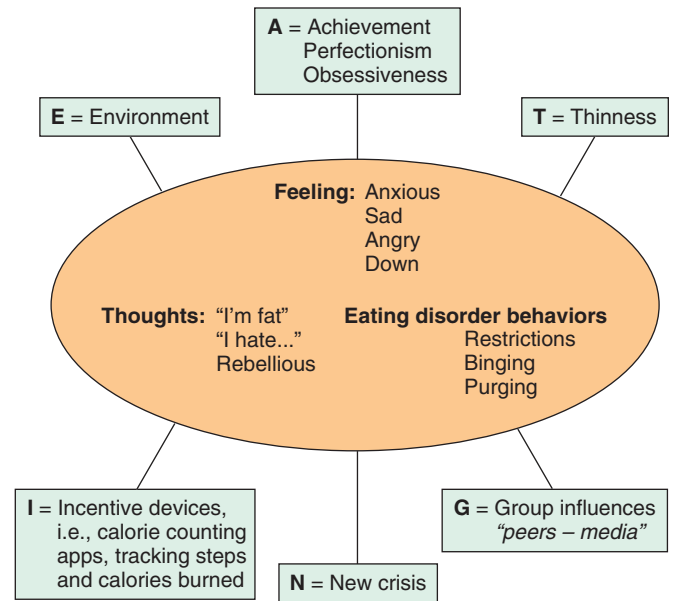

FIGURE 70.1 The “eating” disorder cycle.

FIGURE 70.2 The slippery slope to eating disorders.

TABLE 70.1 Diagnostic Criteria for Anorexia Nervosa

Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to body weight <85% of ideal)*

Intense fear of gaining weight or becoming fat, even though underweight

Denial of the seriousness of the low body weight—a disturbance in the way in which one's body weight or shape is experienced

Amenorrhea in postmenarche females*

*The diagnostic criteria may be difficult to meet in a younger adolescent; therefore allow for a wide spectrum of clinical features.

TABLE 70.2 When to Hospitalize an Anorexic Patient

Weight loss >25% ideal body weight*

Risk of suicide

Bradycardia, hypothermia

Dehydration, hypokalemia, dysrhythmias

Outpatient treatment fails

*Less weight loss may trigger hospitalization in a young adolescent.

anger, self-blame, focusing attention on the child, ignoring the disorder, or approving the behavior.

The physician should be nonjudgmental, collect information, and assess the differential diagnosis. The **differential diagnosis** of weight loss includes gastroesophageal reflux, peptic ulcer, malignancy, chronic diarrhea, malabsorption, inflammatory bowel disease, increased energy demands, hypothalamic lesions, hyperthyroidism, diabetes mellitus, and Addison disease. Psychiatric disorders must also be considered (e.g., drug abuse, depression, obsessive-compulsive disorder).

The **clinical features** of anorexia can include wearing oversized, layered clothing to hide appearance or, conversely, tight-fitting clothing to exaggerate appearance. Other signs include fine hair on the face and trunk (lanugo-like hair), rough and scaly skin, bradycardia, hypothermia, decreased body mass index, erosion of tooth enamel (due to acid from emesis), and acrocyanosis of the hands and feet. Signs of hyperthyroidism should not be present (see [Chapter 175](#)). The diagnostic criteria for anorexia nervosa are listed in [Table 70.1](#).

Treatment and Prognosis

Treatment requires a multidisciplinary approach with family-based therapy (FBT). Feeding is accomplished through voluntary intake of regular foods, nutritional formula orally, or by nasogastric tube. When vital signs are stable, discussion and negotiation of a detailed treatment contract with the patient and the parents are essential. The first step is to restore body weight. Hospitalization may be necessary ([Table 70.2](#)). When 80% of normal weight is achieved, the patient is given freedom to gain weight at a personal pace. The *prognosis* includes a 3–5% mortality rate (suicide, malnutrition), the development of bulimic symptoms (30% of individuals), and persistent anorexia nervosa syndrome (20% of individuals).

TABLE 70.3 Acute Management of Patients Admitted with Anorexia Nervosa Because of Medical Instability

- Feed slowly with dietitian advice.
- Monitor potassium level as refeeding can cause hypokalemia and hypomagnesemia.
- Monitor vital signs carefully including orthostatic changes in heart rate and blood pressure.
- Observe individual at risk of self-harm.
- Observe individual at risk of increasing exercise even if in bed.
- Involve psychiatry team involvement early in admission to start individual- and family-based therapy.

TABLE 70.4 Diagnostic Criteria for Avoidant/Restrictive Food Intake Disorder (ARFID)

Failure to meet appropriate nutrition/energy needs associated with:

- Significant weight loss (or failure to gain weight in a younger person)
- Significant nutritional deficiency
- Dependence on enteral feeding or nutritional supplements
- Psychosocial functioning affected
- No distortion of body weight or shape image
- No physical or mental reason for abovementioned criteria

BULIMIA NERVOSA

The prevalence of bulimia nervosa is 5% in female college students. The female:male ratio is 10:1. Binge-eating episodes consist of large quantities of what the adolescent perceives as forbidden foods or leftovers, consumed rapidly, followed by vomiting. Metabolic abnormalities can result from the excessive vomiting or laxative and diuretic intake. Binge-eating episodes and the loss of control over eating often occur in young women who are overweight with a history of dieting. The diagnostic criteria for bulimia nervosa is depicted in [Table 70.3](#).

Nutritional, educational, and self-monitoring techniques are used to increase awareness of the maladaptive behavior, following which efforts are made to change the eating behavior. Patients with bulimia nervosa may respond to antidepressant therapy, which may help impulse control and/or depression. There may be family histories of affective disorders. Patients feel embarrassed, guilty, and ashamed of their actions. Attempted suicide and completed suicide (5%) are important concerns.

AVOIDANT RESTRICTIVE FOOD INTAKE DISORDER (ARFID)

ARFID is similar to anorexia nervosa without the body image distress ([Table 70.4](#)). ARFID can present at any age and may be associated with other mental and physical illnesses.

PEARLS FOR PRACTITIONERS

See *Adolescent Medicine: Pearls for Practitioners* at the end of this section.

CHAPTER 71

Substance Abuse

The age at which street drugs are first used is decreasing (<12 years), and female use is rising. Ninety percent of adult smokers begin their habit during the adolescent years. Marijuana and stimulant drug use are increasing. Inhalant use (glue solvents, aerosol products) is prevalent among younger adolescents and in Native Americans. The use of *club drugs* by adolescents from upper-income groups at rave parties (3,4-methylenedioxymethamphetamine [ecstasy]) and so-called date-rape drugs (γ -hydroxybutyrate or flunitrazepam [Rohypnol]) has risen sharply. Anabolic steroid use has increased among adolescent boys seeking enhanced athletic performance.

A history of drug use should be taken in a nonjudgmental and supportive manner and should include the types of substances as well as the frequency, timing, circumstances, and outcomes of substance use. Table 71.1 is a helpful screening tool. There are few physical findings even with chronic adolescent substance use. An adolescent may present in an overdose

TABLE 71.1 CRAFFT: A Screening Tool for Adolescent Substance Abuse

C	Car	Driving under the influence of drugs
R	Relax	Using drugs to relax, fit in, feel better
A	Alone	Drugs/alcohol consumption while alone
F	Forgetting	Forgetting things as a result of drugs/alcohol
F	Family/friends	Family and friends tell teen to stop/cut down
T	Trouble	Getting into trouble because of drugs/alcohol

or in an intoxicated state, or in a psychosis triggered by a hallucinogen, such as phencyclidine (angel dust). Club drugs have direct (coma and seizures) and indirect (sexual assault and dehydration) adverse effects. Anabolic steroids also have direct (gynecomastia and testicular atrophy) and indirect (mood swings and violence) adverse effects.

ACUTE OVERDOSE

Many drugs (most commonly alcohol, amphetamines, opiates, and cocaine) can result in a toxicologic emergency, often with first-time use (Table 71.2). Initial management should be directed at appropriate supportive medical treatment, with follow-up counseling after the toxic effects have diminished.

ACUTE AND CHRONIC EFFECTS

Heavy alcohol use can cause acute gastritis and acute pancreatitis. Intravenous drug use can result in hepatitis B, bacterial endocarditis, osteomyelitis, septic pulmonary embolism, infection, and AIDS. Chronic marijuana or tobacco use is associated with bronchoconstriction and bronchitis. Compulsive drug or alcohol use results in an adolescent being unable to navigate out of the psychosocial sequelae that attend such habituation (e.g., stealing, prostitution, drug dealing, unemployment, school failure, social isolation).

TREATMENT

Specific management of substance use by adolescents depends on many individual patient factors. Because of the highly addictive (physical and psychological) nature of many substances, residential drug treatment facilities are suggested, especially for younger adolescents.

PEARLS FOR PRACTITIONERS

See *Adolescent Medicine: Pearls for Practitioners at the end of this section.*

TABLE 71.2 Substances Abused by Adolescents: Names and Acute Effects

SUBSTANCE (STREET/ALTERNATIVE NAME)	EFFECTS AND FACTS	ROUTE OF ADMINISTRATION (TIME OF ACTION)	DETECTION
Alcohol/liquor	Disinhibition, ataxia, slurred speech, respiratory and CNS depression	Oral (depends on amount and tolerance)	Urine and blood
Nicotine	Relaxation, CNS dependence, \uparrow blood pressure, \uparrow heart rate, \downarrow temperature	Inhaled (minutes); snuffed, dipped, chewed	Urine up to 1 mo
Marijuana (cannabis, weed, joints)	Euphoria, relaxation, \uparrow appetite, \downarrow reaction time	Inhaled (minutes) Oral (30 min+)	Urine up to 1 mo
STIMULANTS			
Cocaine (coke, crack)	Alertness, euphoria Insomnia, \downarrow appetite, irritability, paranoia	Inhaled and snorted (quick high); oral (longer effect)	Urine up to 48 hr
Amphetamines (bennies, black beauties, ice)	Insomnia, \downarrow appetite, irregular heartbeat, hypertension	Inhaled, oral, injection	

TABLE 71.2 Substances Abused by Adolescents: Names and Acute Effects—cont'd

SUBSTANCE (STREET/ ALTERNATIVE NAME)	EFFECTS AND FACTS	ROUTE OF ADMINISTRATION (TIME OF ACTION)	DETECTION
HALLUCINOGENS			
Mescaline (buttons, cactus, mesc)	Psychosis, dilated pupils	Injected, sniffed, ingested (onset: 20–90 min; duration 6–12 hr)	Immunoassay
Psilocybin (magic mushrooms, shrooms)	Dysphoria	Ingested (dry, raw mushrooms; tea) (onset: 20–90 min; duration 6–12 hr)	
LSD (acid)	“Artistic high” “Lucy in the sky with diamonds”	Oral: tablets, liquid, absorbed through mouth using drug-soaked paper (onset: 20–90 min; duration 6–12 hr)	
Phencyclidine (PCP, angel dust)	Microdots in many colors Can induce suicide attempts	Ingested, inhaled, injected (onset: 20–90 min; duration 6–12 hr)	
MDMA (ecstasy, molly) (both stimulant and hallucinogen)	Euphoria, drowsiness, memory impairment	Oral: tablet or liquid (duration: 3–6 hr)	Ecstasy not detected by urine screen
Codeine and morphine	Euphoria, ataxia, miosis, slurred speech	Oral, IV, smoked, snorted, and sniffed	Urine or blood
Heroin (H, horse, smack)	Euphoria, alternating wakefulness and drowsiness	Injected, smoked, snorted	
Opium and heroin (free base)	A common adolescent mix	Injected, smoked	
Oxycodone (cotton, hillbilly)	Pain relief, sedation	Oral, IV, inhaled	
TRANQUILIZERS			
Flunitrazepam (Rohypnol, roofies, date-rape drugs)		Often mixed in alcohol	Urine 1–24 hr
Sedatives (barbs, downers)	Sedation	Oral	Urine or blood
Inhalants (solvents, gasoline)	Like alcohol	Inhaled	
Anabolic steroids	To enhance athletic performance	Oral	Urine

Common side effects (with suggested treatment) of substance abuse drugs are paranoia (haloperidol), seizures (diazepam), hyperthermia (slow cooling), hypertension (β blockers), and opiate overdose (naloxone).

CNS, Central nervous system; MDMA, 3,4-ethylenedioxy-N-methylamphetamine; LSD, lysergic acid diethylamide; PCP, phencyclidine.

PEARLS FOR PRACTITIONERS

CHAPTER 67

Overview and Assessment of Adolescents

General Adolescent

- Leading causes of adolescent deaths in the United States include unintentional injuries (i.e., motor vehicle crashes), suicide, homicide.
- Physical symptoms in an adolescent can be related to psychosocial problems.
- A psychosocial history, including protective and risk-taking behaviors, is important.

Key elements for interviewing an adolescent alone:

- Discussing confidentiality
- Separating the caregiver and adolescent
- Being nonjudgmental—build rapport by discussing activities (social media), movies, etc.
- Use HEADSSS approach (home, education [friends/bullies], activities/alcohol, drugs [including e-cigarettes], diet, depression/suicide, sexual activity, self).
- Explain which issues cannot be kept confidential: suicidal intent, serious harm to someone else, or experiencing or planning physical or sexual abuse/neglect.

Mature Minor

- Has competence and capacity to understand (is not age specific)
- Can be treated without parental consent
- Any intervention should be in the best interest of the minor (and documented)

CHAPTER 68

Well-Adolescent Care

Laboratory and Physical Changes

- High hematocrit values (boys > girls) occur because of androgenic stimulation of the bone marrow.
- Alkaline phosphatase levels increase during puberty because of rapid bone turnover.
- Worsening of mild scoliosis can occur during growth spurt.
- Female puberty: Whites: thelarche (breast budding) 10 yr then pubarche (pubic hair) 11 yr; Blacks: thelarche and pubarche ~ same timing (8 yr, +8–9 mo)
 - Growth spurt occurs 1 year after thelarche at Tanner stage 3 breast
 - Menarche, mean age 12.1 yr (Black), 12.8 yr (White)
- Boys: onset 9–14 yr (Tanner stages 1–2) with testicular enlargement; pubarche (axillary and facial hair, body odor, mild acne)

- Penile enlargement, then growth spurt

STAGE	AGE	CHARACTERISTICS
Early teens	10–14	Focus on appearance; invincible; peer group is everything; no tomorrow; concrete thinking
Middle teens	15–17	Risk taking; experimentation; questioning (Who am I?); no tomorrow; concrete thinking
Late teens	18–21	Future planning; separate from family; partner; formal operational thinking

CHAPTER 69

Adolescent Gynecology

- Evaluation for primary amenorrhea should be initiated by age 15 with secondary sexual characteristics, age 13 without secondary sexual characteristics, or earlier in the presence of cyclic pelvic pain, suspicion of an eating disorder, or hyperandrogenism.
- Pregnancy should be excluded in any adolescent presenting with amenorrhea.
- Treatment in reversible causes of hypothalamic amenorrhea (disordered eating/eating disorder, stress) are directed at changing the underlying state to allow resumption of menses.
- Physiologic anovulation is the most common etiology of abnormal uterine bleeding (AUB) in adolescents; treatment may be required if the associated symptoms affect health status or quality of life.
- A coagulopathy should be considered in adolescents with heavy menstrual bleeding that begins at menarche, especially with anemia or a family/personal history of bleeding.
- Polycystic ovary syndrome (PCOS) is difficult to diagnose in adolescence as it overlaps with many physiologic changes in puberty; the diagnosis should be considered with the persistence of both infrequent menstrual bleeding and clinical or biochemical hyperandrogenism.
- First-line therapies for primary dysmenorrhea should consider the need for contraception for an adolescent and include combined hormonal contraceptives, progestin-only contraception, and levonorgestrel intrauterine device (IUD).
- Failure of nonsteroidal antiinflammatory drugs (NSAIDs) and hormonal contraceptives for dysmenorrhea should prompt investigation for secondary etiologies such as endometriosis, pelvic inflammatory disease (PID), or müllerian anomalies.

- Multidisciplinary adolescent-specific antenatal care can decrease risks associated with teen pregnancy, such as preterm birth, low birthweight infants, and neonatal admissions to intensive care settings.
- Long-acting reversible contraceptives are an acceptable method for adolescents with high continuation rates and should be offered as first-line methods.
- All sexually active teens should be counseled on emergency contraception (EC), in particular those using only condoms.

CHAPTER 70

Eating Disorders

- Anorexia nervosa occurs in 1–2% of teenage girls. There is a female:male ratio of 20:1. Initial signs are behavioral changes in eating, exercise, and mood. Physical signs include oversized clothing, fine hair on face and trunk (lanugo-like hair), bradycardia, hypothermia, decreased body mass index, and erosion of tooth enamel. Diagnostic criteria may be difficult to meet in a younger adolescent.
- Bulimia occurs in 5% of females (with a female:male ratio of 10:1). Patients with bulimia demonstrate binge eating at least twice a week for 3 months or eating excessive food within a set period of time. There is a sense of lack of control, and patients exhibit behavior to prevent gaining weight (vomiting, laxatives, diuretics, and exercise).
- Avoidant/restrictive food intake disorder (ARFID) is similar to anorexia nervosa without the body distress. It can

occur at any age and may be associated with other physical and mental health problems.

- Anorexic patients should be hospitalized when weight loss exceeds 25% of ideal body weight (less weight loss accepted in young adolescent), with a risk of suicide or when outpatient treatment fails. Physiologic signs include bradycardia, hypothermia, dehydration, hypokalemia, and dysrhythmias.

CHAPTER 71

Substance Abuse

- Use the screening tool CRAFFT (car, relax, alone, forgetting, family/friends, trouble) to screen for risk-taking behaviors.
- Substances abused by adolescents may include:
 - Depressants, barbiturates, tranquilizers (Rohypnol, “roofies,” date-rape drugs), opioids (heroin, oxycontin, γ -hydroxybutyrate [GHB]), stimulants (amphetamines [“ice”], cocaine [“crack”], methylphenidate [Ritalin]), hallucinogens (D-lysergic acid diethylamide [LSD], phencyclidine [PCP, “angel dust”], psilocybin [“magic mushrooms”]), marijuana (cannabis, “weed”), ecstasy (club drugs: combinations [i.e., of hallucinogens and amphetamines]), anabolic steroids
- Common side effects (with suggested treatment) of substance abuse drugs are paranoia (haloperidol), seizures (diazepam), hyperthermia (slow cooling), hypertension (β blockers), and opiate overdose (naloxone).

IMMUNOLOGY

John R. Routes | James W. Verbsky

CHAPTER 72

Immunologic Assessment

The major components of host defense include anatomic barriers and the innate and adaptive immune systems (Fig. 72.1). Integrity of the **anatomic and mucociliary barrier** (i.e., skin and mucous membranes) is essential for protection against infection (Table 72.1). The **innate immune system** acts as the first line of defense against pathogens, responding rapidly but nonspecifically before development of the more versatile **adaptive immune system**. The innate immune system includes soluble factors, including acute-phase proteins, cytokines, chemokines, and complement, as well as cellular components, including neutrophils, monocytes/macrophages, innate lymphoid cells, and natural killer (NK) cells. The adaptive immune system consists of T and B lymphocytes and their effector molecules (Table 72.2).

Recognition of pathogens by the innate immune system is facilitated by receptors on macrophages, NK cells, and neutrophils that recognize conserved pathogen motifs called **pathogen-associated molecular patterns (PAMPs)** such as lipopolysaccharide of gram-negative bacteria, lipoteichoic acid of gram-positive bacteria, mannans of yeast, and specific nucleotide sequences of bacterial and viral DNA. Recognition of PAMPs by the innate immune system leads to the production of cytokines that initiate inflammation and induce an acute phase response (e.g., C-reactive protein, mannose-binding lectin, complement) and chemokines that recruit inflammatory cells; this results in activation of the adaptive immune system. Complement protein activation on pathogens facilitates their uptake by phagocytic cells or results in lysis of pathogens. Polymorphonuclear neutrophils ingest pyogenic bacteria and some fungi. Macrophages are effective in killing facultative intracellular organisms such as *Mycobacterium*, *Toxoplasma*, *Salmonella*, and *Legionella*. NK lymphocytes mediate cytotoxic activity against virus-infected cells and cancer cells.

FIGURE 72.1 Integrated human immune system. The human microbial defense system can be simplistically viewed as consisting of three levels: (1) anatomic and physiologic barriers, (2) innate immunity, and (3) adaptive immunity. In common with many classification systems, some elements are difficult to categorize. For example, natural killer T cells and dendritic cells could be classified as being on the cusp of innate and adaptive immunity rather than being firmly in one camp. (From Turvey SE, Broide DH. Innate immunity. *J Allergy Clin Immunol.* 2010;125:S24-S32 [Fig. 1].)

TABLE 72.1 Anatomic and Mucociliary Defects that Result in Recurrent or Opportunistic Infections

ANATOMIC DEFECTS IN UPPER AIRWAYS
Aspiration syndromes (gastroesophageal reflux, ineffective cough, foreign body)
Cleft palate, choanal atresia, eustachian tube dysfunction
Adenoidal hypertrophy
Nasal polyps
Obstruction of paranasal sinus drainage (osteomeatal complex disease), encephaloceles
Post-traumatic or congenital sinus tracts (CSF rhinorrhea)
ANATOMIC DEFECTS IN THE TRACHEOBRONCHIAL TREE
Tracheoesophageal fistula, bronchobiliary fistula, CPAM
Pulmonary sequestration, bronchogenic cysts
Vascular ring
Tumor, foreign body, or enlarged lymph nodes
PHYSIOLOGIC DEFECTS IN UPPER AND LOWER AIRWAYS
Primary ciliary dyskinesia syndromes
Cystic fibrosis
Bronchopulmonary dysplasia
Bronchiectasis
Allergic disease (allergic rhinitis, asthma)
Chronic cigarette smoke exposure
OTHER DEFECTS
Burns
Exfoliative cutaneous lesions*
Chronic atopic dermatitis
Ureteral obstruction, vesicoureteral reflux
IV drug use
Central venous line, artificial heart valve, CSF shunt, peritoneal dialysis catheter, urinary catheter
Dermal sinus tract

CPAM, Congenital pulmonary airway malformation; CSF, cerebrospinal fluid; IV, intravenous.

*Toxic epidermal necrolysis, Steven-Johnson syndrome, epidermolysis bullosa.

The key features of the **adaptive immune system** are antigen specificity and the development of immunologic memory, produced by expansion and maturation of antigen-specific T cells and B cells. Antibodies (immunoglobulin) produced by **B cells** neutralize toxins released by pathogens, opsonize pathogens to facilitate uptake by phagocytic cells, activate complement causing cytolysis of the pathogen, and direct NK cells to kill infected cells through antibody-mediated cytotoxicity. **T cells** kill virus-infected cells and cancer cells, activate macrophages to kill intracellular pathogens, and deliver signals necessary for B-cell antibody synthesis and memory B-cell formation. Immunodeficiency can result from defects in one

or more components of innate or adaptive immunity, and lead to recurrent, chronic, opportunistic, or life-threatening infections. Primary immunodeficiency diseases are relatively rare individually, but together they cause significant chronic disease, morbidity, and mortality (Table 72.3).

HISTORY

The frequency, severity, and location of infections and the pathogens involved can help differentiate infections in a normal host from infections in an immunodeficient patient (see Table 72.3). Frequent infections, intractable infections, invasive or deep seeded infections, infections that require multiple courses of oral or intravenous antibiotics, or infections with opportunistic pathogens suggest a primary immunodeficiency. Recurrent sinopulmonary infections with encapsulated bacteria suggest a defect in antibody-mediated immunity because these pathogens evade phagocytosis. Failure to thrive, diarrhea, malabsorption, and infections with opportunistic pathogens (i.e., fungi, *Candida* sp., *Pneumocystis jirovecii*) suggest T-cell immunodeficiency. Recurrent viral infections can result from T-cell or NK-cell deficiency. Deep-seated abscesses and infections with *Staphylococcus aureus*, *Serratia marcescens*, and *Aspergillus* suggest a disorder of neutrophil function, such as chronic granulomatous disease (CGD). **Delayed separation of the umbilical cord**, especially in the presence of omphalitis, severe periodontal disease, and poorly formed abscesses, suggests leukocyte adhesion deficiency (LAD). Invasive neisserial infections or early-onset autoimmunity may suggest a complement defect.

Age of onset of symptoms can be helpful in defining an immune deficiency, although significant variability occurs. Neutrophil defects (e.g., congenital neutropenia, LAD, CGD) typically present in the first several months of life. Antibody defects (e.g., congenital agammaglobulinemia) and severe T-cell defects (e.g., severe combined immunodeficiency [SCID]) typically present after 3 months of life after maternal antibody levels have waned. Presentation with symptoms of an antibody deficiency later in life (adolescence or adulthood) suggests common variable immunodeficiency (CVID) rather than congenital agammaglobulinemia, although milder phenotypes of primary immunodeficiency disease may not present until later in life. The presence of associated problems, such as congenital heart disease and hypocalcemia (DiGeorge syndrome), abnormal gait and telangiectasia (ataxia-telangiectasia), atopic dermatitis (hyper-IgE syndrome, Omenn syndrome), and easy bruising or bleeding (Wiskott-Aldrich syndrome), can be informative in guiding the work-up. Early-onset autoimmunity, such as autoimmune cytopenias, and early-onset inflammatory bowel disease are important risk factors for development of primary immunodeficiencies. A **family history** of a primary immune deficiency or death of a young child due to infections should prompt an immune evaluation, particularly in the setting of recurrent infections.

PHYSICAL EXAMINATION

A meticulous physical examination is essential in the evaluation of possible primary immunodeficiencies. Height and weight percentiles, nutritional status, and presence of subcutaneous fat should be assessed to exclude failure to thrive, which is present in many serious primary immunodeficiencies.

TABLE 72.2 Cytokines and Chemotactic Cytokines and Their Functions

FACTOR	SOURCE	FUNCTION
IL-1	Macrophages	Co-stimulatory effect on T cells, enhances antigen presentation, acute phase response, fever
IL-2	T cells	Primary T-cell growth factor; B-cell and NK-cell growth factors; required for T-regulatory cell function and survival
IL-3	T cells	Mast cell growth factor; multiclonal-stimulating factor
IL-4	T cells	T-cell growth factor; enhances IgE synthesis; enhances B-cell differentiation; mast cell growth
IL-5	T cells	Enhances eosinophil differentiation; enhances immunoglobulin synthesis; enhances IgA synthesis
IL-6	T cells, macrophages, fibroblasts, endothelium	Enhances immunoglobulin synthesis, antiviral activity, induces acute phase response, fever, hematopoietic effects
IL-7	Stromal cells	Enhances growth of pre-T cells
IL-8	T cells, macrophages, epithelium	Neutrophil-activating protein; T-lymphocyte and neutrophil chemotactic factor
IL-9	T cells	Acts in synergy with IL-4 to induce IgE production, mast cell growth
IL-10	T cells, including regulatory T cells, macrophages	Cytokine synthesis inhibitory factor; suppresses macrophage function; enhances B-cell growth; inhibits IL-12 production; suppresses inflammation at mucosal surfaces
IL-12	Macrophages, neutrophils	NK-cell stimulatory factor; cytotoxic lymphocyte maturation factor; enhances IFN- γ synthesis; inhibits IL-4 synthesis
IL-13	T cells	Enhances IgE synthesis; enhances B-cell growth; inhibits macrophage activation; causes airway hyperreactivity
IL-17	T cells	Induces IL-1 β and IL-6 synthesis, important in fungal infections
IL-18	Macrophages	Enhances IFN- γ synthesis
IFN- γ	T cells	Macrophage activation; inhibits IgE synthesis; antiviral activity
TGF- β	T cells, including regulatory T cells, many other cells	Inhibits T-cell and B-cell proliferation and activation, induces T-regulatory cells
RANTES	T cells, endothelium	Chemokine for monocytes, T cells, eosinophils
MIP-1 α	Mononuclear cells, endothelium	Chemokine for T cells; enhances differentiation of CD4 ⁺ T cells
Eotaxin 1, 2, and 3	Epithelium, endothelium, eosinophils, fibroblasts, macrophages	Chemokine for eosinophils, basophils, and Th2 cells
IP-10	Monocytes, macrophages, endothelium	Chemokine for activated T cells, monocytes, and NK cells

IFN, Interferon; Ig, immunoglobulin; IL, interleukin; NK, natural killer; RANTES, regulated on activation, normal T expressed and secreted; TGF- β , transforming growth factor β ; Th2, T-helper 2.

A comprehensive examination of the upper and lower respiratory tract should be performed, paying careful attention for the presence or absence of tonsillar tissue, scarring or perforation of the tympanic membranes, purulent discharge from the nares, oral thrush, aphthous ulcers, or abnormal breath sounds such as rales and rhonchi. Abnormalities in the respiratory tract examination may be consistent with past or ongoing upper or lower respiratory tract infections. A complete lymph node examination should also be performed, including lymph nodes that are frequently not examined such as axillary, inguinal, popliteal, and supraclavicular lymph nodes. Absent tonsillar and lymphoid tissue occur in severe combined immunodeficiency and congenital forms of agammaglobulinemia, whereas lymphadenopathy and splenomegaly are found

in CVID and autoimmune lymphoproliferative syndrome (ALPS). The presence or absence of skin abnormalities such as petechiae, scarring from recurrent skin infections, severe eczema, telangiectasias or chronic infections (molluscum contagiosum, candida) may help lead to the diagnosis of a variety of primary immunodeficiencies such as hyper-IgE syndrome, ataxia-telangiectasia, Wiskott-Aldrich syndrome, or mucocutaneous candidiasis.

DIFFERENTIAL DIAGNOSIS

There are many secondary causes of immunodeficiency that should be considered, particularly if the immunologic testing is nonrevealing (Table 72.4). In patients with primary

TABLE 72.3 Clinical Characteristics of Primary Immunodeficiencies	
B-CELL DEFECTS	
Recurrent pyogenic infections with extracellular encapsulated organisms (such as <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> type b, and group A streptococcus), <i>Mycoplasma</i> sp., and <i>Ureaplasma</i> sp., as well as <i>Giardia</i> and enteroviruses	
Otitis, sinusitis, recurrent pneumonia, bronchiectasis, and conjunctivitis	
Few problems with fungal or viral infections (except enterovirus and poliomyelitis)	
Diarrhea common, especially secondary to infection with <i>Giardia lamblia</i> and due to enteropathy	
Minimal growth retardation	
Long-term survival expected with early diagnosis and treatment except in cases with severe autoimmunity-immune dysregulation	
COMPLEMENT DEFECTS	
Recurrent bacterial infections with extracellular encapsulated organisms, such as <i>S. pneumoniae</i> and <i>H. influenzae</i>	
Susceptibility to recurrent infections with <i>Neisseria meningitidis</i>	
Increased incidence of autoimmune disease	
Severe or recurrent skin and respiratory tract infection	
T-CELL DEFECTS	
Recurrent infections with common pathogens as well as less virulent pathogens or opportunistic organisms, such as fungi, <i>Candida</i> sp., atypical mycobacteria, <i>Pneumocystis jirovecii</i> , viruses, and protozoa as well as bacteria	
Growth retardation, malabsorption, diarrhea, and failure to thrive common	
Anergy	
Susceptible to graft versus host disease from nonirradiated blood or from maternal engraftment	
Fatal reactions may occur from live virus or bacille Calmette-Guérin vaccination	
Increased incidence of malignancy	
Poor survival beyond infancy or early childhood in the absence of stem cell transplantation	
NEUTROPHIL DEFECTS	
Recurrent dermatologic infections with bacteria such as <i>Staphylococcus</i> , <i>Pseudomonas</i> , and <i>Escherichia coli</i> , <i>Nocardia</i> , and fungi such as <i>Aspergillus</i>	
Subcutaneous, lymph node, lung, and liver abscesses	
Pulmonary infections common, including abscess and pneumatocele formation, contributing to chronic disease	
Bone and joint infection common	
Delayed separation of umbilical cord	
Absence of pus at site(s) of infection	
Poor wound healing	
TOLL-LIKE RECEPTOR DEFECTS	
Recurrent bacteremia, meningitis; pneumococcus, <i>Staphylococcus aureus</i> , <i>Pseudomonas</i> , meningococcus; herpes simplex	
Lack of fever	
Early-onset infections with <i>S. aureus</i> or <i>Streptococcus pyogenes</i> with a normal immune workup	

TABLE 72.4 Causes of Secondary Immunodeficiency	
VIRAL INFECTIONS	
HIV (destroys CD4 T cells)	
Measles	
Rubella	
Influenza	
METABOLIC DISORDERS	
Diabetes mellitus	
Malnutrition	
Advanced renal or liver disease	
Sickle cell disease	
Zinc and vitamin deficiency	
Multiple carboxylase deficiency	
Burns	
PROTEIN-LOSING STATES	
Nephrotic syndrome	
Protein losing enteropathy	
OTHER CAUSES	
Prematurity	
Immunosuppressive agents (e.g., corticosteroids, radiation, and antimetabolites)	
Malignancy (leukemia, Hodgkin disease, nonlymphoid cancer)	
Acquired asplenia	
Acquired neutropenia (autoimmune, viral, or drug induced)	
Stem cell transplantation/graft versus host disease	
Systemic lupus erythematosus and other autoimmune diseases	
Sarcoidosis	

immunodeficiencies, infections develop at multiple sites (e.g., ears, sinuses, lungs, skin); individuals with anatomic problems (e.g., sequestered pulmonary lobe, ureteral reflux) experience infections confined to a single anatomic site. Asplenia is associated with recurrent and severe infections, even in the presence of protective antibody titers. Infection with HIV should be considered at any age in any patient presenting with a history of opportunistic infections.

DIAGNOSTIC EVALUATION

The diagnosis of patients with primary immunodeficiency diseases depends on early recognition of signs and symptoms followed by laboratory tests to evaluate immune function (Fig. 72.2; see Table 72.3).

Laboratory Tests

A diagnosis of primary immunodeficiency disease cannot be established without the use of laboratory tests guided by the

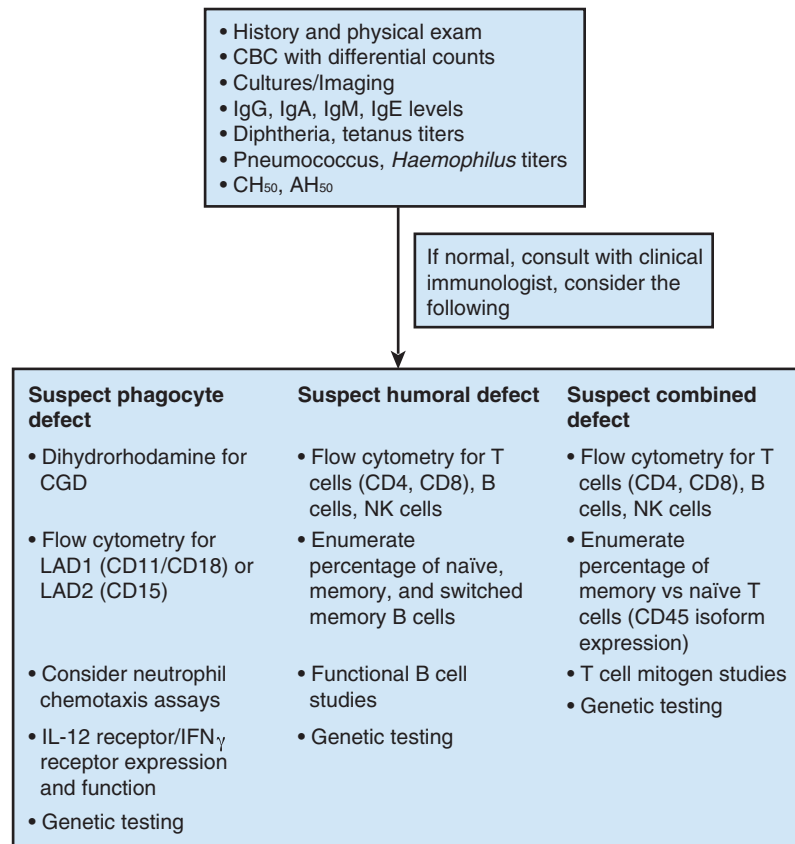

FIGURE 72.2 Initial work-up and follow-up studies of patients with suspected immune deficiency. Consultation with a clinical immunologist is recommended to guide advanced testing and interpret results. *CBC*, Complete blood count; *CGD*, chronic granulomatous disease; *IFN*, interferon; *Ig*, immunoglobulin; *IL*, interleukin; *LAD*, leukocyte adhesion defect; *NK*, natural killer cell. (From Kliegman RM, Lye PS, Bordini BJ, et al., eds. *Nelson Pediatric Symptom-Based Diagnosis*. Philadelphia: Elsevier; 2018 [fig. 41.1].)

clinical history (Table 72.5). A **complete blood count with differential** should always be obtained to identify neutropenia or lymphopenia (SCID) as well as the presence of eosinophils (allergic disease) and anemia (chronic disease). **Serum immunoglobulin levels (serum IgG, IgA, IgM, and IgE)** are essential. Antibody levels vary with age, with normal adult values of immunoglobulin G (IgG) at full-term birth from transplacental transfer of maternal IgG, a physiologic nadir occurring between 3 and 6 months of age, and a gradual increase to adult values over several years. IgA and IgM are low at birth and increase gradually over several years; IgA takes the longest to reach normal adult values. Low albumin levels with low immunoglobulin levels suggest low synthetic rates for all proteins or increased loss of proteins, as in protein-losing enteropathy. Elevated immunoglobulin levels suggest intact B-cell immunity and can be found in diseases with recurrent infections, such as CGD, primary ciliary dyskinesia, cystic fibrosis, HIV infection, and autoimmune diseases. Elevated IgE levels occur in a number of immune deficiencies such as hyper-IgE syndrome as well as in atopic diseases, allergic bronchopulmonary aspergillosis, and tissue invasive parasites. Undiagnosed atopic disease such as asthma, where viral respiratory tract infections can lead to chronic cough, frequently masquerade as a primary immunodeficiency.

Specific antibody titers after childhood vaccination (tetanus, diphtheria, *Haemophilus influenzae* type b, or *Streptococcus pneumoniae* vaccines) reflect the capacity of the immune system to synthesize specific antibodies and to develop memory B cells. If titers are low, immunization with a specific vaccine and titers obtained 4–6 weeks later can confirm response to the immunization. Poor response to bacterial polysaccharide antigens is normal before 24 months of age but is also associated with specific antibody deficiency. The development of protein-conjugate polysaccharide vaccines prevents infections with encapsulated organisms in early childhood. Antibody responses to the *S. pneumoniae* serotypes found in the 23-valent polysaccharide vaccine, but not in the conjugate vaccine, can be used to test antibody responses to polysaccharide antigens.

Delayed-type hypersensitivity skin tests to protein antigens such as tetanus, diphtheria, *Candida*, or mumps are used as a measurement of T-cell function and specifically demonstrate the presence of antigen-specific T cells and functional antigen-presenting cells. Due to the drawbacks of delayed-type hypersensitivity skin testing (need to be read 72 hours after subcutaneous injection of antigen; occasional exaggerated, painful delayed skin reactions; or anergic responses of control antigens), T-cell proliferation assays (see later) are

TABLE 72.5 Tests for Suspected Immune Deficiency

GENERAL
Complete blood count, including hemoglobin, white blood cell count with differential and morphology, and platelet count including mean platelet volume (MPV)
Radiographs to document infection in chest, sinus, mastoids, and long bones, if indicated by clinical history
Cultures, if appropriate
ANTIBODY-MEDIATED IMMUNITY
Quantitative immunoglobulin levels: IgG, IgA, IgM, IgE, isohemagglutinin titers (anti-A, anti-B, measures IgM function)
Specific antibody levels:
Protein antigens: diphtheria, tetanus
Protein-conjugated antigens: <i>Haemophilus influenzae</i> , <i>Streptococcus pneumoniae</i> (conjugate vaccine)
Polysaccharide antigens: <i>S. pneumoniae</i> (unconjugated vaccine); <i>Salmonella typhi</i> Vi vaccine
B-cell numbers and subsets by flow cytometry
CELL-MEDIATED IMMUNITY
Lymphocyte count and morphology
Delayed hypersensitivity skin tests (<i>Candida</i> , tetanus toxoid, mumps): measure T-cell and macrophage function
T-cell and NK-cell numbers and subsets by flow cytometry T-lymphocyte functional analyses (mitogen responses, cytokines)

often substituted for delayed-type hypersensitivity skin testing to assess T-cell function.

Lymphocyte phenotyping by flow cytometry enumerates the percentage and absolute numbers of T-cell, B-cell, and NK-cell subsets. Flow cytometry can also test for the presence of proteins that are necessary for normal immunity, such as major histocompatibility complex molecules or adhesion molecules, as well as intracellular analysis of signaling proteins and cytokines. **T-cell proliferation** assays to mitogens (phytohemagglutinin, concanavalin A, pokeweed mitogen, or CD3) or antigens (tetanus toxoid or *Candida*) are in vitro assays

that assess the capacity of T cells to proliferate in response to a nonspecific stimulus (mitogens) or the presence of antigen-specific memory T cells (antigens). **Tests for cytokine synthesis, intracellular signaling pathways, or expression of activation markers** may be performed in specialized research laboratories.

Complement assays include the CH₅₀ test, which measures the presence of proteins in the classic pathway of complement (C1, C2, C3, C4), and the AH₅₀ test, which tests the proteins of the alternative pathway of complement (C3, factor B, properdin). If both the CH₅₀ and AH₅₀ levels are abnormal, a defect in the common pathway is likely (C5–C9). Specialized laboratories measure the presence or function of specific complement proteins. Tests for C1-inhibitor antigen levels and function are used to diagnose hereditary or acquired angio-neurotic edema.

Tests for neutrophil function include the nitroblue tetrazolium (NBT) or the more commonly used dihydrorhodamine 123 (DHR) assay. Both the DHR and NBT tests assess the ability of neutrophils to generate a respiratory burst generated by the enzyme complex NADPH oxidase, which is abnormal in CGD. In the DHR test, neutrophils are treated with dihydrorhodamine then activated, which normally leads to the production of superoxide. Superoxide subsequently leads to the production of H₂O₂, which oxidizes the dihydrorhodamine to rhodamine-1,2,3 emitting a robust fluorescent signal which is quantitated by flow cytometry. Neutrophils from CGD patients produce low or no superoxide (markedly reduced fluorescence). Other in vitro tests for neutrophils include phagocytosis, chemotaxis, and bacterial killing, which are available in specialized clinical immunology laboratories. Tests for the expression of adhesion molecules such as CD18 (leukocyte function-associated antigen type 1 [LFA-1]) and CD15 (LFA-2) can also be performed by flow cytometry.

Genetic testing to confirm the diagnosis of a primary immunodeficiency is often needed. Defining a genetic cause facilitates the optimal course of treatment, determining the natural history and prognosis of the disease, and aids in genetic counseling and prenatal diagnosis. Genetic panels, which include genes known to be implicated in specific types of immunodeficiencies, are frequently performed. More extensive genetic testing, such as whole exome sequencing, may be used in particularly complicated cases or when individual genetic panels fail to yield a diagnosis. Fluorescent in situ hybridization or chromosomal microarray studies (preferred) detect specific deletions or duplications that occur in syndromes associated with immunodeficiency (e.g., DiGeorge syndrome).

Diagnostic Imaging

Radiographic studies may screen for commonly found abnormalities associated with the specific immunodeficiency. A CT scan of the chest can reveal bronchiectasis in patients with serious antibody deficiencies such as common variable immunodeficiency. Chest radiographs may detect the presence or absence of a thymus. Abnormalities in the cerebellum are found by MRI in patients with ataxia telangiectasia.

PEARLS FOR PRACTITIONERS

See *Immunology: Pearls for Practitioners* at the end of this section.

CHAPTER 73

Lymphocyte Disorders

Hematopoietic stem cells give rise to lymphoid precursors that develop into T lymphocytes in the thymus or B lymphocytes in the bone marrow (Fig. 73.1). Isolated B-cell disorders result in **antibody deficiency diseases**, whereas T-cell disorders usually cause **combined immunodeficiency** because they are necessary for cell-mediated immunity to clear intracellular pathogens and for antibody synthesis by B cells. Natural killer (NK) cells are an important component of the **innate immune response**, develop from lymphoid precursors, and can kill virus-infected cells and tumor cells. Antibodies can enhance NK-cell function by antibody-mediated cellular cytotoxicity.

ETIOLOGY AND CLINICAL MANIFESTATIONS

Antibody Deficiency Diseases

Disorders of B cells result in an increased susceptibility to infections by encapsulated bacteria, mycoplasma, and certain

viruses. **Agammaglobulinemia** results from the absence or defective function of B cells with subsequent severe decrease in immunoglobulin (Ig) levels and an absence of specific antibody. **X-linked agammaglobulinemia (XLA)**, which accounts for approximately 80% of all congenital agammaglobulinemias, is characterized by a profound deficiency of B cells, severe panhypogammaglobulinemia, and absence of lymphoid tissue (Table 73.1; see Fig. 73.1). The defect is caused by mutations in the gene *Btk* encoding the tyrosine kinase. *Btk* is necessary for downstream signaling of the pre-B-cell receptor and the B-cell antigen receptor, which is necessary for normal differentiation of B cells. **Autosomal recessive agammaglobulinemia** presents similar to XLA, is due to defects in components of the pre-B-cell and B-cell antigen receptor complexes, and includes mutations in the μ heavy-chain gene, $\lambda 5$, $Ig\alpha$, $Ig\beta$, and *BLNK*.

Patients with agammaglobulinemia usually present during the first 6–12 months of life as maternally derived antibodies wane; patients can present years later. These patients develop infections with *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, *Staphylococcus aureus*, *Mycoplasma*, and *Pseudomonas*, organisms for which antibody is an important opsonin. They also have increased susceptibility to giardiasis

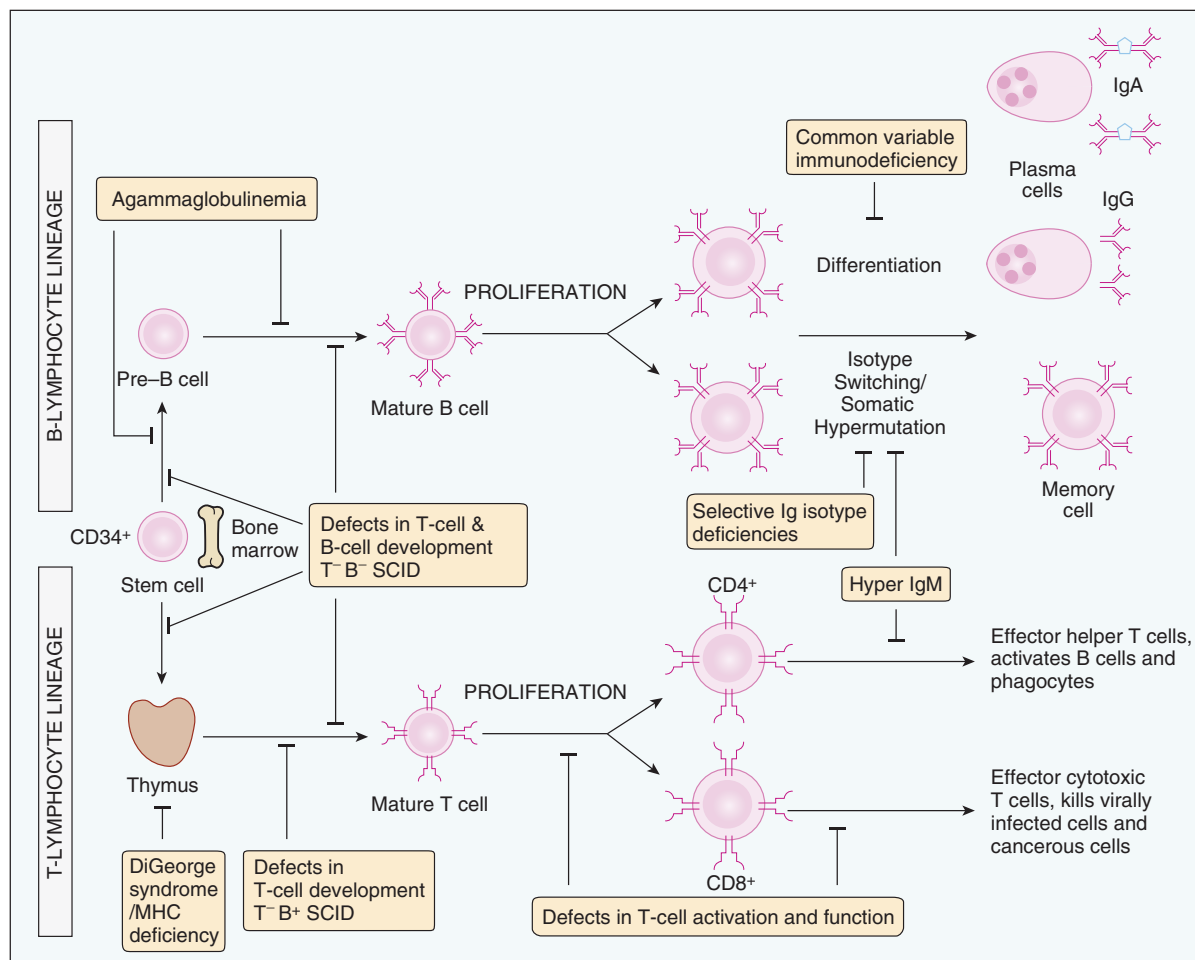

FIGURE 73.1 Sites of cellular abnormalities in congenital immunodeficiencies. In primary immunodeficiency diseases, the maturation or activation of B or T lymphocytes may be blocked at different stages. *B*, B lymphocyte; *Ig*, immunoglobulin; *MHC*, major histocompatibility complex; *SCID*, severe combined immunodeficiency; *T*, T lymphocyte. TABLE 73.1 Antibody Deficiency Diseases

DISORDER	GENETICS	ONSET	MANIFESTATIONS	PATHOGENESIS	ASSOCIATED FEATURES
Agammaglobulinemia	X-linked, AR	Infancy (6–9 mo)	Recurrent infections, sinusitis, pneumonia, meningitis (encapsulated bacteria, enteroviruses, atypical bacteria)	Arrest in B-cell differentiation (pre-B level); mutations in: <i>Btk</i> gene (X-linked); μ -chain, BLNK, $Ig\alpha$, $Ig\beta$, $\lambda 5$, BLNK (AR)	Lymphoid hypoplasia
Common variable immunodeficiency	AR; AD; sporadic	2nd to 3rd decade	Sinusitis, bronchitis, bronchiectasis pneumonia, interstitial lung disease, chronic diarrhea, autoimmune cytopenias, lymphomas	Arrest in plasma cell differentiation, mutations in ICOS, TACI, CD19, CD81, CD20, CD21 and other genetic causes leading to CVID-like disorders	Autoimmune disease, RA, SLE, Graves disease, ITP, malignancy, multisystemic granulomatous disease
Transient hypogammaglobulinemia of infancy		Infancy (3–7 mo)	Recurrent viral and pyogenic infections	Unknown; delayed plasma cell maturation	Frequently in families with other immunodeficiencies
IgA deficiency	Variable	Variable	Most normal, sinopulmonary infections	Failure of IgA expression	IgG subclass deficiency common, autoimmune diseases
IgG subclass deficiency	Variable	Variable	Most normal, sinopulmonary infections	Defect in IgG isotype production	IgA deficiency, ataxia telangiectasia, polysaccharide antibody deficiency
Specific antibody deficiency	Variable	After 2yr of age	Sinopulmonary infections	Unknown	IgG subclass deficiency
Hyper-IgM syndrome	AR	Variable	Sinopulmonary infections	Defect in AID, UNG	Autoimmunity

AD, Autosomal dominant; AID, activation-induced cytidine deaminase; AR, autosomal recessive; Ig, immunoglobulin; ITP, idiopathic thrombocytopenic purpura; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; UNG, uracil-DNA glycosylase.

and enteroviral infections and vaccine-associated poliomyelitis (if immunized with oral live, attenuated poliovirus vaccine).

Common variable immunodeficiency (CVID) is a heterogeneous disorder characterized by hypogammaglobulinemia developing after an initial period of normal immune function, most commonly in the second and third decades of life (see Table 73.1). Serum IgG levels are less than 500 mg/dL (usually <300 mg/dL) with IgA levels less than 10 mg/dL and/or low IgM levels. Secondary causes of hypogammaglobulinemia (e.g., corticosteroids, rituximab, protein losing enteropathy) can present with a preferential reduction in IgG but can have normal IgA or IgM levels. Antibody titers to polysaccharide antigens, such as pneumococcus, are nearly always absent. Reduced specific antibody responses to protein antigens, such as tetanus and diphtheria, are frequently abnormal. T-cell numbers and function are highly variable. Although B-cell numbers are variable, they are typically present, which helps distinguish CVID from congenital agammaglobulinemia. Patients exhibit normal-sized or enlarged tonsils and lymph nodes and may have splenomegaly. They are susceptible to frequent respiratory tract infections due to *S. pneumoniae*, *H. influenzae* type b, and *Mycoplasma*. Gastrointestinal infections with *Giardia*, *Campylobacter*, *Salmonella*, *Helicobacter*, and enteroviruses are common. Noninfectious complications due to autoimmune disease (e.g., autoimmune cytopenias), malignancies (e.g., B-cell lymphomas), and disorders of immune-dysregulation (e.g., multisystemic granulomatous disease, interstitial lung disease, nodular regenerative

hyperplasia of the liver, enteropathy, and inflammatory bowel disease) occur in a substantial proportion of subjects and are the major causes of morbidity and mortality.

The gene defects leading to most cases of CVID are largely unknown. Increasing use of DNA sequencing reveals monogenic disorders as the cause of some CVID or CVID-like immunodeficiencies, especially with early-onset CVID or CVID complicated by autoimmunity or disorders of immune regulation. In patients with early-onset CVID, it is important to exclude congenital agammaglobulinemia and other monogenic disorders that can present with CVID-like immunodeficiencies (e.g., *CLTA4*, *LRBA*, *PIK3CD*). Some patients have a defect in inducible co-stimulator (ICOS), transmembrane activator and calcium-modulating cyclophilin ligand interactor (TACI), CD19, CD21, CD81, or BAFF-R. Before making the diagnosis of CVID, X-linked agammaglobulinemia, X-linked lymphoproliferative disease, or hyper-IgM syndrome as well as other causes of hypogammaglobulinemias (e.g., protein losing enteropathy) should be excluded.

Selective **IgA deficiency** is defined as serum IgA levels less than 10 mg/dL with normal levels of the other Ig isotypes. The diagnosis cannot be confirmed until the patient is at least 4 years of age when IgA levels usually reach adult levels. Selective IgA deficiency occurs in approximately 1 in 500 individuals. Most patients with selective IgA deficiency are asymptomatic. A small percentage of patients present with recurrent sinopulmonary infections, which may be associated with specific antibody deficiency and/or IgG₂ subclass

FIGURE 73.2 Schematic representation of the interaction between a CD4 T cell and a B cell. T-cell activation follows T-cell receptor (TCR) recognition of peptide antigen presented via major histocompatibility complex (MHC) class II molecules resulting in CD40 ligand (CD40L) expression and cytokine synthesis. CD40L stimulates the B cell via CD40, resulting in expression of co-stimulatory molecules (B7) that are important in T-cell priming and cytokine synthesis that drives T-cell differentiation. CD40 and cytokine signaling in B cells activate activation-induced cytidine deaminase (AID) and uracil-DNA glycosylase (UNG) to promote Ig isotype switching and somatic hypermutation. Defects in CD40L cause X-linked hyper-IgM (X-HIM), and defects in CD40, AID, or UNG cause autosomal recessive hyper IgM (AR-HIM). Defects in either CD40L or CD40 affect T-cell co-stimulation and priming, leading to T-cell defects and susceptibility to opportunistic infections, whereas defects in AID and UNG maintain normal T-cell co-stimulation and function.

deficiency. In selected cases, patients may require antibiotic prophylaxis and, rarely, antibody replacement therapy. Patients with IgA deficiency are at increased risk to develop atopic diseases, selected autoimmune diseases, and celiac disease. Some cases of IgA deficiency occur in families, suggesting autosomal inheritance.

IgG subclass deficiency occurs when the level of antibodies in one or more of the four IgG subclasses is selectively decreased while total IgG levels are normal. Normal individuals can express low levels or absence of one or more subclasses, so a history of significant and recurrent infections is important. An inability to synthesize specific antibody titers to protein or polysaccharide antigens is the best marker of clinically significant IgG subclass deficiency that leads to recurrent infections.

Transient hypogammaglobulinemia of infancy is a temporary condition characterized by a prolongation of the physiologic hypogammaglobulinemia of infancy. The Ig nadir at 6 months of age is accentuated, with Ig levels less than 200 mg/dL. Ig levels remain diminished throughout the first year of life and usually increase to normal, age-appropriate levels by 2–4 years of age. The incidence of sinopulmonary infection is increased in some patients. The diagnosis is supported by normal levels of both B and T cells and by normal antibody responses to protein antigens such as diphtheria and tetanus toxoids. The transient nature of this disorder cannot be confirmed, however, until Ig levels return to normal ranges.

Specific antibody deficiency syndrome is characterized by recurrent infections with normal Ig levels and normal lymphocyte numbers and subsets, but an inability to synthesize specific antibody to polysaccharide antigens, such as to the 23-valent pneumococcal vaccine. The pathogenesis of this disorder is unknown. In selected, rare patients, specific antibody deficiency may be responsible for increased sinopulmonary infection and require either antibiotic prophylaxis or immunoglobulin replacement therapy.

Combined Immunodeficiency Diseases

Disorders that affect T-cell development or function usually result in combined immunodeficiency because T cells provide necessary signals for B-cell differentiation. **X-linked hyper-IgM syndrome**, the most common form of hyper-IgM syndrome, is a combined immunodeficiency with deficient T-cell function due to defects in CD40 ligand. Defects in CD40 cause **autosomal recessive hyper-IgM syndrome** and present similarly to X-linked hyper-IgM syndrome (Fig. 73.2; Table 73.2). Hyper-IgM syndrome is characterized by a failure of Ig isotype switching from IgM and IgD to IgG, IgA, or IgE and lack of memory responses. Affected patients have normal or elevated serum levels of IgM with low or absent levels of IgG, IgA, and IgE. Ig isotype switching allows a B cell to maintain antigen specificity while altering Ig function and is directed by cytokines and interaction between CD40 ligand on CD4

DISORDER	GENETICS	ONSET	MANIFESTATIONS	PATHOGENESIS	ASSOCIATED FEATURES
Hyper-IgM syndrome (see Table 73.1)	X-linked, AR	First year	Sinopulmonary infections, opportunistic infections, <i>Pneumocystis jirovecii</i>	Defect in CD40 ligand (X-linked) or CD40 (AR)	Neutropenia, liver disease, cancer
DiGeorge anomaly	22q11.2 (or 10p) deletion	Newborn, early infancy	Hypocalcemic tetany, pyogenic infections, partial or complete T-cell deficiency	Hypoplasia of third and fourth pharyngeal pouch	Congenital heart disease (aortic arch anomalies), hypoparathyroidism, micrognathia, hypertelorism
Severe combined immunodeficiency (T– B+ SCID)	X-linked; AR	1–3 mo	Candidiasis, all types of infections, failure to thrive, chronic diarrhea	Mutation in IL-2R γ chain, Jak3 kinase, ZAP-70, IL-7R α , CD3 subunits	GVHD from maternal-fetal transfusions, severe GVHD from nonirradiated blood transfusion
Severe combined immunodeficiency (T– B– SCID)	AR	1–3 mo	Same as T– B+ SCID	Mutation in RAG1/2, Artemis, ADA/PNP deficiency	Same as T– B+ SCID ADA deficiency: chondroosseous dysplasia PNP deficiency: neurologic disorders
Omenn syndrome	AR	1–3 mo	Same as T– B– SCID, exfoliative erythroderma, lymphadenopathy, hepatosplenomegaly	Hypomorphic mutations in SCID-causing genes (RAG1/2, Artemis)	Restricted T-cell receptor heterogeneity, eosinophilia, elevated IgE
Reticular dysgenesis (T– B– SCID)	AR	1–3 mo	Same as T– B– SCID	Defective maturation of common stem cells due to AK2 mutations	Agammaglobulinemia, alymphocytosis, agranulocytosis
Bare lymphocyte syndrome (MHC class I deficiency)	AR	First decade	Sinopulmonary infections	Mutation in TAP1 or TAP2 (transporter associated with antigen processing)	Decreased CD8 T cells, chronic lung inflammation
Bare lymphocyte syndrome (MHC class II deficiency)	AR	Early infancy	Respiratory tract infections, chronic diarrhea, viral infections	Mutations in CIITA, RFX5, RFXAP, and RFX-B (DNA binding factors)	Decreased CD4 T cells, autoimmune disease

ADA, Adenosine deaminase; AR, autosomal recessive; GVHD, graft versus host disease; IL, interleukin; IL-2R γ , interleukin-2 receptor γ -chain; MHC, major histocompatibility complex; PNP, purine nucleoside phosphorylase; SCID, severe combined immunodeficiency; T– B+, T– cells absent and B cells present; T– B–, T cells absent and B cells absent.

T cells and CD40 on B cells (see Fig. 73.2). Signal transduction via CD40 activates several signaling molecules and transcription factors, including nuclear factor κ B (NF- κ B) and two enzymes, activation-induced cytidine deaminase (AID) and uracil-DNA glycosylase (UNG), which are required for class switching. Autosomal recessive forms of hyper IgM deficiency due to mutations in *AID* or *UNG* also lead to the same abnormal pattern in serum immunoglobulins but without T-cell function abnormality. Thus patients with these forms of hyper-IgM clinically present in a manner similar to antibody deficiencies but do not exhibit susceptibility to opportunistic infections (see Table 73.1).

All patients with hyper-IgM syndrome have increased susceptibility to sinopulmonary infections; patients with defects in CD40 ligand or CD40 are susceptible to opportunistic infections, such as *P. jirovecii* and *Cryptosporidium parvum*. Signaling via CD40 on B cells and other antigen-presenting cells leads to upregulation of co-stimulatory molecules important for promoting T-cell differentiation and for activating cell-mediated immune responses. The hyper-IgM phenotype is also found in an X-linked disorder associated with ectodermal dysplasia, resulting from defects in the gene encoding the NF- κ B essential modulator (NEMO). Patients with defects

in NEMO are susceptible to a wider spectrum of infectious organisms, especially meningitis and infection with atypical mycobacteria, because NF- κ B signaling is important for the function of both innate and adaptive immune systems.

Severe combined immunodeficiency (SCID) is characterized by a profound lack of T-cell numbers or function, and B-cell dysfunction resulting from the absence of B cells from the gene defect itself, or secondary to lack of T-cell function (see Table 73.2). T cells develop from bone marrow-derived precursors in the thymus (see Fig. 73.1), where they undergo several stages of development characterized by DNA recombination of the variable region of T-cell antigen receptor genes to generate a diverse T-cell receptor repertoire. A process of positive selection occurs in the thymus to select thymocytes with antigen receptors that can interact with major histocompatibility complex (MHC) molecules to ensure their survival (see Fig. 73.1). Thymocytes differentiate into CD4 or CD8 T cells if they interact with MHC class II or class I molecules, respectively. Some of the positively selected thymocytes, however, have antigen receptors that recognize self-antigens presented by MHC molecules in the thymus. These cells are deleted in the thymus by a process of negative selection, or they become regulatory T cells. Positive selection and negative selection in

the thymus ensure that the mature T cells that leave the thymus can function with the individual's MHC molecules and recognize a multitude of foreign antigens without mounting autoimmune responses. SCID can result from any specific genetic mutation that interferes with T-cell development in the thymus or T-cell function in the periphery.

Clinical manifestations of SCID include failure to thrive, severe bacterial infections, chronic candidiasis and other fungal infections, chronic viral infections, infection with *Pneumocystis jirovecii* and other opportunistic organisms, and intractable diarrhea. Patients may have a usually non-fatal skin disease similar to eczema, possibly related to **graft versus host disease (GVHD)** from engraftment of maternal lymphocytes. Patients with SCID are extremely susceptible to fatal GVHD from lymphocytes in blood transfusions and can be infected by cytomegalovirus-positive blood products. *Patients with T-cell disorders should always receive irradiated, leukocyte-depleted, cytomegalovirus (CMV)-negative blood products.*

X-linked SCID, the most common cause of SCID, is caused by mutations in the gene coding the common γ -chain of the interleukin 2 (IL-2), IL-4, IL-7, IL-9, IL-15, and IL-21 receptors. Affected patients have no T cells or NK cells in the peripheral blood but have normal numbers of B cells. Ig levels are low or undetectable because there are no CD4 T cells to stimulate B cells. Defects in IL-2 and IL-7 signaling lead to impaired T-cell proliferation and T-cell development, whereas IL-15 is required for NK-cell development. There are many causes of **autosomal recessive SCID**. Defects in Janus kinase 3 (Jak3), which binds to the common γ -chain, results in a similar phenotype as X-linked SCID. Defects in the IL-7 receptor, ZAP-70, and subunits of the CD3 molecule result in a deficiency of T cells with normal B-cell and NK-cell numbers. In addition, there are a variety of defects that affect DNA recombination in T and B cells; these include two genes called *recombinase activating gene (RAG)1* and *RAG2* as well as genes important in DNA excision and repair (e.g., *Artemis*). Defects in any of the genes that abolish DNA recombination or DNA repair result in autosomal recessive SCID with no T or B cells present. Mutations in *RAG1*, *RAG2*, or *Artemis* that do not completely abrogate enzymatic activity result in **Omenn syndrome**, a variant form of SCID that is characterized by exfoliative erythroderma, lymphadenopathy, hepatosplenomegaly, marked eosinophilia, elevated serum IgE, and impaired T-cell function. Patients with Omenn syndrome have T cells in the periphery, but these T cells have a limited T-cell receptor repertoire.

Deficiencies in **adenosine deaminase (ADA)** and **purine nucleoside phosphorylase**, two enzymes involved in the purine salvage pathway, also result in SCID. Accumulation of nucleoside substrates or their metabolic products in the plasma is toxic to lymphocytes, including T, B, and NK cells. Most patients exhibit severe infection early in life, although the diagnosis in patients with partial enzyme function may not be established until after 5 years of age or, occasionally, in adulthood. Patients with late-onset diagnosis are generally lymphopenic; they may have B cells and normal total Ig levels but little functional antibody.

Bare lymphocyte syndrome results from defects in transcription factors that regulate expression of MHC class II molecules or genes that affect transport of antigen peptides, which leads to the absence of either MHC class I or MHC class

II molecules. Lymphoid tissue and B cells may be present in normal amounts, but CD4 T cells are decreased or absent in class II deficiency, whereas CD8 cells are decreased or absent in class I deficiency. Some patients may have normal numbers of CD4 or CD8 T cells, but none of the T cells are functional because peptide antigens cannot be presented to T cells.

DiGeorge syndrome, also known as **velocardiofacial syndrome** or **CATCH 22 syndrome** (cardiac anomalies, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcemia), is the result of dysmorphogenesis of the third and fourth pharyngeal pouches, resulting in hypoplasia of the thymus required for T-cell maturation. Most, but not all, patients with DiGeorge syndrome have a deletion on chromosome 22q11.2. DiGeorge syndrome is classically characterized by hypocalcemic (hypoparathyroidism) tetany, conotruncal and aortic arch anomalies, and increased infections. The diagnosis is established by fluorescent in situ hybridization, chromosomal microarray studies, or a polymerase chain reaction with a DNA probe to detect the chromosomal deletion. The majority of affected patients have partial DiGeorge syndrome, with a less severe immunodeficiency with low T-cell numbers and function that generally improve with age. In complete DiGeorge syndrome, the thymus is absent and present similarly to SCID due to a complete lack of T cells. Importantly, complete DiGeorge syndrome and bare lymphocyte syndrome (both with an intrinsic thymic defect) do not respond well to bone marrow transplantation as do other forms of SCID. Transfer of mature T cells in such patients may confer some immune function. Thymic transplants have been utilized in cases of severe T-cell lymphopenia in DiGeorge syndrome.

Wiskott-Aldrich syndrome is an X-linked disorder characterized by thrombocytopenia, eczema, defects in cell-mediated and humoral immunity, and a predisposition to lymphoproliferative disease (Table 73.3). Wiskott-Aldrich syndrome is caused by mutations of the *WAS* gene coding for the Wiskott-Aldrich syndrome protein (WASP), which is expressed in lymphocytes, platelets, and monocytes. Deficiency of this protein results in elevated levels of IgE and IgA, decreased IgM, poor responses to polysaccharide antigens, waning T-cell function, and profound thrombocytopenia. Opportunistic infections and autoimmune cytopenias become problematic in older children. **Isolated X-linked thrombocytopenia** also results from mutations of *WAS*. One third of patients with Wiskott-Aldrich syndrome die as a result of hemorrhage, and two thirds die as a result of recurrent infection caused by bacteria, cytomegalovirus, *P. jirovecii*, or herpes simplex virus. Hematopoietic stem cell transplantation is the treatment of choice for severe forms of Wiskott-Aldrich syndrome and corrects the immunologic and hematologic problems in these patients.

Ataxia telangiectasia is a syndrome caused by the ataxia telangiectasia mutated (*ATM*) gene on chromosome 11q22.3 (see Table 73.3). Patients have cutaneous and conjunctival telangiectasias and progressive cerebellar ataxia with degeneration of Purkinje cells. IgA deficiency, IgG₂ subclass deficiency of variable severity, low IgE levels, and variably depressed T-cell function may be seen. The normal function of the *ATM* gene appears to be involved in detecting DNA damage and blocking cell division until the damage is repaired. Ataxia telangiectasia cells are exquisitely sensitive to irradiation. Malignancies including leukemia or lymphoma can occur. Diabetes also may be present, and sexual maturation is delayed. There is no uniformly effective therapy, but antimicrobial therapy and

DISORDER	GENETICS	ONSET	MANIFESTATIONS	PATHOGENESIS	ASSOCIATED FEATURES
Wiskott-Aldrich syndrome	X-linked, (Xp11.22)	Early infancy	Thrombocytopenia and bleeding, atopic dermatitis, recurrent infections	53-kDa protein (WASP) defect	Polysaccharide antibody deficiency, small platelets, decreased cell-mediated immunity, lymphoproliferation
Ataxia telangiectasia	AR (11q22.3)	2–5yr	Recurrent otitis media, pneumonia, meningitis with encapsulated organisms	ATM gene mutation Disorder of DNA double-strand break repair	Neurologic and endocrine dysfunction, malignancy, telangiectasis; sensitivity to radiation
Nijmegen breakage syndrome	AR (8q21)	Infancy	Sinopulmonary infections, bronchiectasis, urinary tract infections	Defect in chromosomal repair mechanisms; hypomorphic mutation in <i>NBS1</i> (Nibrin)	Sensitivity to ionizing radiation; microcephaly with mild neurologic impairment; malignancy
Cartilage-hair hypoplasia (short-limbed dwarf)	AR (9p13–21)	Birth	Variable susceptibility to infections	Mutation in <i>RMRP</i>	Metaphyseal dysplasia, short extremities
Chronic mucocutaneous candidiasis (APECED)	AR	3–5yr	Candidal infections of mucous membranes, skin, and nails	Mutations in <i>AIRE</i> gene	Autoimmune endocrinopathies
X-linked lymphoproliferative syndromes	X-linked	Variable	Variable decrease in T-, B-, and NK-cell function, hypogammaglobulinemia	Mutation in <i>SH2D1A</i> (SAP: SLAM-associated protein) or <i>XIAP</i>	Life-threatening Epstein-Barr virus infection, lymphoma or Hodgkin disease, aplastic anemia, lymphohistiocytic disorder
Hyper-IgE syndrome	AD, AR	Variable	Skin and pulmonary abscesses, fungal infections, eczema, elevated IgE	Mutation in <i>STAT3</i> (AD), <i>TYK2</i> (AR), and <i>DOCK8</i> (AR)	Coarse facial features, failure to shed primary teeth, frequent fractures (<i>STAT3</i>), viral and other infections (<i>TYK2</i> and <i>DOCK8</i>)
Interferon- γ , receptor deficiency 1,2	AR, AD	Variable	Recurrent nontuberculous mycobacterium and salmonella infections	Mutations in <i>IFN-γR1</i> , <i>IFN-γR2</i>	Absent interferon signaling
Interleukin 12 receptor β 1 deficiency	AR	Variable	Recurrent nontuberculous mycobacterium and salmonella infections	IL-12 β 1	Absent IL-12 signaling
Interleukin 12p40 deficiency	AR	Variable	Recurrent nontuberculous mycobacterium and salmonella infections	IL-12p40	Lack of IL-12 with resulting low interferon- γ

AD, Autosomal dominant; APECED, autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy; AR, autosomal recessive; NK, natural killer.

intravenous immunoglobulin (IVIG) replacement therapy may be helpful.

Chronic mucocutaneous candidiasis (autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy [APECED]) is characterized by chronic or recurrent candidal infections of the mucous membranes, skin, and nails (see Table 73.3). There is normal antibody production but significantly decreased or absent lymphocyte proliferation and delayed skin reactivity to *Candida*. Patients usually do not respond to topical antifungal therapy and must be treated with oral antifungal agents. In most patients, an autoimmune endocrine disorder develops by early adulthood, such as hypoparathyroidism and Addison disease. Other autoimmune disorders have been reported. The insidious onset requires the need for frequent evaluation for autoimmune endocrine disorders. This disease results from a defect in the gene for the transcription factor autoimmune regulator (*AIRE*), which is necessary for expression of peripheral tissue antigens in the

thymus. In the absence of these tissue antigens in the thymus, defects in negative selection occur, and autoreactive T cells to specific organs (e.g., adrenal glands, parathyroid glands) leads to specific endocrinopathies. Although originally thought to be a T-cell defect, patients with APECED produce neutralizing antibodies to cytokines important in the control of fungal infection, including IL-17.

Patients with **X-linked lymphoproliferative disease** (see Table 73.3) exhibit dysregulated immune responses to Epstein-Barr virus (EBV). Males with this disease are normal until infected with EBV, which is acutely fatal in 80% of patients. X-linked lymphoproliferative type 1 (XLP-1) is caused by a mutation in the gene *SH2D1A*, which codes for an adapter protein involved in signal transduction of lymphocytes. With EBV infection, affected boys exhibit a clinical phenotype similar to hemophagocytic lymphohistiocytosis with extensive expansion of CD8 T cells, hepatic necrosis, and death. Males who survive initial EBV infection have

significant hypogammaglobulinemia and are at high risk for developing aplastic anemia and lymphoma. A similar disorder is seen in males with mutations in *XIAP*, which results in X-linked lymphoproliferative disorder type 2. The patients can also present with early-onset colitis and do not exhibit a susceptibility to lymphoma.

Hyper-IgE syndrome is characterized by markedly elevated serum IgE levels, a rash that resembles atopic dermatitis, eosinophilia, and staphylococcal abscesses of the skin, lungs, joints, and viscera (see Table 73.3). Infections with *H. influenzae* type b, *Candida*, and *Aspergillus* also may occur. These patients have coarse facial features, joint laxity, osteopenia with fractures, and may have giant pneumatoceles in the lungs after staphylococcal pneumonias. Although serum IgG, IgA, and IgM levels are normal, humoral immune responses to specific antigens are reduced, as is cell-mediated immunity. Long-term treatment with antistaphylococcal medications is indicated, and Ig replacement therapy may be helpful. Most patients have an autosomal dominant form of inheritance, whereas some patients have an autosomal recessive inheritance. Mutations in the *TYK2* and *DOCK8* genes cause autosomal recessive forms of hyper-IgE syndrome, and mutations in the *STAT3* gene cause autosomal dominant hyper-IgE syndrome, which is the most common form of hyper-IgE syndrome.

TREATMENT

The approach to therapy of lymphocyte disorders depends on the diagnosis, clinical findings, and laboratory findings (Table 73.4). When immunodeficiency is suspected and while the evaluation is in process, all blood products need to be irradiated and negative for cytomegalovirus. Lymphocytes present in blood products can cause fatal GVHD in patients with SCID. Cytomegalovirus infection can be fatal in an immunodeficiency patient undergoing stem cell transplantation. Live-virus vaccines should be withheld from patients and household members until a diagnosis is established.

Infections should be treated with appropriate antibiotics; **antibiotic prophylaxis** can be used to prevent recurrent infections, provide a better quality of life, and decrease possible consequences. Patients with severe T-cell deficiencies should receive prophylaxis against *Pneumocystis*, fungi, and herpesviruses (CMV and EBV), as well as immunoglobulin replacement therapy until treatment with stem cell transplantation. Patients with milder forms may benefit from **vaccination** with protein-conjugate vaccines to *H. influenzae* type b and *S. pneumoniae*.

Ig replacement therapy, intravenously or subcutaneously, is a lifesaving therapy for patients with severe antibody deficiency diseases and SCID. Intravenous or subcutaneous gammaglobulin contains polyclonal IgG antibodies isolated from at least 1,000 healthy donors, and its use provides passive immunity against common microorganisms and reduces the frequency and severity of infection in most patients. Ig replacement therapy is usually administered at a total monthly dose of 400–600 mg/kg of body weight administered intravenously every 3–4 weeks or subcutaneously by infusion pump every 1–2 weeks. IVIG therapy should be monitored by regularly measuring trough Ig levels and, more important, the patient's clinical course. Patients who continue to have recurrent infections, especially in the last week before the administration of IVIG, may require higher doses or more frequent

TABLE 73.4 General Management of Patients with Immunodeficiency

Avoid transfusions with blood products unless they are irradiated and cytomegalovirus negative.
Avoid live-virus vaccines, especially in patients with severe T-cell deficiencies or agammaglobulinemia, and in household members.
Use prophylaxis to <i>Pneumocystis jirovecii</i> in T-cell immunodeficiency; in X-linked hyper-IgM, consider antifungal prophylaxis in T-cell immunodeficiency.
Follow pulmonary function in patients with recurrent pneumonia.
Use chest physiotherapy and postural drainage in patients with recurrent pneumonia.
Consider using prophylactic antibiotics essential in severe immunodeficiencies and in patients with severe bronchiectasis.
Examine diarrheal stools for <i>Giardia lamblia</i> and <i>Clostridium difficile</i> .
Avoid unnecessary exposure to individuals with infection.
Boil water for T-cell defects and hyper-IgM syndrome (<i>Cryptosporidium</i> risk).
Use Ig for severe antibody deficiency states (400–600 mg/kg monthly IV or SC).

Ig, Immunoglobulin; IV, intravenous; SC, subcutaneous.

administration. A combination of prophylactic antibiotics and Ig replacement therapy may be indicated in patients who continue to have recurrent infections. **Complications of IVIG** therapy include transfusion reactions with chills, fever, and myalgias. Pretreatment with an antihistamine, an antipyretic, and a slower rate of infusion usually prevents these reactions in subsequent infusions. Headache from aseptic meningitis can develop after IVIG therapy, usually in the first 24 hours. It most often responds to treatment with ibuprofen. Allergic reactions to IVIG may rarely occur in patients with absent IgA. Subcutaneous administration of Ig has fewer adverse effects but may be complicated by local reactions at the site(s) of infusion. In rare cases, Ig replacement therapy has been linked to the development of pulmonary emboli, stroke, myocardial infarction, or renal failure, particularly in subjects with underlying medical issues. The risk of transmission of infectious agents, despite preparation from large numbers of selected donors, is extremely low.

Therapy for severe T-cell disorders is stem cell transplantation, preferably from a human leukocyte antigen–matched sibling (see Chapter 76). Some patients continue to have poor B-cell function after stem cell transplantation and require lifelong Ig replacement therapy. GVHD, in which the transplanted cells initiate an immune response against the host tissues, is the main complication of stem cell transplantation. Patients with the ADA deficiency form of SCID who lack matched sibling donors can receive repeated intramuscular replacement doses of ADA, stabilized by coupling to polyethylene glycol. Gene therapy has been performed in patients with common γ -chain deficiency and ADA deficiency by transfer of a normal gene into bone marrow stem cells, which are infused into the patient. Gene therapy for common γ -chain deficiency (X-SCID) and ADA deficiency results in immune reconstitution in most patients. However, in X-SCID, but not

ADA-SCID, initial gene therapy trials were complicated by the development of leukemia in the majority of patients. Newer viral vectors have been developed that appear not to cause leukemia, making it a likely option in the future for some forms of SCID. Gene therapy for ADA-SCID has been approved by the European Medicines Agency (equivalent of the U.S. Food and Drug Administration) and is currently a therapeutic option in European countries.

PREVENTION AND NEWBORN SCREENING

Population-based screening programs to detect SCID in newborns is routine in the United States, parts of Europe, South America, and Asia. The T-cell receptor excision circle (TREC) assay is the newborn screening test for SCID. The TREC assay enumerates the numbers of a specific TREC isolated from the DNA extracted serving as a biomarker for normal, newly formed, naïve T cells. Absent or severely low TREC assays indicate low or absent numbers of naïve T cells and identify infants with SCID. Newborn screening for SCID is highly sensitive in identifying infants prior to the development of infectious complications and substantially decreases mortality following stem cell transplantation. Newborn screening for SCID has also led to the identification of additional genetic causes of SCID.

PEARLS FOR PRACTITIONERS

See *Immunology: Pearls for Practitioners* at the end of this section.

CHAPTER 74

Neutrophil Disorders

Neutrophils play important roles in immunity and wound healing; their primary function is ingesting and killing pathogens. Neutrophil disorders can result from deficient cell numbers or defective function (Table 74.1). Patients with neutrophil disorders are susceptible to a variety of bacterial infections and certain fungi. Suggestive signs include mucous membrane infections (gingivitis), abscesses in the skin and viscera, lymphadenitis, poor wound healing, delayed umbilical cord separation, or absence of pus. Neutrophils develop in the bone marrow from hematopoietic stem cells by the action of several colony-stimulating factors (CSFs), including stem cell factor, granulocyte-monocyte CSF, granulocyte CSF (G-CSF), and interleukin-3 (IL-3). On leaving the bone marrow, mature neutrophils are found in the circulation or reside in the marginating pool. Adhesion molecules are necessary for neutrophils to roll and adhere to vascular endothelium and extravasate from the blood into sites of infection, where they phagocytose and kill pathogens, especially those coated by complement or antibodies. Chemotactic factors, including the complement fragment C5a, IL-8, and bacterial formulated peptides, mobilize neutrophils to enter tissues and sites of infections. Neutrophils kill ingested pathogens using enzymes contained in their granules and by the production of superoxide by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase.

Immunodeficiencies may result from abnormalities in the production, turnover, adherence and/or extravasation, or killing mechanisms by neutrophils.

ETIOLOGY AND CLINICAL MANIFESTATIONS

Disorders of Neutrophil Numbers

The normal neutrophil count varies with age. **Neutropenia** is defined as an absolute neutrophil count (ANC) less than $1,500/\text{mm}^3$ for White children 1 year of age or older. Black children normally have lower total white blood cell and neutrophil counts. The effect of neutropenia depends on its severity. The susceptibility to infection is minimally increased until the ANC is less than $1,000/\text{mm}^3$. Most patients do well with an ANC greater than $500/\text{mm}^3$. At these levels, localized infections are more common than generalized bacteremia. Serious bacterial infections are more common with an ANC less than $200/\text{mm}^3$. The major types of infections associated with neutropenia are cellulitis, pharyngitis, gingivitis, lymphadenitis, abscesses (cutaneous or perianal), enteritis (typhlitis), and pneumonia. The sites of the infection are usually colonized heavily with normal bacterial flora that becomes invasive in the presence of neutropenia. Neutropenia may be congenital or acquired (Table 74.2) and may be associated with specific diseases, especially infections (Table 74.3), or result from drug reactions (Table 74.4).

There are several forms of congenital neutropenia. **Severe congenital neutropenia (Kostmann syndrome)** is an autosomal recessive disorder in which myeloid cells fail to mature beyond the early stages of the promyelocyte due to mutations in the *HAX-1* gene (see Table 74.1). The peripheral blood may show an impressive monocytosis. Exogenous G-CSF is commonly used to treat this disorder by increasing the production of neutrophils. Acute myeloid leukemia has developed in a few patients who have survived into adolescence. Stem cell transplantation may be curative. Defects in *G6PC3*, *GF11*, and other genes have also been shown to cause severe congenital neutropenia. **Cyclic neutropenia** is a stem cell disorder in which all marrow elements cycle resulting in transient neutropenia. It may be transmitted as an autosomal dominant, recessive, or sporadic disorder. Because of the short half-life of neutrophils in the blood (6–7 hours) compared to platelets (10 days) and red blood cells (120 days), neutropenia is the only clinically significant abnormality. The usual cycle is 21 days, with neutropenia lasting 4–6 days, accompanied by monocytosis and often by eosinophilia. Severe, debilitating bone pain is common when the neutrophil count is low. G-CSF results in increasing neutrophil numbers and a shorter duration of neutropenia. Defects in *ELANE*, the gene encoding for neutrophil elastase, has been found in patients with cyclic neutropenia. Further analysis has demonstrated *ELANE* mutations in some cases of severe congenital neutropenia.

Severe congenital neutropenia that may be either persistent or cyclic also is a component of **Shwachman-Diamond syndrome**, an autosomal recessive syndrome of pancreatic insufficiency accompanying bone marrow dysfunction (see Table 74.1). This is a panmyeloid disorder in which neutropenia is the most prominent manifestation. Metaphyseal dysostosis and dwarfism may occur. Patients usually respond to G-CSF. A gain of function mutation in the Wiskott-Aldrich

TABLE 74.1 Phagocytic Disorders

NAME	GENETICS	DEFECT	COMMENT
Congenital neutropenia, cyclic neutropenia	AR (<i>HAX1</i> , <i>GFI1</i> , others) AD (<i>GFI1</i> , <i>ELANE</i>)	Severe neutropenia	Cellulitis, pharyngitis, gingivitis, lymphadenitis, abscesses, typhlitis, and pneumonia
Chronic granulomatous disease	X-linked (gp91 ^{phox}), AR (p22 ^{phox} , p47 ^{phox} , and p67 ^{phox})	Bactericidal	X-linked recessive (66%), autosomal recessive (33%); eczema, osteomyelitis, granulomas, abscesses caused by <i>Staphylococcus aureus</i> , <i>Burkholderia cepacia</i> , <i>Aspergillus fumigatus</i> , colitis
Chédiak-Higashi syndrome (1q42l-44)	AR (<i>LYST</i>)	Bactericidal plus chemotaxis; poor natural killer function	Autosomal recessive; oculocutaneous albinism, neuropathy, giant neutrophilic cytoplasmic inclusions; malignancy, neutropenia
Myeloperoxidase deficiency	AR (<i>MPO</i>)	Bactericidal, fungicidal but low risk of infections	Reduced chemiluminescence; autosomal recessive (1:4,000); persistent candidiasis in diabetic patients
Glucose-6-phosphate dehydrogenase deficiency	AR (<i>G6PD</i>)	Bactericidal	Phenotypically similar to chronic granulomatous disease
Leukocyte adhesion deficiency type 1, 2, and 3	AR (<i>ITGB2</i> , <i>FUCT1</i> , <i>FERMT3</i> , respectively)	Adherence, chemotaxis, phagocytosis; reduced lymphocyte cytotoxicity	Type 1: Delayed separation or infection of umbilical cord; lethal bacterial infections without pus; neutrophilia Type 2: Also short stature Type 3: Also bleeding disorder
Shwachman-Diamond syndrome	AR (<i>SBDS</i>)	Chemotaxis, neutropenia	Pancreatic insufficiency, metaphyseal chondrodysplasia; autosomal recessive
WHIM	AD (<i>CXCR4</i>)	Impaired chemokine receptor	Low IgG, warts, myelokathexis
Mono MAC	AD (<i>GATA2</i>)	Monocytopenia, macrophage dysfunction	Mycobacterial, viral, fungal, bacterial opportunistic infections, warts, pulmonary alveolar proteinosis, lupus

AR, Autosomal recessive; AD, autosomal dominant; Mono MAC, monocytopenia, B- and NK-cell lymphopenia, opportunistic infections, virus-induced cancers, myelodysplasia; WHIM, warts, hypogammaglobulinemia, infections, myelokathexis.

syndrome protein has also been associated with an X-linked form of severe congenital neutropenia. **Benign congenital neutropenia** is a condition where significant neutropenia develops but in whom major infectious complications do not occur. Many patients whose ANC ranges from 100–500/mm³ have an increased frequency of infections, particularly respiratory infections, but the major problem is the slow resolution of infections that develop. Severe congenital neutropenia may be associated with severe combined immunodeficiency in **reticular dysgenesis**, a disorder of hematopoietic stem cells affecting all bone marrow lineages due to mutations in the *AK2* gene.

Isoimmune neutropenia occurs in neonates as the result of transplacental transfer of maternal antibodies to fetal neutrophil antigens. The mother is sensitized to specific neutrophil antigens on fetal leukocytes that are inherited from the father and are not present on maternal cells. Isoimmune neonatal neutropenia, similar to isoimmune anemia and thrombocytopenia, is a transient process (see Chapters 62 and 151). Cutaneous infections are common, and sepsis is rare. Early treatment of infection while the infant is neutropenic is the major goal of therapy. Intravenous immune globulin may decrease the duration of neutropenia.

Autoimmune neutropenia usually develops in children 5–24 months of age and often persists for prolonged periods. Neutrophil autoantibodies may be IgG, IgM, IgA, or a combination of these. Usually the condition resolves in 6 months to 4 years. Although intravenous immune globulin and corticosteroids have been used, most patients respond to G-CSF.

Autoimmune neutropenia may rarely be an early manifestation of systemic lupus erythematosus, rheumatoid arthritis, or autoimmune lymphoproliferative disease.

Disorders of Neutrophil Migration

Neutrophils normally adhere to endothelium and migrate to areas of inflammation by the interaction of membrane proteins, called *integrins* and *selectins*, with endothelial cell adhesion molecules. A hallmark of defects in neutrophil migration is the absence of pus at sites of infection. In **leukocyte adhesion deficiency type I (LAD-I)**, infants lacking the β_2 integrin CD18 exhibit the condition early with failure of separation of the umbilical cord (often 2 months after birth) with attendant omphalitis and sepsis (see Table 74.1). The neutrophil count usually is greater than 20,000/mm³ because of failure of the neutrophils to adhere normally to vascular endothelium and to migrate out of blood to the tissues (Fig. 74.1). Cutaneous, respiratory, and mucosal infections occur. Children with this condition often have severe gingivitis. Sepsis can lead to death in early childhood. This disorder is transmitted as an autosomal recessive trait. Stem cell transplantation can be lifesaving.

LAD-II results from impairment of neutrophil rolling along the vascular wall, which is the first step in neutrophil migration into tissues and at sites of infection. Rolling is mediated by sialylated and fucosylated tetrasaccharides related to the sialylated Lewis X (S-LeX) blood group found on the surface of neutrophils, monocytes, and activated lymphocytes binding

to selectin molecules on vascular endothelium (see Fig. 74.1). LAD-II results from a defect in the FUTC1 protein resulting in abnormal fucose metabolism leading to the absence of S-LeX blood group on the surface of neutrophils and other leukocytes. Patients with LAD-II are also dysmorphic, have short stature, and experience severe developmental delay. LAD-III is a rare disorder caused by defects in the KINDLIN-3 protein

resulting in defective neutrophil adhesion as well as platelet defects. Defective migration of neutrophils has also been described in **hyper-IgE syndrome** and with mutations in the RAC2 gene (see Chapter 73 and Table 74.1).

FIGURE 74.1 Steps in the emigration of neutrophils from the vascular space. Neutrophils are depicted entering the marginating pool in a postcapillary venule, and the effector molecules participating in each event are indicated in *gray* text. Initial capture is mediated by interactions between neutrophil/leukocyte (L)-selectin and endothelial cell (E, P)-selectins and their respective carbohydrate ligands on the opposing cell surface (e.g., P-selectin glycoprotein ligand-1 [PSGL-1]), whereas integrins (e.g., very late antigen 4 [VLA4]) are responsible for firm adherence. Selectin-mediated signaling slows the rolling or tumbling neutrophils, partially countering the shear forces resulting from blood flow. Chemokines diffusing into the bloodstream from sites of microbial invasion in the tissues bind to specific receptors and activate the neutrophil, which is then arrested by integrin-dependent interactions. The activated neutrophil flattens against the endothelium and crawls along the luminal surface of the vessel wall. Platelet-endothelial cell adhesion molecule-1 (PECAM-1), junctional adhesion molecules (JAMs), and endothelial cell-selective adhesion molecule (ESAM) localized to interendothelial cell junctions interact with PECAM-1 and CD99 on the neutrophil surface to permit neutrophil migration between and through endothelial cells. Once in the tissues, the polarized neutrophils move up the mediator concentration gradient to reach the site of microbial invasion. Philadelphia: Elsevier; 2020 [fig. 8.3].)

Disorders of Neutrophil Function

Defects in neutrophil function are relatively rare inherited disorders and tend to be associated with a marked susceptibility to bacterial and fungal infection. **Chronic granulomatous disease (CGD)** is a disorder of white blood cells that results from defective intracellular killing of bacteria and pathogens by neutrophils and macrophages because of an inability to activate the “respiratory burst,” the catalytic conversion of molecular oxygen to superoxide (O_2^-). NADPH oxidase is the enzyme that catalyzes the respiratory burst and consists of five essential subunits: gp91^{phox}, p22^{phox}, p47^{phox}, p67^{phox}, and p40^{phox}. Additionally, cytochrome B-245 (Eros) is necessary for gp91^{phox}-p22^{phox} heterodimer formation, which is essential for NADPH oxidase function. Defects in any of these enzymes lead to CGD and an inability to kill catalase-positive pathogens such as *Staphylococcus aureus* and enteric gram-negative bacteria (*Burkholderia*) and fungi (*Aspergillus fumigatus*, *Candida albicans*). The gp91^{phox} gene, located on chromosome Xp21.1, is responsible for the most common form of the disease. The other gene defects are inherited in an autosomal recessive manner. Glucose-6-phosphate dehydrogenase is also involved in the production of superoxide, and severe forms of glucose-6-phosphate dehydrogenase deficiency also result in CGD. Patients with CGD characteristically have lymphadenopathy, hypergammaglobulinemia, hepatosplenomegaly, dermatitis, failure to thrive, anemia, chronic diarrhea, and abscesses. Infections occur in the lungs, the middle ear, gastrointestinal tract, skin, urinary tract, lymph nodes, liver, and bones. Granulomas are prominent and may obstruct the pylorus or ureters.

Chédiak-Higashi syndrome, an abnormality of secondary granules, is an autosomal recessive disorder caused by a mutation in a cytoplasmic protein (LYST) thought to be involved in organellar protein trafficking, resulting in a fusion of the primary and secondary granules in neutrophils. Giant granules are present in many cells, including lymphocytes, platelets,

and melanocytes. Patients usually have partial oculocutaneous albinism. The defect in Chédiak-Higashi syndrome results in defective neutrophil and natural killer-cell function, leading to recurrent and sometimes fatal infections with streptococci and staphylococci. Most patients progress to an accelerated phase associated with Epstein-Barr virus infection and characterized by a **lymphoproliferative syndrome** with generalized lymphohistiocytic infiltrates, fever, jaundice, hepatomegaly, lymphadenopathy, and pancytopenia. The condition resembles hemophagocytic lymphohistiocytosis.

LABORATORY DIAGNOSIS

The evaluation of a neutropenic child depends on clinical signs of infection, family and medication history, age of the patient, cyclic or persistent nature of the condition, signs of bone marrow infiltration (malignancy or storage disease), and evidence of involvement of other cell lines. Neutropenia is confirmed by a complete blood count and differential. A bone marrow aspirate and biopsy may be necessary to determine whether the neutropenia is due to a failure of production in the bone marrow, infiltration of the bone marrow, or reflect loss of neutrophils in the periphery. Antineutrophil antibodies can be useful in the diagnosis of autoimmune neutropenia, although their interpretation can be difficult.

Neutrophil chemotactic defects can be excluded by the presence of neutrophils at the site of infection. The **Rebuck skin window** is a 4-hour *in vivo* test for neutrophil chemotaxis that is not performed routinely by most laboratories. *In vitro* studies of neutrophil chemotaxis and migration are available in specialized laboratories. Flow cytometry for the presence of adhesion molecules, such as CD18 or CD15, can help diagnose leukocyte adhesion defects. Point mutations that affect the function of the adhesion molecule but do not alter antibody binding are missed using flow cytometry. CGD can be diagnosed by the flow cytometry-based test using

dihydrorhodamine 123 or the nitroblue tetrazolium test (see Chapter 72). Light microscopy of neutrophils for the presence of giant granules can help diagnose Chédiak-Higashi syndrome.

TREATMENT

Therapy for neutropenia depends on the underlying cause. Patients with severe bacterial infections require broad-spectrum antibiotics; the resolution of neutropenia is the most important prognostic factor. Most patients with severe congenital neutropenia or autoimmune neutropenia respond to therapy with G-CSF. Granulocyte transfusion should be reserved for life-threatening infection. Chronic mild neutropenia not associated with immunosuppression can be managed expectantly with prompt antimicrobial treatment of soft tissue infections, which usually are caused by *S. aureus* or group A streptococcus.

In the past, CGD has been treated by antimicrobial prophylaxis with trimethoprim-sulfamethoxazole, itraconazole, and interferon- γ . Stem cell transplantation has become the preferred treatment if an acceptable human leukocyte antigen-matched donor can be identified. Prompt diagnosis and treatment of infections are required in CGD. Because *A. fumigatus* can cause serious infection in patients with CGD, moldy hay, decomposing compost, and other nests of fungi must be avoided.

PROGNOSIS AND PREVENTION

The prognosis depends on the particular defect. Milder and transient defects in neutrophil numbers have a better prognosis. Prolonged absence of neutrophils or their function has a poor prognosis, especially with the risk of bacterial and fungal sepsis. Stem cell transplantation has improved the prognosis of CGD and is also the treatment of choice for other severe neutrophil defects that cannot be managed with G-CSF. As in other genetic defects, prenatal diagnosis and genetic counseling are possible for all known gene mutations.

PEARLS FOR PRACTITIONERS

See *Immunology: Pearls for Practitioners* at the end of this section.

CHAPTER 75

Complement System

The **complement system** consists of plasma and membrane proteins that function in the innate immune response as well as in facilitating adaptive immunity. **Complement proteins** can kill pathogens with or without antibodies, opsonize pathogens to facilitate their uptake by phagocytes, or mediate inflammation. The complement system can be activated through three pathways—classic, alternative, or lectin—that involve a cascadelike, sequential activation of complement factors resulting in an amplified response (Fig. 75.1). Disorders of the complement system predispose to recurrent infection, autoimmunity, and angioedema (Table 75.1).

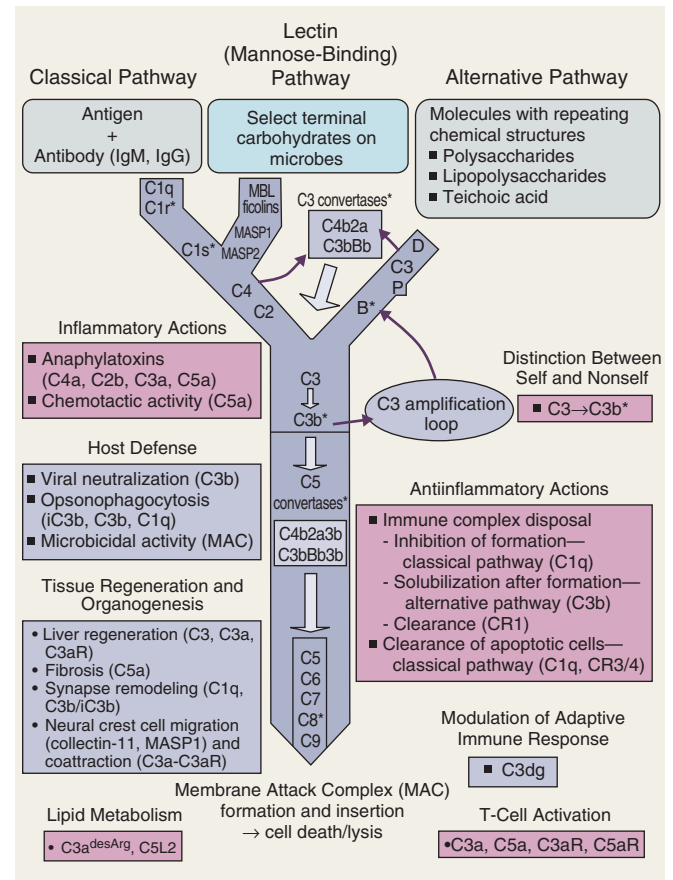

FIGURE 75.1 The complement cascade. Within each pathway, the components are arranged in order of their activation and aligned opposite their functional and structural analogues in the other pathways. Rounded boxes relate to activation of the pathways; squared boxes reflect complement functions; asterisks indicate sites of down-regulation of complement activity. *B*, Factor B; *C*, complement; *CR1*, complement receptor 1; *D*, factor D; *Ig*, immunoglobulin; *MAC*, membrane attack complex; *MASP*, MBL-associated serine protease; *MBL*, mannose-binding lectin; *P*, properdin. (From Ram S. Complement and deficiencies. In Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 9th ed. Philadelphia: Elsevier; 2020 [fig. 9.1].)

ETIOLOGY

The three pathways for complement activation are initiated by different mechanisms. The classic pathway is activated by antigen-antibody complexes or by C-reactive protein. The alternative pathway is spontaneously active at a low level; it may be activated by C3b generated through classic complement activation or by spontaneous hydrolysis of C3 on microbial surfaces and is amplified when active C3 binds to factor B which is cleaved by factor D to form the C3 convertase, C3bBb. The lectin pathway is initiated by the interaction of mannose-binding lectin with microbial carbohydrate. Mannose-binding protein-associated proteases (MASP) cleave C4 and C2. Figure 75.1 depicts the steps in each of these pathways that converge with the generation of C3b and result in the formation of a membrane attack complex (MAC). The MAC is a complex of C5b, C6, C7, C8, and C9 molecules that is common to all three pathways (see Fig. 75.1). The MAC generates pores in the cell membrane, leading to lysis of the cells. C3a and C5a, produced by cleavage of C3 and C5, respectively, can

release histamine from mast cells and basophils, leading to increased vascular permeability and smooth muscle contraction. C5a attracts phagocytes to the site of complement activation and can cause degranulation of phagocytic cells. C3b acts as an opsonin when attached to the surface of a pathogen by binding to phagocytes via complement receptor 1 (CR1). Its degradation product, iC3b, can bind to CR3 on the surface of phagocytes leading to the ingestion of the C3b-coated or iC3b-coated pathogen. iC3b and its breakdown product C3dg can bind complement receptor 2 (CR2) on B cells leading to activation and differentiation.

The complement system is under tight regulation because it has potent inflammatory activity and the potential to cause significant damage to host cells. The complement cascade is inherently regulated by the short half-life of C4b and C3b and by instability of the C3 convertases, C4b2b, and C3bBb. C1-inhibitor regulates the cascade by blocking active sites on C1r, C1s, and the MASP. Factor I destabilizes C3 convertase complexes and degrades the active fragments. Other inhibitors include membrane proteins, such as decay accelerating factor, CR1, membrane cofactor protein (MCP), and plasma proteins such as C4b-binding protein, factor H, and factor I. Formation of the MAC can be blocked by cell surface CD59, protein S, and other plasma proteins. Deficiency of any of these regulatory proteins can result in an inflammatory response, tissue damage, or excessive complement consumption.

Disorders of complement proteins can result from inherited deficiency or can be secondary to increased consumption. The consequences of decreased complement depend on the affected factor (see Table 75.1). **Deficiencies of early components** of the classic pathway (C1, C2, or C4) are not usually associated with severe infections, although patients with C2 deficiency may present with recurrent infections with encapsulated bacteria. Patients with C1, C2, or C4 deficiency are susceptible to autoimmune diseases, especially systemic lupus erythematosus. The exact mechanism of this susceptibility is not known but is thought to arise from the role of these early components in clearing immune complexes.

Deficiency of properdin, C3, or the terminal components predisposes patients to severe recurrent infections. Deficiency of C3, the major opsonin, due to a genetic defect or secondary to excessive consumption, predisposes patients to infections, especially with encapsulated organisms. Deficiency of one of the terminal components that compose the MAC predisposes patients to infection with *Neisseria meningitidis*. Complement deficiency may be found in 40% of patients presenting with recurrent neisserial infections. Deficiency of mannose-binding lectin may be associated with an increased frequency of bacterial infections, but the clinical significance of mannose binding lectin deficiency is controversial.

Congenital deficiency of C1-inhibitor results in **hereditary angioedema**, characterized by recurrent episodes of nonpruritic angioedema lasting 48–72 hours that occur spontaneously or after minor trauma, stress, or anxiety. Intestinal edema can cause acute abdominal pain; edema of the upper airway can be life threatening and may necessitate emergency tracheostomy. Importantly, the angioedema in this disorder is not responsive to corticosteroids, and this feature is useful in distinguishing from more common forms of idiopathic angioedema. Hereditary angioedema is inherited as an autosomal dominant disease and results from a heterozygous deficiency of C1-inhibitor leading to serum levels less than 30% of normal values. Some mutations (type II hereditary angioedema) result in normal levels of C1-inhibitor with defective function. Hereditary angioedema with normal C1-inhibitor (formally known as hereditary edema type 3) may occur due to mutations in factor XII, but the etiology in most cases is unknown. An acquired form of angioedema results from autoantibodies to C1-inhibitor in lymphoid malignancies or autoimmune disorders but is uncommon in childhood. C1-inhibitor is a regulator of Hageman factor (clotting factor XIIa), clotting factor XIa, plasma kallikrein, and plasmin in addition to C1r and C1s. Lack of inhibition of the contact system, Hageman factor, and plasma kallikrein leading to the overproduction of bradykinin is responsible for the development of angioedema.

Deficiencies in the complement regulatory proteins factor H, factor I, and MCP result in **atypical hemolytic uremic syndrome, membranoproliferative glomerulonephritis type II**, and have been linked to **age-related macular degeneration**.

LABORATORY STUDIES

The **CH₅₀ test** tests the classic complement pathway function, based on an antibody-dependent hemolytic assay, which measures the serum dilution that results in lysis of 50% of sheep red blood cells. The CH₅₀ test depends on the function of all nine complement proteins, C1 through C9. The **AH₅₀ test**, which measures complement activation using

red blood cells from different species (e.g., rabbit) that can activate the alternative pathway without antibody, is less widely available than the CH₅₀ test and requires the alternative pathway components and C5–C9. Abnormal results of both tests indicate a deficiency in a terminal component common to both pathways (C5–C9), whereas an abnormal result of CH₅₀ or AH₅₀ indicates a deficiency of an early component (C1q, C2, C4, or C3) or of the alternative pathway (factor B, properdin), respectively. If the CH₅₀ or AH₅₀ levels are abnormal, individual components can be analyzed in specialized laboratories.

Low C1-inhibitor levels or function results in chronically decreased C4 levels and decreased C2 levels during acute attacks. Therefore C4 levels are commonly used as a screening test for hereditary angioedema type 1 and type 2, but definitive diagnosis requires determination of C1-inhibitor levels and function. Low C1 levels are found in acquired C1-inhibitor deficiency, which distinguishes it from hereditary angioedema. Tests for autoantibodies to C1-inhibitor can be performed by enzyme-linked immunosorbent assay.

TREATMENT

Specific treatment of complement deficiencies with component replacement is not available. Long, frequent courses of antibiotics constitute the primary therapy. Immunization of patients and close contacts with pneumococcal and meningococcal vaccines may be useful, but infections may still occur in immunized complement-deficient patients. Replacement of complement proteins by plasma transfusion has been used in some patients with C2 deficiency, factor H deficiency, or factor I deficiency. MCP deficiency is treated with renal transplantation because it is a membrane protein.

There are several therapeutic options available for **C1-inhibitor deficiency**. Acute attacks of angioedema in this disorder should be treated as promptly as possible with plasma derived or recombinant C1-inhibitor, icatibant, a bradykinin B₂-receptor antagonist, or ecallantide, a kallikrein inhibitor. Importantly, the angioedema in these disorders is not responsive to epinephrine, antihistamines, or corticosteroids. In the case of acute airway obstruction nonresponsive to medications, an emergency tracheostomy may be required.

Long-term prophylaxis of hereditary angioedema can be treated by several medications. The prophylactic use of an oral attenuated androgen (**stanozolol** or **danazol**), which increases serum concentrations of C1-inhibitor, can be used; adverse effects, including masculinization in females, growth arrest, and hepatitis, limit their use. Chronic administration of recombinant or plasma derived C1-inhibitor or lanadelumab, a human monoclonal antibody to kallikrein, is increasingly used in the disorder. Alternatively, prompt breakthrough treatment with icatibant or ecallantide is also used. Angiotensin-converting enzyme inhibitors, such as captopril, should be avoided in patients with C1-inhibitor deficiency because these drugs can precipitate episodes of angioedema by inhibiting degradation of kinins that mediate angioedema formation.

PEARLS FOR PRACTITIONERS

See *Immunology: Pearls for Practitioners* at the end of this section.

CHAPTER 76

Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation (HSCT) can cure some patients with primary immunodeficiency disease (Table 76.1). Use of HSCT is limited to immunodeficiency diseases, some metabolic storage diseases (see Chapters 55 and 56), malignancies (see Chapter 154), aplastic anemia (see Chapter 150), hemoglobinopathies (see Chapter 150), and a few other disorders.

The principle of HSCT is to replace a patient's defective bone marrow stem cells with normal stem cells. Hematopoietic stem cells reside in the bone marrow but can also be obtained from peripheral blood or cord blood. Peripheral blood does not contain a significant proportion of stem cells unless the donor's bone marrow is actively stimulated to generate stem cells. Cord blood is a good source of stem cells and is used for sibling and unrelated HSCT.

Major histocompatibility complex (MHC) compatibility is crucial in the choice of a stem cell donor to avoid rejection of the donor cells by the host immune system and to prevent **graft versus host disease (GVHD)** caused by contaminating mature T cells. The donor stem cells give rise to T cells that develop in the host thymus and need to interact with donor and host antigen-presenting cells. In cases with MHC mismatched donors, mature T cells need to be removed from the donor to reduce the risk of GVHD; this complication outweighs the disadvantage of a prolonged time of 90–120 days before T-cell development. Patients are at risk for developing **B-cell lymphoproliferative disease**, usually associated with Epstein-Barr virus, when T-cell depletion techniques are used, likely due to the delay in T-cell engraftment.

The most important factor affecting outcomes in HSCT is the similarity of the donor MHC. The best outcomes are obtained using MHC-identical siblings (25% chance of a matched sibling) as donors, followed by matched unrelated donors. Unlike transplantation for other disorders, MHC haploidentical bone marrow from a parent (preferred) or a sibling can be used to treat severe combined immunodeficiency (SCID), likely the result of these patients lacking functioning T cells. Stem cells from a partially mismatched donor, such as a parent, can give rise to a functioning immune system because the patient shares at least half of the MHC molecules with the donor stem cells.

MHC molecules are highly polymorphic, and typing is currently performed on DNA rather than by serology. Bone marrow and cord blood registries are available worldwide. Searching and identifying a donor can be a lengthy process, especially for some underrepresented ethnic backgrounds. Finding a suitable cord blood donor is faster because the cord blood already has been obtained and stored, whereas bone marrow donors have to be identified, located, and tested.

Patients with SCID require definitive treatment as survival is unlikely beyond 1 or 2 years of age. Stem cell transplantation is the main option for treatment of SCID, although gene therapy will likely become an increasingly used therapeutic option in the future. The development of transplantation using T-cell-depleted, haploidentical bone marrow from a

Cyclic neutropenia
Chédiak-Higashi syndrome
Leukocyte adhesion deficiency type I
Familial hemophagocytic lymphohistiocytosis

parent for SCID has provided almost every patient with SCID a potential donor. The mother is the preferred source for haploidentical bone marrow, if she is able to donate, because some transfer of maternal T cells can occur during pregnancy, and these maternal T cells can reject cells obtained from the father. The need for conditioning prior to stem cell transplantation for SCID is controversial and an area of ongoing research. In nations that use newborn screening for SCID, the long-term survival rate after stem cell transplantation is over 90% reflecting the improvement in outcomes that occur with transplantation prior to infection.

DNA sequencing is often needed to obtain a genetic diagnosis to ascertain the cause of a primary immunodeficiency. Consequently, information about the natural history of these disorders is increasingly available and a better, more informed decision on the need for stem cell transplantation can be made. In those cases where a genetic diagnosis is not obtained, several factors are taken into consideration when considering stem cell transplantation such as age, severity of the immunodeficiency, functional status of the patient and availability of a human leukocyte antigen (HLA)-matched donor. Disorders of B cells have not been treated with HSCT in the past because in many cases these disorders respond well to antibody replacement therapy. Furthermore, normal immunoglobulin production does not necessarily occur following stem cell transplantation in a substantial percentage of patients, despite

normal donor B-cell engraftment. Regardless, stem cell transplantation is commonly used to treat a number of combined immunodeficiencies (see Table 76.1).

COMPLICATIONS

Rejection of the grafted stem cells is the first potential complication of HSCT and depends on the immunocompetence of the patient, the degree of MHC incompatibility, and the number of stem cells administered. Preconditioning with cytotoxic drugs such as busulfan and cyclophosphamide can prevent graft rejection but may be complicated by pulmonary toxicity and by venoocclusive disease of the liver, which results from damage to the hepatic vascular endothelium and can be fatal. Conditioning prior to stem cell transplantation results in anemia, leukopenia, and thrombocytopenia, making patients susceptible to infection and bleeding disorders. Neutropenic precautions should be maintained, and patients supported with red blood cell and platelet transfusions until the red blood cell, platelet, and neutrophil lineages engraft. Reduced intensity preconditioning is increasingly used to prevent graft rejection and decrease the adverse effects of more intensive forms of conditioning. **B-cell lymphoproliferative disorders** due to Epstein-Barr virus infection can develop after T-cell-depleted bone marrow transplantation. GVHD can arise from an MHC-mismatched transplantation or from mismatch in minor histocompatibility antigens that are not tested before transplantation. T-cell depletion of haploidentical bone marrow reduces the risk of GVHD. Patients with SCID transplanted with T-cell-depleted haploidentical bone marrow do not usually develop severe GVHD. **Acute GVHD** begins 6 or more days after transplantation due to transfer of mature lymphocytes or can result from transfusion of nonirradiated blood products in patients with no T-cell function. Acute GVHD presents with fever, skin rash, and severe diarrhea. Patients develop a high, unrelenting fever; a morbilliform maculopapular erythematous rash that is painful and pruritic; hepatosplenomegaly and abnormal liver function tests; and nausea, vomiting, abdominal pain, and watery diarrhea. Acute GVHD is staged from grades 1–4, depending on the degree of skin, fever, gastrointestinal, and liver involvement. **Chronic GVHD** typically occurs after acute GVHD, is diagnosed after 100 days, and can develop without acute GVHD or after acute GVHD has resolved. Chronic GVHD is characterized by skin lesions (hyperkeratosis, reticular hyperpigmentation, fibrosis, and atrophy with ulceration), limitation of joint movement, interstitial pneumonitis, and immune dysregulation with autoantibody and immune complex formation.

PEARLS FOR PRACTITIONERS

CHAPTER 72

Immunologic Assessment

- Primary immune deficiency disorders (PIDDs) result in severe, recurrent, or unusual (opportunistic) infections.
- Secondary causes of immune deficiency (e.g., protein losing enteropathy, drug effects, impaired barrier function such as eczema or burns, anatomic defects, malignancies) should be excluded in the evaluation of primary immunodeficiencies.
- PIDDs typically present in childhood but can occur at any age, and the age of onset can give clues to the diagnosis.
 - Congenital neutropenia and other phagocyte defects typically present with infections in the first several months of life.
 - Severe combined immunodeficiency (SCID) and other serious combined immunodeficiencies present within the first year of life.
 - Antibody deficiencies typically present after 6 months of age but can present after several years of life.
 - Common variable immunodeficiency (CVID) typically presents in young adulthood.
- The type and location of infections can help to narrow the diagnosis.
 - Gingivitis, poor wound healing, omphalitis, granulomas, or abscesses without pus point to a neutrophil/phagocyte defect.
 - Recurrent sinopulmonary infections suggest a humoral or B-cell defect.
 - Infections with opportunistic infections or severe viral infections suggests a T-cell or combined immunodeficiency.
 - *Neisseria* infections or early-onset autoimmunity may represent a complement defect.
- The initial work-up of a suspected PIDD is guided by the type and locations of the infections as noted earlier. However, a complete blood count (CBC) with differential should be obtained in all patients with a suspected PIDD.
 - Suspected neutrophil/phagocyte defects: CBC with differential, examination of peripheral smear and dihydrorhodamine 123 (DHR) or nitroblue tetrazolium (NBT) test, which examines the integrity of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase pathway. Bone marrow biopsy is performed when more than one blood lineage is affected or there is a poor response to therapy.
 - Suspected humoral or B-cell disorder: immunoglobulin G (IgG), IgA, IgM levels; specific titers to diphtheria, tetanus, and pneumococcus
 - Suspected T-cell or combined defect: IgG, IgA, IgM levels; specific titers to diphtheria, tetanus, and pneumococcus; flow cytometry for lymphocyte subsets
 - Suspected complement defects: CH₅₀, AH₅₀
- Genetic testing is increasingly used to obtain a definitive diagnosis and has implications as to treatment and long-term monitoring. In addition, expanded genetic sequencing panels allow for the rapid and economical diagnosis of many PIDDs.
- Treatment of PIDDs is tailored to the diagnosis.
 - Humoral/B-cell defects are treated with immunoglobulin replacement.
 - Neutrophil/phagocyte defects are treated with granulocyte colony-stimulating factor (G-CSF) or hematopoietic stem cell transplant (HSCT).
 - T-cell/combined defects are treated with antibody replacement therapy and antimicrobial (bacterial, viral fungal) prophylaxis until HSCT can be performed.
 - Complement defects are treated with frequent vaccinations and in some cases antibiotic prophylaxis.
- Practical aspects of patients with PIDDs
 - No live-virus vaccines. If patient has SCID, family members should not receive live viral vaccines.
 - Clean water sources, which may involve boiling water. Bottled water is not acceptable.
 - All blood products given to patients with PIDDs should be cytomegalovirus (CMV) negative and irradiated.
 - Limit sick contacts.

CHAPTER 73

Lymphocyte Disorders

- Agammaglobulinemia may be inherited as either an X-linked or autosomal recessive disorder.
- Patients with agammaglobulinemia have an increased risk of infection with bacteria as well as enteroviruses and giardia.
- Common variable immunodeficiency (CVID) has low IgG levels with low IgA or IgM levels.
- Patients with CVID are at risk for infection, autoimmunity, immune dysregulation, and B-cell lymphomas.
- Hyper-IgM syndrome is most commonly X-linked due to CD40L deficiency and is a combined immunodeficiency.
- Severe combined immunodeficiency (SCID) diseases present with failure to thrive, severe bacterial or virus infections, diarrhea, eczema-like skin rash, and graft versus host

disease from transfused lymphocytes and requires early stem cell transplantation.

- DiGeorge syndrome is characterized by hypocalcemia, congenital heart disease, T-cell immunodeficiency, and deletions on chromosome 22q11.2.

CHAPTER 74

Neutrophil Disorders

- Neutrophil disorders may manifest with abscesses, lymphadenitis, gingivitis, poor wound healing, delayed separation of the umbilical cord, or poor pus formation.
- Neutropenia is defined as an absolute neutrophil count of less than $1,500/\text{mm}^3$ in White children over 1 year of age. It is somewhat lower in Black children.
- Cyclic neutropenia has ~21-day cycles of low neutrophil counts that then recover.
- Autoimmune neutropenia develops in children between 5 and 24 months of age and may persist; it responds to G-CSF.
- Chronic granulomatous disease results from defective intracellular neutrophil killing of bacteria that produce catalase.

CHAPTER 75

Complement System

- Deficiencies of early components of the classic complement pathway are associated with encapsulated bacteria, and deficiencies of the late components of the complement cascade are associated with neisserial infections.
- Patients with C1, C2, or C4 deficiency are at risk for autoimmune diseases (systemic lupus erythematosus).
- Deficiency of C1-inhibitor produces hereditary angioedema.

CHAPTER 76

Hematopoietic Stem Cell Transplantation

- Hematopoietic stem cell transplantation has been used to treat malignancies, some metabolic disorders, aplastic anemia, immunodeficiency or immune dysregulation syndromes, and hemoglobinopathies.

ALLERGY

Kristen K. Volkman | Asriani M. Chiu

CHAPTER 77

Allergy Assessment

Atopy is a result of complex interactions between multiple genes and environmental factors. It implies specific immunoglobulin E (IgE)-mediated diseases, including allergic rhinitis, asthma, and food allergy. An **allergen** is an antigen that triggers an IgE response in genetically predisposed individuals.

Hypersensitivity disorders of the immune system are classified into four groups, based on the mechanism of tissue inflammation (Table 77.1). **Type I (immediate hypersensitivity) reactions** result from the binding of antigen to cell surface-bound IgE on high-affinity IgE receptors on tissue mast cells, circulating basophils, or both, causing the release of preformed chemical mediators, such as histamine and tryptase, and newly generated mediators, such as leukotrienes, prostaglandins, and platelet-activating factor. These mediators contribute to the development of allergic symptoms, with anaphylaxis as the most profound syndrome. Several hours after the initial response, a **late-phase reaction** may develop with an influx of other inflammatory cells such as basophils, eosinophils, monocytes, lymphocytes, and neutrophils, and their inflammatory mediators. Recruitment of these cells leads to more persistent and chronic symptoms.

Type II (cytotoxic antibody) reactions involve IgM, IgG, or IgA antibodies binding to cell surface antigens and

activating the entire complement pathway resulting in lysis of the cell or release of **anaphylatoxins**, such as C3a, C4a, and C5a (see Chapter 75). These anaphylatoxins trigger mast cell degranulation, resulting in inflammatory mediator release. The target can be cell surface membrane antigens, such as red blood cells causing hemolytic anemia, platelet cell surface molecules, glomerular basement membrane molecules, acetylcholine receptor α chain at the neuromuscular junction, and thyroid-stimulating hormone receptor on thyroid cells causing Graves disease.

Type III (immune complex) reactions involve the formation of antigen-antibody or immune complexes that enter into the circulation and are deposited in tissues such as blood vessels and filtering organs (i.e., liver, spleen, and kidney). These complexes initiate tissue injury by activating the complement cascade and recruiting neutrophils that release their toxic mediators. Local reactions caused by the injection of antigen into tissue are called **Arthus reactions**. The administration of large amounts of antigen leads to **serum sickness**. Other type III reactions include hypersensitivity pneumonitis and some vasculitic syndromes.

Type IV (cellular immune-mediated or delayed-hypersensitivity) reactions involve recognition of antigen by sensitized T cells. Antigen-presenting cells present peptides on the cell surface in association with major histocompatibility complex class II (MHC-II) molecules. Memory T cells recognize the peptide/MHC-II complex resulting in cytokine release (e.g., interferon- γ , tumor necrosis factor- α , and

TABLE 77.1 Gell and Coombs Classification of Hypersensitivity Disorders

TYPE	INTERVAL BETWEEN EXPOSURE AND REACTION	EFFECTOR MOLECULE	TARGET OR ANTIGEN	EXAMPLES OF MEDIATORS	EXAMPLES
I Immediate Late phase	<30min 2–12hr	IgE	Pollens, food, venom, drugs	Histamine, tryptase, leukotrienes, prostaglandins, platelet-activating factor	Anaphylaxis, urticaria, allergic rhinitis, allergic asthma
II Cytotoxic antibody	Variable (min–hr)	IgM, IgG, IgA	Red blood cells, platelets	Complement	Hemolytic anemia, thrombocytopenia, Goodpasture syndrome
III Immune complex	1–3 wk after drug exposure	Antigen-antibody complexes	Blood vessels, liver, spleen, kidney, lung	Complement, anaphylatoxin	Serum sickness, hypersensitivity pneumonitis
IV Delayed type	2–7 days after drug exposure	Lymphocytes	<i>Mycobacterium tuberculosis</i> , chemicals	Cytokines (IFN- γ , TNF α , GM-CSF)	TB skin test reactions, contact dermatitis, graft-vs-host disease

GM-CSF, Granulocyte-macrophage colony-stimulating factor; IFN- γ , interferon- γ ; TB, tuberculosis; TNF α , tumor necrosis factor- α .

granulocyte-macrophage colony-stimulating factor), which activates and attracts tissue macrophages. **Contact allergies** (e.g., nickel dermatitis and poison ivy) and immunity to tuberculosis are examples of type IV reactions.

HISTORY

The history may reveal allergic symptoms after exposure to a potential trigger that usually has occurred upon previous exposures.

A family history of allergic disease is often present in affected patients. If one parent has allergies, the risk that a child will develop an allergic disease is 25%. If both parents have allergies, the risk increases to 50–70%. Other atopic diseases tend to occur in families.

PHYSICAL EXAMINATION

Allergic disease may involve the skin, nose, eyes, lungs, or gastrointestinal tract alone or in combination. Many patients have more than one organ system involved.

Children with allergic rhinitis exhibit frequent nasal itching and rubbing of the nose with the palm of the hand, called the **allergic salute**, which leads to a transverse nasal crease across the nose. Pale nasal mucosa and edematous turbinates are common examination findings. **Allergic shiners**, blue-gray to purple discoloration below the lower eyelids attributed to venous congestion, along with swollen eyelids or conjunctival injection, are often present in children. Dermatologic findings of atopy include pruritic, erythematous plaques of atopic dermatitis, prominent creases under the lower eyelids (**Dennie-Morgan folds** or **Dennie lines**), urticaria, and **keratosis pilaris** (see [Chapter 80](#)). Wheezing may be noted on auscultation of the lower respiratory tract.

INITIAL DIAGNOSTIC EVALUATION

Screening Tests

Atopy is characterized by elevated levels of IgE ([Table 77.2](#)) and **eosinophilia** (3–10% of white blood cells or an absolute eosinophil count of >250 eosinophils/mm³) with a predominance of T helper (Th)2 cytokines, including interleukin 4 (IL-4), IL-5, and IL-13. Extreme eosinophilia suggests a nonallergic disorder such as infection, hypereosinophilic syndrome, drug reaction, or malignancy ([Table 77.3](#)).

There are two methods for identifying allergen-specific IgE: *in vivo* skin testing and *in vitro* serum testing ([Table 77.4](#)). **In vivo skin testing** introduces allergen into the skin via a prick/puncture or intradermal injection. The allergen diffuses through the skin to interact with IgE that is bound to mast cells. Cross-linking of IgE causes mast cell degranulation, which results in histamine release and the development of a **central wheal** and **erythematous flare**. The wheal and flare are measured 15–20 minutes after the allergen has been applied. Properly performed skin tests are the most sensitive method for detecting the presence of allergen-specific IgE.

In vitro serum testing, such as immunoassays like the enzyme-linked immunosorbent assay (**ELISA**), measures levels of antigen-specific IgE. Many allergists and laboratories regard the ImmunoCAP System (ThermoFisher Scientific, Waltham, MA) as the method of choice. This method uses

discontinue medications such as antihistamines that interfere with skin test results, or who are noncompliant for skin testing. The presence of specific IgE antibodies suggests sensitization *but is not sufficient* for the diagnosis of allergic disease. Diagnosis must be based on the physician's assessment of the entire clinical picture, including the history and physical examination, the presence of specific IgE antibodies, and the correlation with IgE-mediated symptoms.

DIAGNOSTIC IMAGING

Diagnostic imaging has a limited role in the evaluation of allergic disease. Chest radiography may be helpful with the differential diagnosis of asthma. Sinus radiography and computed tomography may be useful, but when these images are abnormal, they do not distinguish allergic disease from non-allergic disease.

PEARLS FOR PRACTITIONERS

See Allergy: *Pearls for Practitioners* at the end of this section.

to allergens, irritants, viral infections, and exercise). It also results in edema, increased mucus production in the lungs, influx of inflammatory cells into the airway tissue, and epithelial cell denudation. Chronic inflammation can lead to **airway remodeling**, which results from a proliferation of extracellular matrix proteins and vascular hyperplasia and may lead to irreversible structural changes and progressive loss of pulmonary function.

EPIDEMIOLOGY

Asthma is the most common chronic disease of childhood in industrialized countries, affecting over 5 million children younger than 18 years of age in the United States (7.5% of children). In adults, females are more likely than males to have asthma, but in children the reverse is true. In 2016 in the United States, pediatric hospitalizations for asthma exceeded 80,000, and there were nearly 550,000 emergency department visits for pediatric asthma. Mortality from asthma occurs; in 2018, 192 deaths were attributed to asthma. For children, the death rate is 2.6 per million.

CLINICAL MANIFESTATIONS

Children with asthma have symptoms of coughing, wheezing, shortness of breath, exercise intolerance, or chest tightness. The history should elicit the frequency, severity, and precipitating factors as well as a family history of asthma and allergy. Common exacerbating factors include respiratory viral infections, exposure to allergens and irritants (e.g., smoke, air pollution, strong odors, fumes), exercise, emotions, and change in weather/humidity. Nocturnal symptoms are common. Rhinosinusitis, gastroesophageal reflux, and aspirin can aggravate asthma. Treatment of these conditions may lessen the frequency and severity of asthma.

During acute episodes, tachypnea, tachycardia, cough, wheezing, and a prolonged expiratory phase may be present. Physical findings may be subtle. Wheezing may not be prominent if there is poor aeration from airway obstruction. As the attack progresses, cyanosis, diminished air movement, retractions, agitation, inability to speak, tripod sitting position, diaphoresis, and pulsus paradoxus (decrease in blood pressure of >15 mm Hg with inspiration) may be observed. Physical examination may show evidence of other atopic diseases such as eczema or allergic rhinitis.

LABORATORY AND IMAGING STUDIES

While no single test or study can confirm the diagnosis of asthma, many elements contribute to establishing the diagnosis.

Objective measurements of pulmonary function aid in the diagnosis and direct the treatment of asthma. **Spirometry** is used to monitor response to treatment, assess degree of reversibility with therapeutic intervention, and measure the severity of an asthma exacerbation. Children older than 5 years of age can usually perform spirometry maneuvers. **Peak expiratory flow** offers a simple, inexpensive way to measure asthma control at home; variability in predicted peak flow reference values make spirometry preferred over peak flow measures in the diagnosis of asthma. For younger children who cannot perform spirometry maneuvers or peak flow, a therapeutic trial of controller medications aids in the diagnosis of asthma.

CHAPTER 78

Asthma

ETIOLOGY

Inflammatory cells (mast cells, eosinophils, T lymphocytes, neutrophils), chemical mediators (histamine, leukotrienes, platelet-activating factor, bradykinin), and chemotactic factors (cytokines, eotaxin) mediate the underlying inflammation found in asthmatic airways. Inflammation contributes to **airway hyperresponsiveness** (airways constricting in response

Measurement of a biomarker, **exhaled nitric oxide (FeNO)**, reflects eosinophilic airway inflammation and provides information on those patients who may better respond to corticosteroid treatment, aids in monitoring response to therapy and dose optimization, and detects nonadherence to corticosteroid therapy.

Allergy skin testing should be included in the evaluation of all children with persistent asthma but not during an exacerbation of symptoms. Positive skin test results, identifying sensitization to **aeroallergens** (e.g., pollens, mold, dust mite, pet dander), correlate strongly with bronchial allergen provocative challenges. In vitro serum tests, such as enzyme-linked immunosorbent assay (ELISA), are generally less sensitive in defining clinically pertinent allergens, are more expensive, and require several days for results, compared to several minutes for skin testing (see Table 77.4).

A **chest x-ray** should be performed with the first episode of asthma or with recurrent episodes of undiagnosed cough or wheeze to exclude anatomic abnormalities. Repeat chest x-rays are not needed with new episodes unless there is fever (suggesting pneumonia) or localized findings on physical examination.

DIFFERENTIAL DIAGNOSIS

Many childhood conditions can cause wheezing and coughing like asthma (Table 78.1), but not all cough and wheeze is asthma. Misdiagnosis delays correcting the underlying cause and exposes children to inappropriate therapy (Table 78.2).

Allergic bronchopulmonary aspergillosis is a hypersensitivity reaction to antigens of the mold *Aspergillus fumigatus*. It occurs primarily in patients with steroid-dependent asthma and in patients with cystic fibrosis.

TREATMENT

Optimal medical treatment of asthma includes several key components: environmental control, pharmacologic therapy, and patient education, including attainment of self-management skills. Because many children with asthma have coexisting allergies, steps to minimize allergen exposure should be taken (Table 78.3). For all children with asthma, exposures to tobacco and wood smoke and to persons with viral infections should be minimized. Influenza immunization is indicated. Asthma medications can be divided into long-term control medications and quick-relief medications.

Long-Term Control Medications

Inhaled Corticosteroids

Inhaled corticosteroids (ICS) are the most effective antiinflammatory medications for the treatment of chronic, persistent asthma and are the preferred therapy when initiating long-term control therapy. Early intervention with ICS reduces morbidity but does not alter the natural history of asthma. Regular use reduces airway hyperreactivity, the need for rescue bronchodilator therapy, risk of hospitalization, and risk of death from asthma. ICS are available as inhalation aerosols, dry powder inhalers, and a nebulizer solution.

The potential risks of ICS are favorably balanced with their benefits. A reduction in growth velocity may occur with poorly controlled asthma or ICS use. Low-to-medium dose ICS may decrease growth velocity, although these effects are small (approximately 1 cm in the first year of treatment), generally not progressive, and may be reversible. Height measurements should be monitored. ICS do not have clinically significant adverse effects on hypothalamic-pituitary-adrenal axis function, glucose metabolism, subcapsular cataracts, or glaucoma when used at low-to-medium doses in children. Rinsing the mouth after inhalation and using large volume spacers help lessen the local adverse effects of dysphonia and candidiasis and decrease systemic absorption from the gastrointestinal tract. ICS should be titrated to the lowest dose needed to maintain control of a child's asthma. For children with severe asthma, high-dose ICS may be needed to minimize oral

TABLE 78.3 Controlling Factors Contributing to Asthma Severity

MAJOR INDOOR TRIGGERS FOR ASTHMA	SUGGESTIONS FOR REDUCING EXPOSURE	
Viral upper respiratory tract (e.g., RSV, rhinovirus, influenza virus)	Limit exposure to viral infections	
	Annual influenza immunization	
Tobacco smoke, wood smoke	No smoking around the child or in child's home	
	Help parents and caregivers quit smoking	
	Eliminate use of wood stoves and fireplaces	
Dust mites	ESSENTIAL ACTIONS	
	Encase pillow, mattress, and box spring in allergen-impermeable encasements	
	Wash bedding in hot water weekly	
	DESIRABLE ACTIONS	
	Avoid sleeping or lying on upholstered furniture	
	Minimize number of stuffed toys in child's bedroom	
	Reduce indoor humidity to <50%	
	If possible, remove carpets from bedroom and play areas; if not possible, vacuum weekly	
	Animal dander	Remove the pet from the home or keep outdoors (if removal is not acceptable)
		Keep pet out of bedroom/no sleeping with pet
Use a filter on air ducts in child's room		
Wash pet weekly (the evidence to support this has not been firmly established)		
Cockroach allergens	Do not leave food or garbage exposed	
	Pesticides	
	Sealing cracks and holes	
Indoor mold	Avoid vaporizers	
	Reduce indoor humidity to <50%	
	Use of mold inhibiting cleaner	
	Use of dehumidifier	
	Fix leaky faucets, pipes	

RSV, Respiratory syncytial virus.

corticosteroid use, but other add-on therapy should be considered (see the following sections).

Leukotriene Modifiers

Leukotrienes, synthesized via the arachidonic acid metabolism cascade, are potent mediators of inflammation and smooth

muscle bronchoconstriction. Leukotriene modifiers are oral, daily-use medications that inhibit these biologic effects in the airway. Two classes of leukotriene modifiers include cysteinyl leukotriene receptor antagonists (zafirlukast and montelukast) and leukotriene synthesis inhibitors (zileuton). The leukotriene receptor antagonists have much wider appeal than zileuton. Zafirlukast is approved for children older than 5 years of age and is given twice daily. Montelukast is dosed once daily at night as 4-mg granules or chewable tablets (for children 6 months to 5 years of age), 5-mg chewable tablets (6–14 years of age), and 10-mg tablets (≥ 15 years of age). Pediatric studies show the usefulness of leukotriene modifiers in mild asthma and the attenuation of exercise-induced bronchoconstriction. These agents may be helpful as steroid-sparing agents in patients with asthma that is more difficult to control.

Long-Acting β_2 Agonists

Long-acting β_2 agonists (LABAs) relax airway smooth muscle for 12–24 hours but do not have any significant antiinflammatory effects. LABAs are not intended for use as monotherapy, but adding a LABA to ICS therapy is more beneficial than doubling the dose of inhaled corticosteroids. Multiple formulations are available. Formoterol is approved for use in children older than 5 years of age for maintenance asthma therapy and for prevention of exercise-induced asthma. It has a rapid onset of action similar to albuterol (15 min) and is dosed twice daily. Salmeterol is approved for children 4 years of age or older, has an onset of 30 min, and is given twice daily. Vilanterol, an ultralong-acting β_2 agonist, is approved in patients aged 18 years and older and has the advantage of once-daily dosing. Combination ICS/LABA products are available. Because combination inhalers administer two medications simultaneously, compliance is generally improved.

Theophylline

Theophylline was more widely used previously, but because current management is aimed at inflammatory control, its use has declined. It is mildly to moderately effective as a bronchodilator and is considered an alternative, add-on treatment to low- and medium-dose inhaled corticosteroids. Its therapeutic window is narrow necessitating monitoring of blood levels.

Biologics

Biologic agents are genetically engineered proteins that target specific antibodies, inflammatory molecules, and receptors; several biologics are U.S. Food and Drug Administration (FDA) approved for the treatment of asthma in children (Table 78.4). Omalizumab, the first biologic approved for asthma, is a humanized anti-IgE monoclonal antibody that prevents binding of free IgE to high-affinity receptors on basophils and mast cells. It is delivered by subcutaneous injection every 2–4 weeks, depending on body weight and pretreatment serum IgE level.

Mepolizumab is an add-on maintenance therapy for severe asthma with an eosinophilic phenotype. It decreases the production and survival of eosinophils, a major inflammatory cell involved in asthma pathogenesis.

Dupilumab binds to the IL-4 receptor, which blocks intracellular signaling of IL-4 and IL-13. This medication can be administered at home.

Benralizumab binds the IL-5 receptor inhibiting IL-5 activity and induces eosinophil apoptosis. Reslizumab also binds

to IL-5, preventing its binding to the IL-5 receptor but is only approved for patients over 18 years of age.

Quick-Relief Medications

Short-Acting β_2 Agonists

Short-acting β_2 agonists (SABAs) such as albuterol and levalbuterol are effective bronchodilators that relax bronchial smooth muscle within 5–10 minutes of administration. These effects last 4–6 hours. Generally, a SABA is prescribed for acute symptoms and as prophylaxis before allergen exposure and exercise. The inhaled route is preferred because adverse effects—tremor, prolonged tachycardia, and irritability—are less. Overuse of SABAs implies inadequate control, and a change in medications may be warranted. The definition of *bronchodilator overuse* depends on the severity of the child's asthma; use of more than one metered-dose inhaler canister per month or daily use suggests poor control.

Anticholinergic Agents

Ipratropium bromide is a short-acting anticholinergic bronchodilator that relieves bronchoconstriction, decreases mucus hypersecretion, and counteracts cough-receptor irritability by binding acetylcholine at the muscarinic receptors found in bronchial smooth muscle. It seems to have an additive effect with SABAs when used for acute asthma exacerbations.

A long-acting anticholinergic agent (tiotropium) is approved for use in moderate to severe persistent asthma in children 6 years or older. It inhibits muscarinic receptors on bronchial smooth muscle to induce bronchodilation.

Oral Corticosteroids

Short bursts of oral corticosteroids (1–10 days) are administered to children with acute exacerbations. The usual dose is 1–2 mg/kg/day of prednisone for 5 days or 0.6 mg/kg/day of dexamethasone for 1–2 days. Oral corticosteroids are available in liquid or tablet formulations. Prolonged use of oral corticosteroids can result in systemic adverse effects such as hypothalamic-pituitary-adrenal suppression, cushingoid features, weight gain, hypertension, diabetes, cataracts, glaucoma, impaired immunity, osteoporosis, and growth suppression. Children with severe asthma may require oral corticosteroids over extended periods. The dose should be tapered as soon as possible to the minimum effective dose, preferably administered on alternate days (for prednisone).

Administration of one or two doses of dexamethasone for the treatment of *acute asthma* exacerbations is used, usually in an emergency room setting for intermittent, mild persistent, or moderate persistent asthma. This long-acting oral corticosteroid has properties that may increase compliance with therapy, decrease missed school days, and decrease readmission rates.

Approach to Therapy

Therapy is based on the concept that chronic airway inflammation is a fundamental feature of asthma, which can vary in intensity over time, requiring treatment to be adjusted accordingly. Classification of asthma severity is emphasized for initiation of therapy in patients not currently receiving controller

medications. Assessing control is emphasized for monitoring and adjusting therapy. A stepwise approach is used for management of infants and young children 0–4 years of age, children 5–11 years of age (Fig. 78.1), and youths 12 years or older, and adults (Fig. 78.2). Medication type, dose, and dosing intervals are determined by the level of asthma severity or asthma control. Therapy is then increased (**stepped up**) as necessary and decreased (**stepped down**) when possible. A short-acting bronchodilator should be available for all children with asthma. A child with intermittent asthma has asthma symptoms less than two times per week. To determine whether a child is having more persistent asthma, using the **Rules of Two** is helpful: daytime symptoms occurring two or more times per week or nocturnal awakenings two or more times per month implies a need for daily antiinflammatory medication.

Inhaled corticosteroids are the preferred initial long-term control therapy for children of all ages (Fig. 78.3). Daily long-term control therapy is recommended for infants and young children 0–4 years of age who had four or more episodes of wheezing in the previous year that lasted more than 1 day, affected sleep, and who have a positive asthma predictive index. For children over 5 years of age with moderate persistent asthma, combining long-acting bronchodilators with low-to-medium doses of inhaled corticosteroids improves lung function and reduces rescue medication use. For children with severe persistent asthma, a high-dose inhaled corticosteroid combined with a long-acting bronchodilator is the preferred therapy. The guidelines also recommend that treatment be reevaluated within 4–6 weeks of initiating therapy. Once asthma is under control, control should be assessed on an ongoing basis every 1–6 months. Asthma should be well controlled for at least 3 months before stepping down therapy.

COMPLICATIONS

Most asthma exacerbations can be successfully managed at home. **Status asthmaticus** is an acute exacerbation of asthma that does not respond adequately to therapeutic measures and may require hospitalization. Exacerbations may progress over several days or occur suddenly and can range in severity from mild to life threatening. Significant respiratory distress, dyspnea, wheezing, cough, and a decrease in **spirometry** or **peak expiratory flow rate (PEFR)** characterize deterioration in asthma control. During a severe episode, pulse oximetry is helpful in monitoring oxygenation. In status asthmaticus, arterial blood gases may be necessary for measurement of ventilation. As airway obstruction worsens and chest compliance decreases, carbon dioxide retention can occur. In the face of tachypnea, a *normal* P_{CO_2} (35–45 mm Hg) indicates impending respiratory arrest.

First-line management of asthma exacerbations includes supplemental oxygen if needed and repetitive or continuous administration of SABAs. Early administration of oral or intravenous corticosteroids (Fig. 78.4) is important in treating the underlying inflammation. Administration of anticholinergic agents (ipratropium) with bronchodilators decreases rates of hospitalization and duration of time in the emergency department. Intravenous magnesium sulfate may be administered in the emergency department if there is clinical deterioration despite treatment with β_2 agonists, ipratropium, and systemic corticosteroids. The typical dose of magnesium

		Step up if needed (first check inhaler technique, adherence, environmental control, and comorbid conditions) Assess control Step down if possible (and asthma is well controlled at least 3 months)						
		Step 1	Step 2	Step 3	Step 4	Step 5	Step 6	Notes
Children 0–4 years of age		Persistent asthma: Daily medication Consult with asthma specialist if Step 3 care or higher is required. Consider consultation at Step 2.						<ul style="list-style-type: none"> The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs. If an alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up. If clear benefit is not observed within 4–6 weeks, and patient's/family's medication technique and adherence are satisfactory, consider adjusting therapy or an alternative diagnosis. Studies on children 0–4 years of age are limited. Step 2 preferred therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children. Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur.
	Preferred	SABA PRN	Low-dose ICS	Medium-dose ICS	Medium-dose ICS + LABA or Montelukast	High-dose ICS + LABA or Montelukast	High-dose ICS + LABA or Montelukast + Oral corticosteroids ICS	
	Alternative		Cromolyn or Montelukast					
		Each Step: Patient Education and Environmental Control						
	Quick-Relief Medication	<ul style="list-style-type: none"> SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms. With viral respiratory symptoms: SABA q 4–6 hours up to 24 hours (longer with physician consult). Consider short course of oral systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbations. Caution: Frequent use of SABA may indicate the need to step up treatment. See text for recommendations on initiating daily long-term-control therapy.						Key: Alphabetical listing is used when more than one treatment option is listed within either preferred or alternative therapy. ICS, Inhaled corticosteroid; LABA, inhaled long-acting beta ₂ -agonist; LTRA, leukotriene receptor antagonist, oral corticosteroids, oral systemic corticosteroids; SABA, inhaled short-acting beta ₂ -agonist
Children 5–11 Years of Age		Persistent Asthma: Daily Medication Consult with asthma specialist if Step 4 care or higher is required. Consider consultation at Step 3.						<ul style="list-style-type: none"> The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs. If an alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up. Theophylline is a less desirable alternative due to the need to monitor serum concentration levels. Steps 1 and 2 medications are based on Evidence A. Step 3 ICS and ICS plus adjunctive therapy are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group; Steps 4–6 are based on expert opinion and extrapolation from studies in older children and adults. Immunotherapy for Steps 2–4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than adults. Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur.
	Preferred	SABA PRN	Low-dose ICS	Low-dose ICS + LABA, LTRA, or Theophylline	Medium-dose ICS + LABA	High-dose ICS + LABA	High-dose ICS + LABA + Oral corticosteroids	
	Alternative		Cromolyn LTRA Nedocromil, or Theophylline	Medium-dose ICS	Medium-dose ICS + LTRA or Theophylline	High-dose ICS + LTRA or Theophylline	High-dose ICS + LTRA or Theophylline + Oral corticosteroids	
		Each Step: Patient Education and Environmental Control, and Management of Comorbidities Steps 2–4: Consider subcutaneous allergen immunotherapy for patients who have persistent, allergic asthma.						
	Quick-Relief Medication	<ul style="list-style-type: none"> SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-minute intervals as needed. Short course of oral systemic corticosteroids may be needed. Caution: Increasing use of SABA or use >2 days a week for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment.						Key: Alphabetical listing is used when more than one treatment option is listed within either preferred or alternative therapy. ICS, Inhaled corticosteroid; LABA, inhaled long-acting beta ₂ -agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta ₂ -agonist

sulfate is 25–75 mg/kg (maximum 2.0 g) intravenously administered over 20 min. Intramuscular epinephrine or subcutaneous terbutaline is rarely used except when severe asthma is associated with anaphylaxis or is unresponsive to continuous administration of SABAs.

PROGNOSIS

For some children, symptoms of wheezing with respiratory infections subside in the preschool years, whereas others have more persistent asthma symptoms. Prognostic indicators for children younger than 3 years of age who are at risk for persistent asthma are known as the Modified Asthma Predictive Index for children (Table 78.5). Atopy is the strongest predictor for wheezing continuing into persistent asthma (Table 78.6).

PREVENTION

Education plays an important role in helping patients and their families adhere to the prescribed therapy and needs to begin at the time of diagnosis. Successful education involves teaching basic asthma facts, explaining the role of medications, teaching environmental control measures, and improving patient skills in the use of spacer devices for metered-dose inhalers and peak flow monitoring. Families should have an asthma management plan (Fig. 78.5) for daily care and for exacerbations.

Peak flow monitoring is a self-assessment tool that may be helpful for children with asthma over 5 years of age who are poor perceivers of airway obstruction, have moderate to severe asthma, or have a history of severe exacerbations. Peak flow monitoring also can be useful in children who are still learning to recognize asthma symptoms. It must be emphasized that

Drug	Low Daily Dose			Medium Daily Dose			High Daily Dose

Key: *DPI*, Dry power inhaler; *HFA*, hydrofluoroalkane; *MDI*, metered-dose inhaler; *NA*, not available (either not approved, no data available, or safety and efficacy not established for this age group)

Therapeutic Issues:

- The most important determinant of appropriate dosing is the clinician's judgment of the patient's response to therapy. The clinician must monitor the patient's response on several clinical parameters and adjust the dose accordingly. Once control of asthma is achieved, the dose should be carefully titrated to the minimum dose required to maintain control.
- Preparations are not interchangeable on a µg or per puff basis. This figure presents estimated comparable daily doses. See EPR-3 Full Report 2007 for full discussion.
- Some doses may be outside package labeling, especially in the high-dose range. Budesonide nebulizer suspension is the only inhaler corticosteroid (ICS) with FDA-approved labeling for children <4 years of age.
- For children <4 years of age: The safety and efficacy of ICSs in children <1 year has not been established. Children <4 years of age generally require delivery of ICS (budesonide and fluticasone HFA) through a face mask that should fit snugly over nose and mouth and avoid nebulizing in the eyes. Wash face after each treatment to prevent local corticosteroid side effects. For budesonide, the dose may be administered 1–3 times daily. Budesonide suspension is compatible with Albuterol, Ipratropium, and Levalbuterol nebulizer solutions in the same nebulizer. Use only jet nebulizers, as ultrasonic nebulizers are ineffective for suspensions. For Fluticasone HFA, the dose should be divided 2 times daily; the low dose for children <4 years of age is higher than for children 5–11 years of age due to lower dose delivered with face mask and data on efficacy in young children.

Potential Adverse Effects of Inhaled Corticosteroids:

- Cough, dysphonia, oral thrush (candidiasis).
- Spacer or valved holding chamber with non-breath-actuated MDIs and mouthwashing and spitting after inhalation decrease local side effects.
- A number of the ICSs, including Fluticasone, Budesonide, and Mometasone, are metabolized in the gastrointestinal tract and liver by CYP 3A4 isoenzymes. Potent inhibitors of CYP 3A4, such as Ritonavir and Ketoconazole, have the potential for increasing systemic concentrations of these ICSs by increasing oral availability and decreasing systemic clearance. Some cases of clinically significant Cushing syndrome and secondary adrenal insufficiency have been reported.
- In high doses, systemic effects may occur, although studies are not conclusive, and clinical significance of these effects has not been established (e.g., adrenal suppression, osteoporosis, skin thinning, and easy bruising). In low-to-medium doses, suppression of growth velocity has been observed in children, but this effect may be transient, and the clinical significance has not been established.

From Liu AH, Martinez FD. Natural history of allergic diseases and asthma. In: Leung DYM, Szeffler SJ, Bonilla FA, et al., eds. Pediatric Allergy: Principles and Practice. 3rd ed. Philadelphia: Elsevier; 2016 (fig. 2.4).

peak flow monitoring is not for the diagnosis of asthma but for monitoring.

A child's personal best PEFr is the highest value achieved over a 2-week period when asthma is controlled. Percentages based on the best PEFr reading may then be incorporated into a written asthma management plan as a means of providing an objective indication of airway obstruction to guide home-based asthma care. Limitations exist, however, to PEFr: they are effort and technique dependent, peak flow meters may lose accuracy with time, and appropriate range meters (low vs high) must be provided.

Utilizing PEFr and written asthma management plans simultaneously may impact asthma monitoring and management. Children with asthma should be seen not only when they are ill but also when they are healthy. Regular office visits allow the health care team to review adherence to medication and control measures and to determine whether doses of medications need adjustment.

PEARLS FOR PRACTITIONERS

See Allergy: *Pearls for Practitioners* at the end of this section.

TABLE 78.6 Risk Factors for Persistent Asthma	
Allergy	Atopic dermatitis

Asthma Action Plan

For: _____ Doctor: _____ Date: _____

Doctor's Phone Number _____ Hospital/Emergency Department Phone Number _____

GREEN ZONE

Doing Well

- No cough, wheeze, chest tightness, or shortness of breath during the day or night
- Can do usual activities

And, if a peak flow meter is used,
Peak flow: more than _____
 (80 percent or more of my best peak flow)

My best peak flow is: _____

Identify and avoid and control the things that make your asthma worse, like (list here):

How much to take _____

When to take it _____

Take these long-term-control medicines each day (include an anti-inflammatory).

YELLOW ZONE

Asthma is Getting Worse

- Cough, wheeze, chest tightness, or shortness of breath, or
- Waking at night due to asthma, or
- Can do some, but not all, usual activities

-Or-
Peak flow: _____ to _____
 (50 to 79 percent of my best peak flow)

First ↑

Add: quick-relief medicine—and keep taking your GREEN ZONE medicine.

_____ (short-acting beta₂-agonist) 2 or 4 puffs, every 20 minutes for up to 1 hour
 Nebulizer, once

If applicable, remove yourself from the thing that made your asthma worse.
 If your symptoms (and peak flow, if used) return to GREEN ZONE after 1 hour of above treatment:
 Continue monitoring to be sure you stay in the green zone.

-Or-

If your symptoms (and peak flow, if used) do not return to GREEN ZONE after 1 hour of above treatment:
 Take: _____ (short-acting beta₂-agonist) 2 or 4 puffs or Nebulizer _____ mg per day. For _____ (3–10) days
 Add: _____ (oral corticosteroid) _____ mg before/ within _____ hours after taking the oral corticosteroid.
 Call the doctor _____ (phone)

Second ↑

RED ZONE

Medical Alert!

- Very short of breath, or
- Quick-relief medicines have not helped, or
- Cannot do usual activities, or
- Symptoms are same or get worse after 24 hours in Yellow Zone.

-Or-
Peak flow: less than _____
 (50 percent of my best peak flow)

Take this medicine:

_____ (short-acting beta₂-agonist) 4 or 6 puffs or Nebulizer
 _____ (oral corticosteroid) _____ mg

Then call your doctor NOW. Go to the hospital or call an ambulance if

- You are still in the red zone after 15 minutes AND
- You have not reached your doctor.

DANGER SIGNS

- Trouble walking and talking due to shortness of breath
- Lips or fingernails are blue

Take 4 or 6 puffs of your quick-relief medicine **AND** Go to the hospital or call for an ambulance _____ (phone) **NOW!**

Bethesda, MD: U.S. Department of Health and Human Services; 2007:119. <https://www.nhlbi.nih.gov/sites/default/files/media/docs/asthsumm.pdf>.)

CHAPTER 79

Allergic Rhinitis

ETIOLOGY

Rhinitis describes diseases that involve inflammation of the nasal epithelium and is characterized by sneezing, pruritus, rhinorrhea, and congestion. There are many different causes of rhinitis in children, but approximately half of all cases are caused by allergies.

Allergic rhinitis, commonly known as **hay fever**, is caused by an IgE-mediated allergic response. During the early allergic phase, mast cells degranulate and release preformed chemical mediators, such as histamine and tryptase, and newly generated mediators such as leukotrienes, prostaglandins, and platelet-activating factor. After a quiescent phase in which other cells are recruited, a late phase occurs approximately 4–8 hours later. Eosinophils, basophils, CD4 T cells, monocytes, and neutrophils release their chemical mediators, which leads to the development of chronic nasal inflammation.

Allergic rhinitis can be seasonal, perennial, or episodic depending on the specific causative allergen and exposure. Some children experience perennial symptoms with seasonal exacerbations. **Seasonal allergic rhinitis** is caused by airborne pollens, which have seasonal patterns. Typically, trees pollinate in the spring, grasses in late spring to summer, and weeds in the summer and fall. The pollen, microscopic in size, can travel airborne hundreds of miles and be inhaled easily into the respiratory tract. **Perennial allergic rhinitis** is primarily caused by indoor allergens, such as house dust mites, animal dander, mold, and cockroaches. **Episodic rhinitis** occurs with intermittent exposure to allergens, such as visiting a friend's home where a pet lives.

EPIDEMIOLOGY

Chronic rhinitis is one of the most common disorders encountered in infants and children. Overall allergic rhinitis is observed in 10–25% of the general population, with children and adolescents more commonly affected than adults. The prevalence of physician-diagnosed allergic rhinitis has been estimated at 40%.

CLINICAL MANIFESTATIONS

The hallmark symptoms of allergic rhinitis are clear thin rhinorrhea, nasal congestion, sneezing paroxysms, and pruritus of the eyes, nose, ears, and palate. Postnasal drip may result in frequent attempts to clear the throat, nocturnal cough, and hoarseness. It is important to correlate the onset, duration, and severity of symptoms with seasonal or perennial exposures, changes in the home or school environment, and exposure to nonspecific irritants such as tobacco smoke.

The physical examination includes a thorough nasal examination and an evaluation of the eyes, ears, throat, chest, and skin. Physical findings may be subtle. Classic physical findings include pale or bluish, boggy and edematous nasal turbinates with clear, watery secretions. Frequent nasal itching and rubbing of the nose superiorly with the palm of the hand, the **allergic salute**, can lead to a transverse nasal crease found across the nose. Children may produce clucking sounds by rubbing

the soft palate with their tongue. Oropharyngeal examination may reveal lymphoid hyperplasia of the posterior oropharynx, visible mucus, or both. Orthodontic abnormalities may be seen in children with chronic mouth breathing. **Allergic shiners**, dark, edematous infraorbital areas caused by venous congestion, along with eyelid edema or conjunctival injection, are often present in children. Retracted tympanic membranes from eustachian tube dysfunction or serous otitis media also may be seen. Evidence of other atopic diseases, such as asthma or eczema, may be present, which helps lead the clinician to the correct diagnosis.

LABORATORY AND IMAGING STUDIES

Allergy testing can be performed by in vivo skin tests or by in vitro serum tests (enzyme-linked immunosorbent assay [ELISA]) to pertinent allergens found in the patient's environment (see Table 77.4). Skin tests (prick/puncture) provide immediate and accurate results. Positive tests correlate strongly with nasal and bronchial allergen provocative challenges. In vitro serum tests are useful for patients with diffuse dermatitis, dermatographism, poor tolerance to skin testing, or for those taking medications that interfere with skin testing. Disadvantages of serum tests include increased cost, inability to obtain immediate results, and reduced sensitivity compared with skin tests. Testing should include relevant allergens in the home and regional flora. Broad screening testing without regard to symptoms is not recommended. Measurement of total serum IgE or blood eosinophils generally is not helpful. The presence of eosinophils on the nasal smear suggests a diagnosis of allergy, but eosinophils also can be found in patients with **nonallergic rhinitis with eosinophilia**. Nasal smear eosinophilia is often predictive of a good clinical response to nasal corticosteroid sprays but is not commonly performed in clinical practice.

DIFFERENTIAL DIAGNOSIS

Rhinitis can be divided into allergic and nonallergic rhinitis (Table 79.1). Nonallergic rhinitis describes a group of nasal diseases in which there is no evidence of allergic etiology. It can be divided further into nonanatomic and anatomic etiologies. The most common form of nonallergic rhinitis in children is infectious rhinitis, which may be acute or chronic. Acute infectious rhinitis (**the common cold**) is caused by viruses, including rhinoviruses and coronaviruses, and typically resolves within 7–10 days (see Chapter 102). An average child has three to six common colds per year, with the most affected being younger children and children attending day care. Infection is suggested by the presence of sore throat, fever, and poor appetite, especially with a history of exposure to others with colds. Chronic infectious **rhinosinusitis**, or sinusitis, should be suspected if there is mucopurulent nasal discharge with symptoms that persist beyond 10 days (see Chapter 104). Classic signs of acute sinusitis in older children include facial tenderness, tooth pain, headache, and fever. Classic signs are usually not present in young children who may present with postnasal drainage with cough, throat clearing, halitosis, and rhinorrhea. The character of the nasal secretions with infectious rhinitis varies from purulent to minimal or absent. Coexistence of middle ear disease, such as otitis media or eustachian tube dysfunction, may be additional clues of infection.

TABLE 79.1 Classification of the Etiology of Rhinitis in Children

ALLERGIC	NONALLERGIC	
	Nonanatomic	Anatomic
Seasonal	Nonallergic, noninfectious (vasomotor) rhinitis	Adenoidal hypertrophy
Perennial	Infectious rhinosinusitis	CSF rhinorrhea
Episodic	Nonallergic rhinitis with eosinophilia	Choanal atresia
	Rhinitis medicamentosa	Congenital anomalies
		Foreign body
		Nasal polyps
		Septal deviation
		Tumors
		Turbinate hypertrophy

CSF, Cerebrospinal fluid.

Nonallergic, noninfectious rhinitis (formerly known as *vasomotor rhinitis*) can manifest as rhinorrhea and sneezing in children with profuse clear nasal discharge. Exposure to irritants, such as cigarette smoke and dust, and strong fumes and odors, such as perfumes and chlorine in swimming pools, can trigger these nasal symptoms. **Nonallergic rhinitis with eosinophilia syndrome** is associated with clear nasal discharge and eosinophils on nasal smear and is seen infrequently in children. Cold air (**skier's nose**), hot/spicy food ingestion (**gustatory rhinitis**), and exposure to bright light (**reflex rhinitis**) are examples of nonallergic, noninfectious rhinitis. Treatment with topical ipratropium before exposure may be helpful.

Rhinitis medicamentosa is due primarily to overuse of topical nasal decongestants, such as oxymetazoline, or phenylephrine, resulting in rebound nasal congestion. This condition is not common in younger children. Adolescents or young adults may become dependent on these over-the-counter medications. Treatment requires discontinuation of the offending decongestant spray, topical corticosteroids, and frequently a short course of oral corticosteroids.

The most common anatomic problem seen in young children is obstruction secondary to **adenoidal hypertrophy**, which can be suspected from symptoms such as mouth breathing, snoring, hyponasal speech, sleep disordered breathing, and persistent rhinitis with or without chronic otitis media (see Chapter 135). Infection of the nasopharynx may be secondary to infected hypertrophied adenoid tissue.

Nasal polyps typically appear as bilateral, gray, glistening tissue originating from the sinus ostia and may be associated with anosmia, nasal obstruction, and clear or purulent nasal discharge. Nasal polyps are rare in children younger than 10 years of age, but if present they warrant evaluation for an underlying disease process such as cystic fibrosis or primary ciliary dyskinesia. **Aspirin exacerbated respiratory disease** consists of asthma, aspirin sensitivity, and nasal polyps with chronic or recurrent sinusitis.

Foreign bodies are seen more commonly in young children who place food, small toys, stones, or other objects in their nose. The index of suspicion should be raised by a history of unilateral, purulent nasal discharge or foul odor. The foreign body can often be seen on anterior nasal examination.

TREATMENT

Management of allergic rhinitis is based on disease severity, impact of the disease on the patient, and the ability of the patient to comply with recommendations. Treatment modalities include allergen avoidance, pharmacologic therapy, and immunotherapy. Environmental control and steps to minimize allergen exposure, similar to preventive steps for asthma, should be implemented whenever possible (see Table 78.3).

Pharmacotherapy

Intranasal corticosteroids are the most effective pharmacologic therapy for treatment of allergic and nonallergic rhinitis. These include beclomethasone, budesonide, ciclesonide, flunisolide, fluticasone, mometasone, and triamcinolone. These topical agents work to reduce inflammation, edema, and mucus production. They are effective for symptoms of nasal congestion, rhinorrhea, pruritus, and sneezing but less helpful for ocular symptoms. Daily administration is necessary for maximum effectiveness. Nasal corticosteroid sprays have been used safely in long-term therapy. Deleterious effects on adrenal function or nasal membranes have not been reported when these agents are used appropriately. The most common adverse effects include local irritation, burning, and sneezing, which occur in 10% of patients. Nasal bleeding from improper technique (spraying the nasal septum) can occur. Rare cases of nasal septal perforation have been reported.

Antihistamines are the medications used most frequently to treat allergic rhinitis. They are useful in treating rhinorrhea, sneezing, nasal itching, and ocular itching but are less helpful in treating nasal congestion. **First-generation antihistamines**, such as diphenhydramine and hydroxyzine, easily cross the blood-brain barrier with sedation as the most common reported adverse effect. Use of first-generation antihistamines in children has an adverse effect on cognitive and academic function. In very young children, a paradoxical stimulatory central nervous system effect resulting in irritability and restlessness has been noted. Other adverse effects of first-generation antihistamines include anticholinergic effects, such as blurred vision, urinary retention, dry mouth, tachycardia, and constipation. **Second-generation antihistamines**,

such as cetirizine, desloratadine, fexofenadine, levocetirizine, and loratadine, are less likely to cross the blood-brain barrier resulting in less sedation. Cetirizine, fexofenadine, levocetirizine, and loratadine are available without prescription. Azelastine and olopatadine, topical nasal antihistamine sprays, are approved for children older than 5 years and 6 years, respectively.

Decongestants, taken orally or intranasally, may be used to relieve nasal congestion. Oral medications, such as pseudoephedrine and phenylephrine, are available either alone or in combination with antihistamines. Adverse effects of oral decongestants include insomnia, nervousness, irritability, tachycardia, tremors, and palpitations; oral decongestants are not recommended for children less than 4 years old. For older children participating in sports, oral decongestant use may be restricted. Topical nasal decongestant sprays are effective for immediate relief of nasal obstruction but should not be used more than 3 consecutive days to prevent rhinitis medicamentosa.

Topical ipratropium bromide, an anticholinergic nasal spray, is used primarily for nonallergic rhinitis and rhinitis associated with viral upper respiratory infection. Leukotriene modifiers have been studied in the treatment of allergic rhinitis. Montelukast is approved for use in seasonal allergic rhinitis.

Allergen Immunotherapy

If environmental control measures and medication intervention are only partially effective or produce unacceptable adverse effects, immunotherapy may be recommended. The mechanism of action for allergen immunotherapy is complex but includes increased production of an IgG-blocking antibody, decreased production of specific IgE, and alteration of cytokine expression produced in response to an allergen challenge. Immunotherapy is effective for desensitization to pollens, dust mites, and cat and dog proteins. Use in young children may be limited by the need for frequent injections. *Subcutaneous immunotherapy* (injections or “allergy shots”) must be administered in a physician’s office with 30 min of observation after the allergen injection. Anaphylaxis may occur, and the physician must be experienced in the treatment of these severe adverse allergic reactions. *Sublingual immunotherapy* (tablets placed under the tongue) is only indicated for ragweed pollen, some grass pollens, and dust mite allergy. It can be used in children 10 years or older. The first dose must be given in a physician’s office, but subsequent doses can be administered at home.

COMPLICATIONS

Approximately 60% of children with allergic rhinitis have symptoms of bronchial hyperresponsiveness (see [Chapter 78](#)). Chronic allergic inflammation leads to chronic cough from postnasal drip, eustachian tube dysfunction and otitis media, sinusitis, and tonsillar and adenoid hypertrophy, which may lead to obstructive sleep apnea. Children with allergic rhinitis may experience sleep disturbances, limitations of activity, irritability, and mood and cognitive disorders that adversely affect their performance at school and their sense of well-being.

PROGNOSIS AND PREVENTION

Seasonal allergic rhinitis is a common and prominent condition that may not improve as children grow older. Patients become more adept at self-management. Perennial allergic rhinitis improves with allergen control of indoor allergens.

Removal or avoidance of the offending allergen is advised. The only effective measure for minimizing pet allergen exposure is removal of the pet from the home. Avoidance of pollen and outdoor molds can be accomplished by staying indoors in a controlled environment. Air conditioning and keeping windows and doors closed lower exposure to pollen. High-efficiency particle air filters reduce exposure to allergens (e.g., pet dander). Sealing the mattress and pillow in allergen-proof encasings is the most effective strategy for reduction of dust mite allergen. Bedding should be washed in hot water (>130°F) every week.

PEARLS FOR PRACTITIONERS

See *Allergy: Pearls for Practitioners* at the end of this section.

CHAPTER 80

Atopic Dermatitis

ETIOLOGY

Atopic dermatitis is a chronic, pruritic, relapsing inflammatory skin condition. The pathogenesis is multifactorial and involves a complex interplay of genetics, immunologic abnormalities, impaired skin barrier function, environmental interactions, and infectious triggers. A diverse set of genes encoding epidermal structural proteins (filaggrin) and elements of the immune system play a major role in atopic dermatitis.

Several immunoregulatory abnormalities have been described in patients with atopic dermatitis. There is an exaggerated cutaneous inflammatory response to environmental triggers, including irritants and allergens. Activated Langerhans cells in the dermis expressing surface-bound immunoglobulin E (IgE) stimulate T cells. In acute lesions, activated Th2 lymphocytes infiltrate the dermis. They initiate and maintain local tissue inflammation primarily through interleukin 4 (IL-4), IL-13, and IL-5, promoting IgE production (IL-4, IL-13) and eosinophil differentiation (IL-5). As the disease progresses from an acute to chronic phase, the Th2 response switches to Th1/Th0 response. Chronic lesions are characterized by increased IL-12 and IL-18.

Patients with atopic dermatitis have **hyperirritable skin**; many factors can cause the disease to worsen or relapse. Known triggers include anxiety and stress, climate (extremes of temperature and humidity), irritants, allergens, and infections. Approximately 30% of infants and young children with severe atopic dermatitis have coexisting food allergies. The more severe the atopic dermatitis and the younger the patient, the more likely a food allergy will be identified as a contributing factor. Egg allergy is the most common cause of food-induced eczematous reactions.

FIGURE 80.1 Atopic dermatitis typical cheek involvement. (From Eichenfield LF, Frieden IJ, Esterly NB. *Textbook of Neonatal Dermatology*. Philadelphia: Saunders; 2001:242.)

EPIDEMIOLOGY

The prevalence of atopic dermatitis increased two- to threefold over the past 30 years. Approximately 15–20% of children and 2–10% of adults are affected. Atopic dermatitis often starts in early infancy. Approximately 50% of affected children show symptoms in the first year of life, and 80% experience disease onset before 5 years of age. Atopic dermatitis is often the first manifestation of the **atopic march**. Approximately 80% of children with atopic dermatitis develop other allergic diseases, such as asthma or allergic rhinitis. Symptoms of dermatitis often disappear at the onset of respiratory allergy.

CLINICAL MANIFESTATIONS

The clinical manifestations of atopic dermatitis vary with age. In infants, atopic dermatitis involves the face, scalp, cheeks, and extensor surfaces of the extremities (Fig. 80.1). The diaper area is spared. In older children, the rash localizes to the antecubital and popliteal fossae, head, and neck. In adolescents and adults, **lichenified plaques** are seen in flexural areas (Fig. 80.2) and head and neck regions. Pruritus has a significant impact on the child and family's quality of life since it is often worse at night, disturbing sleep. Physical examination may also show hyperlinearity of the palms and soles, dermatographism, pityriasis alba, creases under the lower eyelids (**Dennie-Morgan folds** or **Dennie lines**), and **keratosis pilaris** (asymptomatic horny follicular papules on the extensor surfaces of the arms).

LABORATORY AND IMAGING STUDIES

The diagnosis of atopic dermatitis is based on clinical features rather than laboratory tests (Table 80.1). Skin biopsy is of little

FIGURE 80.2 Rubbing and scratching the inflamed flexural areas cause thickened (lichenified) skin. (From Habif T. *Clinical Dermatology*. 4th ed. Philadelphia: Elsevier; 2004 [fig. 5.13].)

value, but may be performed to exclude other skin diseases that mimic atopic dermatitis. Skin testing or serum specific IgE testing may be helpful in assessing the contribution of food or environmental allergies to disease expression if history is suggestive.

DIFFERENTIAL DIAGNOSIS

Many conditions share signs and symptoms of atopic dermatitis (Table 80.2). Infants presenting in the first year of life with failure to thrive, recurrent skin or systemic infections, and scaling, erythematous rash should be evaluated for immunodeficiency disorders. Wiskott-Aldrich syndrome is an X-linked recessive syndrome characterized by atopic dermatitis, thrombocytopenia, small-sized platelets, and recurrent infections. Langerhans cell histiocytosis is characterized by hemorrhagic or petechial lesions. **Scabies** is an intensely pruritic skin condition caused by the human scabies mite. The presence of burrows in interdigital spaces and flexor surfaces of the wrists, elbows, axilla, or genitals is pathognomonic. Burrows may be few in number or absent, however.

TREATMENT

The goals of eczema therapy are to reduce the number and severity of flares and to increase duration of disease-free periods. Successful management involves skin hydration

TABLE 80.1 Clinical Features of Atopic Dermatitis

ESSENTIAL FEATURES
<ul style="list-style-type: none"> • Pruritus • Facial and extensor eczema in infants and children • Flexural eczema in adults • Chronic or relapsing dermatitis
FREQUENTLY ASSOCIATED FEATURES
<ul style="list-style-type: none"> • Personal or family history of atopic disease • Xerosis • Cutaneous infections • Nonspecific dermatitis of the hands or feet • Elevated serum IgE levels • Positive immediate-type allergy skin tests • Early age of onset
OTHER FEATURES
<ul style="list-style-type: none"> • Ichthyosis, palmar hyperlinearity, keratosis pilaris • Pityriasis alba • Nipple eczema • Dermatographism and delayed blanch response • Anterior subcapsular cataracts, keratoconus • Dennie-Morgan infraorbital folds, orbital darkening • Facial erythema or pallor • Perifollicular accentuation

From Noovak N, Leung DYM. Role of barrier dysfunction and immune response in atopic dermatitis. In: Leung DYM, Szeffler SJ, Bonilla FA, et al., eds. *Pediatric Allergy: Principles and Practice*. 3rd ed. Philadelphia: Elsevier; 2016:438.

with emollients, pharmacologic therapy to reduce pruritus and inflammation, and identification and avoidance of triggers. Patients with atopic dermatitis have impaired skin barrier function and enhanced transepidermal water loss. Daily, lukewarm baths for 15–20 minutes followed immediately by the application of fragrance-free emollients to retain moisture are a major component of therapy. Prevention of xerosis is important for pruritus control and for maintaining the integrity of the epithelial barrier. Emollients should be ointments or creams. Lotions are not as effective because they contain water or alcohol and may have a drying effect owing to evaporation. A mild nonsoap cleanser also is recommended.

Topical antiinflammatory agents, including corticosteroids and immunomodulators, are the cornerstone of therapy for acute flares and prevention of relapses. Topical corticosteroids are used for reducing inflammation and pruritus. They are effective for the acute and chronic phases of the disease. Ointments generally are preferred over creams and lotions because of enhanced potency due to easier skin penetration. Corticosteroids are ranked by potency into seven classes. The least potent corticosteroid that is effective should be used. Higher potency corticosteroids may be necessary to diminish the dermatitis flare but should be used for limited periods. Low-potency nonfluorinated corticosteroids should be used on the face, intertriginous areas (groin, axilla), and large areas to reduce the risk of adverse effects. Reduced efficacy of topical corticosteroids may be related to disease severity rather than glucocorticoid resistance. Local adverse effects (skin atrophy and striae) and systemic adverse effects

(hypothalamic-pituitary-adrenal axis suppression and hyperglycemia) are related to the potency, length of use, and applied surface area. In infants and younger children, the possibility of corticosteroid-induced adverse effects may be greater. When control of inflammatory lesions is achieved, most patients can be managed with emollients and low-potency topical corticosteroids.

The topical calcineurin inhibitors tacrolimus and pimecrolimus are second-line agents for short-term and intermittent

treatment of atopic dermatitis in patients (≥ 2 years) unresponsive to or intolerant of other therapies. These agents may be used on all body locations and are especially useful on delicate skin sites, such as the face, neck, and axilla, without the adverse effect of cutaneous atrophy seen with topical corticosteroids. Crisaborole, a topical phosphodiesterase 4 (PDE-4) inhibitor, is approved for treatment of mild to moderate atopic dermatitis in patients age 2 and older and offers an alternative to topical corticosteroids or calcineurin inhibitors. The most common adverse effect of both calcineurin and PDE-4 inhibitors is local skin irritation.

In cases of severe, refractory atopic dermatitis, systemic medications may be considered including systemic corticosteroids, cyclosporine, dupilumab, and, rarely, antimetabolites such as mycophenolate mofetil or methotrexate. Phototherapy is also considered for patients who have failed standard treatments.

COMPLICATIONS

Defective cell-mediated immunity leads to increased susceptibility to many bacterial, viral, and fungal infections of the skin. More than 90% of patients with atopic dermatitis have colonization of lesional skin with *Staphylococcus aureus* (*S. aureus*), and more than 75% of patients have colonization of uninvolved skin. Colonization and infection by *S. aureus* are associated with disease severity. *S. aureus* secretes exotoxins that act as superantigens, stimulating T cells and increasing IgE production. Secondarily infected atopic dermatitis often presents as impetiginous, pustular lesions with crusting and honey-colored exudate. Topical antibiotics, such as mupirocin or retapamulin, can be used to treat local areas of infection. Oral antibiotics such as cephalexin, dicloxacillin, or amoxicillin-clavulanate can be used for multifocal disease or for infection around the eyes and mouth that is difficult to treat topically. Bacterial cultures may be helpful in patients who do not respond to oral antibiotics or who have infection after multiple antibiotic courses given the increasing incidence of community-acquired methicillin-resistant *S. aureus*.

Herpes simplex superinfection of affected skin, or **Kaposi varicelliform eruption** or **eczema herpeticum**, results in vesiculopustular lesions that appear in clusters and can become hemorrhagic. Herpes simplex virus infection can be misdiagnosed as bacterial infection and should be considered if skin lesions fail to respond to antibiotics. Coxsackieviruses may produce similar lesions.

Widespread infections with human papillomavirus (warts) and molluscum contagiosum are also common in children with atopic dermatitis.

PROGNOSIS

Atopic dermatitis is a chronic, relapsing skin disorder that tends to be more severe and prominent in young children. Symptoms become less severe in two thirds of children, with complete remission for approximately 20%. More widespread early onset disease that is concomitant with asthma and allergic rhinitis, family history of atopic dermatitis, and elevated serum IgE levels may predict a more persistent course. Patients and families should be taught that a single cause and cure for atopic dermatitis is unlikely, but that good control is possible for the majority of affected patients.

PREVENTION

An important step in the management of atopic dermatitis is to identify and avoid allergens and irritants including soaps, detergents, fragrances, chemicals, smoke, and extremes of temperature and humidity. Since wool and synthetic fabrics can be irritating to the skin, 100% cotton fabric is preferred. Sweating is a recognized trigger. Fingernails should be trimmed frequently to minimize excoriations from scratching.

In infants and younger children who do not respond to the usual therapies, identifying and removing a food allergen from the diet may lead to clinical improvement. Food allergy is not a common trigger for older patients. Other environmental exposures, such as dust mites, can also contribute to the disease state; using allergen-proof encasings on pillows and bedding can be helpful.

PEARLS FOR PRACTITIONERS

See *Allergy: Pearls for Practitioners* at the end of this section.

CHAPTER 81

Urticaria, Angioedema, and Anaphylaxis

ETIOLOGY

Urticaria, commonly referred to as **hives**, is swelling of the dermis and one of the most common skin conditions seen in clinical practice. **Angioedema** results from a process similar to urticaria, but the reaction extends below the dermis. Urticaria and angioedema occur in response to the release of inflammatory mediators including histamine, leukotrienes, platelet-activating factor, prostaglandins, and cytokines from mast cells residing in the skin. A variety of stimuli can trigger mast cells to release their chemical mediators. Typically mast cells degranulate when antigen cross-links cell surface immunoglobulin E (IgE). Release of mediators results in vasodilation, increased vascular leak, and pruritus. In addition, basophils from the peripheral blood can localize to tissue and release mediators. Patients with urticaria have elevated histamine content in the skin that is more easily released.

Anaphylaxis is mediated by IgE, whereas **anaphylactoid reactions** result from mechanisms that are due to nonimmunologic mechanisms. Both reactions are acute, severe, and can be life threatening due to massive release of inflammatory mediators.

Not all mast cell activation is IgE mediated. Immunologic, nonimmunologic, physical, and chemical stimuli can produce degranulation of mast cells and basophils. **Anaphylatoxins**, C3a and C5a, can cause histamine release in a non-IgE-mediated reaction. Anaphylatoxins are generated in serum sickness (see Chapter 82) and in infectious, neoplastic, and rheumatic diseases. In addition, mast cell degranulation can occur from direct pharmacologic effect or physical or mechanical activation, such as urticaria after exposure to opiate medications or dermatographism (see later).

Urticaria and angioedema can be classified into three subcategories: acute, chronic, and physical. **Acute urticaria** and

ACUTE URTICARIA	CHRONIC URTICARIA
Food	Physical
Medication	Chronic spontaneous (formerly idiopathic)
Insect sting or bite	Autoantibody associated
Infection	Neoplastic
Contact allergy	Idiopathic
Transfusion reaction	Autoinflammatory diseases
Idiopathic	

angioedema are hives and diffuse swelling that last less than 6 weeks. Often the history is quite helpful in eliciting the cause of the acute reaction (Table 81.1). An IgE mechanism is more commonly found in acute urticaria than in chronic urticaria. In the pediatric population, viral illnesses are responsible for the majority of acute urticaria.

Chronic urticaria and **angioedema** are characterized by persistence of symptoms beyond 6 weeks (see Table 81.1). Some have daily symptoms of hives and swelling, whereas others have intermittent or recurrent episodes. Chronic urticaria can be idiopathic with unknown causal factors. Thirty-five to 40% of chronic urticaria cases have an autoimmune process due to IgG autoantibodies binding directly to IgE or the high-affinity IgE receptor. **Physical urticaria** and **angioedema** are characterized by known eliciting external factors that may include pressure, cold, heat, exercise, vibration, or exposure to sun.

The most common physical urticaria is dermatographism, affecting 2–5% of persons. **Dermatographism** means “writing on the skin” and is easily diagnosed by firmly scratching the skin with a blunt point, such as the wooden tip of a cotton swab or tongue depressor. It is characterized by an urticarial reaction localized to the site of skin trauma. It has been suggested that trauma induces an IgE-mediated reaction causing histamine to be released from the mast cells.

Cholinergic urticaria, characterized by the appearance of 1- to 3-mm wheals surrounded by large erythematous flares after an increase in core body temperature, occurs commonly in young adults. Lesions may develop during strenuous exercise, after a hot bath, or with emotional stress. The lack of airway symptoms differentiates it from exercise-induced anaphylaxis.

Cold urticaria occurs with exposure to cold and may develop within minutes on areas directly exposed to cold or on rewarming of the affected areas. Ingestion of cold drinks may precipitate lip swelling. Cold urticaria syndromes can be categorized into acquired and familial disorders. Severe reactions resulting in death can occur with swimming or diving into cold water. Patients must never swim alone, should avoid total body exposure to cold, and should have autoinjectable epinephrine available.

Hereditary angioedema (HAE) is an autosomal dominant disease due to a deficiency of C1-esterase inhibitor. The genetic defect may be caused by spontaneous mutation since approximately 25% of cases occur in patients without any family history. The disease is estimated to affect approximately 10,000

persons in the United States. It is characterized by unpredictable, recurrent attacks of episodic swelling that involves the face, peripheral extremities, genitalia, abdomen, oropharynx, and pharynx. Episodes are often triggered by trauma. Asphyxiation from laryngeal attacks is a significant cause of mortality. Patients with HAE rarely have urticaria associated with angioedema, and the swelling is not relieved with antihistamines or oral corticosteroids. Most patients (85%) have **type I** disease, which is due to decreased production of C1-esterase inhibitor. A minority of patients (15%) have **type II** disease, which is due to production of dysfunctional C1-esterase inhibitor. A low C4 level serves as an initial screening test. Patients with reduced C4 should have quantitative and functional levels of C1-esterase inhibitor measured. C2 levels are low during an acute attack. **HAE with normal C1 inhibitor** patients have normal laboratory evaluation of C1-esterase inhibitor. These patients are more typically females. Treatment for HAE is divided into on-demand treatment for acute attacks and prophylaxis. Prophylactic C1 inhibitor concentrate has advantage over other prophylactic therapies in terms of availability, effectiveness, and side effects. Bradykinin is an important mediator in the pathophysiology of HAE, and newer treatments are aimed at blocking this mediator.

Anaphylactic reactions are type I IgE-mediated reactions and result from many causes (Table 81.2). Cross linking of cell surface IgE by allergen leads to high-affinity IgE receptor activation on the mast cells and basophils resulting in release of mediators, including histamine, tryptase, tumor necrosis factor, platelet-activating factor, leukotrienes, prostaglandins, and cytokines. Other cell types involved in the reactions include monocytes, macrophages, eosinophils, neutrophils, and platelets. The mediator release results in the clinical picture of anaphylaxis.

Anaphylactoid reactions are due to nonimmunologic mechanisms. Mast cells and basophils can be activated by direct, nonspecific stimulation, although the exact underlying mechanism is unknown. Reactions to opiates and radiocontrast material are classic examples. Complement system activation also can result in mast cell and basophil activation. **Anaphylatoxins**, C3a and C5a, are named because of their ability to trigger mediator release and are generated in serum sickness. There are other causes of anaphylactoid reactions for which the mechanism has not been clarified.

FIGURE 81.1 Examples of urticaria. (From Zitelli BJ, Davis HW, eds. *Pediatric Physical Diagnosis Electronic Atlas*. Philadelphia: Mosby; 2018.)

EPIDEMIOLOGY

Urticaria and angioedema are common skin conditions affecting 15–25% of individuals at some point in their lives. Most cases of urticaria are self-limited, but for some patients they are chronic. In approximately 50% of patients, urticaria and angioedema occur together. In the remaining 50%, 40% have urticaria alone and 10% have angioedema alone. The incidence of anaphylaxis in children is unknown.

CLINICAL MANIFESTATIONS

Raised, erythematous lesions with pale centers that are intensely pruritic characterize **urticaria** (Fig. 81.1). The lesions vary in size and can occur anywhere on the body. Typically, urticaria arise suddenly and may resolve within 1–2 hours or may persist for up to 24 hours. **Angioedema** is a similar process that involves the deeper dermis or subcutaneous tissue, with swelling as the principal symptom. Generally, angioedema is not pruritic, may be mildly painful, and persists for longer than 24 hours. In rare cases it may become life threatening if swelling affects the upper airway.

The clinical manifestations of **anaphylaxis** and **anaphylactoid reactions** are the same for children and adults. The signs and symptoms vary and can range from mild skin findings to a fatal reaction. Ninety percent of patients present with cutaneous symptoms, including urticaria, angioedema, flushing, and warmth, but the absence of dermal symptoms does not exclude the diagnosis of anaphylaxis. Other affected organ systems include the respiratory tract (rhinorrhea, oropharyngeal edema, laryngeal edema, hoarseness, stridor, wheezing, dyspnea, and asphyxiation), cardiovascular system (tachycardia, hypotension, shock, syncope, and arrhythmias), gastrointestinal tract (nausea, abdominal pain, diarrhea, and vomiting) and neurologic system (syncope, seizure, dizziness, and a sense of impending doom). The severity of an anaphylactic reaction is often proportionate to the speed of symptom onset. A *clinical*

diagnosis of anaphylaxis can be made when there is acute onset of symptoms with involvement of the skin and/or mucosal tissue along with one of the following: respiratory compromise, reduced blood pressure, or end-organ dysfunction (total of two affected organ systems) (Fig. 81.2). Similarly, if a patient has a known exposure to a personal allergen, anaphylaxis should be diagnosed with skin symptoms (hives, swollen lips/tongue), respiratory compromise, or persistent gastrointestinal symptoms or if the patient has reduced blood pressure following the known exposure.

LABORATORY AND IMAGING STUDIES

The laboratory evaluation of patients with urticaria and angioedema must be tailored to the clinical situation. Acute urticaria and angioedema do not require specific laboratory evaluation except to document the suspected cause. For patients with chronic urticaria and angioedema, current recommendations advise against routine lab testing unless history suggests a potential etiology. Patients with recurrent angioedema *without* urticaria should be evaluated for HAE (Table 81.3).

Measurement of the mast cell mediators, histamine and tryptase, may be helpful when the diagnosis of anaphylaxis is in question. A tryptase level is a more useful test because histamine is released quickly, has a very short half-life, and is often difficult to detect in the serum. Serum tryptase levels peak 1–1.5 hours after anaphylaxis. Elevated levels may be helpful in establishing the diagnosis, but normal tryptase levels do not rule out the diagnosis. It is best to measure a serum tryptase level 1–2 hours after the onset of symptoms. It also can be measured retrospectively on stored serum that is less than 2 days old.

DIFFERENTIAL DIAGNOSIS

The diagnosis of urticaria and angioedema is straightforward; finding the etiology may be more difficult. Other dermatologic

conditions can mimic urticaria. **Erythema multiforme** has target-shaped, erythematous, macular, or papular lesions that may look similar to urticaria, but the lesions are fixed and last for several days. Other dermatologic diseases such as dermatitis herpetiformis and bullous pemphigoid are quite pruritic, and early on, the lesions may resemble urticaria. Mastocytosis is characterized by mast cell infiltration of various organs, including the skin. Some patients have skin lesions similar in

appearance to urticaria rather than the classic urticaria pigmentosa. Urticaria pigmentosa appears as hyperpigmented, red-brown macules that may coalesce. When these lesions are stroked, they urticate, which is called the **Darier sign**. A rare disorder that should be included in the differential diagnosis of urticaria is **Muckle-Wells syndrome**. It is an autosomal dominant autoinflammatory disorder characterized by episodic urticaria presenting in infancy with sensorineural deafness,

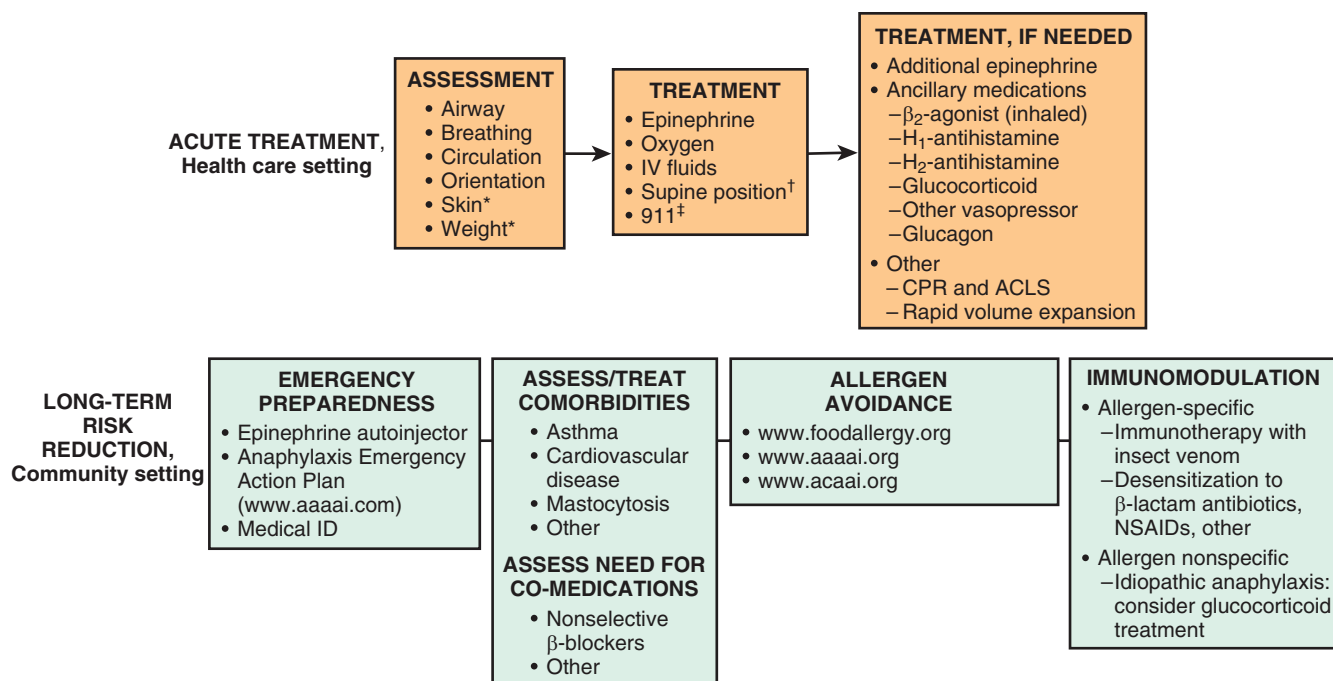

FIGURE 81.3 Summary of anaphylaxis management. Acute treatment is the same regardless of the mechanism or trigger involved in anaphylaxis. In contrast, for long-term risk reduction, avoidance measures and immunomodulation are trigger specific; currently immunomodulation is available only for a minority of individuals with anaphylaxis. All at-risk individuals need to have comorbidities and current medications assessed, be taught the importance of emergency preparedness, and be instructed in the use of autoinjectable epinephrine. ACLS, Advanced cardiac life support; CPR, cardiopulmonary resuscitation; CVS, cardiovascular; GI, gastrointestinal; ID, identification (e.g., bracelet, wallet card); IV, intravenous; NSAIDs, nonsteroidal antiinflammatory drugs. *The skin should be inspected, and weight estimation is important, especially in infants and children, and also in overweight and obese teens and adults, to calculate an optimal dose of epinephrine and other medications needed in treatment and resuscitation. [†]Supine position, as tolerated, to prevent empty ventricle syndrome. [‡]Call 911/emergency medical services for anaphylaxis occurring in community health care facilities such as medical, dental, or infusion clinics, where optimal backup might not be available for resuscitation. (From Simon FER. Anaphylaxis. *J Allergy Clin Immunol.* 2008;121:S405.)

amyloidosis, arthralgias, and skeletal abnormalities. Also rare, **Schnitzler syndrome** is characterized by chronic urticaria, macroglobulinemia, bone pain, anemia, fever, fatigue, and weight loss. **Urticarial vasculitis** is a small vessel vasculitis with histologic features of a leukocytoclastic response. The main distinguishing feature is that the lesions last longer than 24 hours, may be tender, and leave behind skin pigmentation. Skin biopsy is required for definitive diagnosis.

The diagnosis of anaphylaxis is usually apparent from the acute and often dramatic onset of multisystem involvement of the skin, respiratory tract, and cardiovascular system. Sudden cardiovascular collapse in the absence of cutaneous symptoms suggests vasovagal collapse, seizure disorder, aspiration, pulmonary embolism, or myocardial infarction. Laryngeal edema, especially with abdominal pain, suggests HAE. Many patients with anaphylaxis are initially thought to have septic shock (see Chapter 40).

TREATMENT

Avoidance of triggering agents is important in the management of acute urticaria and angioedema. Most cases resolve spontaneously. However, use of antihistamines will provide symptom relief. If acute urticaria and angioedema do not respond to this therapy, a short course of oral steroids may be considered.

Chronic urticaria treatment employs H₁ antihistamines. Second-generation H₁ antihistamines, such as cetirizine, desloratadine, fexofenadine, levocetirizine, and loratadine, are preferred because they have fewer adverse effects. If second-generation H₁ antihistamine monotherapy does not provide adequate relief, increasing the dose of antihistamines is indicated as is the addition of a sedating H₁ antihistamine at bedtime or H₂ antihistamines, such as cimetidine or famotidine. While results on the effectiveness of antileukotriene medications as mono- or add-on therapy are mixed, a trial of this medication can be considered. Omalizumab, a monoclonal anti-IgE antibody, has proven to be effective for chronic urticaria. Other immunomodulating agents, such as cyclosporine, hydroxychloroquine, methotrexate, cyclophosphamide, and intravenous immunoglobulin, have also been used. However, data supporting their use are limited, and they require laboratory monitoring due to potential adverse effects. Corticosteroids are effective in treating chronic urticaria, although adverse effects from long-term use mandate using the lowest effective dose for a brief time.

Anaphylaxis is a medical emergency. Prompt recognition and immediate treatment are crucial (Fig. 81.3). *Early administration of intramuscular epinephrine is the mainstay of therapy and should be given at the same time basic measures of cardiopulmonary resuscitation are being performed.* If the child is not in a medical setting, emergency medical services should be

activated. Supplemental oxygen and intravenous fluid should be administered with the child lying in Trendelenburg. An airway must be secured as intubation or tracheotomy may be required. Additional pharmacologic therapies, such as corticosteroids, antihistamines, H₂-receptor antagonists, and bronchodilators, may be given to improve symptoms. Up to 15% of people with anaphylaxis have **biphasic** or **protracted anaphylaxis**. The **biphasic reaction** is a recurrence of anaphylactic symptoms after an initial remission, typically occurring within 4–6 hours after the initial reaction. A person with **protracted anaphylaxis** has signs and symptoms that persist for hours or even days despite treatment, although this is rare.

PREVENTION

Prevention of urticaria, angioedema, and anaphylaxis focuses on avoidance of known triggers. A referral to an allergy specialist for a thorough history, diagnostic testing if indicated, and recommendations for avoidance of triggers is suggested for patients following severe reactions or anaphylaxis. Skin testing and serum IgE-specific testing are available for foods, inhalants, insect venoms, drugs (penicillin), vaccines, and latex. Educating the patient and family members about the signs and symptoms of anaphylaxis and using autoinjectable epinephrine early result in better outcomes. Fatal anaphylaxis has occurred despite timely and appropriate treatment. Medical alert jewelry with appropriate information should be worn. Medications such as β blockers, angiotensin-converting enzyme inhibitors, and monoamine oxidase inhibitors should be discontinued because they may exacerbate anaphylaxis or interfere with its treatment.

PEARLS FOR PRACTITIONERS

See *Allergy: Pearls for Practitioners* at the end of this section.

antibodies, and alternative pharmacotherapies has greatly reduced the incidence of serum sickness.

CLINICAL MANIFESTATIONS

The symptoms of serum sickness typically occur 7–21 days after the administration of drugs, foreign proteins, or infections. Symptom onset may be more rapid (within 1–4 days) in previously sensitized individuals. The classic clinical manifestations consist of fever, polyarticular arthralgias, lymphadenopathy, and cutaneous symptoms. Cutaneous lesions vary and may include urticaria, angioedema, erythema multiforme, morbilliform rash, and palpable purpura or serpiginous rash at the interface of the dorsal and palmar or plantar aspects of the hands and feet. Carditis, glomerulonephritis, Guillain-Barre syndrome, encephalomyelitis, and peripheral neuritis are rare complications.

LABORATORY AND IMAGING STUDIES

Laboratory tests may show an elevated erythrocyte sedimentation rate, thrombocytopenia, and depressed complement (C3 and C4) levels. Skin biopsy specimens show immune deposits of IgM, IgA, IgE, or C3. Hematuria, proteinuria, or both may be present. The diagnosis is established by history of exposure to an inciting cause, characteristic clinical manifestations, and laboratory testing showing circulating immune complexes and depressed complement levels.

TREATMENT AND PREVENTION

Serum sickness is self-limited and resolves within 1–2 weeks. Treatment is symptomatic relief. Antihistamines may be administered to relieve pruritus. Nonsteroidal antiinflammatory drugs reduce fever and joint pain, and in severe cases, systemic glucocorticoids may be considered. Allergy skin testing does not predict the likelihood of serum sickness development and is not indicated. The primary means of prevention is to avoid exposure to the implicated cause.

PEARLS FOR PRACTITIONERS

See *Allergy: Pearls for Practitioners* at the end of this section.

CHAPTER 82

Serum Sickness

ETIOLOGY

Serum sickness is a type III hypersensitivity reaction (see Table 77.1). The patient's immune system recognizes the proteins in a drug or antiserum as foreign and produces antibodies against them. The newly formed antibodies bind with the foreign protein to form antigen-antibody or immune complexes, which may enter the circulation and be deposited in blood vessels and filtering organs. These complexes cause tissue injury by activating the complement cascade and recruiting neutrophils, resulting in increased capillary permeability, toxic mediator release, and tissue damage.

EPIDEMIOLOGY

Common inciting agents include blood products and foreign proteins, such as antithymocyte globulin and antivenoms. Medications frequently implicated include penicillin, sulfonamides, minocycline, cefaclor, hydantoin, and thiazides. The availability of *human-derived* biologics, bioengineered

CHAPTER 83

Insect Allergies

ETIOLOGY

Systemic allergic reactions usually result from stinging insects of the order **Hymenoptera**, which include **apids** (honeybee and bumblebee), **vespids** (yellow jacket, wasp, yellow-face and white-face hornets, Asian giant hornets), and **formicids** (fire and harvester ants). Honeybees have a barbed stinger that remains embedded after a sting. Yellow jackets are responsible for most allergic reactions in most parts of the United States, whereas wasps are the most frequent cause of sting reactions in Texas. Fire ants are found in southeastern and south-central United States. Asian giant

hornets are an invasive species detected in Washington state in 2019.

Biting insects rarely cause anaphylaxis. Anaphylaxis has been described, however, after the bites from the kissing bug *Triatoma*, bed bugs, blackflies, and deerflies. Large local reactions from biting insects, such as mosquitoes, fleas, and flies, are a more common occurrence; large local reactions to mosquito bites are known as **skeeter syndrome**. The reaction appears urticarial, is caused by the salivary secretions deposited by the biting insect, and does not represent an allergic response.

EPIDEMIOLOGY

Insect sting allergy may develop at any age and typically manifests after several uneventful stings. Although children are stung more frequently than adults, systemic allergic reactions occur in only about 1% of children and 3% of adults. Reactions in adults are generally more severe than in children and can result in death. Large local reactions to insect stings are more common in children, with an estimated incidence of 20% for children and 10% for adults.

CLINICAL MANIFESTATIONS

The diagnosis of insect sting allergy is dependent on the history of the reaction and the presence of venom-specific IgE. Normal reactions to insect stings, observed in 90% of children, include localized pain, swelling, and erythema at the sting site that usually subside within 24 hours. Large local reactions are usually late-phase, IgE-mediated reactions, with large swelling, contiguous to the sting site that develops over 24–48 hours and resolves within 2–7 days. Virtually all individuals with large local reactions have similar reactions with subsequent stings. Systemic reactions are IgE mediated. They can be mild and nonlife threatening with cutaneous symptoms only or life threatening with respiratory, cardiovascular, or neurologic symptoms of anaphylaxis (see Chapter 81). Toxic reactions may result if a person receives a large number of simultaneous stings (50–100). Symptoms include malaise, nausea, and emesis resulting from the toxic effects of the venom. Unusual reactions, such as vasculitis, nephrosis, neuritis, serum sickness, and encephalitis, may occur as delayed reactions (Table 83.1).

LABORATORY AND IMAGING STUDIES

A positive skin test to Hymenoptera venom extract demonstrates the presence of venom-specific IgE and in the context of a positive sting reaction history helps identify specific insects to which an individual is allergic. Venom-specific IgE antibodies also may be measured by in vitro serum tests. Both testing methods should be considered complementary because neither test alone detects all patients with insect sting allergy. Future reactions correlate more with past individual patterns than the level of sensitivity of venom skin testing or serum-specific IgE testing.

Pediatric patients presenting with history of anaphylaxis to stinging insect venoms require evaluation of a baseline tryptase level to screen for an underlying mast cell disorder in addition to assessment of specific IgE. Patients with mast cell disorders are at higher risk for severe reactions to stings.

TABLE 83.1 Classification of Insect Sting Reactions

REACTION TYPE	CHARACTERISTICS
Normal	<2 in. in diameter
	Transient pain and erythema
	Duration <24 hr
Large local reaction	>2 in. in diameter
	Swelling contiguous to the site
Systemic	Duration 2–7 days
Nonlife threatening	Immediate generalized reaction confined to the skin (erythema, urticaria, angioedema)
Life threatening	Immediate generalized reaction not confined to the skin with respiratory (laryngeal edema, bronchospasm) or cardiovascular (hypotension, shock) symptoms
Toxic	Follows multiple simultaneous stings, produced by exogenous vasoactive amines in venom
Unusual	Serum sickness, vasculitis, nephrosis, neuritis, encephalitis
	Symptoms start several days to weeks after the insect sting

Likewise, they are more likely to have no skin manifestations during their reaction, systemic reactions to vespid stings, hypotensive anaphylaxis, and negative evaluation of specific IgE despite a highly suggestive history. Mast cell disorders have further implications for venom immunotherapy. During immunotherapy, these patients have higher risk of side effects, higher risk of systemic sting reactions, and higher risk of relapse after discontinuing therapy. They should receive venom immunotherapy indefinitely.

DIFFERENTIAL DIAGNOSIS

A history of an immediate systemic reaction is necessary before venom testing and consideration of immunotherapy. Testing for venom-specific IgE without a history of a systemic reaction to a sting is not recommended. Identification of the offending insect is often unreliable. Honeybee stings may be identified by the stinger that remains in place. Vespid stings are usually unprovoked and occur at summer's end when the insects are more aggressive.

TREATMENT

Local reactions should be treated by cleaning the site, applying cold compresses, and administering oral antihistamines and analgesics. Stingers should be removed promptly. Occasionally, large local reactions may be mistaken for cellulitis. Infection is unlikely if the reaction occurs within 24–48 hours after a sting. Treatment is with an oral corticosteroid for 4–5 days rather than oral antibiotics.

Treatment of systemic reactions is guided by the severity of the reaction, but epinephrine is the cornerstone of therapy and should be administered without delay for all anaphylactic reactions. Antihistamines may be administered concurrently with epinephrine. Corticosteroids should be given to prevent prolonged symptoms. For severe reactions, intravenous fluids and epinephrine, oxygen, and respiratory support in an intensive care unit may be needed. After acute care of a systemic sting reaction, patients should be provided an epinephrine autoinjector, referral to an allergist, and instructions on prevention of insect stings.

COMPLICATIONS

At least 50–100 fatalities per year in the United States are attributed to insect sting reactions. Most deaths (80%) occur in adults older than 40 years of age; only 2% occur in individuals younger than 20 years of age. Approximately half of deaths occur in persons without a previous history of a sting reaction.

PROGNOSIS

Successfully avoiding the stinging insect is the most important prognostic factor. More than 85% of adults who complete 5 years of immunotherapy tolerate sting challenges without systemic reactions for 5–10 years after completion.

PREVENTION

Measures to reduce the chance of accidental sting include exterminating infested areas, avoiding eating or drinking outdoors, wearing long pants and shoes, and avoiding brightly colored clothing, fragrances, or hairspray when outdoors. Common insect repellents are not effective against Hymenoptera.

Current recommendations are to administer **venom immunotherapy** to individuals who have had a systemic life-threatening reaction from an insect sting and have positive venom skin tests or elevated venom-specific IgE. All persons with a history of systemic reactions to stinging insects should be instructed in the use of an epinephrine autoinjector and encouraged to wear medical information jewelry. Children and adults who have had only a cutaneous reaction generally do not require immunotherapy because their risk of life-threatening reaction is low.

PEARLS FOR PRACTITIONERS

See *Allergy: Pearls for Practitioners* at the end of this section.

reactions. **Food intolerances** such as lactose intolerance represent a nonimmune reaction. **Food allergy** or hypersensitivity reactions encompass immune reactions to food and can be divided further into immunoglobulin E (IgE)-mediated reactions, which are typically rapid in onset, and non-IgE-mediated reactions.

Oral tolerance is the suppression of the immune response to the array of dietary elements ingested daily. **Food allergy** or **hypersensitivity reactions** are the result of immune reactions to glycoproteins and develop in genetically predisposed individuals. In children, cow's milk, eggs, peanuts, soybean, wheat, tree nuts, fish, and shellfish cause 90% of IgE-mediated reactions. In older children and adults, peanuts, tree nuts, fish, and shellfish account for most reactions. Exposure to the allergenic food protein results in cross linking of cell surface-specific IgE molecules found on mast cells and basophils resulting in activation and degranulation. Numerous potent mediators and cytokines are released within minutes to hours of ingestion. Non-IgE-mediated reactions typically occur hours to days after the allergen ingestion and manifest as gastrointestinal symptoms. A cell-mediated immune mechanism may be responsible.

Approximately 6–8% of children are affected with food allergy. In adults, estimates vary from 2–10%.

CLINICAL MANIFESTATIONS

Symptoms of hypersensitivity reactions vary from single-system involvement of the skin, gastrointestinal tract, or respiratory tract to multisystem involvement in anaphylaxis. Non-IgE-mediated food allergy typically presents during infancy as proctitis/proctocolitis, enteropathy, or enterocolitis (Table 84.1).

LABORATORY AND IMAGING STUDIES

In suspected IgE-mediated food reactions, skin prick allergy testing and serum-specific IgE testing to foods help confirm the suspected food allergy. Despite the availability of two methods to evaluate food allergy, neither test can predict the severity of the reaction nor the quantity of food ingested to elicit symptoms. Positive skin tests or serum-specific tests to foods in the context of a positive history can only indicate risk of an allergic reaction when exposed to that allergen.

DIAGNOSIS

A careful history focuses on symptoms, the time interval from ingestion to onset of symptoms, the quantity of food necessary to evoke the reaction, the most recent reaction, patterns of reactivity, and associated factors such as exercise and medication use. Skin prick testing can be performed to confirm suspected IgE-mediated food allergies. The history dictates what food allergens should be evaluated. Testing to a wide variety of food allergens as a screening tool has little clinical value and is strongly discouraged. A negative skin test virtually excludes an IgE-mediated mechanism. A positive skin test indicates sensitization but does not prove clinical reactivity and must be interpreted in the context of the history.

An in vitro serum-specific IgE assay can be used to help confirm clinical allergy. Many allergists and laboratories regard the ImmunoCAP system as the method of choice. These tests

CHAPTER 84

Adverse Reactions to Foods

ETIOLOGY AND EPIDEMIOLOGY

An **adverse reaction to food** is a generic description of any untoward reaction after food ingestion, including toxic reactions such as food poisoning and nontoxic reactions, which can be subdivided further into nonimmune and immune

TABLE 84.1 Adverse Food Reactions				
DISORDER	AGE GROUP	CHARACTERISTICS	DIAGNOSIS	PROGNOSIS/COURSE
IgE-MEDIATED				
Food allergy	Any	Symptom onset: min–2 hr of urticaria, angioedema, cough, wheeze, dyspnea, rhinitis, conjunctivitis, nausea, abdominal pain, emesis, diarrhea, altered mental status, loss of consciousness, death	History, positive SPT, and/or serum food IgE Confirmatory OFC	Variable, food dependent Milk, soy, egg, and wheat typically outgrown Peanut, tree nuts, seeds, and shellfish typically persist
Pollen-food allergy syndrome (oral allergy syndrome)	Any, most common in young adults (50% of birch pollen allergic adults)	Immediate symptoms on contact of raw fruit or vegetables with oral mucosa Pruritus, tingling, erythema, or angioedema of the lips, tongue, oropharynx, throat pruritus/tightness	History, positive SPT with raw fruits or vegetables, OFC positive with raw fruit, negative with cooked	Severity of symptoms may vary with pollen season Symptoms may improve with pollen immunotherapy in subset of patients
IgE- AND/OR NON-IgE-MEDIATED				
Allergic eosinophilic esophagitis	Any, but especially infants, children, adolescents	Children: chronic/intermittent symptoms of gastroesophageal reflux, emesis, dysphagia, abdominal pain, irritability Adults: abdominal pain, dysphagia, food impaction	History, positive SPT, and/or food IgE in 50%, but poor correlation with clinical symptoms Elimination diet and OFC Endoscopy, biopsy provides conclusive diagnosis and response to treatment information	Variable, not well established, improvement with elimination diet within 6–8 wk Elemental diet may be required Often responds to swallowed topical steroids
Allergic eosinophilic gastroenteritis	Any	Chronic/intermittent abdominal pain, emesis, irritability, poor appetite, failure to thrive, weight loss, anemia, protein-losing gastroenteropathy	History, positive SPT, and/or food IgE in 50%, but poor correlation with clinical symptoms, elimination diet, and OFC Endoscopy, biopsy provides conclusive diagnosis and response to treatment information	Variable, not well established, improvement with elimination diet within 6–8 wk Elemental diet or systemic steroids may be required
Atopic dermatitis	Infant and child; 90% start <5 yr	Relapsing pruritic vesiculopapular rash; generalized in infants, localized to flexor areas in older children; food allergy in about 35% of children with severe atopic dermatitis	History, SPT, and/or serum food IgE level; elimination diet and OFC	60–80% improve significantly or allergy resolves by adolescence
Asthma	Any	Chronic cough, wheezing, dyspnea; food allergy is risk factor for intubation in children who have asthma	History, SPT, and/or serum food IgE level; OFC	Varies
NON-IgE-MEDIATED				
Food protein-induced allergic proctocolitis	Young infants (<6 mo), frequently breast-fed	Blood-streaked or heme-positive stools, otherwise healthy appearing	History, prompt response (resolution of gross blood in 48 hr) to allergen elimination Biopsy conclusive but not necessary in vast majority	Majority able to tolerate milk or soy by 1–2 yr of age
Food protein-induced enterocolitis syndrome	Young infants	Chronic: emesis, diarrhea, failure to thrive on chronic exposure Subacute: repetitive emesis, dehydration (15% shock), diarrhea on repeat exposure after elimination period Breast-feeding protective	History, response to dietary restriction; OFC; SPT is negative	Most resolve in 1–3 yr; rarely persists into late teenage years

Continued

DISORDER	AGE GROUP	CHARACTERISTICS	DIAGNOSIS	PROGNOSIS/COURSE
Food protein-induced enteropathy	Young infants; incidence has decreased	Protracted diarrhea, (steatorrhea), emesis, failure to thrive, anemia in 40%	History, endoscopy, and biopsy Response to dietary restriction	Most resolve in 1–2yr
Celiac disease (gluten-sensitive enteropathy)	Any	Chronic diarrhea, malabsorption, abdominal distention, flatulence, failure to thrive, or weight loss May be associated with oral ulcers and/or dermatitis herpetiformis	Biopsy diagnostic: villous atrophy Screening with serum IgA antitissue transglutaminase and antigliadin Resolution of symptoms with gluten elimination and relapse on oral challenge	Lifelong
Contact dermatitis	Any; more common in adults	Relapsing, pruritic eczematous rash, often on hands or face; often occurs in occupational contact with food stuff	History, patch testing	Varies
Dermatitis herpetiformis	Any	Intensely pruritic vesicular rash on extensor surfaces and buttocks	Biopsy diagnostic, shows IgA granule deposits at the dermal-epidermal junction; resolves with dietary gluten avoidance	Lifelong
Pulmonary hemosiderosis (Heiner syndrome)	Infants, children (rare)	Chronic cough, hemoptysis, lung infiltrates, wheezing, anemia; described in cow's milk- and buckwheat-allergic infants	History, SPT and serum food IgE negative but milk and buckwheat IgG precipitins positive; lung biopsy with deposits of IgG and IgA	

OFC, Oral food challenge; SPT, skin prick test.

Modified from Nowak-Węgrzyn A, Burks AW, Sampson HA. Reactions to foods. In: Adkinson Jr NF, Bochner BS, Burks AW, et al., eds. Middleton's Allergy: Principles and Practice. 9th ed. Philadelphia: Elsevier; 2020:1294-1325e.1 (table 79.7).

provide supplementary information to skin tests. Researchers have tried to determine levels of food-specific IgE at which clinical reactions are highly likely to occur (Table 84.2). Patients with allergen-specific IgE levels greater than 95% of the predictive value will likely be symptomatic upon ingestion, so an oral food challenge is not necessary. Monitoring the allergen-specific IgE level and/or wheal size on skin prick testing may be helpful in predicting whether a child has outgrown the food allergy. *Oral food challenges remain the standard of diagnosis* and can be performed to determine whether a child has developed oral tolerance to the food allergen.

Component resolved diagnostics (CRD) have gained attention in the area of food allergy testing. CRD is a testing method that employs allergens purified from natural sources or recombinant DNA technology. Thus an individual allergen is being evaluated versus whole allergens in hopes of improved information about risk, tolerance, and prognosis. CRD is helpful in peanut, cow's milk, egg, and hazelnut allergy but not for soy allergies.

TREATMENT

Currently, the main treatment modality of IgE-mediated food allergy is avoidance. This requires the education of the patient and family on how to avoid ingestion of the responsible allergen and when to initiate therapy if ingestion occurs. If the food allergen is ingested and symptoms of an IgE-mediated reaction ensue, autoinjectable epinephrine should be immediately administered intramuscularly followed by emergent evaluation by medical personnel. There is no role for antihistamines in this setting because the severity of the reaction is unpredictable. There are approximately 100 deaths per year due to

food allergies, and most cases are secondary to a delay or no administration of epinephrine.

Oral immunotherapy entails ingesting *increasing* amounts of the food allergen to achieve desensitization. Pharmaceutical-grade peanut protein containing relevant peanut allergens (*Arachis hypogaea*) is U.S. Food and Drug Administration (FDA) approved for oral immunotherapy in children aged 4–17 years of age. This treatment modality is not a cure but mitigates the allergic reaction should peanut be accidentally ingested.

Other novel therapies for IgE-mediated food allergy aim to either desensitize patients to food allergens or induce tolerance. Sublingual immunotherapy requires placing increasing doses of food allergen under the tongue. This treatment is effective for desensitization, but compliance is poor. In epicutaneous therapy, food allergens are embedded in a patch that is applied to the skin. While still in clinical trials, these therapies may become common clinical practice.

COMPLICATIONS

Anaphylaxis is the most serious complication of allergic food reactions and can result in death (see Chapter 81). Patients need to be monitored for alterations in growth and potential nutritional deficiencies from food avoidance. This is especially important for children avoiding multiple foods or if one of their food allergens is cow's milk.

PROGNOSIS AND PREVENTION

The natural history of food allergies or “is my child going to outgrow this?” is a common concern of parents. For cow's

TABLE 84.2 Interpretation of Serum IgE Antibody Concentrations

FOOD		FOOD-SPECIFIC IgE ANTIBODY CONCENTRATIONS AT OR ABOVE WHICH CLINICAL REACTIONS ARE HIGHLY LIKELY (KUa/L)	POSITIVE PREDICTIVE VALUE (%)
Egg	>2yr of age	7	98
	≤2yr of age	0.35	95
Milk	>2yr of age	15	95
	≤1yr of age	5	95
Peanut		14	99
Fish		20	99
Soybean		30	73
Wheat		26	74
Tree nuts		~15	≈95

Modified from Nowak-Węgrzyn A, Burks AW, Sampson HA. Reactions to foods. In: Adkinson Jr NF, Bochner BS, Burks AW, et al., eds. Middleton's Allergy: Principles and Practice. 9th ed. Philadelphia: Elsevier; 2020:1294-1325.e1 (table 79-11).

milk-allergic patients who have multiple food allergies, asthma, and allergic rhinitis, 21% of patients have persistent milk allergy at age 16 years; 85% of children who do not have additional atopic disease develop cow's milk *tolerance* by 3 years of age. Similarly, 66% of children with egg allergy but no other atopic disease develop tolerance by 5 years of age; 32% of those with additional atopic disease will still be sensitive to egg by age 16 years. The natural histories of soy and wheat allergy are similar: oral tolerance in 25–29% by age 4 years, 45–56% by age 6 or 8 years, and 65–69% by age 10 or 12 years. Twenty percent of children with peanut allergy outgrow their allergy. Nine percent of tree nut allergic patients will develop oral tolerance. Food allergies to seafood continue to be a life-long affliction.

Avoidance of the suspect food is crucial. Careful reading of food labels is a priority. Medical information jewelry with appropriate information should be worn. The Food Allergy Research & Education organization (www.foodallergy.org) is a useful educational resource for families and physicians.

Recommendations for prevention of allergic diseases aimed at the *high-risk* newborn who has not manifested atopic disease include (1) exclusive breast-feeding for the first 4–6 months or (2) using an extensively hydrolyzed formula for the first 4–6 months and introducing solid foods one at a time between 4 and 6 months of age. Other approaches, such as maternal avoidance diets during pregnancy and during lactation or avoidance of allergenic foods for infants beyond 6 months of age, are unproven.

Early introduction of peanuts in high-risk infants significantly decreases the development of peanut allergy; this effect is durable.

PEARLS FOR PRACTITIONERS

See Allergy: *Pearls for Practitioners* at the end of this section.

CHAPTER 85

Adverse Reactions to Drugs

ETIOLOGY

An **adverse drug reaction** is defined as an unwanted, negative consequence associated with the use of a drug or biologic agent. Drug reactions can be classified as immunologic or nonimmunologic reactions (Table 85.1). Nearly 75–80% of adverse drug reactions are caused by a predictable, nonimmunologic mechanism; between 5% and 10% of all drug reactions are explained by an immune-mediated mechanism (see Table 77.1). The remaining drug reactions are caused by an unpredictable mechanism, which may or may not be immune mediated. Many drug reactions cannot be classified because the exact immune mechanism has not been defined. Most drugs cannot elicit an immune response because of their small size; rather, the drug or a metabolite acts as a hapten and binds to larger molecules, such as tissue or serum proteins, a process called **haptenation**. The multivalent hapten-protein complex forms a new immunogenic epitope that stimulates T- and B-lymphocyte responses.

EPIDEMIOLOGY

Drug reactions to penicillins and cephalosporins are the most common allergic drug reactions encountered in the pediatric population. Approximately 6–10% of children are labeled as *penicillin allergic*; however, less than 1% of people have a true immunoglobulin E (IgE)-mediated reaction. Risk factors for drug reactions include previous drug exposure, increasing age (>20 years of age), parenteral or topical administration, higher dose, intermittent repeated exposure, and a genetic predisposition of slow drug metabolism. An atopic background does not predispose an individual to the development of drug reactions but may indicate a greater risk of serious reaction.

CLINICAL MANIFESTATIONS

Allergic reactions can be classified as **immediate (anaphylactic) reactions**, which occur within 60 min of drug administration; **accelerated reactions**, which begin 1–72 hours after drug administration; and **late reactions**, which occur after 72 hours. The most common form of adverse drug reaction is cutaneous. Accelerated reactions are usually dermatologic or serum sickness reactions. Late reactions include desquamating dermatitis, Stevens-Johnson syndrome, toxic epidermal necrolysis, and serum sickness.

LABORATORY AND IMAGING STUDIES

Skin prick testing protocols are standardized for penicillin and are well described for other agents, such as local anesthetics, muscle relaxants, vaccines, and insulin. Positive skin testing to such reagents confirms the presence of antigen-specific IgE and supports the diagnosis of a type I hypersensitivity reaction in the appropriate clinical setting. Patch testing is the most reliable way to test for allergy to topically applied drugs.

TABLE 85.1 Classification of Adverse Drug Reactions	
TYPE	EXAMPLE
IMMUNOLOGIC	
Type I reaction (IgE mediated)	Anaphylaxis from β -lactam antibiotic
Type II reaction (cytotoxic)	Hemolytic anemia from cephalosporins
Type III reaction (immune complex)	Serum sickness from antithymocyte globulin
Type IV reaction (delayed, cell mediated)	Contact dermatitis from topical antihistamine
Specific T-cell activation	Morbilloform rash from sulfonamides
Fas/Fas ligand-induced apoptosis	Stevens-Johnson syndrome; toxic epidermal necrolysis
Other	Drug-induced lupuslike syndrome; anticonvulsant hypersensitivity syndrome
NONIMMUNOLOGIC	
Predictable	
Pharmacologic adverse effect	Dry mouth from antihistamines; tremor from albuterol
Secondary pharmacologic adverse effect	Thrush while taking antibiotics; <i>Clostridium difficile</i> -associated colitis (pseudomembranous colitis) from clindamycin (and other antibiotics)
Drug toxicity	Hepatotoxicity from methotrexate
Drug-drug interactions	Increased carbamazepine levels with clarithromycin
Drug overdose	Hepatic necrosis from acetaminophen
Unpredictable	
Pseudoallergic	Anaphylactoid reaction after radiocontrast media
Idiosyncratic	Hemolytic anemia in a patient with G6PD deficiency after primaquine therapy
Intolerance	Tinnitus after a single, small dose of aspirin

G6PD, Glucose-6-phosphate dehydrogenase.

Modified from Riedl MA, Casillas AM. Adverse drug reactions: types and treatment options. *Am Fam Physician*. 2003;68(9):1781–1790.

DIFFERENTIAL DIAGNOSIS

The broadest experience with managing adverse drug reactions is with penicillin. Penicillin allergy should be evaluated when the individual is well and not in acute need of treatment. Penicillin skin testing is helpful for IgE-mediated reactions because of its negative predictive value; only 1–3% of patients with negative skin tests have a reaction, which is mild, when re-exposed to penicillin. Skin testing for penicillin should be performed using the major determinant, penicilloyl polylysine (available as Pre-Pen [ALK-Abelló, Inc, Hørsholm, Denmark]), and minor determinants, which include penicillin G, penicilloate, and penilloate. Skin testing to penicillin does not predict non-IgE-mediated reactions. For patients with a history consistent with serum sickness or desquamative-type reactions, skin testing should not be performed, and penicillin should be avoided indefinitely.

The risk of having an allergic reaction to a cephalosporin in a child who has reacted positively to penicillin skin testing is less than 2%. It is believed that the first-generation cephalosporins are more likely than second-generation or third-generation cephalosporins to be cross reactive. This is due to the chemical similarity of side chains of the β -lactam ring between penicillin and first-generation cephalosporins.

TREATMENT

If penicillin skin testing is positive, penicillin should be avoided, and an alternative antibiotic should be used. If there is a definite need for penicillin, **desensitization** can be accomplished by administration of increasing amounts of drug over a short time in a hospital setting. The exact mechanism of desensitization is unclear; however, it is thought to render mast cells unresponsive to the drug. Depending on the half-life, the drug must be given at least twice daily to maintain desensitization. If the drug is stopped for longer than 48 hours, the patient is no longer *desensitized* and the same protocol must be repeated before continuing antibiotic use.

For other antibiotics, the relevant allergenic determinants produced by metabolism or degradation are not well defined. Skin testing to the native antibiotic in nonirritating concentrations can be performed. However, a negative response does not exclude allergy while a positive response suggests the presence of IgE-mediated allergy. In the case of a negative skin test response, a graded challenge or test dose may be administered, depending on the clinical history of the reaction. Patients who have experienced Stevens-Johnson syndrome, toxic epidermal necrolysis, or serum sickness should not be challenged.

Management of nonpharmacologic drug reactions varies; some reactions may be managed symptomatically while others require avoidance or reduced dose of the offending agent.

COMPLICATIONS

Anaphylaxis is the most serious complication of IgE-mediated drug reactions and can result in death (see [Chapter 81](#)).

PROGNOSIS

Most drug reactions do not seem to be allergic in nature. Repeated, intermittent exposure during childhood or early adulthood contributes to an increased incidence of adverse drug reactions in adults.

PREVENTION

Avoidance of the suspect drug is paramount. Medical information jewelry with appropriate information should be worn. In the medical community, responsible antibiotic use has been emphasized to improve patient outcomes, decrease selection for resistant organisms, and minimize spread of multidrug-resistant organisms. Ideally, sensitive and specific testing to any drug for allergy evaluation is highly desirable. However, standardized testing reagents do not exist for antibiotics other than penicillin. The penicillin family of antimicrobials is very effective to treat a multitude of pediatric infections; limiting their use due to suspected drug allergy may result in undesirable outcomes. In addition to skin testing, oral penicillin challenge may be a useful tool to safely de-label patients with a history of low-risk reactions.

One of the most common concerns in regard to allergic drug reactions is cross reactivity between penicillin and cephalosporins. In children with a history of penicillin allergy, it is important to determine whether they are truly allergic by skin testing to penicillin using the major and minor determinants. If penicillin skin testing is negative, there is a very low risk

of an allergic reaction to cephalosporins. A positive penicillin skin test leads to use of an alternate non-cross reacting antibiotic, a graded challenge to the required cephalosporin under appropriate monitoring or desensitization to the required cephalosporin.

For children with a history of a cephalosporin allergy who require another cephalosporin, consider using a graded challenge with a cephalosporin with a different side chain.

PEARLS FOR PRACTITIONERS

CHAPTER 77

Allergy Assessment

- Type I immediate hypersensitivity reactions involve immunoglobulin E (IgE) antibodies bound to mast cell and basophil cell surfaces. Upon binding of antigen to these antibodies, chemical mediators such as histamine, tryptase, leukotrienes, and prostaglandins are released, resulting in allergic symptoms, the most serious syndrome being anaphylaxis.
- Type II cytotoxic antibody reactions, such as hemolytic anemia and Goodpasture syndrome, occur when antibodies (IgM, IgG, or IgA) bind to cell surface antigens causing complement activation and, ultimately, cell lysis or release of anaphylatoxins.
- Type III immune complex reactions result when antigen-antibody complexes are formed causing injury to vasculature and organs such as liver, spleen, and kidney. The classic type III reaction is serum sickness.
- Type IV delayed type hypersensitivity reactions result when T cells recognize antigens in the context of major histocompatibility complex class II, which activates cytokine release. Contact dermatitis to poison ivy represents an example of type IV delayed hypersensitivity reactions.
- The history, family history, and physical examination may indicate existing atopic disease in patients.
- Allergic rhinitis, allergic asthma, and food allergies are examples of atopic disease involving IgE antibodies.
- Of the two methods for assessing antigen-specific IgE antibodies, in vivo skin testing (via prick or intradermal testing) is the most sensitive. Serum-based testing with quantitative

fluorescent immunoassay is useful in those patients unable to have skin testing performed.

- The presence of specific IgE antibodies does not equate to diagnosis of allergic disease; positive results must be correlated with the history. Therefore obtaining screening tests of multiple allergens is not recommended.

CHAPTER 78

Asthma

- Asthma involves many different cells, chemical mediators, and chemotactic factors resulting in airway inflammation and airway hyperresponsiveness. Typical symptoms include cough, wheeze, shortness of breath, and chest tightness.
- Evaluation of patients with asthma should include history, response to treatment, spirometry (>5 years of age), allergy testing, and chest radiograph, if warranted.
- Treatment of asthma involves numerous interventions: environmental control of potential allergens, patient and caregiver education, reduction of exposure to nonspecific irritants such as secondhand tobacco smoke, pharmacologic therapy, and yearly influenza vaccination.
- To relieve smooth muscle airway bronchoconstriction, short-acting β_2 agonists should be employed on an as-needed basis and/or prior to physical activity.
- The most effective antiinflammatory pharmacologic therapy for persistent asthma is inhaled corticosteroids. Due to steroid side effects, it is important to find the minimum dose that is able to achieve control and minimize risk and impairment from the disease.
- All metered-dose inhalers need to be administered with the use of an AeroChamber to maximize lung deposition of the medication.
- For some patients with more severe asthma, additional therapies may be required to achieve treatment goals: combination therapy with long-acting β_2 agonists, leukotriene modifiers, theophylline, biologic agents, anticholinergic agents, allergen immunotherapy, and oral corticosteroids.
- Use of peak flow monitoring and written asthma action plans may assist patients and their parents with at-home monitoring and adherence to medical therapy.
- Asthma exacerbations may be treated with frequent administration of short-acting bronchodilators and a course of systemic corticosteroids. Despite these interventions, status asthmaticus may ensue, requiring supplemental oxygen, continuous bronchodilation, intravenous corticosteroids, blood gas monitoring, magnesium sulfate, and/or hospitalization.

CHAPTER 79

Allergic Rhinitis

- Allergic rhinitis and conjunctivitis are IgE-mediated atopic diseases in response to relevant aeroallergens in a perennial and/or seasonal fashion. Common symptoms include nasal pruritus, sneezing, clear rhinorrhea, nasal obstruction, lacrimation, ocular pruritus, and conjunctival injection.

- Like asthma, treatment for allergic rhinitis and conjunctivitis employs numerous modalities: education, avoidance of triggers, pharmacologic therapy, and immunotherapy.
- The most effective pharmacologic class of medications for the treatment of allergic rhinitis is intranasal corticosteroids. Other treatments include oral and nasal antihistamines, oral decongestants, and leukotriene modifiers.

CHAPTER 80

Atopic Dermatitis

- Atopic dermatitis is a chronic relapsing skin condition characterized by pruritus and skin inflammation. The pathogenesis is complex and multifactorial.
- Restoring the skin barrier is an important treatment modality as is control of pruritus, reduction of inflammation, and minimizing exposure to known triggers.
- In severe atopic dermatitis, 30% of patients may have a food allergy trigger; for moderate eczema, 15%; for mild, less than 10%.

CHAPTER 81

Urticaria, Angioedema, and Anaphylaxis

- The pathophysiology of urticaria involves swelling of the dermis due to inflammatory mediators released from skin mast cells.
- Angioedema is swelling below the dermis.
- Acute urticaria refers to urticaria occurring less than 6 weeks of duration; chronic urticaria occurs for 6 weeks or more. A causal agent is more likely to be found in acute urticaria such as a food, medication, insect sting, infection, blood transfusion, or contact agent. With chronic urticaria, an etiology is less likely to be found, and most cases are idiopathic.
- Physical urticaria refers to lesions due to physical stimuli such as dermatographia, cold, heat, and/or exercise and pressure.
- There are two types of hereditary angioedema, and both are inherited in an autosomal dominant fashion. Type I accounts for the majority of cases and is due to decreased production of C1-esterase inhibitor. Patients with type II have normal levels of C1-esterase inhibitor, but function is reduced.
- Patients with hereditary angioedema with normal C1 inhibitor experience angioedema like type I and II hereditary angioedema but have normal levels and function of C1-esterase inhibitor.
- Anaphylaxis refers to a syndrome of symptoms (usually involving two or more organ systems) due to type I immediate hypersensitivity. Causative agents are numerous.
- Anaphylactoid reactions result from direct, nonspecific mast cell and basophil activation but are not immune mediated. Examples include reactions to radiocontrast media and opiates.

CHAPTER 82

Serum Sickness

- Serum sickness is the prototypical type III reaction where antibody binds to antigen forming immune complexes that can cause vascular injury or end-organ damage. Symptoms classically are fever, arthralgias, lymphadenopathy, and rash.

CHAPTER 83

Insect Allergies

- Stinging insect hypersensitivity refers to allergic reactions to Hymenoptera, which include bees, yellow jackets, wasps, hornets, and fire ants. Biting insects such as the kissing bug, bed bugs, blackflies, and deerflies have also caused anaphylaxis.
- Patients of any age who suffer from anaphylaxis due to Hymenoptera stings with positive specific IgE testing benefit from immunotherapy and should have an autoinjector of epinephrine. However, pediatric and adult patients who experience only cutaneous symptoms do not require testing, immunotherapy, or epinephrine since their risk of life-threatening reaction is low.

CHAPTER 84

Adverse Reactions to Foods

- Cow's milk, egg, soy, wheat, peanut, tree nut, finned fish, and shellfish account for 90% of IgE-mediated food allergies in children.

- Positive food skin- and/or serum-specific IgE testing alone does not equate to clinical reactivity and must be interpreted in the context of the history.
- The clinical history should dictate what food allergens should be tested; testing to many different foods as a screening tool has very little clinical value and is strongly discouraged.
- Neither skin nor serum testing for food allergies can predict severity of allergy nor the amount required to elicit a reaction. Only risk for an allergic reaction can be inferred from a positive allergy test to a food.
- Currently, treatment of food allergies is avoidance and the use of autoinjectable epinephrine in the case of accidental ingestion resulting in symptoms. Oral immunotherapy with pharmaceutical-grade peanut protein containing relevant allergens is now FDA approved.
- Studies indicate that even for high-risk infants, early introduction of peanut into the diet decreased the development of peanut allergy.

CHAPTER 85

Adverse Reaction to Drugs

- Predictable adverse drug reactions are classified as either immunologic or nonimmunologic with the former being less common.
- Standardized allergy skin testing for reactions due to IgE is available for penicillin determinants but unavailable for most other medications. Drug challenges and drug desensitization may be an appropriate approach in this setting.

RHEUMATIC DISEASES OF CHILDHOOD

Grant D. Syverson

CHAPTER 86

Rheumatic Assessment

The **rheumatic diseases (collagen vascular or connective tissue diseases)** of childhood are characterized by autoimmunity and inflammation, which may be localized or generalized. The classic rheumatic diseases of children include juvenile idiopathic arthritis (JIA), systemic lupus erythematosus (SLE), and juvenile dermatomyositis (JDM). Vasculitis can be a component of many rheumatic diseases. **Musculoskeletal pain syndromes** are a set of overlapping conditions characterized by poorly localized, diffuse pain. Scleroderma (systemic sclerosis), Behçet syndrome, and Sjögren syndrome are rare in childhood. The differential diagnosis of rheumatologic disorders typically includes infections, postinfectious processes, and malignancies (Table 86.1).

HISTORY

The patient history, one of the most important tools in diagnosing rheumatic diseases, can identify symptoms that reflect the source of the inflammation, including whether it is localized or systemic. Symptoms of systemic inflammation can be nonspecific. **Fever**, caused by cytokine release, can take many patterns. A hectic fever, without periodicity or pattern, is commonly found in vasculitides such as Kawasaki disease but also occurs in children with underlying infection. Certain illnesses, such as systemic JIA, produce a patterned fever with regular temperature spikes once or twice a day. Other rheumatic illnesses may cause low-grade fevers. Charting the child's fever pattern, particularly in the absence of antipyretics, is useful. Rashes occur in many forms, from evanescent to fixed and scarring (see Table 86.1). Other systemic symptoms (malaise, anorexia, weight loss, and fatigue) can vary from mild to debilitating.

Symptoms of localized inflammation vary depending on the involved site. **Arthritis**, or inflammation of the synovium (**synovitis**), leads to joint pain, swelling, decreased range of motion, and functional limitations. Stiffness (gelling) is commonly described in the morning or after periods of inactivity and improves with movement. Children may refrain from or alter activities or sports participation. **Enthesitis** is inflammation at the insertion of a ligament to a bone. **Serositis**, inflammation of serosal lining such as pleuritis, pericarditis, or peritonitis, gives rise to chest pain, shortness of breath, or abdominal pain. **Myositis**, inflammation of the muscle, may

lead to symptoms of muscle pain, weakness, or difficulty performing tasks of daily living. **Vasculitis**, inflammation of the blood vessels, leads to nonspecific symptoms of rash (petechiae, purpura) and edema when small vessels deep in the papillary dermis are involved; involvement of medium-sized vessels results in a circumscribed tender nodule, and large vessel disease can lead to claudication and hypertension.

PHYSICAL EXAMINATION

A thorough history and physical examination is frequently sufficient to narrow the differential diagnosis and elicit the diagnosis. The child's overall appearance, evidence of growth failure, or failure to thrive may point to a significant underlying inflammatory disorder. The head and neck examination may show evidence of mucosal ulceration seen in diseases such as SLE. The eye examination may show pupillary irregularity and synechiae from uveitis or the nonpurulent conjunctivitis of Kawasaki disease. Diffuse lymphadenopathy may be found and is nonspecific. The respiratory and cardiac examinations may show pericardial or pleural friction rubs, indicating serositis. Splenomegaly or hepatomegaly raises suspicion of activation of the reticuloendothelial system that occurs in systemic JIA or SLE.

The joint examination is crucial for the diagnosis of arthritis and may identify evidence of inflammation, such as joint swelling, effusion, tenderness, and warmth from increased blood flow. Joint contractures may be seen if the process is chronic. The joint lining, or synovium, may be thickened from chronic inflammation. Activation of epiphyseal growth plates in an area of arthritis can lead to localized bony proliferation and limb length discrepancies. Conversely, inflammation at sites of immature growth centers may lead to maldevelopment of bones, such as the carpals or tarsals, resulting in crowding, or the temporomandibular joints, resulting in micrognathia. A rash or evidence of underlying skin disorders, such as skin thickening from scleroderma or sclerodactyly, may be noted. Chronic Raynaud phenomenon may result in nail fold capillary changes, ulceration, or digital tuft wasting.

COMMON MANIFESTATIONS

The rheumatic diseases of childhood encompass a heterogeneous group of diseases with a shared underlying pathogenesis: chronic inflammation from a disordered immune response. This leads to inflammation directed against native proteins, with secondary increases in numbers of activated lymphocytes, inflammatory cytokines, and circulating antibodies. This

TABLE 86.1 Differential Diagnosis of Pediatric Arthritis Syndromes

antibody production can be nonspecific, or it can be targeted against specific native proteins, leading to subsequent disease manifestations (Table 86.2). Although immune system hyperactivity may be self-limited, the hallmark of most rheumatic diseases of childhood is chronicity or the perpetuation of the inflammatory process, which can lead to long-term disability.

INITIAL DIAGNOSTIC EVALUATION

Although rheumatic diseases sometimes present with nonspecific symptoms, especially early in the course, over time a characteristic set of symptoms and physical findings can be elicited. In conjunction with carefully chosen testing, an appropriate differential diagnosis is made, and eventually the correct diagnosis and treatment plan is developed.

Most rheumatologic diagnoses are established by clinical findings and fulfillment of classification criteria. Laboratory testing should be judicious and based on a differential diagnosis rather than random screening in search of a diagnosis. Laboratory tests confirm clinical diagnoses rather than develop them.

LABORATORY TESTING

Evidence of an underlying systemic inflammation may be indicated by elevated acute phase reactants, especially the erythrocyte sedimentation rate, but also the white blood cell count, platelet count, and C-reactive protein. The complete blood count may demonstrate a normochromic, normocytic anemia of chronic disease. These laboratory findings are nonspecific for any particular rheumatologic diagnosis. Certain laboratory tests may help confirm a diagnosis, such as autoantibody production in SLE or muscle enzyme elevation in JDM, or identify increased risk for complications, such as uveitis in a patient with JIA with a positive antinuclear antibody.

DIAGNOSTIC IMAGING

Radiologic studies should focus on areas of concern identified by history or physical examination. Radiography of joints in patients with arthritis on examination may be beneficial, but radiographic abnormalities may lag far behind the clinical examination. Tests with greater sensitivity, such as magnetic resonance imaging (MRI), may be useful when trying to differentiate between synovitis and traumatic soft tissue injury. MRI may also be useful to identify evidence of central nervous system involvement with SLE or evidence of myositis with JDM.

See Rheumatic Diseases of Childhood: Pearls for Practitioners at the end of this section.

CHAPTER 87

IgA Vasculitis (Henoch-Schönlein Purpura)

ETIOLOGY

Henoch-Schönlein purpura (HSP) (immunoglobulin A vasculitis [IgAV]) is a vasculitis of unknown etiology characterized by inflammation of small blood vessels with leukocytic infiltration of tissue, hemorrhage, and ischemia. The immune complexes associated with IgAV are predominantly composed of IgA, suggesting a hypersensitivity process.

EPIDEMIOLOGY

IgAV is the most common systemic vasculitis of childhood and cause of *nonthrombocytopenic* purpura, with an incidence of 13 per 100,000 children. It occurs primarily in children 3–15 years of age, although it has been described in adults. IgAV is

slightly more common in males than females and occurs more frequently in the winter than in the summer months.

CLINICAL MANIFESTATIONS

IgAV is characterized by rash, arthritis, and, less frequently, gastrointestinal or renal vasculitis. The hallmark of IgAV is **palpable purpura**, caused by small vessel inflammation in the skin, leading to extravasation of blood into the surrounding tissues, frequently with IgA deposition. The rash is classically found in dependent areas: below the waist, on the buttocks, and on lower extremities (Fig. 87.1). The rash can begin as small macules or urticarial lesions but rapidly progresses to purpura with areas of ecchymosis. The rash also can be accompanied by edema, particularly of the calves and dorsum of the feet, scalp, and scrotum or labia. IgAV occasionally is associated with encephalopathy, pancreatitis, and orchitis.

Arthritis occurs in 80% of patients with IgAV and is most common in the lower extremities, particularly the ankles and

FIGURE 87.1 Distribution of Henoch–Schönlein purpura. Palpable purpuric lesions are most common on the lower extremities and buttocks but can appear on the arms, face, and ears; the trunk is usually spared. (From Dinulos JGH, ed. *Habib's Clinical Dermatology: A Color Guide to Diagnosis and Therapy*. 7th ed. Philadelphia, PA: Elsevier; 2021:738 [fig. 18.18].)

knees. The arthritis is acute and very painful, with refusal to bear weight. Joint swelling can be confused with peripheral edema seen with the rash of IgAV.

Gastrointestinal involvement occurs in about one half of affected children and most typically presents as mild to moderate crampy abdominal pain, due to ischemia caused by small vessel involvement of the gastrointestinal tract. Less commonly, significant abdominal distention, bloody diarrhea, intussusception, or abdominal perforation occurs and requires emergent intervention. Gastrointestinal involvement is typically seen during the acute phase of the illness. Arthritis and gastrointestinal symptoms may precede the onset of rash.

One third of children with IgAV develop renal involvement, which can be acute or chronic. Although renal involvement is mild in most cases, acute glomerulonephritis manifested by hematuria, hypertension, or acute renal failure can occur. Most cases of glomerulonephritis occur within the first few months of presentation, but, rarely, patients develop late renal disease, which ultimately can lead to chronic renal disease, including renal failure.

LABORATORY AND IMAGING STUDIES

Erythrocyte sedimentation rate, C-reactive protein, and white blood cell count are elevated in patients with IgAV. The platelet count is the most important test, because IgAV is characterized by *nonthrombocytopenic purpura* with a normal, or even high, platelet count, differentiating IgAV from other causes of purpura that are associated with thrombocytopenia such as autoimmune thrombocytopenia, systemic lupus erythematosus, or leukemia. A urinalysis screens for evidence of hematuria. A serum blood urea nitrogen and creatinine should be obtained to evaluate renal function. Testing the stool for blood may identify evidence of gut ischemia. Any question of gut perforation requires radiologic investigation. If performed, the skin biopsy will show leukocytoclastic vasculitis (LCV) with predominant IgA deposition differentiating it from other forms of LCV.

DIFFERENTIAL DIAGNOSIS

The diagnosis of IgAV is based on the presence of two of four criteria (Table 87.1), which provides 87.1% sensitivity and 87.7% specificity for the disease. The differential diagnosis includes other systemic vasculitides, particularly granulomatosis with

TABLE 87.1 Criteria for Diagnosis of Immunoglobulin A (IgA) Vasculitis (Henoch–Schönlein Purpura)

CRITERIA	DEFINITION
Palpable purpura	Raised, palpable hemorrhagic skin lesions in the absence of thrombocytopenia
Bowel angina	Diffuse abdominal pain or the diagnosis of bowel ischemia
Diagnostic biopsy	Histologic changes showing granulocytes in the walls of arterioles or venules; IgA deposits in vessel wall
Pediatric age group	Age <20 yr at onset of symptoms

*The diagnosis of IgA vasculitis is based on the presence of two of four criteria.

Behçet syndrome
Central nervous system vasculitis

polyangiitis (Table 87.2) and diseases associated with thrombocytopenic purpura, such as idiopathic thrombocytopenic purpura or leukemia.

TREATMENT

Therapy for IgAV is supportive. A short-term course of nonsteroidal antiinflammatory drugs can be administered for the acute arthritis or skin manifestations. Systemic corticosteroids usually are reserved for children with significant pain from gastrointestinal disease. A typical dosing regimen is prednisone (1–2 mg/kg/day, maximum 60 mg/day) with a gradual taper plan over 4–6 weeks. Recurrence of abdominal pain and other symptoms as corticosteroids are weaned necessitate the longer course of treatment. Acute nephritis typically is treated with corticosteroids but may require more aggressive immunosuppressive therapy.

COMPLICATIONS

Most cases of IgAV are monophasic, lasting 3–4 weeks and resolving completely. The rash can wax and wane, however, for 1 year after the initial episode of IgAV. Parents should be warned regarding possible recurrences. The arthritis of IgAV does not leave any permanent joint damage; it does not typically recur. Gastrointestinal involvement can lead to temporary abnormal peristalsis that poses a risk of intussusception, which may be followed by complete obstruction or infarction

with bowel perforation. Any child with a recent history of IgAV who presents with acute abdominal pain, obstipation, or diarrhea should be evaluated for intussusception. Renal involvement rarely may lead to renal failure.

PROGNOSIS

The prognosis of IgAV is excellent. Most children have complete resolution of the illness without any significant sequelae. IgAV patients with renal disease (elevated blood urea nitrogen, persistent high-grade proteinuria) are at highest risk for long-term complications such as hypertension or renal insufficiency, particularly if the initial course was marked by significant nephritis. There is a long-term risk of progression to end-stage renal disease in less than 1% of children with IgAV. The rare patients who develop end-stage renal disease may require renal transplantation. IgAV may recur in the transplanted kidney.

PEARLS FOR PRACTITIONERS

See *Rheumatic Diseases of Childhood: Pearls for Practitioners* at the end of this section.

CHAPTER 88

Kawasaki Disease

ETIOLOGY

Kawasaki disease (KD) is a vasculitis of unknown etiology that is characterized by multisystem involvement and inflammation of small to medium-sized arteries with resulting aneurysm formation.

EPIDEMIOLOGY

KD is the second most common vasculitis of childhood. It is more common in children of Asian descent. It has been described in variable frequency in all parts of the world; the highest frequency is in Japan. KD most commonly occurs more often in males, in children younger than 5 years of age, with a peak between 2 and 3 years; it is rare in children older than 7 years. The incidence in the United States is approximately 6 per 100,000 children who are younger than 5 years of age. A seasonal variability has been described with a peak between February and May, but the disease occurs throughout the year. In the United States KD is the leading cause of acquired heart disease in children.

CLINICAL MANIFESTATIONS

The clinical course of KD can be divided into three phases, each with unique manifestations. Aneurysmal involvement of the coronary arteries is the most important manifestation of KD.

Acute Phase

The acute phase of KD, which lasts 1–2 weeks, is marked by sudden onset of a high, hectic **fever** without an apparent source. The onset of fever is followed by **conjunctival erythema**; mucosal

FIGURE 88.1 (A) Kawasaki disease. Hyperemia of the tongue with prominent lingual papillae (“red strawberry tongue”). (B) The conjunctivitis in this patient demonstrates the notable periorbital sparing (halo of noninvolvement adjacent to the iris). (C) Nonpitting edema of the hand in a young male with Kawasaki disease. (D) Confluent, erythematous patches and plaques of the sole in a young boy with Kawasaki disease. (From Paller AS, Mancini AJ. *Hurwitz Clinical Pediatric Dermatology*. 5th ed. Philadelphia, PA: Elsevier; 2016:504–505 [figs. 21-20, 21-23, 21-24, 21-26].)

changes, including dry, **cracked lips** and a **strawberry tongue**; **cervical lymphadenopathy**; and swelling of the hands and feet (Fig. 88.1). Conjunctivitis is bilateral, bulbar, and nonsuppurative. Cervical lymphadenopathy is found in 70% of children and should be greater than 1.5 cm in diameter for the purposes of diagnosis. A rash, which can vary in appearance, occurs in 80% of children with KD and may be particularly accentuated in the inguinal area and on the chest. Extreme irritability is prominent, especially in infants. Abdominal pain and hydrops of the gallbladder, cerebrospinal fluid pleocytosis, sterile pyuria, and arthritis, particularly of medium-sized to large joints, may occur. Carditis in the acute phase may be manifested by tachycardia, shortness of breath, or overt heart failure. **Giant coronary artery aneurysms**, which are rare but occur most commonly in very young children, can appear during this phase.

Subacute Phase

The subacute phase, which lasts until about week 4, is characterized by gradual resolution of fever (if untreated) and other symptoms. **Desquamation** of the skin, particularly of the fingers and toes, appears at this point. The platelet count, previously normal or slightly depressed, increases to a significant degree (often >1 million/ mm^3). This phase heralds the onset of **coronary artery aneurysms**, which may also appear in the convalescent phase and pose the highest risk of morbidity and mortality. Risk factors for development of coronary artery aneurysms include prolonged fever, prolonged elevation of inflammatory parameters such as the erythrocyte sedimentation rate (ESR), age younger than 1 year or older than 6 years, poor response to therapy, and male gender.

Convalescent Phase

The convalescent phase begins with the disappearance of clinical symptoms and continues until the ESR returns to normal, usually 6–8 weeks after the onset of illness. Linear nail creases

known as Beau lines of the fingernails may appear during this phase.

LABORATORY AND IMAGING STUDIES

It is particularly important to exclude other causes of fever, notably infection. It is appropriate to obtain blood and urine cultures and to perform a chest x-ray. In the acute phase, inflammatory parameters are elevated, including white blood cell count, C-reactive protein (CRP), and the ESR, which can be profoundly elevated (often >80 mm/hr). Platelet counts may be inappropriately low or normal. A lumbar puncture, if performed to exclude infection, may reveal pleocytosis. Tests of hepatobiliary function may be abnormal. Greatly elevated platelet counts develop during the subacute phase. The development of coronary artery aneurysms is monitored by performing two-dimensional echocardiograms, usually during the acute phase, at 1–2 weeks, and again at 4–6 weeks. More frequent echocardiograms and, potentially, coronary angiography are indicated for patients who develop coronary artery abnormalities.

DIFFERENTIAL DIAGNOSIS

The diagnosis of KD is based on the presence of fever for more than 5 days without an identifiable source and the presence of four of five other clinical criteria (Table 88.1).

The diagnosis of **incomplete (atypical) KD**, which occurs more commonly in infants, is made when fever is present for at least 5 days, even if only two or three clinical criteria are present, particularly in the presence of coronary artery aneurysms. The diagnosis of KD should be considered in infants younger than 6 months of age with fever for at least 7 days even if no other criteria are present. Because many of the manifestations of KD are found in other illnesses, many diagnoses must be considered and excluded before the diagnosis of KD can be established (Table 88.2).

TABLE 88.1 Criteria for Diagnosis of Kawasaki Disease

Fever of >5-day duration associated with at least four* of the following five changes:

Bilateral nonsuppurative conjunctivitis

One or more changes of the mucous membranes of the upper respiratory tract, including pharyngeal injection, dry fissured lips, injected lips, and “strawberry” tongue

One or more changes of the extremities, including peripheral erythema, peripheral edema, periungual desquamation, and generalized desquamation

Polymorphous rash, primarily truncal

Posterior cervical lymphadenopathy >1.5cm in diameter

Disease cannot be explained by some other known disease process

*A diagnosis of Kawasaki disease can be made if fever and only three changes are present in conjunction with coronary artery disease documented by two-dimensional echocardiography or coronary angiography.

TABLE 88.2 Differential Diagnosis of Kawasaki Disease

INFECTIOUS

Scarlet fever

Multisystem inflammatory syndrome in children (SARS-CoV-2)

INFLAMMATORY

Juvenile idiopathic arthritis (systemic)

Polyarteritis nodosa

Behçet syndrome

HYPERSENSITIVITY

Drug reaction

Stevens-Johnson syndrome

Multisystem inflammatory disease–children (MIS-C) is a complication of COVID-19 characterized by fever, rash, non-purulent conjunctivitis, gastrointestinal symptoms, cardiac involvement (myocarditis, coronary artery lesions), shock, marked inflammation (elevated CRP, fibrinogen, ESR, ferritin, procalcitonin), and a positive serologic test for SARS-CoV-2

(often with a negative polymerase chain reaction [PCR] for the virus). In the absence of a positive serologic test, it is often difficult to distinguish from KD.

TREATMENT

Intravenous immunoglobulin (IVIG) is the mainstay of therapy for KD, although the mechanism of action is unknown. A single dose of IVIG (2 g/kg over 12 hours) usually results in rapid defervescence and resolution of clinical illness in most patients and, more important, reduces the incidence of coronary artery aneurysms. Aspirin is initially given in **anti-inflammatory doses** (60–80 mg/kg/day divided every 6 hours) in the acute phase. Once the fever resolves, aspirin is reduced to **antithrombotic doses** (3–5 mg/kg/day as a single dose) and given through the subacute and convalescent phases, usually for 4–6 weeks, until follow-up echocardiography documents the absence or resolution of coronary artery aneurysms.

Up to 10% of children with KD initially fail to respond satisfactorily to IVIG therapy. Most of these patients respond to retreatment with IVIG, but an alternative preparation of IVIG may be required. Corticosteroids or infliximab are used less frequently in KD, as opposed to other vasculitides, but may have a role during the acute phase if active carditis is apparent or for children with persistent fever after two doses of IVIG.

COMPLICATIONS

Most cases resolve without sequelae. Myocardial infarction has been documented, most likely caused by stenosis of a coronary artery at the site of an aneurysm. Coronary artery aneurysms found on autopsy in older children following sudden cardiac death may have been due to past KD. Other complications are listed in Table 88.3.

TABLE 88.3 Complications of Kawasaki Disease

Coronary artery thrombosis

Peripheral artery aneurysm

Coronary artery aneurysms

Myocardial infarction

Myopericarditis

Heart failure

Kawasaki shock syndrome

Hydrops of gallbladder

Aseptic meningitis

Irritability

Arthritis

Sterile pyuria (urethritis)

Thrombocytosis (late)

Diarrhea

Pancreatitis

Peripheral gangrene

PROGNOSIS

IVIg reduces the prevalence of coronary artery disease from 20–25% in children treated with aspirin alone to less than 5% in children treated with IVIg and aspirin. Prolonged inflammation (>10 days) puts the patient at greater risk for developing coronary artery aneurysms. Other than the risk of persistent coronary artery aneurysms, KD has an excellent prognosis.

PEARLS FOR PRACTITIONERS

See *Rheumatic Diseases of Childhood: Pearls for Practitioners* at the end of this section.

CHAPTER 89

Juvenile Idiopathic Arthritis

ETIOLOGY

The chronic arthritides of childhood include several types, the most common of which is juvenile idiopathic arthritis (JIA). The classification of JIA includes several other types of juvenile arthritis, such as enthesitis-related arthritis, spondyloarthropathies, and psoriatic arthritis. The etiology of this autoimmune disease is unknown. The common underlying manifestation of this group of illnesses is the presence of chronic **synovitis**, or inflammation of the synovial lining of the joint. The synovium becomes thickened and hypervascular with infiltration by lymphocytes, which also can be found in the synovial fluid along with inflammatory cytokines. The inflammation leads to production and release of tissue proteases and collagenases.

If left untreated, the inflammation can lead to tissue destruction, particularly of the articular cartilage and, eventually, the underlying bony structures.

EPIDEMIOLOGY

JIA is the most common chronic rheumatologic disease of childhood, with a prevalence of 1:1,000 children. The disease has two peaks, one at 1–3 years and one at 8–12 years, but it can occur at any age. Females are affected more commonly than males, particularly with the oligoarticular form of the illness.

CLINICAL PRESENTATION

JIA can be divided into several subtypes, depending on the number of joints involved (<5 vs ≥ 5), the presence of sacroiliac or axial involvement, and the presence of systemic features, each with particular disease characteristics (Table 89.1). Although the onset of the arthritis is slow, the actual joint swelling is often noticed acutely by the child or parent, such as after an accident or fall, and can be confused with trauma (even though traumatic effusions are rare in children). Children often develop pain and stiffness in the joint that limit use, but refusing to walk or severe pain is rare. Morning stiffness and gelling also can occur in the joint and, if present, can be followed in response to therapy.

On physical examination, signs of inflammation are present, including joint tenderness, erythema, and effusion (Fig. 89.1). Joint range of motion may be limited because of pain, swelling, or contractures from lack of use. In children, because of the presence of an active growth plate, it may be possible to find bony abnormalities of the surrounding bone, causing bony proliferation and localized growth disturbance.

TABLE 89.1 Features of Juvenile Idiopathic Arthritis Subgroups

FEATURE	OLIGOARTICULAR	POLYARTICULAR	SYSTEMIC	ENTHESITIS RELATED
No. joints	< 5	≥ 5	Varies, usually ≥ 5	Varies
Types of joints	Medium to large (also small in extended oligoarthritis)	Small to medium	Small to medium	Medium to large, including sacroiliac joints
Gender predominance	F > M (especially in younger children)	F > M	F = M	M > F
Systemic features	None	Some constitutional	Prominent	Some constitutional
Eye disease	+++ (uveitis)	++ (uveitis)	+ (uveitis)	++ (iritis)
Extraarticular manifestations	None	None	Systemic features, MAS, lung disease	Enthesopathy, psoriasis, bowel disease
ANA positivity	++	+	—	—
RF or anti-CCP positivity		+ (in older children with early-onset RA)		N/A
Outcomes	Excellent, >90% complete remission	Excellent with proper diagnosis and treatment Some risk of disability	Significantly improved with newer therapies	Variable

ANA, Antinuclear antibody; CCP, cyclic citrullinated peptide; MAS, macrophage activation syndrome; RA, rheumatoid arthritis; RF, rheumatoid factor.

FIGURE 89.1 An affected knee in a patient with oligoarticular juvenile idiopathic arthritis. Note sizable effusion, bony proliferation, and flexion contracture.

In a lower extremity joint, a leg length discrepancy may be appreciable if the arthritis is asymmetric.

All children with chronic arthritis are at risk for chronic **iridocyclitis** or **uveitis**. There is an association between human leukocyte antigens (HLAs; HLA-DR5, HLA-DR6, and HLA-DR8) and uveitis. The presence of a positive **antinuclear antibody** identifies children with arthritis who are at higher risk for chronic uveitis. Although all children with JIA are at increased risk, the subgroup of children, particularly young girls, with oligoarticular (less than five affected joints) JIA and a positive antinuclear antibody are at highest risk, with an incidence of uveitis of 80%. The uveitis associated with JIA can be asymptomatic until the point of visual loss, making it the primary treatable cause of blindness in children. It is crucial for children with JIA to undergo regular ophthalmologic screening with a slit-lamp examination to identify anterior chamber inflammation and to initiate prompt treatment of any active disease.

Oligoarticular Juvenile Idiopathic Arthritis

Oligoarticular JIA is defined as the presence of arthritis in fewer than five joints within 6 months of diagnosis. This is the most common form of JIA, accounting for approximately 50% of cases.

Oligoarticular JIA presents in young children, with a peak at 1–3 years. The arthritis is found in medium-sized to large joints; the knee is the most common joint involved, followed by the ankle and the wrist. It is unusual for small joints, such as the fingers or toes, to be involved, although this may occur. Neck and hip involvement are uncommon; however, temporomandibular joint involvement occurs in more than 75% of patients. Children with oligoarticular JIA may be otherwise

well without any evidence of systemic inflammation (fever, weight loss, or failure to thrive) or any laboratory evidence of systemic inflammation (elevated white blood cell count or erythrocyte sedimentation rate). A subset of these children later develops polyarticular disease (called *extended oligoarthritis*).

Polyarticular Juvenile Idiopathic Arthritis

Polyarticular JIA describes children with arthritis in five or more joints within the first 6 months of diagnosis and accounts for about 20–30% of cases. Children with polyarticular JIA tend to have symmetric arthritis, which can affect any joint but typically involves the small joints of the hands, feet, ankles, wrists, and knees. The cervical spine can be involved, leading to fusion of the spine over time. In contrast to oligoarticular JIA, children with polyarticular disease can present with evidence of systemic inflammation, including malaise, low-grade fever, growth retardation, anemia of chronic disease, and elevated markers of inflammation. Polyarticular JIA can present at any age, although there is a peak in early childhood. There is a second peak in adolescence, but these children differ by the presence of a positive **rheumatoid factor** or **anticyclic citrullinated protein (anti-CCP) antibody** and most likely represent a subgroup with true adult rheumatoid arthritis; the clinical course and prognosis are similar to the adult entity.

Systemic Juvenile Idiopathic Arthritis

A small subgroup of patients (approximately 10%) with juvenile arthritis does not present with onset of arthritis but rather with preceding **systemic inflammation**. This form of JIA, thought to be an autoinflammatory (rather than autoimmune) disease, manifests with a typical recurring, spiking fever, usually once or twice per day, which can occur for several weeks to months. This is accompanied by a rash, typically **morbilliform** and **salmon colored**. The rash may be evanescent and occur at times of high fever only. Rarely, the rash can be urticarial in nature. Internal organ involvement also occurs. Serositis, such as pleuritis and pericarditis, occurs in 50% of children. Pericardial tamponade may rarely occur. Hepatosplenomegaly occurs in 70% of children. Children with systemic JIA appear sick; they have significant constitutional symptoms, including malaise and failure to thrive. Laboratory findings show inflammation, with elevated erythrocyte sedimentation rate, C-reactive protein, white blood cell count, and platelet counts and anemia. The arthritis of JIA can follow the systemic inflammation by 6 weeks to 6 months. The arthritis is typically polyarticular in nature and can be extensive and resistant to treatment, placing these children at highest risk for long-term disability, although recent advances in therapy have led to a dramatic improvement in disease outcomes.

Enthesitis-Related Arthritis

Enthesitis-related arthritis (ERA) describes a group of arthritides that include inflammation of the axial skeleton, sacroiliac joints, peripheral large joints, and entheses (inflammation of tendinous insertions) and were previously referred to as spondyloarthropathies. These include juvenile ankylosing spondylitis, psoriatic arthritis, reactive arthritis, arthritis of inflammatory bowel disease, and undifferentiated juvenile arthritis. This group

of diseases can also present with peripheral arthritis and can be initially classified in other subgroups. It is only later, when the patient develops evidence of sacroiliac arthritis, psoriasis, or gastrointestinal disease, that the diagnosis becomes clear (Table 89.2). Other important features of this group include the frequent presence of HLA-B27 and the need for earlier treatment with tumor necrosis factor (TNF) blockers as axial disease can have a poor response to conventional disease-modifying antirheumatic drugs (DMARDs) like methotrexate.

LABORATORY AND IMAGING STUDIES

History and physical exam are the most important diagnostic tools for juvenile arthritis. Most children with oligoarticular JIA have no laboratory abnormalities. Children with polyarticular and systemic disease commonly show elevated acute phase reactants and anemia of chronic disease. In all pediatric patients with joint or bone pain, a complete blood count should be performed to exclude leukemia, which also can present with limb pain (see Chapter 155). Oligoarticular and polyarticular patients with JIA should have an antinuclear antibody test to help identify those at higher risk for uveitis. Older children and adolescents with polyarticular disease should also have a rheumatoid factor and anti-CCP antibody performed to identify children with early-onset adult rheumatoid arthritis.

Diagnostic arthrocentesis may be necessary to exclude suppurative arthritis in children who present with acute onset of monoarticular symptoms or patients with severe pain. The synovial fluid white blood cell count is typically less than 50,000–100,000/mm³ and should be predominantly lymphocytes, rather than neutrophils seen with suppurative arthritis. Gram stain, polymerase chain reaction (PCR), and culture should be negative (see Chapter 118).

The most common radiologic finding in the early stages of JIA is a normal bone x-ray. Over time, periarticular osteopenia, resulting from decreased mineralization, is most commonly found. Growth centers may be slow to develop, whereas there may be accelerated maturation of growth plates or evidence of bony proliferation. Erosions of bony articular surfaces may be a late finding. If the cervical spine is involved, fusion of C1–4 may occur, and atlantoaxial subluxation may be demonstrable.

DIFFERENTIAL DIAGNOSIS

The diagnosis of JIA is established by the presence of arthritis, the duration of the disease for at least 6 weeks, and exclusion of other possible diagnoses. Although a presumptive diagnosis of systemic JIA can be established for a child during the systemic phase, a definitive diagnosis is not possible until arthritis develops. Children must be younger than 16 years of age at the time of onset of the disease; the diagnosis of JIA does not change when the child becomes an adult. Because there are so many other causes of arthritis, these disorders need to be excluded before providing a definitive diagnosis of JIA (Table 89.3). The acute arthritides can affect the same joints as JIA but have a shorter time course.

TREATMENT

The treatment of JIA focuses on suppressing inflammation, preserving and maximizing function, preventing deformity, and preventing blindness. Nonsteroidal antiinflammatory drugs (NSAIDs) are often the first choice in the treatment of JIA. Naproxen, sulindac, ibuprofen, indomethacin, and others have been used successfully. Systemic corticosteroid medications, such as prednisone and prednisolone, should be avoided in all but the most extreme circumstances, such as for severe systemic JIA with internal organ involvement or for significant active arthritis leading to functional disability. In this circumstance, the corticosteroids are used as **bridging therapy** until other medications take effect. For patients with isolated inflamed joints, intraarticular corticosteroids may be helpful at any point in the treatment course.

Methotrexate, preferably given subcutaneously, has become the drug of choice for polyarticular and systemic JIA, which may not respond to baseline agents alone, and for oligoarticular patients who do not respond to standard therapy and have high disease activity and risk factors for poor prognosis. Methotrexate can cause bone marrow suppression and hepatotoxicity; regular monitoring can minimize these risks. Leflunomide, with a similar adverse effect profile to methotrexate, has also been used. Biologic agents that inhibit TNF α and block the inflammatory cascade, including **etanercept**,

infliximab, and **adalimumab**, are effective in the treatment of JIA and are superior to methotrexate in the spondyloarthropathy group. **Anakinra**, an interleukin 1 (IL-1) receptor antagonist, **canakinumab**, an IL-1 β monoclonal antibody, and **tocilizumab**, a monoclonal antibody to the IL-6 receptor are very beneficial in the treatment of systemic JIA.

COMPLICATIONS

Complications with JIA result primarily from the loss of function of an involved joint secondary to contractures, bony fusion, or loss of joint space. Physical and occupational therapies, professionally and through home programs, are crucial to preserve and maximize function. More serious complications stem from associated uveitis; if left untreated, it can lead to serious visual loss or blindness.

A very serious complication of systemic JIA, **macrophage activation syndrome (MAS)**, has received increasing recognition. Occurring in more than 10% of systemic JIA patients, MAS can be seen in the context of overwhelming inflammation, which leads to activation of proliferation of T lymphocytes and macrophages, resulting in overwhelming release of proinflammatory cytokines. The patient develops high fevers, hepatosplenomegaly, lymphadenopathy, and a bleeding diathesis. Laboratory studies reveal pancytopenia, elevated ferritin, transaminases, and triglycerides, as well as elevated soluble CD25. There is evidence of disseminated intravascular coagulation with low fibrinogen, increased D-dimer, and abnormal blood smear. Bone marrow sampling may identify mature macrophages displaying **hemophagocytic** activity. MAS can lead to multisystem organ failure. Even with early detection and aggressive treatment, mortality rates for MAS approximate 8%.

PROGNOSIS

The prognosis of JIA can be excellent if diagnosed early and treated appropriately. Remission rates vary depending on the subtype. Children with oligoarticular JIA uniformly tend to do well; children with polyarticular disease and systemic disease constitute most children with functional disability. Systemic disease, a positive rheumatoid factor or anti-CCP antibody, poor response to therapy, and the presence of bony erosions on x-ray all connote a poorer prognosis. The importance of physical and occupational therapy cannot be overstated because when the disease remits, the physical limitations remain with the patient into adulthood.

PEARLS FOR PRACTITIONERS

See Rheumatic Diseases of Childhood: Pearls for Practitioners at the end of this section.

CHAPTER 90

Systemic Lupus Erythematosus

ETIOLOGY

Systemic lupus erythematosus (SLE) is a multisystem disorder of unknown etiology characterized by a production of large amounts of **circulating autoantibodies**. This antibody production may be due to loss of T-lymphocyte control on B-lymphocyte activity, leading to hyperactivity of B lymphocytes, which leads to nonspecific and specific antibody and autoantibody production. These antibodies form immune complexes that become trapped in the microvasculature,

leading to inflammation and ischemia. Monogenetic defects in complement or genes in the interferon production pathway are responsible for a small percentage of patients with SLE.

EPIDEMIOLOGY

Although SLE affects primarily females ages 20–40, approximately 5% of cases present in childhood, mainly around puberty. SLE is rare in children younger than 9 years of age. Although there is a female predominance of this disease in adolescence and adulthood, there is an equal gender distribution in children. The overall prevalence of SLE in the pediatric population is 10–25 cases per 100,000 children and is highest among non-Whites.

Clinical Manifestations

Patients with SLE can present either in an abrupt fashion with fulminant disease or in an indolent manner (Tables 90.1 and 90.2). Nonspecific symptoms are common but can be quite profound and may include significant fatigue and malaise, low-grade fever, and weight loss.

Skin disease can be a prominent finding, occurring in up to 90% of patients. A raised, erythematous rash on the cheeks, called a *malar butterfly rash*, is common (Fig. 90.1). This rash can also occur across the bridge of the nose, on the forehead, and on the chin but spares the nasolabial folds. **Photosensitivity** can be problematic, particularly during summer months. Both rashes improve with appropriate therapy. The rash of **discoid lupus**, by contrast, is an inflammatory process that disrupts the dermal-epidermal junction, resulting in permanent scarring and loss of pigmentation in the affected area. If discoid lupus occurs in the scalp, permanent alopecia ensues because of loss of hair follicles. **Alopecia** and **Raynaud phenomenon** occur, although are not specific for SLE. Livedo reticularis also can occur.

Mouth and nasal sores from mucosal ulceration are a common complaint and can lead to ulceration and perforation of the nasal septum. Because of reticuloendothelial system stimulation, lymphadenopathy and splenomegaly are common findings. In particular, axillary lymphadenopathy can be a sensitive indicator of SLE activity. Serositis can be seen, with chest pain and pleural or pericardial friction rubs or frank effusion.

Renal involvement is one of the most serious manifestations of SLE and is common in pediatric SLE, occurring in 20–80% of children. Renal disease may range from microscopic proteinuria or hematuria to gross hematuria, nephrotic syndrome, and renal failure. Hypertension or the presence of edema suggests lupus renal disease.

Arthralgias and arthritis are common. The arthritis is rarely deforming and typically involves the small joints of the hands; any joint may be involved. Myalgias or frank myositis, with muscle weakness and muscle fatigability, may occur. SLE can affect the central nervous system (CNS), leading to a myriad of symptoms ranging from poor school performance and difficulty concentrating to seizures, psychosis, and stroke.

LABORATORY AND IMAGING STUDIES

Testing for SLE is performed to establish the diagnosis, determine prognosis, and monitor response to therapy. Although

TABLE 90.1 American College of Rheumatology Criteria for Diagnosis of Systemic Lupus Erythematosus*

PHYSICAL SIGNS	
Malar butterfly rash	
Discoid lupus	
Photosensitivity	
Oral and nasopharyngeal ulcers	
Nonerosive arthritis (more than two joints with effusion and tenderness)	
Pleuritis, ascites, or pericarditis (serositis)	
Seizures or psychosis in absence of metabolic toxins or drugs	
LABORATORY DATA	
Renal disease (nephritis):	
Proteinuria (>500 mg/24 hr) or	
Cellular casts (RBC, granular, or tubular)	
Hematologic disease:	
Hemolytic (autoimmune) anemia with reticulocytosis or	
Leukopenia (<4,000 on two occasions) or	
Lymphopenia (<1,500 on two occasions) or	
Thrombocytopenia (<100,000/mm ³)	
SEROLOGIC DATA	
Positive anti-dsDNA or	
Positive anti-Sm or	
Evidence of presence of antiphospholipid antibodies	
IgG or IgM anticardiolipin antibodies or	
Lupus anticoagulant or	
False-positive VDRL for >6 mo	
Positive ANA in absence of drugs known to induce lupus	

*These are the 1997 revised criteria for diagnosing systemic lupus erythematosus (SLE). A patient must have 4 of the 11 criteria to establish the diagnosis of SLE. These criteria may be present at the same or at different times during the patient's illness. Additional, less specific diagnostic manifestations are noted in Table 90.2.

ANA, Antinuclear antibody; RBC, red blood cell; VDRL, Venereal Disease Research Laboratory.

nonspecific, a positive **antinuclear antibody** is found in more than 99% of patients with SLE, usually at high titers. Because of its high sensitivity, a negative antinuclear antibody has a high negative predictive value for SLE. The presence of **antibodies to double-stranded DNA** should raise suspicion for SLE; these antibodies are present in most patients with SLE and are found almost exclusively in the disease. Titers of anti-double-stranded DNA antibodies are quantifiable and can vary with disease activity. Antibodies directed against Sm (Smith) are specific to SLE but found in only approximately 30% of persons with SLE. Antibodies to Ro (SSA) and La (SSB) can also be found in patients with SLE but also occur in patients with Sjögren syndrome.

Patients with SLE can have antibodies directed against phospholipids, which also can be seen in other rheumatologic

diseases and in primary antiphospholipid syndrome. These antibodies lead to an increased risk of arterial and venous thrombosis and can be detected by the presence of anticardiolipin antibodies, a false-positive Venereal Disease Research Laboratory (VDRL) test, or a prolonged activated partial thromboplastin time.

Hematologic abnormalities also are prevalent with SLE. Leukopenia, primarily manifest as lymphopenia, is common. Thrombocytopenia and anemia of chronic disease may be found. Patients with SLE can develop a Coombs-positive autoimmune hemolytic anemia. Excessive antibody production can lead to polyclonal hypergammopathy, with an elevated globulin fraction in the serum. Excessive circulating antibodies and immune complexes also lead to the consumption of complement proteins, with low levels of C3 and C4 and decreased complement function as measured by CH50. Effective therapy returns the low complement levels to normal. This is one way to monitor therapy, except in patients with familial deficiency in complement components, which itself predisposes to SLE.

Urinalysis may show hematuria and proteinuria, identifying patients with lupus nephritis. Serum blood urea nitrogen and creatinine evaluate renal function. Hypoalbuminemia and hypoproteinemia may be present due to leakage at the glomerular level. Elevation of muscle enzymes may be a clue for the presence of myositis. Elevated cerebrospinal fluid (CSF) protein and an elevated IgG-to-albumin ratio when comparing CSF with serum (IgG index) can indicate antibody production in the CSF and help diagnose SLE affecting the CNS. CNS lupus has a specific pattern on gadolinium-enhanced magnetic resonance imaging.

DIFFERENTIAL DIAGNOSIS

Because SLE is a multisystem disease, it can be difficult to diagnose early in the disease course. Suspicion must be high in patients who present with diffuse symptoms, particularly adolescent girls. Many of the clinical manifestations of SLE are found in other inflammatory illnesses and during acute or chronic infection. Criteria have been developed for the diagnosis of SLE (see Table 90.1). The presence of 4 of 11 of these criteria has 98% sensitivity and 97% specificity for SLE.

TREATMENT

Corticosteroids have been the mainstay of treatment for SLE for decades. Initial use of pulse methylprednisolone and high-dose oral prednisone (up to 2 mg/kg) frequently is required, followed by cautious tapering to minimize recurrence of symptoms. Nonsteroidal antiinflammatory drugs have been used to treat the arthralgias and arthritis associated with SLE. Hydroxychloroquine is used not only for the treatment of lupus skin disease, such as discoid lupus, but as maintenance therapy. Hydroxychloroquine treatment results in longer periods of remission, reduces vascular complications, and improves dyslipidemia.

Corticosteroids and hydroxychloroquine frequently are not sufficient therapies for lupus nephritis or cerebritis. Cyclophosphamide is effective for the most severe forms of lupus nephritis, with significant improvements in outcome and decreased rates of progression to renal failure. Azathioprine and mycophenolate mofetil have roles in the treatment of lupus nephritis due to the improved side effect profile compared to cyclophosphamide. CNS lupus responds to cyclophosphamide. For patients who are not able to tolerate the tapering of corticosteroids, the use of steroid-sparing agents, such as azathioprine, methotrexate, or mycophenolate mofetil, may be indicated.

Patients with SLE should be counseled to wear sun block and avoid sun exposure because exposure to the sun precipitates flares of the disease. Because of this prohibition, patients benefit from calcium and vitamin D supplementation to reduce the risk of osteoporosis that may result from prolonged corticosteroid use. Early treatment of hyperlipidemia to decrease long-term cardiovascular complications is also indicated.

COMPLICATIONS

Long-term complications include avascular bone necrosis secondary to corticosteroid use, infections, and myocardial infarction. Adult patients with SLE develop accelerated atherosclerosis, not only because of prolonged corticosteroid use but also due to the underlying chronic inflammation. All patients with SLE should be counseled regarding their weight and maintaining an active lifestyle to reduce other cardiac risk factors.

PROGNOSIS

Outcomes for SLE have improved significantly over the past several decades and depend largely on the organ systems that are involved. Worse prognoses are seen in patients with severe lupus nephritis or cerebritis, with risk of chronic disability or progression to renal failure. With advances in therapy for

the disease and the success of renal transplantation, however, most patients live well into adulthood.

PEARLS FOR PRACTITIONERS

See Rheumatic Diseases of Childhood: Pearls for Practitioners at the end of this section.

CHAPTER 91

Juvenile Dermatomyositis

ETIOLOGY

The etiology of juvenile dermatomyositis (JDM) is unknown. It is characterized by the activation of T and B lymphocytes, leading to a vasculopathy affecting small vessels of skeletal muscle, with immune complex deposition and subsequent inflammation of blood vessels and muscle and inflammation of the skin. JDM may follow infections, allergic reactions, or sun exposure, but no causal relationship has been shown.

EPIDEMIOLOGY

JDM is a rare disease, with an incidence of up to 0.32:100,000 children. JDM can occur in all age groups with a peak incidence between 5 and 14 years. The disease is slightly more common in females than males.

CLINICAL MANIFESTATIONS

Dermatomyositis tends to present in a slow, progressive fashion, with insidious onset of fatigue, malaise, and progressive muscle weakness, accompanied by low-grade fevers and rash. Some children present in an acute fashion, however, with rapid onset of severe disease.

The muscle disease of JDM primarily affects the proximal muscles, particularly the hip and shoulder girdles, and the abdominal and neck muscles. Children have difficulty climbing steps, getting out of chairs, and getting off the floor. The patient may have a positive **Gower sign**. In severe cases, the patient is not able to sit up from a supine position or even lift the head off the examination table (see [Chapter 182](#)). If muscles of the upper airway and pharynx are involved, the patient's voice will sound nasal, and the patient may have difficulty swallowing.

A classic **JDM rash** occurs on the face and across the cheeks but also can be found on the shoulders and back (**shawl sign**). Patients may have **heliotrope discoloration** of the eyelids. Scaly, red plaques (**Gottron papules**) classically are found across the knuckles but can be found on the extensor surfaces of any joint. Patients may have periungual erythema and **dilated nail fold capillaries**. Less commonly, patients develop cutaneous vasculitis, with inflammation, erythema, and skin breakdown.

At some point, approximately 15% of patients with JDM develop arthritis that commonly affects small joints but may involve any joint. Raynaud phenomenon, hepatomegaly, and splenomegaly may also occur.

LABORATORY AND IMAGING STUDIES

Many patients with JDM have no evidence of systemic inflammation (normal blood count and erythrocyte sedimentation rate). Evidence of myositis can be identified in 98% of children with active JDM by elevated serum muscle enzymes, including aspartate aminotransferase, alanine aminotransferase, creatine phosphokinase, aldolase, and lactate dehydrogenase. Myositis-specific antibodies can identify subsets of JDM patients with shared clinical features. Electromyography and muscle biopsy can document the myositis. Noncontrast magnetic resonance imaging is a sensitive and noninvasive means of demonstrating muscle inflammation.

DIFFERENTIAL DIAGNOSIS

Diagnosis of JDM is based on the presence of documented muscle inflammation in the setting of classic rash (Table 91.1). A small percentage of children have muscle disease without skin manifestations, but polymyositis is sufficiently rare in children that they should have a muscle biopsy to exclude other causes of muscle weakness, such as muscular dystrophy (particularly in boys). The differential diagnosis also includes postinfectious myositis and other immune or congenital myopathies (see Chapter 182).

TREATMENT

Methotrexate, supplemented by short-term use of systemic corticosteroids, is the cornerstone of therapy for JDM. Initial treatment with pulse intravenous methylprednisolone is followed by several months of tapering doses of oral prednisone. Early institution of methotrexate significantly decreases the duration of corticosteroid use and its associated toxicities. Intravenous immunoglobulin can provide significant benefit as an adjunctive therapy. In severe or refractory cases, it may be necessary to use cyclosporine, mycophenolate, azathioprine, tacrolimus, or cyclophosphamide. Hydroxychloroquine or dapsone has been used for the skin manifestations. These drugs do not significantly affect the muscle disease. Exposure to the sun worsens the cutaneous manifestations and exacerbates the muscle disease; sunlight may lead to flare. Patients should be advised to wear sun block and refrain from prolonged sun exposure. Accordingly, supplementation with calcium and active forms of vitamin D is also indicated.

TABLE 91.1 Criteria for Diagnosis of Juvenile Dermatomyositis

Rash typical of dermatomyositis
Symmetric proximal muscle weakness
Elevated muscle enzymes (ALT, AST, LDH, CPK, and aldolase)
EMG abnormalities typical of dermatomyositis (fasciculations, needle insertion irritability, and high-frequency discharges)
Positive muscle biopsy specimen with chronic inflammation

*To make a definitive diagnosis of dermatomyositis, four of five criteria are required.

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; CPK, creatine phosphokinase; EMG, electromyography; LDH, lactate dehydrogenase.

COMPLICATIONS

The most serious complication of JDM is the development of **calcinosis**. Dystrophic calcification can occur in the skin and soft tissues in any area of the body; it ranges from mild to extensive (**calcinosis universalis**). Although it is difficult to predict who will develop calcinosis, it occurs more commonly in children with cutaneous vasculitis, prolonged disease activity, or delays in onset of therapy. Patients with JDM who develop vasculitis also are at risk for gastrointestinal perforation and gastrointestinal bleeding. JDM has been associated with lipoatrophy and insulin resistance, which can progress to type 2 diabetes. Control of insulin resistance frequently leads to improvement in muscle disease in these patients.

PROGNOSIS

The outcome of JDM depends greatly on the extent of muscle disease and the time between disease onset and initiation of therapy. JDM follows one of three clinical courses: a monophasic course, in which patients are treated and improve without significant sequelae; a chronic recurrent course; and a chronic progressive course marked by poor response to therapy and resulting loss of function. Patients who ultimately develop calcinosis are at risk for chronic loss of mobility, depending on the extent of calcium deposition. The association of dermatomyositis with malignancy seen in adults does not occur in children.

PEARLS FOR PRACTITIONERS

See *Rheumatic Diseases of Childhood: Pearls for Practitioners* at the end of this section.

CHAPTER 92

Musculoskeletal Pain Syndromes

GROWING PAINS

Growing pains, or benign musculoskeletal pains of childhood, occur in up to 37% of school-age children. The peak age range is 3–12 years; the syndrome seems to be more common in males than females. There is no known etiology, although there seems to be a familial predisposition.

Children with growing pains complain of deep, crampy pain in the legs that is not centered in the joints. It most typically occurs in the evening or as nocturnal pain that occasionally can awaken the child from sleep. Growing pains tend to be more common in children who are extremely active; bouts are exacerbated by increased physical activity. The physical examination is unremarkable, with no evidence of arthritis or muscular tenderness or weakness. Laboratory studies or x-rays, if performed, are normal.

The **diagnosis** of growing pains is based on a typical history and a normal physical examination. It is important to consider leukemia as a cause of nocturnal leg pain in children of this age group, so it may be prudent to document a normal complete blood count.

The **treatment** of growing pains consists of reassurance and a regular bedtime ritual of stretching and relaxation. The pain can be relieved by massage. Some patients may benefit from a nighttime dose of acetaminophen or an analgesic dose of a nonsteroidal antiinflammatory drug (NSAID). Occasionally nocturnal awakening has been of long duration, leading to disruptive behavior patterns. In these cases, intervention must be aimed at decreasing the secondary gain associated with nighttime parental attention and should focus on sleep hygiene. Other than the negative behavioral patterns that can occur, there are no significant complications. Growing pains are not associated with other illnesses and resolve over time.

BENIGN HYPERMOBILITY

Hypermobility syndromes are disorders of unknown etiology that cause musculoskeletal pain secondary to excessive mobility of joints. These disorders most commonly present in children 3–10 years of age. Females are more commonly affected than males. There is a familial predisposition to hypermobility syndromes. Specific diseases causing hypermobility include Marfan syndrome, homocystinuria, Stickler syndrome, Ehlers-Danlos syndromes, osteogenesis imperfecta, Williams syndrome, and trisomy 21. Most children with hypermobility do not have an identifiable associated syndrome or disease.

Hypermobility can be isolated to a specific joint group or can present as a generalized disorder. Symptoms vary depending on the joints involved. The most consistent symptom is pain, which may occur during the day or night. The discomfort increases after exertion and can interfere with physical activity. Children with hypermobility of the ankles or feet may complain of chronic leg or back pain.

Joint hypermobility may be quite marked. Range of motion may be exaggerated with excessive flexion or extension at the metacarpophalangeal joints, wrists, elbows, or knees (genu recurvatum) (Fig. 92.1). There may be excessive pronation of the ankles. Hypermobility of the foot (flat foot; *pes planus*) is shown by the presence of a longitudinal arch of the foot that disappears with weight bearing and may be associated with a shortened Achilles tendon (see Chapter 200). These findings are rarely associated with tenderness on examination. No laboratory test abnormalities are apparent, and radiographs of affected joints are normal.

The diagnosis of isolated hypermobility is made on the basis of physical examination with demonstration of exaggerated mobility of a joint. Generalized hypermobility is diagnosed by the presence of sufficient criteria (Table 92.1) and the absence of evidence of other underlying disorders. Excessive skin elasticity, easy bruisability, or mitral valve prolapse suggests **Ehlers-Danlos syndrome** or **Marfan syndrome** rather than benign hypermobility.

The **treatment** of hypermobility consists of reassurance and regular stretching, similar to treatment for other benign musculoskeletal disorders. NSAIDs can be administered as needed but do not need to be prescribed on a regular basis. Arch supports can be helpful in children with symptomatic pes planus but are not indicated in the absence of symptoms. Many patients benefit from formal physical therapy and conditioning exercises. Benign hypermobility tends to improve with increasing age and is not associated with long-term complications.

FIGURE 92.1 Hyperextension of the knees—an example of hypermobility.

TABLE 92.1 Criteria for Hypermobility

MODIFIED CRITERIA OF CARTER AND WILKINSON

Three of Five Are Required to Establish a Diagnosis of Hypermobility:

- Touch thumb to volar forearm
- Hyperextend metacarpophalangeal joints so fingers parallel forearm
- $>10^\circ$ hyperextension of elbows
- $>10^\circ$ hyperextension of knees
- Touch palms to floor with knees straight

BEIGHTON SCALE

- ≥ 6 points defines hypermobility: touch thumb to volar forearm (one point each for right and left)
- Extend fifth metacarpophalangeal joint to 90° (one point each for right and left)
- $>10^\circ$ hyperextension of elbow (one point each for right and left)
- $>10^\circ$ hyperextension of knee (one point each for right and left)
- Touch palms to floor with knees straight (one point)

Other Noncriteria Features of Many Children with Hypermobility:

- Put heel behind head
- Excessive internal rotation to hip
- Excessive ankle dorsiflexion
- Excessive eversion of the foot
- Passively touch elbows behind the back

Data from Carter C, Wilkins J. Persistent joint laxity and congenital dislocation of the hip. *J Bone Joint Surg Br.* 1964;46:40–45.

MYOFASCIAL PAIN SYNDROMES AND FIBROMYALGIA

The myofascial pain syndromes are a group of noninflammatory disorders characterized by diffuse musculoskeletal pain, the presence of multiple **tender points**, fatigue, malaise, and poor sleep patterns. The etiology of these disorders is unknown, although there seems to be a familial predisposition. Although these disorders sometimes follow viral infection or trauma, no causal relationship has been shown. The myofascial pain syndromes are most common in adults but can occur in children (particularly >12 years of age). The syndromes are more common in females than in males. The prevalence of fibromyalgia in children has been reported to be 6%.

Patients with myofascial pain syndromes complain of long-standing diffuse pain in muscles and in the soft tissues around joints that can occur at any time of day, awaken the patient from sleep, and interfere with regular activities. There is frequently a high degree of school absenteeism, despite maintaining adequate school performance. A significant percentage of patients with myofascial pain syndromes exhibit symptoms consistent with anxiety and depression. Stressful life events, family dysfunction, and emotional, physical, or sexual abuse may precede these conditions.

Physical examination is typically unremarkable with the exception of the presence of specific points that are painful—not just tender—to digital palpation. Pain is often out of proportion with the exam, and patients will report significant pain without other physical clues. There is no evidence of arthritis or muscular weakness. Some patients experience postural autonomic dysfunction and others report disordered thinking or “brain fog.”

Patients with myofascial pain syndromes frequently undergo extensive medical testing because of the concern for underlying inflammatory disease. These tests are invariably normal. Children may have a false-positive antinuclear antibody, which is found in up to 20% of the normal pediatric population.

The **diagnosis** of myofascial pain syndrome is based on the presence of multiple tender points in the absence of other illness. To fulfill strict criteria for a diagnosis of fibromyalgia, the patient must have a history of diffuse pain for at least 3 months and the presence of multiple pain sites and an elevated symptom profile as measured by formal instruments. It is important to exclude underlying inflammatory diseases, such as systemic lupus erythematosus, or the postinfectious fatigue that characteristically follows Epstein-Barr virus and influenza

virus infection. Mood and conversion disorders also should be considered.

Treatment consists of pain control and restoration of function. Physical therapy, psychologic therapy, development of coping mechanisms, and education about sleep hygiene and the concept of the pain response system are all highly valuable interventions. Patients may require medications, such as amitriptyline to regulate sleep or gabapentin to reduce pain sensitivity. Because of the disability associated with myofascial pain syndromes, patients and parents frequently believe that the child has a serious underlying condition that makes education and reassurance crucial. It should be emphasized that there is no simple cure, and time and perseverance are required.

The long-term outcomes in the myofascial pain syndromes vary. Patients and families who focus on therapy and are positive in their approach tend to have better outcomes. Patients who demand prolonged evaluations, especially from multiple health care providers, may do more poorly. Overall, children with fibromyalgia and myofascial pain syndromes have better prognoses than their adult counterparts.

PEARLS FOR PRACTITIONERS

CHAPTER 86

Rheumatic Assessment

- The hallmarks of rheumatic diseases of childhood are inflammation (localized or generalized) and autoimmunity.
- The differential diagnosis of rheumatologic disease typically includes infections, postinfectious processes, and malignancy.
- The diagnosis of most rheumatologic diseases can be made from the history and physical exam in conjunction with carefully chosen confirmatory laboratory or radiologic tests.
- Enthesitis is inflammation at the insertion of a ligament to a bone such as at the heel.
- Vasculitis often results in a petechial or purpuric rash.
- Morning stiffness may be seen in rheumatologic disorders and is suggestive of inflammatory joint disease.

- Certain laboratory tests will reveal generalized inflammation, such as an elevated white blood cell or platelet count or an elevated erythrocyte sedimentation rate or C-reactive protein; they may also reveal the presence of an anemia of chronic disease. Other laboratory tests, such as those that measure autoantibodies, are used to detect only specific disorders.

CHAPTER 87

IgA Vasculitis (Henoch-Schönlein Purpura)

- Immunoglobulin A vasculitis (IgAV) is a small vessel vasculitis of unknown etiology. The hallmark of IgAV is non-thrombocytopenic palpable purpura, which predominantly occurs on the buttocks and lower extremities. Other features include arthritis, gastrointestinal, and renal involvement.
- The differential diagnosis includes other vasculitis syndromes, leukemia, and immune thrombocytopenic purpura.
- Treatment of IgAV is largely supportive; nonsteroidal anti-inflammatory drugs are used for arthritis. In rare cases, such as gastrointestinal (GI) involvement or active nephritis, steroids are used with a prolonged taper plan.
- The prognosis of IgAV is excellent. Most cases of IgAV are uniphasic and resolve within 3–4 weeks, but the GI symptoms can recur as steroids are weaned, and the rash of IgAV can recur for 12–15 months. In rare cases, patients can develop chronic renal disease.
- Immunoglobulin (Ig)A is often present in skin and renal lesions.

CHAPTER 88

Kawasaki Disease

- Kawasaki disease is a vasculitis that typically affects children under the age of 7 and runs a triphasic course: acute, subacute, and convalescent. The acute phase, which lasts 1–2 weeks, is characterized by a high, hectic fever, followed by conjunctival erythema, mucosal changes, cervical lymphadenopathy, swelling of the hands and feet, and elevated inflammatory parameters. The subacute phase is noted by desquamation of the skin, reactive thrombocytosis, and development of coronary artery aneurysms. The convalescent phase, which occurs 6–8 weeks into the illness, is characterized by the resolution of symptoms and development of dystrophic nail changes.
- The diagnosis of Kawasaki disease is made based on the presence of fever for more than 5 days without an identifiable source and the presence of four of five other clinical criteria: bilateral nonsuppurative conjunctivitis, mucosal changes, extremity changes, polymorphous rash, and posterior cervical lymphadenopathy greater than 1.5 cm in diameter.
- The most serious complication of Kawasaki disease is coronary artery aneurysms. The main treatment of Kawasaki disease is intravenous Ig, which reduces the incidence of coronary artery aneurysms from 20–25% to less than 5%.

CHAPTER 89

Juvenile Idiopathic Arthritis

- Juvenile idiopathic arthritis (JIA) is the most common rheumatologic disease of childhood and is classified into subtypes including oligoarticular, polyarticular, systemic, juvenile psoriatic arthritis, and enthesitis-related arthritis (spondyloarthropathies).
- Chronic arthritis is characterized by gradual onset, morning stiffness and joint pain, swelling, erythema, and limitation of range of motion, either from pain or contracture. Due to the presence of active growth plates, patients also develop localized growth disturbance, which causes the ends of the surrounding bones to be longer and wider.
- Systemic JIA differs from the other subtypes of arthritis, as the presence of arthritis is preceded by a systemic inflammatory process characterized by high diurnal fever, rash, hepatosplenomegaly, and elevated inflammatory parameters.
- The treatment of JIA consists in controlling the inflammation and preserving joint function. Nonsteroidal anti-inflammatory medications are considered first line of therapy, followed by methotrexate and then biologic agents. Steroids are used sparingly as bridge therapy and are not used for maintenance therapy. Prognosis of JIA overall is excellent with an overall 85% complete remission rate. Higher rates of remission are seen in the oligoarticular group and are lowest in the systemic and polyarticular groups.
- The most common complication of JIA is uveitis. The uveitis is frequently asymptomatic until the point of visual loss and therefore requires regular screening with a slit-lamp exam. All children with JIA are at increased risk for uveitis, but those with a positive antinuclear antibody are at even higher risk and need to be screened more often.
- The most severe complication of systemic JIA is macrophage activation syndrome (MAS), caused by massive release of cytokines with overwhelming inflammation leading to pancytopenia, liver dysfunction, disseminated intravascular coagulation, and multiorgan failure. Even with appropriate treatment, mortality rates from MAS are approximately 8%.

CHAPTER 90

Systemic Lupus Erythematosus

- Systemic lupus erythematosus (SLE) is a multisystem disease characterized by large amounts of circulating both nonspecific and specific autoantibodies, which form an immune complex that becomes trapped in the microvasculature, leading to inflammation and ischemia.
- The most serious features of SLE are nephritis and central nervous system (CNS) involvement, which can lead to long-term morbidity. Other features include malar rash, discoid rash, photosensitivity, mucosal ulceration, arthritis, myositis, and hemolytic anemia. Diagnosis is made based on specific criteria, including screening with sensitive autoantibodies such as antinuclear antibody and

confirming diagnosis with specific autoantibodies such as the anti–double-stranded DNA antibody and anti-Smith antibody.

- Corticosteroids have been the mainstay of treatment for SLE. For more aggressive disease, including renal or CNS disease, medications like cyclophosphamide may be used. In patients for which steroids cannot be reduced, steroid-sparing agents such as methotrexate, mycophenolate mofetil, or azathioprine may be used.
- Long-term outcomes in SLE have improved significantly and are determined primarily by the presence or absence of nephritis or neurologic involvement, with most patients living well into adulthood.

CHAPTER 91

Juvenile Dermatomyositis

- Juvenile dermatomyositis (JDM) is a rare disease characterized by inflammation of muscles and skin, leading to stereotypical rashes. Patients have muscle weakness, particularly in proximal muscle groups, which can develop slowly or in a fulminant fashion. Involvement of muscles of the upper airway can lead to difficulty phonating or swallowing. The skin disease is characterized by a facial rash, heliotrope discoloration of the eyelids, and scaly red patches on extensor surfaces (Gottron papules). Patients can also develop arthritis.
- Diagnosis of JDM is made by the presence of classic rash and myositis, as evidenced by elevated muscle enzymes, muscle biopsy, or abnormal electromyography or magnetic resonance imaging.
- Treatment of JDM consists of an initial course of corticosteroids and a longer course of a steroid-sparing agent—most commonly methotrexate.
- Prognosis in JDM depends greatly on the extent of muscle disease and the time between disease onset and initiation of therapy. Most patients have excellent outcomes, although a small percentage will have a chronic, progressive disease course.
- The most common complication of JDM is calcinosis. Dystrophic calcification can occur in the skin and soft tissues and can range from mild to extensive. Treatments for calcinosis have been largely ineffective.

CHAPTER 92

Musculoskeletal Pain Syndromes

- Growing pains are very common in the pediatric age group, affecting up to 37% of school-age children. Children complain of deep achy pain in their legs, particularly at night, but have no evidence of underlying disease. Treatment is symptomatic, but other causes of nocturnal leg pain, particularly leukemia, should be excluded.
- Hypermobility syndromes can be either generalized, as seen in benign hypermobility or Ehlers-Danlos syndrome, or localized, such as in pes planus (flat feet). Beighton criteria are used to diagnose generalized hypermobility. Treatment is symptomatic and focused on stretching, joint protection, arch supports when appropriate, and nonsteroidal antiinflammatory drug therapy as needed.
- Myofascial pain syndromes, such as fibromyalgia, are characterized by diffuse musculoskeletal pain, tender points, and generalized malaise, fatigue, and poor sleep patterns. These syndromes are noninflammatory, and an underlying cause for the pain cannot be found. Comorbid anxiety and depression is not uncommon.
- The treatment of myofascial pain syndrome consists of pain control and restoration of function. Physical therapy, psychologic therapy, development of coping mechanisms, education about sleep hygiene, and the concept of the pain response system are valuable interventions.

INFECTIOUS DISEASES

Matthew P. Kronman | Claudia S. Crowell | Surabhi B. Vora

CHAPTER 93

Infectious Disease Assessment

Overlapping clinical symptoms caused by infectious and non-infectious illnesses make the diagnosis of some diseases difficult. Clinicians are concerned that, untreated or inappropriately treated, a minor infection may progress to a life-threatening illness. Conversely, unnecessary treatment with antimicrobial agents may lead to emergence of antimicrobial-resistant organisms, antibiotic-associated diarrhea, or allergic reactions. Therefore accurate diagnosis of infectious and noninfectious diseases is critical to ensure the provision of specific treatment only as indicated and thereby reduce the unnecessary use of antibiotics.

A thorough patient assessment, including a detailed history, complete physical examination, and appropriate diagnostic testing, is the cornerstone of optimal care.

INITIAL DIAGNOSTIC EVALUATION

The ability to accurately diagnose specific infections begins with an understanding of the epidemiology; risk factors, including exposures to sick contacts or environmental risks (e.g., travel to endemic areas, zoonoses); and infection susceptibility related either to age (reflecting the maturity of the immune system) or to primary or secondary immunodeficiencies. Obtaining a thorough history and physical examination identifies most of these elements (Tables 93.1 and Table 93.2) and guides the appropriate use of other diagnostic tests.

Unique questions that help identify whether an infection is causing the patient's symptoms include a detailed environmental history (including sick contacts, travel, food, water, and animal exposure) (see Tables 93.1). Certain infections are more common in specific geographic areas. For instance, parasitic infections are more common in tropical climates. Certain fungal infections have specific geographic distribution (coccidioidomycosis in the southwestern United States, blastomycosis in the upper Midwest, and histoplasmosis in central United States). In other areas, fungal pneumonias are rare except in immunocompromised persons.

An immunization history is critical for determining susceptibility to vaccine-preventable diseases. Family history, especially unexpected deaths of infants, may suggest familial immunodeficiency (see Chapters 73 through 76). Localization of symptoms to a specific body site may narrow diagnostic possibilities (see Table 93.2).

A complete physical examination is essential to identify signs of infection, which may be systemic (e.g., fever and shock) or focal (e.g., swelling, erythema, tenderness, and limitation of function). Many infectious diseases are associated with characteristic cutaneous signs (see Table 97.1). Accurate otolaryngologic examination is critical for diagnosing upper respiratory tract infections and otitis media, the most common childhood infectious diseases in the United States.

DIFFERENTIAL DIAGNOSIS

Fever does not always represent infection. Rheumatologic diseases, inflammatory bowel disease, Kawasaki disease, poisoning, periodic fever syndromes, and malignancy also may present with fever. *Children with overwhelming infection may be afebrile or hypothermic.* Common symptoms, such as bone pain or lymphadenopathy that suggest infection, may also be due to leukemia, lymphoma, juvenile idiopathic arthritis, or Kawasaki disease (see Chapters 88, 89, and 153). Acute mental status changes or focal neurologic impairment could be manifestations of infections (encephalitis, meningitis, or brain abscess) or noninfectious causes (trauma, brain or spinal tumors, inflammatory conditions, postinfectious sequelae, or impairment from toxic ingestions or inhalants). Many manifestations of mucosal allergy (rhinitis, diarrhea) may mimic common infectious diseases (see Chapter 77).

Some infections are prone to recurrence, especially if treatment is suboptimal (wrong antimicrobial or insufficient duration). Recurrent, severe, or unusual (opportunistic) infections suggest the possibility of immunodeficiency (see Chapters 72 and 125).

SCREENING TESTS

Laboratory diagnosis of infection includes examination of bacterial morphology using Gram stain, various culture techniques, molecular microbiologic methods (e.g., polymerase chain reaction or matrix-assisted laser desorption/ionization time of flight), and assessment of the immune response with antibody titers or skin testing. The **acute phase response** is a nonspecific metabolic and inflammatory response to infection, trauma, autoimmune disease, and some malignancies. **Acute phase reactants**, such as erythrocyte sedimentation rate, C-reactive protein, and procalcitonin, are commonly elevated during a bacterial infection but are not specific for infection and do not identify any specific infection. These tests can be used to monitor response to therapy.

TABLE 93.1 Clues from the History for Risk of Infection

Season of year
Age
General health
Weight change
Fever—presence, duration, and pattern
Previous similar symptoms
Previous infections and other illnesses
Previous surgeries, dental procedures
Preceding trauma
Presence of outbreaks or epidemics in the community
Exposures to infected individuals
Exposures to farm or feral animals and pets
Exposures to ticks and mosquitoes
Sexual history, including possibility of sexual abuse
Illicit drug use
Transfusion of blood or blood products
Travel history
Daycare or school attendance
Sources of water and food (e.g., undercooked meat, unpasteurized dairy products)
Home sanitary facilities and hygiene
Pica
Exposure to soil-borne and water-borne organisms (e.g., swimming in brackish water)
Presence of foreign bodies (e.g., indwelling catheters, shunt, grafts)
Immunization history
Immunodeficiency (chemotherapy, acquired, congenital)
Current medications

A **complete blood count** is frequently obtained for evidence of infection. The initial response to infection, especially in children, is usually a **leukocytosis** (increased number of circulating leukocytes) with an initial neutrophilic response to both bacterial and viral infections. With most viral infections, this response is transient and is followed quickly by a characteristic mononuclear response. In general, bacterial infections are associated with greater neutrophil counts than viral infections (Table 93.3). A **left shift** is an increase in the numbers of circulating immature cells of the neutrophil series, including band forms, metamyelocytes, and myelocytes. It indicates the rapid release of cells from the bone marrow and is characteristic of both the early stages of infection and, if sustained, bacterial infections. Transient lymphopenia at the beginning of illness and lasting 24–48 hours has been described with many viral infections. **Atypical lymphocytes** are mature T lymphocytes with larger, eccentrically placed, and indented nuclei

classically seen with infectious mononucleosis caused by Epstein-Barr virus. Other infections associated with atypical lymphocytosis include cytomegalovirus infection, toxoplasmosis, viral hepatitis, rubella, roseola, mumps, and some drug reactions. **Eosinophilia** is characteristic of allergic diseases but may be seen with tissue-invasive multicellular parasites, such as the migration of the larval stages of parasites through skin, lung, connective tissue, and viscera. High-grade eosinophilia (>30% eosinophils, or a total eosinophil count >3,000/ μ L) frequently occurs during the muscle invasion phase of trichinellosis, the pulmonary phases of ascariasis and hookworm infection (eosinophilic pneumonia), and the hepatic and central nervous system phases of visceral larva migrans.

Other common screening tests include **urinalysis** for urinary tract infections, transaminases for liver inflammation, and **lumbar puncture** for evaluation of the cerebrospinal fluid if there is concern for meningitis or encephalitis (see Chapters 100 and 101). Various tests may help distinguish viral versus bacterial infection, but definitive diagnosis requires identifying the agent by culture or molecular means.

Cultures are the mainstay of diagnosis of many infections. **Blood cultures** are sensitive and specific for bacteremia, which may be primary or secondary to a focal infection (osteomyelitis, gastroenteritis, pyelonephritis, and endocarditis). Urine cultures are important to confirm urinary tract infection, which may be occult in young infants. Cultures should be obtained with every lumbar puncture, aspiration, or biopsy of other fluid collections or masses. Specific types of cultures (bacterial, fungal, viral, or mycobacterial) are guided by the clinical problem and history.

Antibiotics often are begun before a definitive diagnosis is established, complicating the ability to rely on subsequent cultures for microbiologic diagnosis (see Chapter 95). Although persistent or progressive symptoms, despite antibiotic treatment, may indicate the need to change the regimen, more frequently this indicates the need to stop all antibiotics to facilitate definitive diagnosis by obtaining appropriate cultures. Antibiotics should not be given before obtaining appropriate cultures unless there is a life-threatening situation (e.g., septic shock or increased intracranial pressure).

Rapid tests, such as antigen tests, are useful for preliminary diagnosis and are available for numerous bacterial, viral, fungal, and parasitic infections. **Serologic tests**, using enzyme-linked immunosorbent assay or Western blotting, showing an immunoglobulin M (IgM) response, high IgG titer, or seroconversion between acute and convalescent sera, also can be used for diagnosis. **Molecular tests**, such as **polymerase chain reaction** (PCR: nucleic acid amplification tests) for DNA or RNA, offer the specificity of culture, high sensitivity, and rapid results. PCR is the standard method of testing for viral and some bacterial infections; its limitation is the inability to do antibiotic sensitivity testing.

DIAGNOSTIC IMAGING

The choice of diagnostic imaging modality should be based on the location of the findings and the differential diagnosis. **Plain x-rays** are useful initial tests for respiratory tract infections. **Ultrasonography** is a noninvasive, nonirradiating technique well suited to infants and children for imaging solid organs. It also is useful to identify soft tissue abscesses with lymphadenitis and to diagnose suppurative arthritis of the

SITE	LOCALIZING SYMPTOMS	LOCALIZING SIGNS*
Eye	Eye pain, double vision, photophobia, conjunctival discharge	Periorbital erythema, periorbital edema, drainage, chemosis, limitation of extraocular movements
Ear	Ear pain, drainage	Red, bulging tympanic membrane, drainage from ear canal
Upper respiratory tract	Rhinorrhea, sore throat, cough, drooling, stridor, trismus, sinus pain, tooth pain, hoarse voice	Nasal congestion, pharyngeal erythema, enlarged tonsils with exudate, swollen red epiglottis, regional lymphadenopathy
Lower respiratory tract	Cough, chest pain, dyspnea, sputum production, cyanosis	Tachypnea, crackles, wheezing, localized diminished breath sounds, intercostal retractions
Gastrointestinal tract	Nausea, vomiting, diarrhea, abdominal pain (focal or diffuse), anorexia, weight loss	Hypoactive or hyperactive bowel sounds, abdominal tenderness (focal or generalized), hematochezia
Liver	Anorexia, vomiting, dark urine, light stools	Jaundice, hepatomegaly, hepatic tenderness, bleeding diatheses, coma
Genitourinary tract	Dysuria, frequency, urgency, flank or suprapubic pain, vaginal or urethral discharge	Costovertebral angle or suprapubic tenderness, cervical motion and adnexal tenderness
Central nervous system	Lethargy, irritability, headache, neck stiffness, seizures	Nuchal rigidity, Kernig sign, Brudzinski sign, bulging fontanelle, focal neurologic deficits, altered mental status, coma
Cardiovascular	Dyspnea, palpitations, fatigue, exercise intolerance, chest pain	Tachycardia, hypotension, cardiomegaly, hepatomegaly, splenomegaly, crackles, petechiae, Osler nodes, Janeway lesions, Roth spots, new or change in murmur, distended neck veins, pericardial friction rub, muffled heart sounds
Musculoskeletal	Limp, bone pain, limited function (pseudoparalysis)	Local swelling, erythema, warmth, limited range of motion, point bone tenderness, joint line tenderness

*Fever usually accompanies infection as a systemic manifestation.

VARIABLE	VIRAL	BACTERIAL
Petechiae	Present	Present
Purpura	Rare	If severe
Leukocytosis	Uncommon*	Common
Left-shift (↑ bands)	Uncommon	Common
Neutropenia	Possible	Suggests overwhelming infection
↑ ESR	Unusual*	Common
↑ CRP	Unusual	Common
↑ TNF, IL-1, PAF	Uncommon	Common
↑ Procalcitonin	Unusual	Common
Meningitis (pleocytosis)	Lymphocytic [†]	Neutrophilic
Meningeal signs positive [‡]	Present	Present

*Adenovirus and herpes simplex may cause leukocytosis and increased ESR; Epstein-Barr virus may cause petechiae and increased ESR.

[†]Early viral (enterovirus, arbovirus) meningitis initially may have a neutrophilic pleocytosis.

[‡]Nuchal rigidity, bulging fontanelle, Kernig sign, Brudzinski sign.

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; IL, interleukin; PAF, platelet-activating factor; TNF, tumor necrosis factor.

hip or other joints. **Computed tomography (CT; with contrast enhancement)** and **magnetic resonance imaging (MRI; with gadolinium enhancement)** allow characterization of lesions and precise anatomic localization and are the modalities of choice for the brain. CT shows greater bone detail, and

MRI shows greater tissue detail. MRI is especially useful for diagnosis of osteomyelitis, myositis, and necrotizing fasciitis. High-resolution CT is useful for complicated chest infections. Judicious use of CT scans is important because of the long-term effects of radiation on children's health. CT or MRI is preferred for evaluation of intraabdominal infections. A voiding cystourethrogram may be used to evaluate for vesicoureteral reflux, a predisposing factor for upper urinary tract infections.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 94

Immunization and Prophylaxis

IMMUNIZATION

Childhood immunization has markedly reduced the impact of major infectious diseases. **Active immunization** induces immunity through the administration of all or part of a microorganism or a modified product of a microorganism (e.g., toxoid). **Passive immunization** involves administration of protective antibodies and includes transplacental transfer of maternal antibodies and the administration of preformed antibody, either as immunoglobulin or as monoclonal antibody.

Vaccinations may be with live-attenuated viruses (measles, mumps, rubella [MMR], varicella, nasal influenza, oral polio, rotavirus), inactivated or killed viruses (intramuscular polio, hepatitis A, intramuscular influenza), recombinant products

(hepatitis B, human papillomavirus), or immunogenic components of bacteria (pertussis, *Haemophilus influenzae* type b, *Neisseria meningitidis*, and *Streptococcus pneumoniae*), including toxoids (diphtheria, tetanus). Many purified polysaccharides are T-cell independent antigens that initiate B-cell proliferation without involvement of CD4 T lymphocytes and are poor immunogens in children younger than 2 years of age. Conjugation of a polysaccharide to a **protein carrier** induces a T-cell dependent response in infants and creates immunogenic vaccines for *H. influenzae* type b, *S. pneumoniae*, and *N. meningitidis*.

Childhood immunization standards and recommendations in the United States (Figs. 94.1 and 94.2) are formulated by the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (ACIP), the American Academy of Pediatrics, and the American Academy of Family Physicians. In the United States, due to state laws requiring immunization for school entry, approximately 95% of children entering kindergarten are vaccinated for the common infectious diseases. The ACIP recommends that children in the United States routinely receive vaccines

against 16 diseases (see Fig. 94.1). This schedule includes up to 23 injections in four to five visits by 18 months of age. Children who are at increased risk for pneumococcal infections should receive the pneumococcal polysaccharide vaccine as well. Infants and children who are at increased risk for meningococcal infections should receive the two- or four-dose meningococcal series depending on age. Children who are behind in immunization should receive catch-up immunizations as rapidly as feasible. Infants born prematurely, regardless of birthweight, should be vaccinated at the same chronological age and according to the same schedule as full-term infants and children (see Fig. 94.2). The single exception to this practice is providing hepatitis B vaccine at 1 month of age instead of at birth for infants weighing less than 2,000 g if the mother is hepatitis B virus surface antigen (HB_sAg) negative. Vaccines for adolescents should be given at 11–12 years of age (see Fig. 94.1), with completion of any vaccine series at 13–18 years of age and a booster for *N. meningitidis* at 16 years of age.

Vaccines should be administered after obtaining informed consent. The **National Childhood Vaccine Injury Act** requires

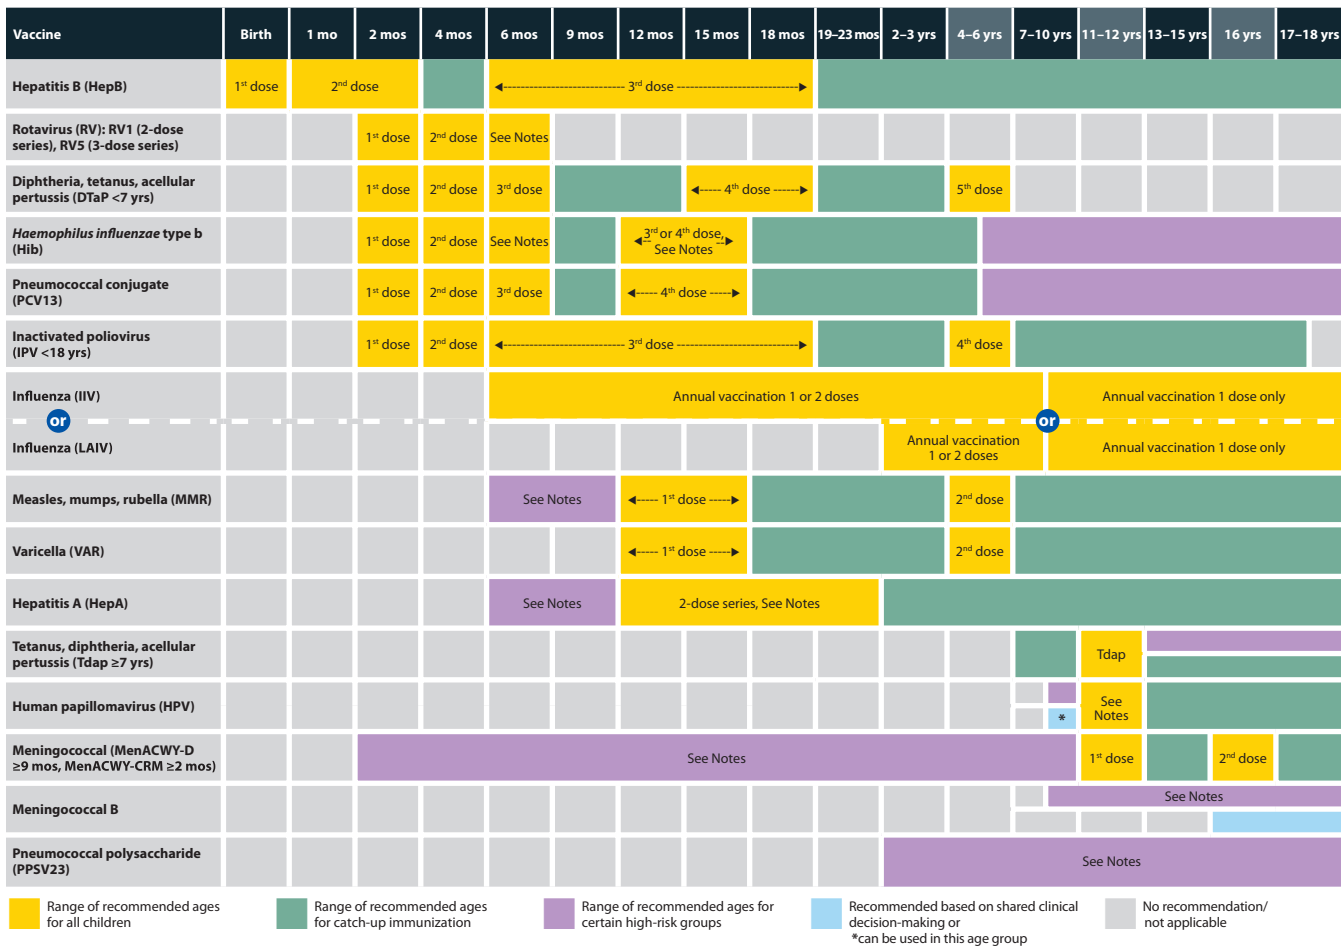

FIGURE 94.1 Recommended immunization schedules for persons aged 0 through 18 years—United States, 2020. These recommendations should be read with the notes provided in the original schedule (see link in credit). For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars. To determine minimum intervals between doses, see the catch-up schedule (Fig. 94.2). School entry and adolescent vaccine age groups are shaded in dark gray along the top row. (Approved by the Advisory Committee on Immunization Practices; American Academy of Pediatrics; American Academy of Family Physicians; and American College of Obstetricians and Gynecologists; Courtesy of the U.S. Department of Health and Human Services, Centers for Disease Control and Prevention. <https://www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html>.)

Children age 4 months through 6 years					
Vaccine	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Hepatitis B	Birth	4 weeks	8 weeks and at least 16 weeks after first dose. Minimum age for the final dose is 24 weeks.		
Rotavirus	6 weeks Maximum age for first dose is 14 weeks, 6 days	4 weeks	4 weeks Maximum age for final dose is 8 months, 0 days.		
Diphtheria, tetanus, and acellular pertussis	6 weeks	4 weeks	4 weeks	6 months	6 months
<i>Haemophilus influenzae</i> type b	6 weeks	No further doses needed if first dose was administered at age 15 months or older. 4 weeks if first dose was administered before the 1 st birthday. 8 weeks (as final dose) if first dose was administered at age 12 through 14 months.	No further doses needed if previous dose was administered at age 15 months or older. 4 weeks if current age is younger than 12 months and first dose was administered at younger than age 7 months and at least 1 previous dose was PRP-T (ActHib, Pentacel, Hiberix) or unknown. 8 weeks and age 12 through 59 months (as final dose) if current age is younger than 12 months and first dose was administered at age 7 through 11 months; OR if current age is 12 through 59 months and first dose was administered before the 1 st birthday and second dose administered at younger than 15 months; OR if both doses were PRP-OMP (PedvaxHIB, Comvax) and were administered before the 1 st birthday.	8 weeks (as final dose) This dose only necessary for children age 12 through 59 months who received 3 doses before the 1 st birthday.	
Pneumococcal conjugate	6 weeks	No further doses needed for healthy children if first dose was administered at age 24 months or older. 4 weeks if first dose was administered before the 1 st birthday. 8 weeks (as final dose for healthy children) if first dose was administered at the 1 st birthday or after.	No further doses needed for healthy children if previous dose administered at age 24 months or older. 4 weeks if current age is younger than 12 months and previous dose was administered at <7 months old. 8 weeks (as final dose for healthy children) if previous dose was administered between 7–11 months (wait until at least 12 months old); OR if current age is 12 months or older and at least 1 dose was given before age 12 months.	8 weeks (as final dose) This dose only necessary for children age 12 through 59 months who received 3 doses before age 12 months or for children at high risk who received 3 doses at any age.	
Inactivated poliovirus	6 weeks	4 weeks	4 weeks if current age is < 4 years. 6 months (as final dose) if current age is 4 years or older.	6 months (minimum age 4 years for final dose).	
Measles, mumps, rubella	12 months	4 weeks			
Varicella	12 months	3 months			
Hepatitis A	12 months	6 months			
Meningococcal ACWY	2 months MenACWY-CRM 9 months MenACWY-D	8 weeks	See Notes	See Notes	

Children and adolescents age 7 through 18 years					
Meningococcal ACWY	Not applicable (N/A)	8 weeks			
Tetanus, diphtheria; tetanus, diphtheria, and acellular pertussis	7 years	4 weeks	4 weeks if first dose of DTap/DT was administered before the 1 st birthday. 6 months (as final dose) if first dose of DTap/DT or Tdap/Td was administered at or after the 1 st birthday.	6 months if first dose of DTap/DT was administered before the 1 st birthday.	
Human papillomavirus	9 years	Routine dosing intervals are recommended.			
Hepatitis A	N/A	6 months			
Hepatitis B	N/A	4 weeks	8 weeks and at least 16 weeks after first dose.		
Inactivated poliovirus	N/A	4 weeks	6 months A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months after the previous dose.	A fourth dose of IPV is indicated if all previous doses were administered at <4 years or if the third dose was administered <6 months after the second dose.	
Measles, mumps, rubella	N/A	4 weeks			
Varicella	N/A	3 months if younger than age 13 years. 4 weeks if age 13 years or older.			

FIGURE 94.2 Catch-up immunization schedule for persons aged 4 months to 18 years who start late or who are more than 1 month behind—United States, 2020. These recommendations provide catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age. Always use this schedule in conjunction with Fig. 94.1 and the notes included in the original recommendations (see link in credit). (Approved by the Advisory Committee on Immunization Practices; American Academy of Pediatrics; American Academy of Family Physicians; and American College of Obstetricians and Gynecologists; Courtesy of the U.S. Department of Health and Human Services, Centers for Disease Control and Prevention. <https://www.cdc.gov/vaccines/schedules/hcp/imz/catchup.html>.)

that all health care providers provide parents or patients with copies of **Vaccine Information Statements** prepared by the Centers for Disease Control and Prevention (<http://www.cdc.gov/vaccines/hcp/vis/index.html>) before administering each vaccine dose.

Most vaccines are administered by intramuscular or subcutaneous injection. The preferred sites for administration are the anterolateral aspect of the thigh in infants and the deltoid region in children and adults. Multiple vaccines can be administered simultaneously at anatomically separate sites (different limbs or separated by >1 in) without diminishing the immune response. MMR and varicella vaccines should be administered simultaneously or more than 28 days apart. The conjugate and polysaccharide pneumococcal vaccines should be spaced at least 8 weeks apart when both are indicated, and the conjugate vaccine should be administered first, if possible. Tuberculosis testing, either with a skin test or gamma interferon release blood test, can be performed at the time of vaccination. If tuberculosis testing is not performed at the same visit as MMR vaccination, then testing should be delayed for 6 weeks as MMR vaccination can temporarily suppress response

to tuberculin antigens. Administration of blood products and immunoglobulin can diminish response to live-virus vaccines administered before the recommended interval.

General contraindications to vaccination include serious allergic reaction (anaphylaxis) after a previous vaccine dose or to a vaccine component, immunocompromised states, or pregnancy (live-virus vaccines), and moderate or severe acute illness with or without fever. History of *anaphylactic-like* reactions to eggs has historically been a contraindication to influenza and yellow fever vaccines, which are produced in embryonated chicken eggs; however, in 2016 the ACIP recommended that even persons with severe egg allergy could receive any licensed influenza vaccine. Current preparations of measles and mumps vaccines, which are produced in chick embryo fibroblast tissue culture, do not contain significant amounts of egg proteins and may be administered without testing children with history of egg allergy. Mild acute illness with or without fever, convalescent phase of illness, recent exposure to infectious diseases, current antimicrobial therapy, breast-feeding, mild to moderate local reaction or low-grade to moderate fever after previous vaccination, and a history of penicillin or

other nonvaccine allergy or receiving allergen extract immunotherapy are **not contraindications** to immunization.

Severe immunosuppression resulting from congenital immunodeficiency, HIV infection, leukemia, lymphoma, cancer therapy, or a prolonged course of high-dose corticosteroids (≥ 2 mg/kg/day for > 2 weeks) predisposes to complications and is a contraindication for live-virus vaccines. For HIV-infected children who do not have evidence of severe immunosuppression, MMR vaccination is recommended as per the regular schedule. Varicella vaccine is contraindicated for persons with cellular immunodeficiency but is recommended for persons with impaired humoral immunity (hypogammaglobulinemia or dysgammaglobulinemia) and at 12 months of age for HIV-infected children without evidence of severe immunosuppression, given as two doses 3 months apart. Rotavirus vaccine should not be given to children with a history of intussusception or severe combined immunodeficiency syndromes.

The National Childhood Vaccine Injury Act requires that clinically significant adverse events after vaccination be reported to the **Vaccine Adverse Event Reporting System (VAERS)** (<http://www.vaers.hhs.gov> or 800-822-7967). Suspected cases of vaccine-preventable diseases should be reported to state or local health department. The act also established the **National Vaccine Injury Compensation Program**, a no-fault system in which persons thought to have suffered an injury or death as a result of administration of a covered vaccine can seek compensation.

PROPHYLAXIS

Prophylaxis may include antibiotics, immunoglobulin or monoclonal antibody, and vaccine, alone or in combination. They may be used preexposure, for perinatal exposure, and postexposure for persons at increased risk for infection. **Primary prophylaxis** is used to prevent infection before a first occurrence. **Secondary prophylaxis** is used to prevent recurrence after a first episode.

Meningococcus

Primary prophylaxis to all close contacts of index cases of *N. meningitidis* infection should be administered as soon as possible (see Chapter 100). Prophylaxis is recommended for

all household contacts, especially young children; child care or preschool contacts in the 7 days before illness onset; contacts with direct exposure to the index patient's secretions through kissing, sharing of toothbrushes or eating utensils in the 7 days before illness onset; and for mouth-to-mouth resuscitation or unprotected contact during endotracheal intubation within 7 days before illness onset. Prophylaxis is also recommended for contacts who frequently sleep or eat in the same dwelling as the index patient or passengers seated directly next to the index case during airline flights lasting longer than 8 hours. Chemoprophylaxis is not recommended for casual contacts with no history of direct exposure to the patient's oral secretions (school or work), indirect contact with the index patient, or medical personnel without direct exposure to the patient's oral secretions. Rifampin twice daily for 2 days and ceftriaxone once (all ages) and ciprofloxacin once for those 18 years of age and older (unless there is no acceptable alternative available) are the recommended regimens. Azithromycin may be used in the case of resistant organisms.

Tetanus

All postexposure wound treatment begins with immediate, thorough cleansing using soap and water, removal of foreign bodies, and debridement of devitalized tissue. Tetanus prophylaxis after wounds and injuries includes vaccination of persons with incomplete immunization and tetanus immunoglobulin for contaminated wounds (soil, feces, saliva), puncture wounds, avulsions, and wounds resulting from missiles, crushing, burns, and frostbite (Table 94.1).

Rabies

Rabies immune globulin (RIG) and rabies vaccine are extremely effective for prophylaxis after exposure to rabies but are of no known benefit after symptoms appear. Because rabies is one of the deadliest infections, recognition of potential exposure and prophylaxis are crucial. Any healthy-appearing domestic animal (dog, cat) responsible for an apparently unprovoked bite should be observed for 10 days for signs of rabies without immediate treatment of the victim. Prophylaxis should be administered if the animal is rabid or suspected to be rabid, or if the animal develops signs of rabies while under observation.

TABLE 94.1 Guide to Tetanus Prophylaxis in Routine Wound Management

HISTORY OF ADSORBED TETANUS TOXOID (DOSES)	CLEAN, MINOR WOUNDS		ALL OTHER WOUNDS*	
	DTaP, Tdap, OR Td [†]	TIG [‡]	DTaP, Tdap, OR Td [†]	TIG [‡]
Fewer than 3 or unknown	Yes	No	Yes	Yes
3 or more	No if < 10 yr since last tetanus-containing vaccine dose	No	No if < 5 yr since last tetanus-containing vaccine dose	No
	Yes if ≥ 10 yr since the last tetanus toxoid-containing vaccine dose	No	Yes if ≥ 5 yr since the last tetanus toxoid-containing vaccine dose	No

*Such as, but not limited to, wounds contaminated with dirt, feces, soil, or saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

[†]Tdap is preferred for children ≥ 7 years of age who have never received Tdap.

[‡]Immune globulin intravenous should be used if TIG is not available.

Tdap, Tetanus and diphtheria toxoids, acellular pertussis vaccine; Td, tetanus-diphtheria toxoid; TIG, tetanus immunoglobulin.

A captured wild animal should be euthanized (by animal control officials) without a period of observation and its brain examined for evidence of rabies. If the biting animal is not captured, particularly if it is a wild animal of a species known to harbor the virus in the region, rabies should be presumed, and prophylaxis administered to the victim. Bats, raccoons, skunks, foxes, coyotes, and bobcats are the most important wild animal potential sources of rabies infection. Prophylaxis also should be provided following exposure to a bat for persons who might be unaware or unable to relate that a bite or direct contact has occurred, such as a sleeping child, or an unattended infant. Local public health departments are important resources for determining rabies risk based on local epidemiology.

All rabies postexposure management begins with immediate thorough cleansing of the bite using soap and water. RIG at a dose of 20 IU/kg should be administered, with the full dose of RIG infiltrated subcutaneously into the area around the wound, if possible. Any remaining RIG that cannot be infiltrated into the wound should be administered as an intramuscular injection. Inactivated rabies vaccine should be administered simultaneously as soon as possible, at a site away from where RIG was administered, with additional vaccine doses at 3, 7, and 14 days.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 95

Antiinfective Therapy

The selection of antiinfective therapy depends on a number of factors: the site of infection and clinical syndrome, host immunity, probable causative agents, the pathogen's susceptibility to antimicrobial agents, the local epidemiology of resistance, the pharmacokinetics of the selected agents, and their pharmacodynamics in specific patient populations.

Empirical or presumptive antiinfective therapy is based on a clinical diagnosis combined with published evidence and experience of the probable causative pathogens. **Definitive therapy** relies on microbiologic diagnosis by isolation or other direct evidence of a pathogen. Microbiologic diagnosis through culture permits characterization of the pathogen's antiinfective drug **susceptibilities** and delivery of the appropriate antiinfective agent to the site of infection in concentrations sufficient to kill or alter the pathogen and facilitate an effective immune response. Antiviral therapy must include consideration of the intracellular nature of viral replication and, to avoid toxicity to host cells, must be targeted to viral-specific proteins, such as the thymidine kinase of herpesviruses or the reverse transcriptase of HIV.

Empirical antimicrobial therapy is best initiated after obtaining appropriate cultures or polymerase chain reaction of fluids or tissues. In high-risk circumstances, such as neonatal sepsis or bacteremia in immunocompromised persons, empirical therapy includes broad-spectrum antimicrobials (see [Chapters 96](#) and [120](#)). Empirical antimicrobial therapy may be tailored to specific pathogens based on the clinical diagnosis

(e.g., streptococcal pharyngitis) or defined risks (e.g., close exposure to tuberculosis). Definitive therapy can additionally minimize drug toxicity, development of resistant microorganisms, and cost.

Antimicrobial agents are an adjunct to the normal host immune response. Infections associated with foreign bodies, such as an intravascular catheter, are difficult to eradicate with antimicrobials alone because of organism-produced biofilms that impair phagocytosis. Similarly, it is difficult for phagocytic cells to eradicate bacteria amid vegetations of fibrin and platelets on infected heart valves. Prolonged bactericidal therapy is required with these infections, and outcomes are not always satisfactory. Foreign body devices may have to be removed if sterilization does not occur promptly. Infections in closed spaces with limited perfusion (e.g., abscesses or chronic osteomyelitis with poorly perfused bone) are difficult to cure without surgical drainage, debridement of the infected tissue, and reestablishment of a good vascular supply.

Optimal antimicrobial therapy requires an understanding of both the **pharmacokinetics** (e.g., bioavailability and tissue penetration) of the administered drugs and their **pharmacodynamics** (e.g., metabolism and excretion by the body) in specific patient populations. The bioavailability of orally administered antibiotics varies depending on the acid stability of the drug, degree of gastric acidity, and whether it is taken with food, antacids, H₂ blockers, or other medications. An ileus, underlying intestinal disease, or profuse diarrhea may alter intestinal transit time and result in unpredictable absorption.

The **site and nature** of the infection may affect the choice of antimicrobials. Aminoglycosides, active against aerobic organisms only, have significantly reduced activity in abscesses with low pH and oxygen tension. Infections of the central nervous system or the eye necessitate treatment with antimicrobials that penetrate and achieve therapeutic levels in these sites.

Limited renal function (as in premature infants or those with renal failure) requires lengthening dosing intervals to allow time for excretion of certain drugs. The larger volume of distribution of certain hydrophilic antimicrobials and increased renal clearance (e.g., in cystic fibrosis) requires higher doses to achieve therapeutic levels. Weight-based dosage regimens may result in overdoses in obese children due to significantly smaller volumes of distribution for hydrophilic drugs. Determining serum drug levels for antibiotics with narrow safety margins (e.g., aminoglycosides and vancomycin) minimizes adverse effects of treatment.

Drug-drug interactions must be considered when multiple antimicrobial agents are used to treat infection, or for patients on other medications (e.g., chemotherapy or immunosuppressants). Use of two or more antimicrobial agents may be justified before organism identification or for the benefit of different mechanisms of action. Several antimicrobials are administered routinely in combination (e.g., trimethoprim-sulfamethoxazole or amoxicillin-clavulanate) because of **synergism** (significantly greater bacterial killing or spectrum of activity than when either is used alone). The use of a bacteriostatic drug, such as a tetracycline, along with a β -lactam agent, effective against growing organisms only, may result in antibiotic **antagonism**, or less bacterial killing in the presence of both drugs, than if either is used alone.

PEARLS FOR PRACTITIONERS

See Infectious Diseases: Pearls for Practitioners at the end of this section.

CHAPTER 96

Fever Without a Focus

Core body temperature is normally maintained within 1–1.5°C in a range of 37–38°C. Normal body temperature is generally considered to be 37°C (98.6°F; range, 97–99.6°F). Normal diurnal variation exists, with maximum temperature in the late afternoon. Rectal temperatures higher than 38°C (>100.4°F) generally are considered abnormal, especially if associated with other symptoms.

Normal body temperature is maintained by a complex regulatory system in the anterior hypothalamus. The development of fever begins with the release of endogenous pyrogens into the circulation as the result of infection, inflammatory processes, or malignancy. Microbes and microbial toxins act as **exogenous pyrogens** by stimulating release of **endogenous pyrogens**, including cytokines such as interleukin 1 (IL-1), IL-6, tumor necrosis factor, and interferons. These cytokines reach the anterior hypothalamus, liberating arachidonic acid, which is metabolized to prostaglandin E₂. Elevation of the hypothalamic thermostat occurs via a complex interaction of complement and prostaglandin E₂ production. Antipyretics (acetaminophen, ibuprofen, aspirin) inhibit hypothalamic cyclooxygenase, decreasing production of prostaglandin E₂. Aspirin is associated with Reye syndrome in children and is not recommended as an antipyretic. The response to antipyretics does not distinguish bacterial from viral infections.

The **pattern of fever** in children may vary, depending on age and the nature of the illness. Neonates may not have a febrile response and may instead be hypothermic despite significant infection, whereas older infants and children younger than 5 years of age may have an exaggerated febrile response with temperatures of up to 105°F (40.6°C) in response to either a serious bacterial infection or an otherwise benign viral infection. Fever to this degree is unusual in older children and adolescents and suggests a serious process. The fever pattern does not reliably distinguish fever caused by infectious microorganisms from that resulting from malignancy, autoimmune diseases, or drugs.

Children with fever without a focus present a diagnostic challenge that includes identifying bacteremia and sepsis. **Bacteremia**, the presence of bacteria in the bloodstream, may be primary or secondary to a focal infection. **Sepsis** is the systemic response to infection that is manifested by hyperthermia or hypothermia, tachycardia, tachypnea, and shock (see Chapter 40). Children with septicemia and signs of central nervous system (CNS) dysfunction (irritability, lethargy), cardiovascular impairment (cyanosis, poor perfusion), or disseminated intravascular coagulation (petechiae, ecchymosis) are readily recognized as **toxic appearing** or **septic**. Most febrile illnesses in children may be categorized as follows:

- **Fever of short duration** accompanied by localizing signs and symptoms, in which a diagnosis can often be established by clinical history and physical examination

- **Fever without localizing signs (fever without a focus)**, frequently occurring in children younger than 3 years of age, in which a history and physical examination fail to establish a cause
- **Fever of unknown origin (FUO)**, defined as daily fever for more than 14 days without an identified etiology despite history, physical examination, and routine laboratory tests, or after 1 week of intense evaluation

FEVER IN INFANTS YOUNGER THAN 2 MONTHS OF AGE

Fever or **temperature instability** in infants younger than 2 months of age is associated with a higher risk of **serious bacterial infections** than in older infants. These younger infants usually exhibit only fever and poor feeding, without localizing signs of infection. Most febrile illnesses in this age group are caused by common viral pathogens, but serious bacterial infections include **bacteremia** (most commonly caused by group B streptococcus [GBS], *Escherichia coli*, and *Listeria monocytogenes* in neonates; and *Streptococcus pneumoniae*, *Haemophilus influenzae* type b [Hib], nontyphoidal *Salmonella*, and *Neisseria meningitidis* in 1- to 3-month-old infants), **urinary tract infection (UTI)** (*E. coli*), **pneumonia** (*S. pneumoniae*, GBS, or *Staphylococcus aureus*), **meningitis** (GBS, *E. coli*, *L. monocytogenes*, *S. pneumoniae*, *N. meningitidis*, Hib, herpes simplex virus [HSV], enteroviruses), **bacterial diarrhea** (*Salmonella*, *Shigella*, *E. coli*), and **osteomyelitis** or **septic arthritis** (*S. aureus* or GBS).

Differentiating between viral and bacterial infections in young infants is difficult, but emerging studies demonstrate that doing so may be possible with the examination of inflammatory markers and gene expression profiles. Febrile infants younger than 2 months of age who appear ill, especially if follow-up is uncertain, and all febrile infants younger than 4 weeks of age should be admitted to the hospital for empirical antibiotics pending culture results. After blood, urine, and cerebrospinal fluid cultures are obtained, broad-spectrum parenteral antibiotics (typically ampicillin with a third-generation cephalosporin such as cefepime or ceftazidime, or with gentamicin) are administered. The choice of antibiotic depends on the pathogens suggested by localizing findings. The possibility of neonatal HSV should also be considered in febrile children younger than 4 weeks, and empirical acyclovir begun in those in whom neonatal HSV is a concern. Well-appearing febrile infants 4 weeks of age and older without an identifiable focus and with certainty of follow-up are at a low risk of developing a serious bacterial infection (0.8% develop bacteremia, and 2% develop a serious localized bacterial infection). Specific criteria identifying these low-risk infants include age older than 1 month, well appearing without a focus of infection, no history of prematurity or prior antimicrobial therapy, a white blood cell (WBC) count of 5,000–15,000/μL, normal urinalysis, procalcitonin below 1.7 ng/mL, and spinal fluid, if obtained, with less than 5–10 WBC/μL. Fecal leukocyte testing and chest radiograph can be considered in infants with diarrhea or respiratory signs. Low-risk infants may be followed as outpatients without empirical antibiotic treatment, or alternatively, may be treated with intramuscular ceftriaxone. Regardless of antibiotic treatment, close follow-up for at least 72 hours, including re-evaluation in 24 hours or immediately with any clinical change, is essential.

FEVER IN CHILDREN 2 MONTHS TO 3 YEARS OF AGE

A common problem is the evaluation of a febrile but well-appearing child 2 months to 3 years of age without localizing signs of infection. Although most of these children have self-limited viral infections, some have **occult bacteremia** (bacteremia without identifiable focus) or UTIs, and a few have severe and potentially life-threatening illnesses. It is difficult, even for experienced clinicians, to differentiate patients with occult bacteremia from those with benign illnesses.

Observational assessment is a key part of the evaluation. Descriptions of normal appearance and **alertness** include *child looking at the observer* and *looking around the room*, with eyes that are *shiny* or *bright*. Descriptions that indicate severe impairment include *glassy eyes* and *stares vacantly into space*. Observations, such as *sitting, moving arms and legs on table or lap*, and *sits without support* reflect normal motor ability, whereas *no movement in caregiver's arms* and *lies limply on table* indicate severe impairment. Normal behaviors, such as *vocalizing spontaneously*, *playing with objects*, *reaching for objects*, *smiling*, and *crying with noxious stimuli*, reflect **playfulness**; abnormal behaviors reflect **irritability**. Normally, crying children are **consolable** and *stop crying when held by*

the caregiver, whereas severe impairment is indicated by *continual cry despite being held and comforted*.

Children between 2 months and 3 years of age are at increased risk for infection with organisms with polysaccharide capsules, including *S. pneumoniae*, Hib, *N. meningitidis*, and nontyphoidal *Salmonella*. Effective phagocytosis of these organisms requires opsonic antibody. Transplacentally acquired maternal immunoglobulin G (IgG) initially provides immunity to these organisms, but as the maternal IgG gradually dissipates, the risk of infection increases. In the United States, use of conjugate Hib and *S. pneumoniae* vaccines has dramatically reduced the incidence of these infections, and determining the child's immunization status is essential to evaluate the risk of these infections. An approach to evaluating these children is outlined in Fig. 96.1.

Most episodes of fever in children younger than 3 years of age have a demonstrable source of infection elicited by history, physical examination, or a simple laboratory test. In this age group, the most commonly identified serious bacterial infection is a UTI. A blood culture to evaluate for occult bacteremia, and urinalysis and urine culture to evaluate for a UTI, should be considered for all children younger than 3 years of age with ongoing fever without localizing signs. Stool culture or molecular testing should be obtained in those with diarrhea

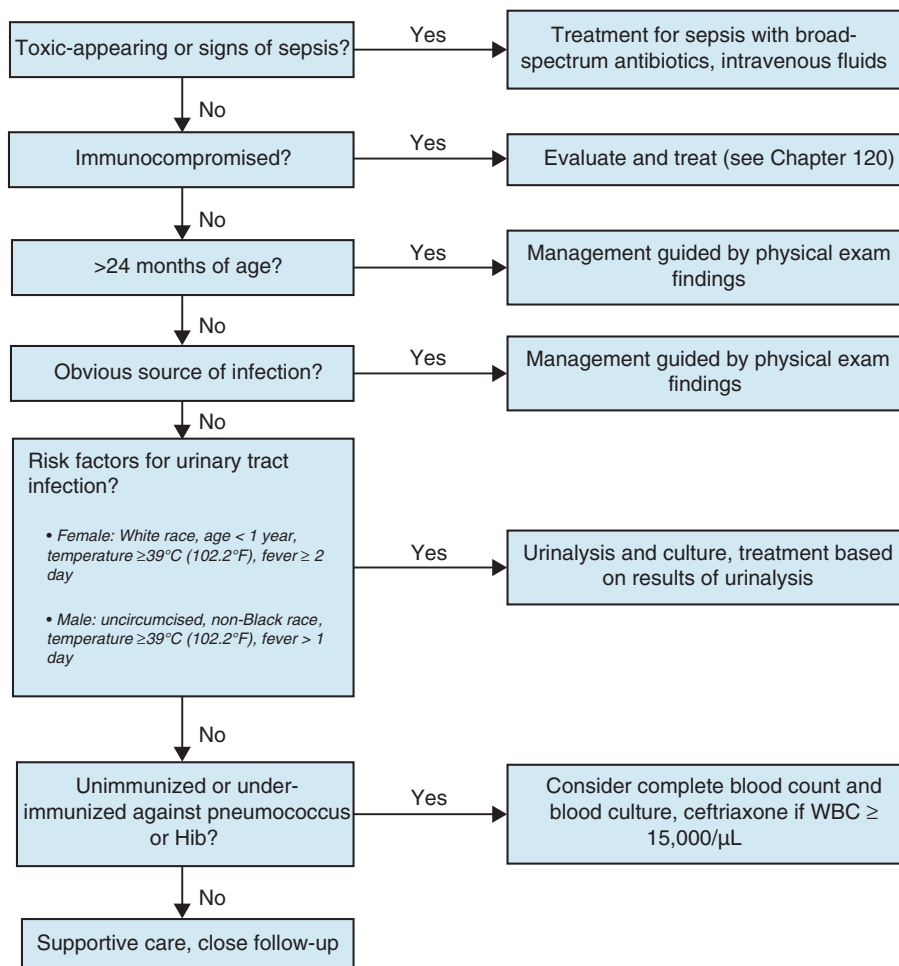

FIGURE 96.1 Algorithm for evaluation and management of fever in infants and children older than 2 months. Hib, *Haemophilus influenzae* type b; WBC, white blood cell count. (Modified from Aronson PL, Neuman MI. Fever in the older child. In: Kliegman RM, St. Geme III JW, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia: Elsevier; 2020 [fig. 203.3].)

marked by blood or mucus. Ill-appearing children should be admitted to the hospital and treated with empirical antibiotics.

Approximately 0.2% of well-appearing febrile children 3–36 months of age vaccinated against *S. pneumoniae* and Hib and without localizing signs have occult bacteremia. Signs associated with occult bacteremia include temperature of 102.2°F (39°C) or greater, WBC count of 15,000/mm³ or more, and elevated absolute neutrophil count, band count, erythrocyte sedimentation rate (ESR), or C-reactive protein (CRP). No combination of demographic factors (socioeconomic status, race, gender, and age), clinical parameters, or laboratory tests in these children reliably predicts occult bacteremia. Occult bacteremia in otherwise healthy children is usually transient and self-limited but may progress to serious localizing infections. Well-appearing children usually are followed as outpatients without empirical antibiotic treatment. Regardless of antibiotic treatment, close follow-up for at least 72 hours, including re-evaluation in 24 hours or immediately with any clinical change, is essential. Children with a positive blood culture require immediate re-evaluation, repeat blood culture, consideration for lumbar puncture, and empirical antibiotic treatment.

Children with **sickle cell disease** have both impaired splenic function and properdin-dependent opsonization that places them at increased risk for bacteremia due to encapsulated

organisms, especially during the first 5 years of life. Children with sickle cell disease and fever who appear seriously ill, have a temperature of 104°F (40°C) or above, or WBC count less than 5,000/mm³ or more than 30,000/mm³ should be hospitalized and treated empirically with antibiotics. Other children with sickle cell disease and fever should have blood culture, empirical treatment with ceftriaxone, and close outpatient follow-up. Osteomyelitis resulting from *Salmonella* or *S. aureus* is more common in children with sickle cell disease; blood culture is not always positive in the presence of osteomyelitis.

FEVER OF UNKNOWN ORIGIN

FUO is defined as a daily temperature greater than 100.4°F (38°C) lasting for more than 14 days without an obvious cause or a fever documented by a health care provider for which the cause could not be identified after at least 8 days of workup despite a complete history, physical examination, and routine screening laboratory evaluation. It is important to distinguish persistent fever from recurrent or periodic fevers, which often represent serial acute illnesses.

The initial FUO evaluation requires a thorough history and physical examination supplemented with a few screening laboratory tests (Fig. 96.2). Additional laboratory and imaging tests are

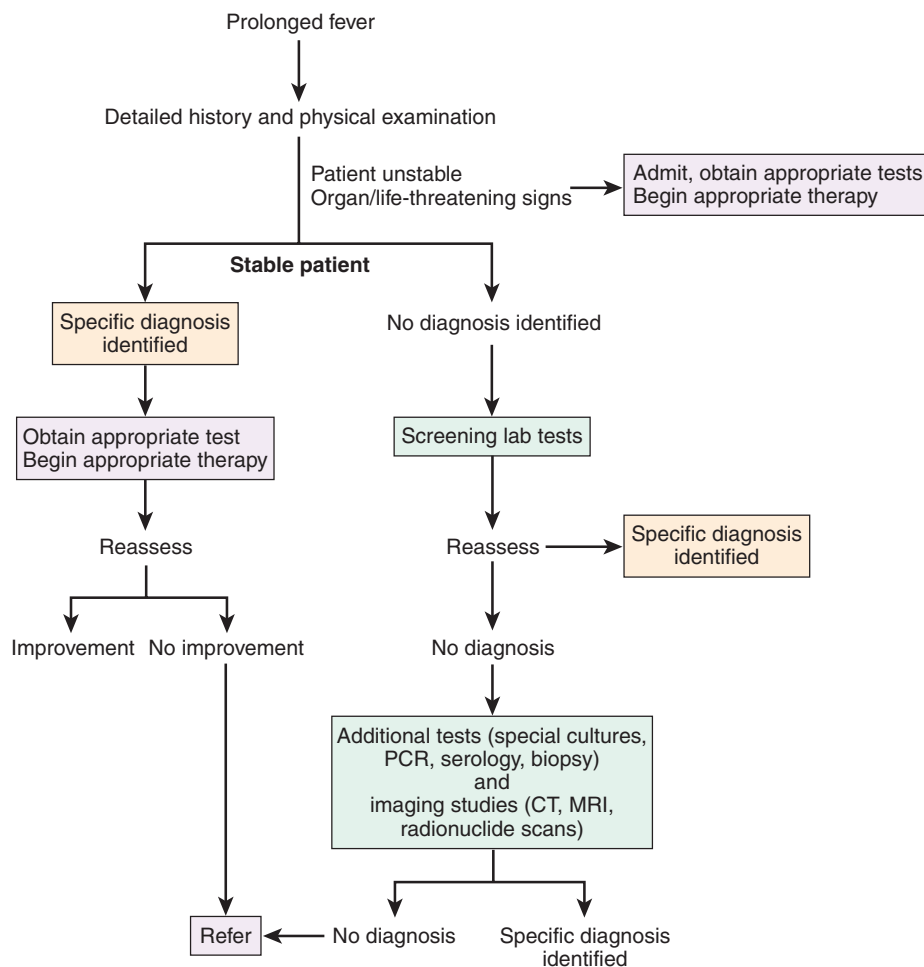

FIGURE 96.2 Approach to the evaluation of fever of unknown origin in children. Screening laboratory tests include complete blood count with and differential, erythrocyte sedimentation rate, C-reactive protein, basic metabolic panel, hepatic transaminase levels, urinalysis, and cultures of urine and blood. Chest radiograph should be included for patients with pulmonary symptoms. *CT*, Computed tomography; *MRI*, magnetic resonance imaging; *PCR*, polymerase chain reaction; *PET*, position emission tomography; *WBC*, white blood cells.

guided by abnormalities on initial evaluation. Important historical elements include the impact the fever has on the child's health and activity; weight loss; the use of drugs, medications, or immunosuppressive therapy; a history of unusual, severe, or chronic infection suggesting immunodeficiency (see Chapter 72); immunizations; exposure to unprocessed or raw foods; a history of pica and exposure to soil-borne or water-borne organisms; exposure to industrial or hobby-related chemicals; blood transfusions; domestic or foreign travel; exposure to animals; exposure to ticks or mosquitoes; ethnic background and family history; recent surgical procedures or dental work; tattooing and body piercing; and sexual activity.

The etiology of most occult infections causing FUO is an unusual presentation of a common disease. Sinusitis, endocarditis, intraabdominal abscesses (perinephric, intrahepatic, subdiaphragmatic), and CNS lesions (tuberculoma, cysticercosis, abscess, toxoplasmosis) may be relatively asymptomatic. **Infections** are the most common cause of FUO in children, accounting for approximately 40–50% of FUO episodes, followed by **inflammatory diseases** (about 20% of all episodes), **malignancy** (about 10% of all episodes), and other etiologies (Table 96.1). Approximately 15% of children with FUO have no diagnosis. Fever eventually resolves in many of these cases, usually without sequelae, although some may develop definable signs of rheumatic disease over time. Common infections causing FUO in patients with known or newly diagnosed **immunodeficiency** include viral hepatitis, Epstein-Barr virus, cytomegalovirus, *Bartonella henselae*, ehrlichiosis, *Salmonella*, and tuberculosis.

Factitious fever or fever produced or feigned intentionally by the patient (**Munchausen syndrome**) or the parent of

a child (**Munchausen syndrome by proxy**) is an important consideration, particularly if family members are familiar with health care practices (see Chapter 22). Fever should be recorded in the hospital by a reliable individual who remains with the patient when the temperature is taken. Continuous observation over a long period and repetitive evaluation are essential.

Screening tests for FUO include complete blood count with WBC and differential, ESR, CRP, procalcitonin, basic metabolic panel, hepatic transaminase levels, urinalysis, and cultures of urine and blood. Chest radiograph should be included for patients with pulmonary symptoms. Additional tests for FUO may include throat culture, stool culture or molecular testing, tuberculin skin test or interferon- γ release assay, HIV, Epstein-Barr virus, cytomegalovirus, and *B. henselae* antibodies. Consultation with infectious disease, immunology, rheumatology, or oncology specialists should be considered. Further tests may include lumbar puncture for cerebrospinal fluid analysis and culture; evaluation for rheumatic disease with antinuclear antibody, rheumatoid factor, ferritin, and serum complement (C3, C4, CH₅₀); uric acid and lactate dehydrogenase; computed tomography or magnetic resonance (often with positron emission tomography [PET] scan) imaging of the chest, abdomen, and head; and bone marrow biopsy for cytology and culture.

PEARLS FOR PRACTITIONERS

TABLE 96.1 Causes of Fever of Unknown Origin in Children —cont'd

Hepatitis viruses	MALIGNANCIES
HIV (and associated opportunistic infections)	Atrial myxoma
Infectious mononucleosis (Epstein-Barr virus)	Cholesterol granuloma
Rickettsial Diseases	Ewing sarcoma
Anaplasmosis	Hepatoma
Ehrlichiosis	Hodgkin disease
Q fever (<i>Coxiella burnetii</i>)	Inflammatory pseudotumor
Rocky Mountain spotted fever	Leukemia
Tick-borne typhus	Lymphoma
Fungal Diseases	Neuroblastoma
Blastomycosis (extrapulmonary)	Pheochromocytoma
Coccidioidomycosis (disseminated)	Wilms tumor
Histoplasmosis (disseminated)	MISCELLANEOUS
Parasitic Diseases	Addison disease
Extraintestinal amebiasis	Anhidrotic ectodermal dysplasia
Baylisascaris	Autonomic neuropathies
Babesiosis	Castleman disease
Malaria	Chronic active hepatitis
Toxoplasmosis	Cyclic neutropenia
Trichinosis	Diabetes insipidus (central and nephrogenic)
Trypanosomiasis	Fabry disease
Visceral larva migrans (<i>Toxocara</i>)	Factitious fever
INFLAMMATORY DISEASES	Familial dysautonomia
Autoimmune lymphoproliferative syndrome	Familial Mediterranean fever
Behçet syndrome	Granulomatous hepatitis
Chronic recurrent multifocal osteomyelitis	Hemophagocytic syndromes
Drug fever	Hypertriglyceridemia
Granulomatosis with polyangiitis	Hypothalamic-central fever
Hypersensitivity pneumonitis	Ichthyosis
Juvenile dermatomyositis	Infantile cortical hyperostosis
Juvenile idiopathic arthritis (systemic onset, Still disease)	Kikuchi-Fujimoto disease
Inflammatory bowel disease (Crohn disease, ulcerative colitis)	Metal fume fever
Kawasaki disease	Pancreatitis
Polyarteritis nodosa	Periodic fever syndromes
Rheumatic fever	Poisoning
Sarcoidosis	Postoperative (pericardiectomy, craniectomy)
Serum sickness	Pulmonary embolism
Systemic lupus erythematosus	Thrombophlebitis
Weber-Christian disease	Thyrotoxicosis

CHAPTER 97

Infections Characterized by
Fever and Rash

Rashes are a common manifestation of many infections; this chapter describes five common childhood viral exanthems characterized by fever and rash. Rash distribution and appearance provide important clues to the differential diagnosis, including other infectious agents (Table 97.1).

MEASLES (RUBEOLA)**Etiology**

Measles (rubeola) is highly contagious and is caused by a single-stranded RNA paramyxovirus with one antigenic type. Humans are the only natural host. The measles virus infects the upper respiratory tract and regional lymph nodes and is spread systemically during a brief, low-titer primary viremia. A secondary viremia occurs within 5–7 days as virus-infected monocytes spread the virus to the respiratory tract, skin, and other organs. The virus is present in respiratory secretions, blood, and the urine of infected individuals. It is transmitted by droplets or via the airborne route and is extremely contagious. Infected persons are contagious from 1–2 days before onset of symptoms—from about 5 days before to 4 days after the appearance of rash; immunocompromised persons can have prolonged excretion of contagious virus.

Epidemiology

Measles remains endemic in regions of the world where measles vaccination is not readily available and is responsible for about 20 million infections and 150,000 deaths annually. There have typically been fewer than 100 cases of measles reported annually in the United States; however, outbreaks have occurred resulting from imported virus after international travel, and in 2019 there were almost 1,300 measles cases in the United States, the highest number in a decade. Infections of nonimmigrant children may occur during outbreaks among those too young to be vaccinated or in communities with low immunization rates. Most young infants are protected by transplacentally acquired maternal antibody until the end of their first year.

Clinical Manifestations

Measles infection is divided into four phases: incubation, prodromal (catarrhal), exanthematous (rash), and recovery. The incubation period is 8–12 days from exposure to symptom onset and a mean of 14 days (range: 7–21) from exposure to rash onset. The manifestations of the 3-day prodromal period are cough, coryza, conjunctivitis, and the pathognomonic **Koplik spots** (gray-white, sand-grain-sized dots on the buccal mucosa opposite the lower molars) that last 12–24 hours. The conjunctiva may reveal a characteristic transverse line of inflammation along the eyelid margin (**Stimson line**). The classic symptoms of cough, coryza, and conjunctivitis continue to occur during the secondary viremia of the exanthematous phase, which often is accompanied by high fever

HBV, Hepatitis B virus; HHV, human herpesvirus.

(40–40.5°C [104–105°F]). The macular rash begins on the head (often above the hairline) and spreads over most of the body in a cephalad-to-caudal pattern over 24 hours. Areas of the rash are often confluent. The rash fades in the same pattern, and illness severity is related to the extent of the rash. It may be petechial or hemorrhagic (**black measles**). As the rash fades, it undergoes brownish discoloration and desquamation. Generalized lymphadenopathy may be noted with the rash, with cervical nodes being most prominent. Mesenteric lymphadenopathy with abdominal pain may be noted with the rash. Otitis media, pneumonia, and diarrhea are more common in infants. Liver involvement is more common in adults.

The term **modified measles** describes mild cases of measles occurring in persons with partial protection against measles. Modified measles occurs in persons vaccinated before 12 months of age or with co-administration of immune serum globulin, in infants with disease modified by transplacentally acquired antibody, or in persons receiving immunoglobulin.

Laboratory and Imaging Studies

Routine laboratory findings are nonspecific and do not aid in diagnosis. Leukopenia is characteristic. In patients with acute encephalitis, the cerebrospinal fluid reveals an increased protein, a lymphocytic pleocytosis, and normal glucose levels. Measles virus culture is not generally available, though identification of measles RNA via reverse transcriptase-polymerase chain reaction (PCR) may be available through state public health departments or the Centers for Disease Control and Prevention (CDC). Serologic testing for immunoglobulin M (IgM) antibodies that appear within 1–2 days of the rash and persist for 1–2 months in unimmunized persons confirms the clinical diagnosis, though IgM antibodies may be present only transiently in immunized people. Suspected cases should be **reported immediately** to the local or state health department.

Differential Diagnosis

The constellation of fever, rash, cough, and conjunctivitis is highly suggestive of measles. Koplik spots are pathognomonic but not always present at the time the rash is most pronounced. Confirmation is by diagnostic antibody increases in acute and convalescent sera. Measles must be differentiated from rubella, roseola, enteroviral or adenoviral infection, infectious mononucleosis, toxoplasmosis, meningococemia, scarlet fever, rickettsial disease, Kawasaki disease, serum sickness, and drug rash.

Treatment

Routine supportive care includes maintaining adequate hydration and antipyretics. High-dose vitamin A supplementation improves the outcome of infants with measles in developing countries. The World Health Organization recommends routine administration of vitamin A for 2 days to children with acute measles, regardless of country of residence.

Complications and Prognosis

Otitis media is the most common complication of measles infection. Interstitial (measles) pneumonia can occur, or pneumonia may result from secondary bacterial infection

with *Streptococcus pneumoniae*, *Staphylococcus aureus*, or group A streptococcus. Persons with impaired cell-mediated immunity may develop **giant cell (Hecht) pneumonia**, which is usually fatal. Myocarditis and mesenteric lymphadenitis are infrequent complications.

Encephalomyelitis occurs in 1–3 per 1,000 cases and usually occurs 2–5 days after the onset of the rash. Early encephalitis probably is caused by direct viral infection of brain tissue, whereas later onset encephalitis is a demyelinating, and probably an immunopathologic, phenomenon. **Subacute sclerosing panencephalitis (SSPE)** is a late neurologic complication of slow measles infection that is characterized by progressive behavioral and intellectual deterioration and eventual death. It occurs in approximately 1 in every million cases of measles, an average of 8–10 years after measles. There is no effective treatment.

Deaths most frequently result from bronchopneumonia or encephalitis, with much higher risk in persons with malignancy, severe malnutrition, age under 5 years, or immunocompromise (such as HIV infection). Late deaths in adolescents and adults usually result from SSPE. Other forms of measles encephalitis in immunocompetent persons are associated with a mortality rate of approximately 15%, with 20–30% of survivors having serious neurologic sequelae.

Prevention

Live measles vaccine prevents infection and is recommended as measles, mumps, and rubella (MMR) for children at 12–15 months and 4–6 years of age. The MMRV (MMR combined with varicella vaccine) is an alternative vaccine for children 12 months to 12 years of age, provided there are no contraindications, but is associated with a higher rate of febrile seizures following administration. The second dose of MMR is not a booster dose but significantly reduces the primary vaccine failure rate, from less than 5% to less than 1%. Contraindications to measles vaccine include immunocompromised states or an immunosuppressive course of corticosteroids (>2 mg/kg/day or >20 mg/day for those weighing >10 kg, for >14 days), pregnancy, or recent administration of immunoglobulin (within 3–11 months, depending on dose). MMR vaccination is recommended for all HIV-infected persons without evidence of severe immunosuppression (low age-specific CD4 T lymphocytes), children with cancer in remission who have not received chemotherapy in the previous 3 months, and children who have not received immunosuppressive corticosteroids in the previous month. Susceptible household contacts with a chronic disease or who are immunocompromised should receive **postexposure prophylaxis** with measles vaccine within 72 hours of measles exposure or immunoglobulin within 6 days of exposure.

RUBELLA (GERMAN OR 3-DAY MEASLES)

Etiology

Rubella, also known as **German measles** or **3-day measles**, is caused by a single-stranded RNA virus with a glycolipid envelope and is a member of the togavirus family. Humans are the only natural host. Rubella virus invades the respiratory epithelium and disseminates via a primary viremia. After replication in the reticuloendothelial system, a secondary viremia ensues, and the virus can be isolated from peripheral blood

monocytes, cerebrospinal fluid, and urine. Rubella virus is most contagious through direct or droplet contact with nasopharyngeal secretions from 2 days before until 5–7 days after rash onset, although the virus may be present in nasopharyngeal secretions from 7 days before until 14 days after the rash.

Infection **in utero** results in significant morbidity from **congenital rubella syndrome (CRS)** with associated ophthalmologic, cardiac, and neurologic manifestations (see Chapter 66). Maternal infection during the first trimester results in fetal infection with generalized vasculitis in more than 90% of cases. Infants with CRS may shed the virus in nasopharyngeal secretions and urine for more than 12 months after birth and transmit it to susceptible contacts.

Epidemiology

In unvaccinated populations, rubella usually occurs in the spring, with epidemics occurring in cycles of every 6–9 years. Approximately 25–50% of cases are subclinical. Fewer than 20 cases of rubella occur annually in the United States. Outbreaks occasionally occur in nonvaccinated groups from internationally imported cases. Transplacentally acquired antibody is protective during the first 6 months of life.

Clinical Manifestations

The incubation period for postnatal rubella is typically 16–18 days (range: 14–21 days). The mild catarrhal symptoms of the prodromal phase of rubella may go unnoticed. The characteristic signs of rubella are retroauricular, posterior cervical, and posterior occipital lymphadenopathy accompanied by an erythematous, maculopapular, discrete rash. The rash begins on the face and spreads to the body, lasting for 3 days, and is less prominent than that of measles. Rose-colored spots on the soft palate, known as **Forchheimer spots**, develop in 20% of patients and may appear before the rash. Other manifestations of rubella include mild pharyngitis, conjunctivitis, anorexia, headache, malaise, and low-grade fever. Polyarthritides, usually of the hands, may occur, especially among adult females, but usually resolves without sequelae. Paresthesias and tendinitis may occur.

Laboratory and Imaging Studies

Routine laboratory findings are nonspecific and generally do not aid in diagnosis. The white blood cell count usually is normal or low, and thrombocytopenia rarely occurs. Diagnosis is confirmed by serologic testing for IgM antibodies (typically positive 5 days after symptom onset) or by a fourfold or greater increase in specific IgG antibodies in paired acute and convalescent sera. CRS cases can have detectable IgM until 3 months of age and stable or rising IgG titers over the first 7–11 months of age. False-positive IgM results can occur. Cases of suspected CRS and postnatal rubella infection should be reported to the local and state health departments.

Differential Diagnosis

The rash must be differentiated from measles, roseola, enteroviral or adenoviral infection, infectious mononucleosis, toxoplasmosis, scarlet fever, rickettsial disease, Kawasaki disease, serum sickness, and drug rash.

Treatment

There is no specific therapy for rubella, and treatment is supportive.

Complications and Prognosis

Other than CRS (see Chapter 66) arising from rubella infection during pregnancy, complications are rare. Death rarely occurs with rubella encephalitis.

Prevention

Live rubella vaccine prevents infection and is recommended as MMR for children at 12–15 months and at 4–6 years of age. After vaccination, rubella virus is shed from the nasopharynx for several weeks, but it is not communicable. In children, rubella vaccine rarely is associated with adverse effects, but in postpubertal females it causes arthralgias in 25% of vaccinated individuals and acute arthritis-like symptoms in 10% of vaccinated individuals. These symptoms typically develop 1–3 weeks after vaccination and last 1–3 days.

Contraindications to rubella vaccine include immunocompromised states or an immunosuppressive course of corticosteroids (>2 mg/kg/day or >20 mg/day for those weighing >10 kg, for >14 days), pregnancy, or recent administration of immunoglobulin (within 3–11 months, depending on dose). Vaccine virus has been recovered from fetal tissues, although no cases of CRS have been identified among infants born to women inadvertently vaccinated against rubella during pregnancy. Nevertheless, women are cautioned to avoid pregnancy for 28 days after receiving the rubella-containing vaccine. All pregnant women should have prenatal serologic testing to determine their immune status to rubella, and susceptible mothers should be vaccinated after delivery and before hospital discharge.

Susceptible, nonpregnant persons exposed to rubella should receive rubella vaccination. Immunoglobulin is not recommended for postexposure prophylaxis of susceptible, pregnant women exposed to rubella.

ROSEOLA INFANTUM (EXANTHEM SUBITUM)

Etiology

Roseola infantum (exanthem subitum, sixth disease) is caused primarily by human herpesvirus type 6 (HHV-6) in most cases, and by HHV-7 in 10–30% of cases. HHV-6 and HHV-7 are large, enveloped double-stranded DNA viruses that are members of the herpesvirus family. Two species of HHV-6 (HHV-6A and HHV-6B) exist, with almost all postnatal infections caused by HHV-6B. These viruses infect mature mononuclear cells and cause a relatively prolonged (3–5 days) viremia during primary infection. They can be detected in the saliva of healthy adults, which suggests, as with other herpesviruses, the development of lifelong latent infection and intermittent viral shedding.

Epidemiology

Transplacentally acquired antibody protects most infants until 6 months of age. The incidence of infection increases

as maternally derived antibody levels decline. By 12 months of age, approximately 60–90% of children have antibodies to HHV-6, and essentially all children are seropositive by 2–3 years of age. The virus is likely acquired from asymptomatic adults who periodically shed these viruses. HHV-6 is a major cause of acute febrile illnesses in infants and may be responsible for up to 20% of visits to the emergency department for children 6–18 months of age.

Clinical Manifestations

Roseola is characterized by high fever (often $>40^{\circ}\text{C}$) with an abrupt onset that lasts 3–5 days. A maculopapular, rose-colored rash erupts coincident with defervescence, although it may be present earlier. The rash usually lasts 1–3 days but may fade rapidly and is not present in all infants with HHV-6 infection. Upper respiratory symptoms, nasal congestion, erythematous tympanic membranes, and cough may occur. Gastrointestinal symptoms are described. Roseola is associated with approximately one third of febrile seizures. Roseola caused by HHV-6 and HHV-7 are clinically indistinguishable, although HHV-6-associated roseola typically occurs in younger infants. Reactivation of HHV-6 following bone marrow transplantation may result in bone marrow suppression, hepatitis, rash, and encephalitis.

Laboratory and Imaging Studies

Routine laboratory findings are nonspecific and do not aid in diagnosis. Encephalitis with roseola is characterized by pleocytosis (30 – 200 cells/ mm^3) with mononuclear cell predominance, elevated protein concentration, and normal glucose concentration. Serologic testing showing a fourfold rise in acute and convalescent sera or documentation of HHV-6 DNA by PCR in the cerebrospinal fluid is diagnostic. PCR has also been used to detect HHV-6 in blood but may not be able to differentiate latent, reactivation, or primary infection. A rising viral titer is indicative of reactivation or primary infection. HHV-6 may also integrate in human chromosomes making viral PCR on white blood cells difficult to interpret.

Differential Diagnosis

The pattern of high fever for 3–5 days without significant physical findings followed by onset of rash with subsequent defervescence is characteristic. Many febrile illnesses may be easily confused with roseola during the preeruptive stage. Serious infections must be excluded, although most children are alert, behave normally, and continue with their usual daily activities.

Treatment

There is no specific therapy for roseola. Routine supportive care includes maintaining adequate hydration and antipyretics. In immunocompromised hosts, use of ganciclovir or foscarnet can be considered.

Complications and Prognosis

The prognosis for roseola is excellent. A few deaths have been attributed to HHV-6, usually in cases complicated by encephalitis or virus-associated **hemophagocytosis syndrome**.

Prevention

No preventative measures are available.

ERYTHEMA INFECTIOSUM (FIFTH DISEASE)

Etiology

Erythema infectiosum (fifth disease) is caused by the human parvovirus B19, a single-stranded DNA virus producing a benign viral exanthem in healthy children. The viral affinity for red blood cell progenitor cells makes it an important cause of aplastic crisis in patients with hemolytic anemias, including sickle cell disease, spherocytosis, and thalassemia. Parvovirus B19 also causes fetal anemia and hydrops fetalis after primary infection during pregnancy. The cell receptor for parvovirus B19 is the **erythrocyte P antigen**, a glycolipid present on erythroid cells. The virus replicates in actively dividing erythroid stem cells, leading to cell death that results in erythroid aplasia and anemia.

Epidemiology

Erythema infectiosum is common. Parvovirus B19 seroprevalence is only 2–9% in children younger than 5 years of age but increases to 15–35% in children 5–18 years and 30–60% in adults. Community epidemics usually occur in the spring. The virus is transmitted by respiratory secretions and by blood product transfusions.

Clinical Manifestations

The incubation period is typically 4–14 days and, rarely, may last 21 days. Parvovirus B19 infections usually begin with a mild, nonspecific illness characterized by fever, malaise, myalgias, and headache. In some cases, the characteristic rash appears 7–10 days later. Erythema infectiosum is manifested by rash, low-grade or no fever, and occasionally pharyngitis and mild conjunctivitis. The rash appears in three stages. The initial stage is typically a **“slapped cheek” rash** with circumoral pallor. An erythematous symmetric, maculopapular, truncal rash appears 1–4 days later, then fades as central clearing takes place, giving a distinctive **lacy, reticulated rash** that lasts 2–40 days (mean: 11 days). This rash may be pruritic, does not desquamate, and may recur with exercise, bathing, rubbing, or stress. Adolescents and adults may experience myalgia, significant arthralgias or arthritis, headache, pharyngitis, coryza, and gastrointestinal upset.

Children with shortened erythrocyte life span (e.g., sickle cell disease) may develop a **transient aplastic crisis**, which is characterized by ineffective erythroid production typically lasting 7–10 days (see Chapter 150). Most children with parvovirus B19-induced transient aplastic crisis have multiple symptoms, including fever, lethargy, malaise, pallor, headache, gastrointestinal symptoms, and respiratory symptoms. The reticulocyte count is extremely low, and the hemoglobin level is lower than usual for the patient. Transient neutropenia and thrombocytopenia also commonly occur. Parvovirus may also cause hepatitis, myocarditis, and the papular-purpuric gloves and socks syndrome.

Persistent parvovirus B19 infection may develop in children with immunodeficiency, causing severe anemia resulting from pure red blood cell aplasia. These children do not display the typical manifestations of erythema infectiosum.

Laboratory and Imaging Studies

Hematologic abnormalities occur with parvovirus infection, including reticulocytopenia lasting 7–10 days, mild anemia, thrombocytopenia, lymphopenia, and neutropenia. Parvovirus B19 can be detected by PCR and by electron microscopy of erythroid precursors in the bone marrow. Serologic tests showing specific IgM antibody to parvovirus are diagnostic, demonstrating an infection that probably occurred in the prior 2–4 months. Parvovirus PCR of blood and cerebrospinal fluid is also available, primarily for use in severe illness or immunocompromised patients.

Differential Diagnosis

The diagnosis of erythema infectiosum in children is established on the basis of the clinical findings of typical facial rash with absent or mild prodromal symptoms, followed by a reticulated rash over the body that waxes and wanes. The differential diagnosis includes measles, rubella, scarlet fever, enteroviral or adenoviral infection, infectious mononucleosis, Kawasaki disease, systemic lupus erythematosus, serum sickness, and drug reaction.

Treatment

There is no specific therapy other than routine supportive care. Transfusions may be required for transient aplastic crisis. Intrauterine transfusion has been performed for hydrops fetalis associated with fetal parvovirus B19 infection. Intravenous immunoglobulin may be used for immunocompromised persons with severe anemia or chronic infection.

Complications and Prognosis

The prognosis for erythema infectiosum is excellent. Fatalities associated with transient aplastic crisis are rare. Parvovirus B19 is not teratogenic, but in utero infection of fetal erythroid cells may result in fetal heart failure, hydrops fetalis, and fetal death. Of the approximately 50% of women of childbearing age susceptible to parvovirus B19 infection, 30% of exposed women develop infection, with 25% of exposed fetuses becoming infected and 10% of these culminating in fetal death.

Prevention

The greatest risk is to pregnant women. Effective control measures are limited. The exclusion of affected children from school is not recommended because children generally are not infectious by the time the rash is present. Good handwashing and hygiene are practical measures that should help reduce transmission.

VARICELLA-ZOSTER VIRUS INFECTION (CHICKENPOX AND ZOSTER)

Etiology

Chickenpox and zoster are caused by varicella-zoster virus (VZV), an enveloped, icosahedral, double-stranded DNA virus that is a member of the herpesvirus family. Humans are the only natural host. **Chickenpox (varicella)** is the manifestation of primary infection. VZV infects susceptible

individuals via the conjunctivae or respiratory tract and replicates in the nasopharynx and upper respiratory tract. It disseminates by a primary viremia and infects regional lymph nodes, the liver, the spleen, and other organs. A secondary viremia follows, resulting in a cutaneous infection with the typical vesicular rash. After resolution of chickenpox, the virus persists in latent infection in the dorsal root ganglia cells. **Zoster (shingles)** is the manifestation of reactivated latent infection of endogenous VZV. Chickenpox is highly communicable in susceptible individuals, with a secondary attack rate of more than 90%. The period of communicability ranges from 2 days before to 7 days after the onset of the rash, when all lesions are crusted.

Epidemiology

In the prevaccine era, the peak age of occurrence was 5–10 years, with peak seasonal infection in late winter and spring. In the postvaccine era, the incidence of varicella has declined in all age groups, with the peak incidence now in 10- to 14-year-olds. Transmission is by direct contact, droplet, and air. Zoster, however, is contagious by direct contact. Only 5% of cases of zoster occur in children younger than 15 years of age. The incidence and severity of zoster are increased in immunocompromised persons.

Clinical Manifestations

The incubation period of varicella is generally 14–16 days, with a range of 10–21 days after exposure. Prodromal symptoms of fever, malaise, and anorexia may precede the rash by 1 day. The characteristic rash appears initially as small red papules that rapidly progress to nonumbilicated, oval, teardrop-like vesicles on an erythematous base. The fluid progresses from clear to cloudy, and the vesicles ulcerate, crust, and heal. New crops appear for 3–4 days, usually beginning on the trunk followed by the head, the face, and, less commonly, the extremities. There may be a total of 100–500 lesions, with all forms of lesions being present at the same time. Pruritus is universal and marked. Lesions may be present on mucous membranes. Lymphadenopathy may be generalized. The severity of the rash varies, as do systemic signs and fever, which generally abate after 3–4 days.

The preruption phase of zoster includes intense localized and burning pain and tenderness (**acute neuritis**) along a dermatome, accompanied by malaise and fever. In several days, the eruption of papules, which quickly vesiculate, occurs in the dermatome or in two adjacent dermatomes. Groups of lesions occur for 1–7 days and then progress to crusting and healing. Thoracic and lumbar regions are typically involved. Lesions generally are unilateral and are accompanied by regional lymphadenopathy. In one third of patients, a few vesicles occur outside the primary dermatome. Any branch of cranial nerve V may be involved, which also may cause corneal and intraoral lesions. Involvement of cranial nerve VII may result in facial paralysis and ear canal vesicles (**Ramsay Hunt syndrome**). Ophthalmic zoster may be associated with ipsilateral cerebritis and stroke. Immunocompromised persons may have unusually severe, painful herpes zoster that involves multiple cutaneous regions and, potentially, visceral dissemination (to liver, lungs, and central nervous system).

Postherpetic neuralgia, defined as pain persisting longer than 1 month, is uncommon in children.

Laboratory and Imaging Studies

Laboratory testing confirmation for diagnosis is usually unnecessary. PCR of vesicular fluid is the current diagnostic method of choice, and genotyping to distinguish vaccine and wild-type strains is available through the CDC. Detection of varicella-specific antigen in vesicular fluid by immunofluorescence using monoclonal antibodies or demonstration of a fourfold antibody increase of acute and convalescent sera is also diagnostic but not as sensitive as PCR.

Differential Diagnosis

The diagnosis of varicella and zoster is based on the distinctive characteristics of the rash. **Eczema herpeticum**, or **Kaposi varicelliform eruption**, is a localized, vesicular eruption caused by herpes simplex virus (HSV) that develops on skin affected by underlying eczema or trauma. The differentiation between zoster and HSV infection may be difficult because HSV may cause eruption that appears to be in a dermatomal distribution. Coxsackievirus A infection has a vesiculopustular appearance, but lesions are usually localized to the extremities and oropharynx. A previously healthy patient with more than one recurrence probably has HSV infection, which can be confirmed by viral culture or PCR.

Treatment

Symptomatic therapy of varicella includes nonaspirin antipyretics, cool baths, and careful hygiene. Routine oral administration of acyclovir is not recommended in otherwise healthy children with varicella. The decision to use antiviral medications, the route, and the duration of treatment depend on host factors and the risk for severe infection or complications. Early therapy with antivirals (especially within 24 hours of rash onset) in immunocompromised persons is effective in preventing severe complications, including pneumonia, encephalitis, and death from varicella. Acyclovir or valacyclovir may be considered in those at risk of severe varicella, such as unvaccinated persons older than 12 years; those with chronic cutaneous or pulmonary disease; receiving short-course, intermittent, or aerosolized corticosteroids; or receiving long-term salicylate therapy. The dose of acyclovir used for VZV infections is much higher than that for HSV.

Antiviral treatment of zoster accelerates cutaneous healing, hastens the resolution of acute neuritis, and reduces the risk of postherpetic neuralgia. Oral famciclovir and valacyclovir have much greater oral bioavailability than acyclovir and are recommended for treatment of zoster in adults. Valacyclovir is approved for use in children 2 years and older, and acyclovir is available for use in all age groups.

Complications and Prognosis

Secondary infection of skin lesions by streptococci or staphylococci is the most common complication. These infections may be mild, resembling impetigo, or life-threatening with

toxic shock syndrome or necrotizing fasciitis. Pneumonia is uncommon in healthy children but occurs in 15–20% of healthy adults and immunocompromised persons. Myocarditis, pericarditis, orchitis, hepatitis, ulcerative gastritis, glomerulonephritis, and arthritis may complicate varicella. Reye syndrome may follow varicella; thus salicylate use is contraindicated during varicella infection.

Neurologic complications frequently include postinfectious encephalitis, cerebellar ataxia, nystagmus, and tremor. Less common neurologic complications include Guillain-Barré syndrome, transverse myelitis, cranial nerve palsies, optic neuritis, and hypothalamic syndrome.

Primary varicella can be a fatal disease in immunocompromised persons as a result of visceral dissemination, encephalitis, hepatitis, and pneumonitis. The mortality rate approaches 15% in children with leukemia who do not receive prophylaxis or therapy for varicella (see [Chapter 72](#)).

A severe form of neonatal varicella may develop in newborns of mothers with primary varicella (but not shingles) occurring 5 days before to 2 days after delivery. The fetus is exposed to a large inoculum of virus but is born before the maternal antibody response develops and can cross the placenta. These infants should be treated as soon as possible with varicella-zoster immunoglobulin (VZIG) or intravenous immunoglobulin if VZIG is unavailable, to attempt to prevent or ameliorate the infection.

Primary varicella usually resolves spontaneously. The mortality rate is much higher for persons older than 20 years of age and for immunocompromised persons. Zoster usually is self-limited, especially in children. Advanced age and severity of pain at presentation and at 1 month are predictors of prolonged pain. Scarring is more common with zoster because of the involvement of the deeper layers of the skin.

Prevention

Children with chickenpox should not return to school until all vesicles have crusted. A hospitalized child with chickenpox and immunocompromised patients with zoster should be isolated in a negative-pressure room to prevent transmission. Zoster transmission can be minimized by covering the affected area.

A live, two-dose attenuated varicella vaccine is recommended for all children. The first dose should be administered at age 12–15 months and the second dose at 4–6 years. The varicella vaccine is 85% effective in preventing any disease and 97% effective in preventing moderately severe and severe disease. Transmission of vaccine virus from a healthy vaccinated individual is rare but possible.

Passive immunity can be provided by VZIG, which is indicated within 96 hours of exposure for susceptible individuals at increased risk for severe illness, such as immunocompromised children and some hospitalized preterm infants. Administration of VZIG does not eliminate the possibility of disease in recipients and prolongs the incubation period up to 28 days.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 98

Cutaneous Infections

SUPERFICIAL BACTERIAL INFECTIONS

Impetigo

Nonbullous or crusted impetigo is caused most often by *Staphylococcus aureus* and occasionally by group A streptococcus. It begins as a single erythematous papulovesicle that progresses to one or many **honey-colored, crusted lesions** weeping serous drainage. **Bullous impetigo** accounts for approximately 10% of all impetigo. The skin lesions are thin-walled (0.5–3 cm) bullae with erythematous margins resembling second-degree burns and are associated with *S. aureus* phage type 71. Impetigo most frequently occurs on the face, around the nares and mouth, and on the extremities. Fever is uncommon. The diagnosis usually is established by the clinical appearance alone.

Recommended treatment for nonbullous impetigo is topical 2% mupirocin, topical retapamulin 1%, or oral anti-staphylococcal antibiotics. Extensive or disseminated lesions, bullous impetigo, lesions around the eyes, or lesions otherwise not amenable to topical therapy are best treated with oral antibiotics. Streptococcal impetigo is associated with increased risk of postinfectious glomerulonephritis, but not acute rheumatic fever (see Chapter 163). Antibiotic treatment does not decrease the risk of postinfectious glomerulonephritis, but it does decrease the possible spread of nephritogenic strains to close contacts. Children with impetigo should remain out of school or day care until 24 hours of antibiotic therapy have been completed.

Cellulitis

Cellulitis is infection involving the subcutaneous tissues and the dermis and is usually caused by *S. aureus* or group A streptococci. Cellulitis typically presents with indurated, warm, and erythematous macules with indistinct borders that can expand. Additional manifestations commonly include fever, lymphangitis, and regional lymphadenitis. **Erysipelas** is a superficial variant of cellulitis usually caused by group A streptococcus that involves the dermis only. The rapidly advancing lesions are tender, bright red in appearance, and have sharp margins. The patients may appear toxic. Blood cultures are recommended for erysipelas. Empirical antibiotic treatment for cellulitis is recommended with a first-generation cephalosporin unless the local *S. aureus* methicillin-resistance rate is high, in which case alternatives include clindamycin or trimethoprim-sulfamethoxazole. Many patients may be managed with oral antibiotics and close follow-up; hospitalization and intravenous antibiotics are recommended for erysipelas and cellulitis of the face, hands, feet, or perineum; those with lymphangitis; and those not responding to outpatient therapy.

Ecthyma usually is caused by group A streptococcus and may complicate impetigo. Initially, it is characterized by a lesion with a rim of erythematous induration surrounding an eschar, which if removed reveals a shallow ulcer. **Ecthyma gangrenosum** is a serious skin infection occurring in immunocompromised persons due to hematogenous spread of

septic emboli to the skin, classically caused by *Pseudomonas aeruginosa*, other gram-negative organisms, or occasionally *Aspergillus*. The lesions begin as purple macules that undergo central necrosis to become exquisitely tender, deep, punched-out ulcers 2–3 cm in diameter with a dark necrotic base, raised red edges, and sometimes a yellowish-green exudate. Fever usually is present.

Necrotizing fasciitis is the most extensive form of cellulitis and involves deeper subcutaneous tissues and fascial planes. It may progress to **myonecrosis** of the underlying muscle. Common causes include *S. aureus* and group A streptococcus alone or in combination with anaerobic organisms, such as *Clostridium perfringens*. Risk factors include underlying immunodeficiency, recent surgery or trauma, and varicella infection. Lesions progress rapidly with raised or sharply demarcated margins, although disease typically extends on a deeper plane beyond superficially evident lesions. Warning signs of necrotizing fasciitis include pain out of proportion to evident skin lesions, shock or toxic appearance, or crepitus due to subcutaneous gas formation by anaerobes. Necrotizing fasciitis is a surgical emergency, and early consultation with an experienced surgeon is recommended. Adjunctive tests such as magnetic resonance imaging can confirm the presence of gas in tissues, but obtaining imaging should not delay surgical consultation. Treatment includes rapid surgical debridement of all necrotic tissues and broad-spectrum intravenous antibiotics, such as clindamycin plus ceftazidime or ceftriaxone, with or without an aminoglycoside or vancomycin.

Folliculitis

Folliculitis refers to small, dome-shaped pustules or erythematous papules predominantly caused by *S. aureus* and is located in hair follicles, with superficial, limited inflammatory reaction in the surrounding tissue. **Furuncles (boils)** are deeper hair follicle infections that manifest as nodules with intense surrounding inflammatory reaction. These occur most frequently on the neck, trunk, axillae, and buttocks. A **carbuncle** represents the deepest of hair follicle infections and is characterized by multiseptate, loculated abscesses. Boils and carbuncles frequently require incisional drainage. Superficial folliculitis can be treated with topical therapy, such as an antibacterial chlorhexidine wash or an antibacterial lotion or solution such as clindamycin 1%, applied twice a day for 7–10 days. Oral antibiotics are necessary for unresponsive cases, or for furuncles and carbuncles.

P. aeruginosa folliculitis (**hot tub folliculitis**) presents as pruritic papules; pustules; or deeper, purple-red nodules predominantly on skin areas covered by a swimsuit after bathing in hot tubs. Folliculitis develops 8–48 hours after exposure, usually without associated systemic symptoms, and resolves in 1–2 weeks without treatment.

Perianal Dermatitis

Perianal dermatitis (perianal streptococcal disease) is caused by group A streptococcus and is characterized by well-demarcated, very tender, marked perianal erythema extending 2 cm from the anus. Manifestations include anal pruritus and painful defecation, sometimes with blood-streaked stools. The differential diagnosis includes diaper dermatitis, candidiasis,

pinworm infection, and anal fissures. Optimal treatment is oral penicillin or amoxicillin.

SUPERFICIAL FUNGAL INFECTIONS

Cutaneous fungal infections are common in children (Table 98.1). The estimated lifetime risk of developing a **dermatophytosis** is 10–20%. Diagnosis is usually established by visual inspection and may be confirmed by potassium hydroxide (KOH) examination or fungal culture of skin scrapings from the margins of the lesion. **Recommended tinea treatment** is usually for 4–6 weeks duration and is continued for 2 weeks after resolution of symptoms; topical anti-fungal creams (e.g., miconazole, clotrimazole, ketoconazole, tolnaftate) are appropriate for tinea corporis, tinea pedis, and tinea cruris, whereas tinea capitis requires oral treatment. The diagnosis of **onychomycosis** should be confirmed by KOH examination and fungal culture. Recommended treatment is terbinafine or itraconazole for at least 12 weeks.

SUPERFICIAL VIRAL INFECTIONS

Herpes Simplex Virus

Primary herpetic infections can occur after inoculation of the virus at any mucocutaneous site. Herpes simplex virus type 1 (HSV-1) is common in children and classically causes gingivostomatitis, whereas HSV-2 classically infects the genitalia as a sexually transmitted infection (see Chapter 116), though HSV-1 may cause approximately 30% of genital herpes, and HSV-2 can cause gingivostomatitis. For the cutaneous manifestations of neonatal HSV infection, see Chapter 65.

Herpes gingivostomatitis involves the gingivae and may spread throughout the oropharynx. Herpes labialis (**cold sores or fever blisters**) is limited to the vermilion border involving skin and mucous membranes. Clinical manifestations of primary HSV gingivostomatitis include typical oropharyngeal vesicular lesions with high fever, malaise, stinging mouth pain, drooling, fetid breath, and cervical lymphadenopathy.

Herpetic skin lesions are quite painful and characteristically begin as erythematous papules that quickly progress to the characteristically grouped, 2- to 4-mm, fluid-filled vesicles on an erythematous base. Removal of the vesicle roof reveals a small, sharply demarcated ulcer with a punched-out appearance. The characteristic grouped vesicles distinguish HSV from chickenpox (see Chapter 97). Within several days, the vesicles become pustular, rupture, and encrust. Diagnosis is made clinically, or with viral culture, fluorescent antibody staining, or, most often, polymerase chain reaction. Scarring is uncommon, but there may be residual hyperpigmentation. After primary infection, the virus remains latent in nerve dorsal root ganglia. About 20–40% of adults experience recurrent oral episodes of HSV labialis throughout life. Recurrences occur in roughly the same location and may be preceded by prodromal symptoms of tingling or burning without fever or lymphadenopathy.

Viral paronychia (**herpetic whitlow**) is a painful, localized infection of a digit, usually of the distal pulp space, with erythematous and occasionally vesiculopustular eruption. It occurs in children who suck their thumbs, bite their nails, and those with herpetic gingivostomatitis. **Herpes gladiatorum** occurs in wrestlers and rugby players who acquire cutaneous herpes from close body contact with other players' cutaneous infections. Cutaneous HSV infection in persons with an

TABLE 98.1 Superficial Fungal Infections

NAME	ETIOLOGY	MANIFESTATIONS	DIAGNOSIS	THERAPY
DERMATOPHYTES				
Tinea capitis (ringworm)	<i>Microsporum audouinii</i> , <i>Trichophyton tonsurans</i> , <i>Microsporum canis</i>	Prepubertal infection of scalp, hairshafts; <i>black dot</i> alopecia; <i>T. tonsurans</i> common in Blacks	<i>M. audouinii</i> fluorescence: blue-green with Wood lamp*; +KOH, culture	Griseofulvin; terbinafine, itraconazole
Kerion	Inflammatory reaction to tinea capitis	Swollen, boggy, crusted, purulent, tender mass with lymphadenopathy; secondary distal <i>id</i> reaction common	As above	As above, plus steroids for <i>id</i> reactions
Tinea corporis (ringworm)	<i>M. canis</i> , <i>Trichophyton rubrum</i> , others	Slightly pruritic ringlike, erythematous papules, plaques with scaling and slow outward expansion of the border; check cat or dog for <i>M. canis</i>	+KOH, culture; <i>M. canis</i> fluorescence: blue-green with Wood lamp; differential diagnosis: granuloma annulare, pityriasis rosea, nummular eczema, psoriasis	Topical miconazole, clotrimazole, terbinafine, tolnaftate, ciclopirox, oxiconazole, or butenafine
Tinea cruris (jock itch)	<i>Epidermophyton floccosum</i> , <i>Trichophyton mentagrophytes</i> , <i>T. rubrum</i>	Symmetric, pruritic, scrotal sparing, scaling plaques	+KOH, culture; differential diagnosis: erythrasma (<i>Corynebacterium minutissimum</i>)	See Tinea corporis, Therapy; wear loose cotton underwear
Tinea pedis (athlete's foot)	<i>T. rubrum</i> , <i>T. mentagrophytes</i>	Moccasin or interdigital distribution, dry scales, interdigital maceration with secondary bacterial infection	+KOH, culture; differential diagnosis: <i>C. minutissimum</i> erythrasma	Medications as above; wear cotton socks
Tinea unguium (onychomycosis)	<i>T. mentagrophytes</i> , <i>T. rubrum</i> , <i>Candida albicans</i>	Uncommon before puberty; peeling of distal nail plate; thickening, splitting of nails	+KOH, culture	Oral terbinafine or itraconazole
Tinea versicolor	<i>Malassezia furfur</i>	Tropical climates, steroids or immunosuppressive drugs; uncommon before puberty; chest, back, arms; oval hypopigmented or hyperpigmented in Blacks, red-brown in Whites; scaling patches	+KOH; orange-gold fluorescence with Wood lamp; differential diagnosis: pityriasis alba	Topical selenium sulfide, oral ketoconazole
YEAST				
Candidiasis	<i>C. albicans</i>	Diaper area, intense erythematous plaques or pustules, isolated or confluent	+KOH, culture	Topical nystatin; oral nystatin treats concomitant oral thrush

*Wood lamp examination uses an ultraviolet source in a completely darkened room. *Trichophyton* usually has no fluorescence. KOH, Potassium hydroxide.

underlying skin disorder (e.g., atopic dermatitis) can result in **eczema herpeticum (Kaposi varicelliform eruption)**, a disseminated cutaneous infection. There may be hundreds of herpetic vesicles over the body, usually concentrated in the areas of skin affected by the underlying disorder.

Treatment with oral valacyclovir or famciclovir may shorten duration of disease for primary and recurrent infection. Prophylactic antiviral therapy may be warranted in those with frequent recurrences. Neonates, persons with eczema, and persons with immunodeficiency are at increased risk for disseminated and severe HSV disease and should receive intravenous acyclovir therapy.

Human Papillomaviruses (Warts)

Warts are caused by the human papillomaviruses (HPVs), non-enveloped, double-stranded DNA viruses that infect skin and

mucous membrane keratinocytes. More than 100 HPV serotypes have been identified, with different serotypes accounting for the variation in location and clinical presentations. There are 15–20 **oncogenic (high-risk)** types, including 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, and 68. HPV types 16 and 18 are associated with 70% of cases of cervical cancer as well as vulvar and vaginal cancers. Regardless of the infecting serotype, all warts are associated with hyperplasia of the epidermal cells.

Warts occur at all ages. **Common warts (verruca vulgaris)**, associated with HPV types 1 and 2, are the most frequent form (71%). They occur in school-age children, with a prevalence of 4–20%. They are transmitted by direct contact or by fomites and have an incubation period of approximately 1 month before clinical presentation. The common wart is a painless, well-circumscribed, small (2–5 mm) papule with a papillated or verrucous surface typically distributed on the fingers, toes, elbows, and knees. They also may be found on the nose, ears, and lips.

Filiform warts are verrucous, exophytic, 2-mm papules that have a narrow or pedunculated base. **Flat warts (verruca plana)** are associated with HPV types 3 and 10 and are multiple, flat-topped, 2- to 4-mm papules clustered on the dorsal surface of the hands, on the soles of the feet (**plantar warts**), or on the face. Plantar warts may be painful because of the effect of pressure and friction on the lesions. **Genital warts (condylomata acuminata)** are associated with the HPV types 6 and 11 (90%). They are flesh-colored, hyperpigmented, or erythematous lesions that are filiform, fungating, or plaquelike in appearance and involve multiple sites on the vulva, vagina, penis, or perineum. Genital warts are the most common sexually transmitted infection, with 1 million new cases annually.

Warts typically are self-limited and resolve spontaneously over years without specific treatment. Treatment options are available for common and flat warts as well as condylomata acuminata. Topical preparations for common and flat warts disrupt infected epithelium (using salicylic acid, liquid nitrogen, or laser therapy) and result in the cure of approximately 75% of patients. Treatment of anogenital warts requires assessment of size, number, patient preference, cost, convenience, and adverse effects (see [Chapter 116](#)). Medications may include topical podophyllotoxin or imiquimod. Additional treatment methods include laser ablation and immunotherapy with intralesional interferon; immunotherapy may result in significant toxicities.

The most serious consequence of HPV infection is **cervical cancer** (>12,000 new cases annually) as well as vulvar, vaginal, penile, anal, and head and neck cancers. Three HPV vaccines are licensed for use in the United States: a quadrivalent vaccine (which protects against serotypes 6, 11, 16, and 18), a bivalent vaccine (types 16 and 18), and a 9-valent vaccine (types 6, 11, 16, 18, 31, 33, 45, 52, and 58), though only the 9-valent vaccine is currently available in the United States. The two- to three-dose regimen of these vaccines (based on age) has more than a 98% efficacy in preventing the precancerous dysplasia that precedes cervical cancer.

Molluscum Contagiosum

Molluscum contagiosum virus, a poxvirus that replicates in host epithelial cells, produces discrete, small (2–4 mm), pearly flesh-colored or pink, nontender, dome-shaped papules with central umbilication. Papules occur most commonly in intertriginous regions, such as the axillae, groin, and neck. They rarely occur on the face or in the periocular region. The infection typically affects toddlers and young children and is acquired through direct contact with infected individuals. Spread occurs by autoinoculation. Infection with molluscum contagiosum may be complicated by a surrounding dermatitis. Severely immunocompromised persons or persons with extensive atopic dermatitis often have widespread lesions.

Diagnosis is clinical. Lesions are self-limited, resolving over months to years, and usually no specific treatment is recommended. Available treatment options are limited to destructive modalities, such as cryotherapy with topical liquid nitrogen, vesicant therapy with topical 0.9% cantharidin, or removal by curettage, and should be reserved for extensive disease.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 99

Lymphadenopathy

ETIOLOGY

Lymphoid tissue steadily enlarges until puberty and subsequently undergoes progressive atrophy. Lymph nodes are most prominent in children 4–8 years of age. Normal lymph node size is less than 10 mm in diameter, with the exceptions of 15 mm for inguinal nodes, 5 mm for epitrochlear nodes, and 2 mm for supraclavicular nodes, which are usually not palpable. **Lymphadenopathy** is enlargement of lymph nodes and occurs in response to a wide variety of infectious, inflammatory, and malignant processes. **Generalized lymphadenopathy** is enlargement of two or more noncontiguous lymph node groups, whereas **regional lymphadenopathy** involves one lymph node group only.

Lymphadenitis is acute or chronic inflammation of lymph nodes. Acute lymphadenitis usually results when bacteria and toxins from a site of acute inflammation are carried via lymph to regional nodes. Numerous infections cause lymphadenopathy and lymphadenitis (Tables 99.1 and 99.2). Causes

of inguinal regional lymphadenopathy also include sexually transmitted infections (see Chapter 116). Regional lymphadenitis associated with a characteristic skin lesion at the site of inoculation defines various **lymphocutaneous syndromes**. **Lymphangitis** is an inflammation of subcutaneous lymphatic channels that presents as an acute bacterial infection, usually caused by *Staphylococcus aureus* and group A streptococci.

Cervical lymphadenitis is the most common regional lymphadenitis among children and is most commonly associated with pharyngitis caused by group A streptococcus (see Chapter 103), respiratory viruses, and Epstein-Barr virus (EBV). Other common infectious causes of cervical lymphadenitis include *Bartonella henselae* (cat-scratch disease) and nontuberculous mycobacteria; tularemia, endemic mycoses, tuberculosis, *Nocardia*, and *Actinomyces* are less common causes.

EPIDEMIOLOGY

Acute cervical lymphadenitis as a complication of group A streptococcal infection parallels the incidence of streptococcal pharyngitis (see Chapter 103). Many cases are caused by *S. aureus*. EBV and cytomegalovirus (CMV) are ubiquitous, with most infections occurring in young children, who may often be asymptomatic or only mildly symptomatic. Risk factors for other specific causes of lymphadenopathy may be indicated by past medical and surgical history; preceding trauma; exposure to animals; contact with persons infected with tuberculosis; sexual history; travel history; food and ingestion history, especially of undercooked meat or unpasteurized dairy products; and current medications.

CLINICAL MANIFESTATIONS

The exact location and detailed measurement of the size, shape, characteristics, and number of involved nodes should be noted, including their consistency, mobility, tenderness, warmth, fluctuance, firmness, and adherence to adjacent tissues. Important findings include presence or absence of dental disease, oropharyngeal or skin lesions, ocular disease, other nodal enlargement, and any other signs of systemic illness, including hepatosplenomegaly and skin lesions.

Acute cervical lymphadenopathy associated with pharyngitis is characterized by small and rubbery lymph nodes in the anterior cervical chain with minimal to moderate tenderness. **Suppurative cervical lymphadenitis**, frequently caused by *S. aureus* or group A streptococcus, shows erythema and warmth of the overlying skin with moderate to exquisite tenderness.

EBV is the primary cause of **infectious mononucleosis**, a clinical syndrome characterized by fever, fatigue and malaise, cervical or generalized lymphadenopathy, tonsillitis, and pharyngitis. The pharynx shows enlarged tonsils with exudate and, sometimes, an enanthem with pharyngeal petechiae. Lymphadenopathy is typically bilateral and is most prominent in the anterior and posterior cervical and submandibular lymph nodes and less commonly involves axillary and inguinal lymph nodes. Other findings include splenomegaly in 50% of cases, hepatomegaly in 10–20%, and maculopapular or urticarial rash in 5–15%. A diffuse, erythematous rash develops in approximately 80% of mononucleosis patients treated with amoxicillin. EBV, a member of the herpesvirus family, infects B lymphocytes and is spread by salivary secretions. After primary infection, EBV is maintained latently in multiple episomes in the cell nucleus of resting B lymphocytes and establishes a life-long infection that remains clinically inapparent. Most persons shed EBV intermittently, with approximately 20% of healthy individuals shedding EBV at any given time.

CMV, *Toxoplasma gondii*, adenoviruses, hepatitis B virus, hepatitis C virus, and acute HIV infection, also known as

acute retroviral syndrome, can cause an infectious mononucleosis-like syndrome with lymphadenopathy. Compared with EBV infection, infectious mononucleosis-like illness caused by CMV has minimal pharyngitis and often more prominent splenomegaly; it often presents with fever only. The most common manifestation of toxoplasmosis is asymptomatic cervical lymphadenopathy, but approximately 10% of cases of acquired toxoplasmosis develop chronic posterior cervical lymphadenopathy and fatigue, usually without significant fever.

The cause of **cat-scratch disease** is *Bartonella henselae*, a small, pleomorphic, gram-negative bacillus that stains with Warthin-Starry silver stain. *B. henselae* causes apparently asymptomatic bacteremia in cats; kittens under 1 year of age are more likely to harbor the organism. *B. henselae* is transmitted to humans by bites and scratches, which may be minor. *B. henselae* also causes bacillary angiomatosis and peliosis hepatis in persons with HIV infection (see Chapter 125). Cat-scratch disease typically presents with a cutaneous papule or conjunctival granuloma at the site of bacterial inoculation, followed by lymphadenopathy of the draining regional nodes. The nodes are tender with suppuration in approximately 10% of cases. Lymphadenopathy may persist 1–4 months. Less common features of cat-scratch disease include erythema nodosum, osteolytic lesions, encephalitis, oculoglandular (Parinaud) syndrome, hepatic or splenic granulomas, endocarditis, polyneuritis, and transverse myelitis.

Lymphadenitis caused by **nontuberculous mycobacteria** usually is unilateral in the cervical, submandibular, or preauricular nodes and is more common in toddlers. The nodes are relatively painless, and firm initially, but gradually soften, rupture, and drain over time. The local reaction is circumscribed, and overlying skin may develop a violaceous discoloration without warmth. Fever and systemic symptoms are minimal or absent. Nontuberculous mycobacteria are ubiquitous in soil, vegetation, dust, and water. *Mycobacterium* species commonly causing lymphadenitis in children includes *M. avium* complex, *M. scrofulaceum*, and *M. kansasii*. *M. tuberculosis* uncommonly causes cervical lymphadenitis.

LABORATORY AND IMAGING STUDIES

Initial laboratory tests of regional lymphadenopathy include a complete blood count and inflammatory markers. Infectious mononucleosis is characterized by lymphocytosis with **atypical lymphocytes**; thrombocytopenia and elevated hepatic enzymes are common.

Cultures of infected skin lesions and tonsillar exudates should be obtained. Isolation of group A streptococci from the oropharynx suggests, but does not confirm, streptococcal cervical lymphadenitis. A blood culture should be obtained from children with systemic signs and symptoms of bacteremia.

Serologic testing (or polymerase chain reaction) for EBV and for *Bartonella henselae* should be obtained if there are appropriate findings. The most reliable test for diagnosis of acute EBV infection is the immunoglobulin M (IgM) antiviral capsid antigen (Fig. 99.1). Heterophile antibody is also diagnostic but is not reliably positive in children younger than 4 years with infectious mononucleosis.

Extended diagnostic work-up for lymphadenopathy is guided by the specific risk factors in the history and physical examination findings. Chest radiograph, throat culture, antistreptolysin O titer, and serologic tests for CMV, HIV,

FIGURE 99.1 Idealized time course for the development of antibody to different Epstein-Barr virus antigens after primary infection with the virus. IgM, Immunoglobulin M; VCA, viral capsid antigen. (From Katz BZ. Epstein-Barr virus [mononucleosis and lymphoproliferative disorders]. In: Long SS, Prober CG, Fischer M, eds. *Principles and Practice of Pediatric Infectious Diseases*. 5th ed. Philadelphia: Elsevier; 2018 [fig. 208-3].)

toxoplasmosis, syphilis, tularemia, *Brucella*, histoplasmosis, and coccidioidomycosis may be indicated. Genital tract evaluation and specimens should be obtained with regional inguinal lymphadenopathy (see Chapter 116). Screening for tuberculosis can be performed using the standard tuberculin skin test (which may be positive with atypical mycobacterial infection) or an interferon- γ release assay (which is uncommonly positive with atypical mycobacterial infection, based on the infecting species).

Aspiration is indicated for acutely inflamed, fluctuant cervical lymph nodes, especially those larger than 3 cm in diameter or not responding to antibiotic treatment. Ultrasound or computed tomography may help in establishing the extent of lymphadenopathy and defining whether the mass is solid, cystic, or suppurative with abscess formation. Pus from fluctuant lesions should be examined by Gram and acid-fast stains and cultured for aerobic and anaerobic bacteria and mycobacteria. Biopsy should be performed if **lymphoma** is suspected because of firm, matted, nontender nodes and other systemic findings.

If the diagnosis remains uncertain and lymphadenopathy persists despite empirical antibiotic therapy for presumed *S. aureus* and group A streptococcus, excisional biopsy of the entire node should be performed, if possible. This is curative for nontuberculous mycobacterial lymphadenitis. Biopsy material should be submitted for histopathology as well as Gram, acid-fast, Giemsa, periodic acid-Schiff, Warthin-Starry silver (*B. henselae*), and methenamine silver stains. Cultures for aerobic and anaerobic bacteria, mycobacteria, and fungi should be performed.

DIFFERENTIAL DIAGNOSIS

Noninfectious causes of cervical swelling and/or lymphadenopathy include congenital (branchial cleft) and acquired cysts, Kawasaki disease, autoimmune diseases (e.g., sarcoidosis, autoimmune lymphoproliferative syndrome [ALPS], or Kikuchi-Fujimoto disease), benign neoplasms, and malignancies.

The differential diagnosis for generalized lymphadenopathy includes juvenile idiopathic arthritis; systemic lupus erythematosus; and serum sickness and other adverse drug reactions, especially with phenytoin and other antiepileptic medications, allopurinol, isoniazid, antithyroid medications, and pyrimethamine. Leukemia, lymphoma, and occasionally neuroblastoma may have lymph nodes that are usually painless, uninflamed, matted, and firm (see [Chapters 155 and 156](#)). A syndrome of **periodic fever, aphthous stomatitis, pharyngitis, and adenitis** is an occasional cause of recurrent fever and cervical lymphadenitis (see [Chapter 103](#)).

TREATMENT

Management of *lymphadenopathy* and *lymphadenitis* depends on patient age, associated findings, node size and location, and severity of the acute systemic symptoms. In children, most cases of cervical lymphadenopathy, without other signs of acute inflammation, require no specific therapy and usually regress within 2–3 weeks. Progression to lymphadenitis or development of generalized lymphadenopathy requires further evaluation.

The specific treatment of cervical lymphadenitis depends on the underlying etiology. Empirical treatment targeting *S. aureus* and group A streptococcus includes a penicillinase-resistant penicillin (e.g., oxacillin) or first-generation cephalosporin (e.g., cefazolin). For patients with hypersensitivity to β -lactam antibiotics, or if community-acquired methicillin-resistant *S. aureus* is suspected, clindamycin is appropriate. Response to empirical antibiotic therapy for suppurative cervical lymphadenitis obviates the need for further evaluation. Absence of a clinical response within 48–72 hours is an indication for further laboratory evaluation and possible aspiration or excisional biopsy and culture.

There is no specific treatment for infectious mononucleosis. Cat-scratch disease usually does not require treatment because the lymphadenopathy resolves in 2–4 months without sequelae. Azithromycin may hasten resolution and reduces node size at 30 days, but no benefit is evident at 90 days. Aspiration and drainage are indicated for suppurative nodes. The recommended treatment of cervical lymphadenitis caused by nontuberculous mycobacteria is complete surgical excision. Antimycobacterial drugs are necessary only if there is recurrence or inability to excise infected nodes completely, or if *M. tuberculosis* is identified, which requires 6 months of antituberculous chemotherapy (see [Chapter 124](#)).

COMPLICATIONS AND PROGNOSIS

Most acute infections caused by *S. aureus* and group A streptococcus respond to treatment and have an excellent prognosis. Complications such as abscess formation, cellulitis, and rarely bacteremia may occur. Abscess formation is treated with incision and drainage in conjunction with appropriate antibiotic therapy.

Infectious mononucleosis usually resolves in 2–4 weeks, but fatigue and malaise may wax and wane for several weeks to months. EBV also is associated with numerous complications during the acute illness. Neurologic complications include seizures, aseptic meningitis syndrome, Bell palsy, transverse myelitis, encephalitis, and Guillain-Barré syndrome. Hematologic complications include Coombs-positive

hemolytic anemia, antibody-mediated thrombocytopenia, hemophagocytic syndrome, and, rarely, aplastic anemia. Corticosteroids have been used for respiratory compromise resulting from tonsillar hypertrophy, which responds rapidly, and for thrombocytopenia, hemolytic anemia, and neurologic complications. Splenic rupture is very rare. **X-linked lymphoproliferative disease**, which results from a mutation of the *SH2D1A* gene located in the Xq25 region, manifests as fulminant infectious mononucleosis with primary EBV infection and progresses to malignant lymphoproliferative disease or dysgammaglobulinemia.

EBV infection, as with other herpesviruses, persists for life, but no symptoms are attributed to intermittent reactivation in immunocompetent hosts. EBV is causally associated with nasopharyngeal carcinoma; Burkitt lymphoma; Hodgkin disease; leiomyosarcoma in immunocompromised persons; and EBV lymphoproliferative disease, especially in posttransplant patients and in those with AIDS.

Lymphadenitis caused by nontuberculous mycobacteria has an excellent prognosis. Surgical excision of cervical lymphadenitis caused by nontuberculous mycobacteria is curative in over 97% of cases.

PREVENTION

The incidence of suppurative regional lymphadenitis reflects the incidence of predisposing conditions, such as dental disease, streptococcal pharyngitis, otitis media, impetigo, and other infections involving the face and scalp. There are no guidelines to prevent lymphadenitis caused by nontuberculous mycobacteria.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 100

Meningitis

ETIOLOGY

Meningitis, inflammation of the leptomeninges, can be caused by bacteria, viruses, or—rarely—fungi. The term **aseptic meningitis** principally refers to viral meningitis, but meningitis with negative cerebrospinal fluid (CSF) bacterial cultures may be seen with other infectious organisms (Lyme disease, syphilis, tuberculosis), parameningeal infections (brain abscess, epidural abscess, subdural empyema), chemical exposure (nonsteroidal antiinflammatory drugs, intravenous immunoglobulin), autoimmune disorders, and other diseases, including Kawasaki disease.

The organisms commonly causing bacterial meningitis (Table 100.1) before the availability of current conjugate vaccines were *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Neisseria meningitidis*. In the United States, the rates of *H. influenzae* type b and *S. pneumoniae* meningitis have declined substantially after the introduction of targeted vaccines. The bacteria causing neonatal meningitis are the same

AGE	MOST COMMON	LESS COMMON
Neonatal	Group B streptococcus <i>Escherichia coli</i> Other enteric gram-negative bacilli	<i>Listeria monocytogenes</i> <i>Enterococcus faecalis</i> <i>Neisseria meningitidis</i> <i>Streptococcus pneumoniae</i> Other streptococci <i>Citrobacter species</i> <i>Salmonella</i> <i>Pseudomonas aeruginosa</i> <i>Haemophilus influenza</i> <i>Staphylococcus aureus</i> (NICU only)
>1–3 months	<i>S. pneumoniae</i> Gram-negative bacilli Group B streptococcus	<i>N. meningitidis</i> <i>Salmonella</i>
>3 months	<i>S. pneumoniae</i> <i>Neisseria meningitidis</i>	Gram-negative bacilli Group B streptococcus

NICU, Neonatal intensive care unit.

as those causing neonatal sepsis (see Chapter 65). In older children, *S. pneumoniae* and *N. meningitidis* remain the most common causes of bacterial meningitis. Staphylococcal meningitis primarily occurs after neurosurgery or penetrating head trauma.

Partially treated meningitis refers to bacterial meningitis complicated by antibiotic treatment before the lumbar puncture (LP), which may result in negative CSF cultures, although other CSF findings suggestive of bacterial infection persist. In this case, the etiology can sometimes be confirmed by polymerase chain reaction (PCR) of the CSF.

The most common viruses causing meningitis are enteroviruses and parechoviruses. Other viruses that can cause meningitis include herpes simplex virus (HSV), Epstein-Barr virus (EBV), cytomegalovirus (CMV), lymphocytic choriomeningitis virus (LCMV), many arboviruses (see Chapter 101), and HIV. The mumps virus can cause meningitis in unvaccinated children. Less frequent infectious causes of meningitis include *Borrelia burgdorferi* (Lyme disease), *Bartonella henselae* (cat-scratch disease), *Mycobacterium tuberculosis*, *Toxoplasma*, fungi (*Cryptococcus*, *Histoplasma*, *Blastomycosis*, and *Coccidioides*), and parasites (*Angiostrongylus cantonensis*, *Naegleria fowleri*, *Baylisascaris*, and *Acanthamoeba*).

EPIDEMIOLOGY

The incidence of bacterial meningitis is highest among children under 1 year of age, especially infants under 2 months of age. Extremely high rates are found in Native Americans, Alaskan Natives, and Australian aboriginals, suggesting that genetic factors play a role in susceptibility. Other risk factors include acquired or congenital immunodeficiencies, functional or anatomic asplenia, cochlear implantation, penetrating head trauma, recent neurosurgical procedure, and crowding, such as that which occurs in some daycare centers or college and military dormitories. A CSF leak (fistula), resulting from congenital anomaly or following a basilar

skull fracture, increases the risk of meningitis, especially that caused by *S. pneumoniae*.

Enteroviruses and parechoviruses cause meningitis with peaks during summer and fall in temperate climates. These infections are more prevalent among infants, school-age children, and immunocompromised persons. The prevalence of arboviral meningitis or encephalitis is determined by geographic distribution and seasonal activity of the arthropod (mosquito) vectors. In the United States, most arboviral infections occur during the summer and fall.

CLINICAL MANIFESTATIONS

Preceding upper respiratory tract symptoms may occur; however, rapid onset is typical of infections with *S. pneumoniae* and *N. meningitidis*. Indications of meningeal inflammation include headache, irritability, nausea, nuchal rigidity, lethargy, photophobia, and vomiting. Fever is usually present. Kernig and Brudzinski signs of meningeal irritation are often positive in children older than 12 months. In young infants, signs of meningeal inflammation may be minimal with only irritability, depressed mental status, and/or poor feeding present. Focal neurologic signs, seizures, arthralgia, myalgia, petechial or purpuric lesions, sepsis, shock, and coma may occur. Symptoms of increased intracranial pressure include headache, diplopia, ptosis, and vomiting; a bulging fontanelle may be present in infants. Papilledema is uncommon unless there is occlusion of the venous sinuses, subdural empyema, or brain abscess.

LABORATORY AND IMAGING STUDIES

If bacterial meningitis is suspected, an LP should be performed unless there is evidence of cardiovascular instability or of increased intracranial pressure (due to the risk of herniation). Routine CSF examination includes a white blood cell count with differential, protein and glucose levels, and Gram stain (Table 100.2). CSF should be cultured for bacteria and, when appropriate, fungi and mycobacteria. PCR is used to diagnose bacterial as well as viral meningitis. Peripheral leukocytosis is common, and blood cultures may be positive depending on the organism and whether there was antibiotic pretreatment. Ideally, CSF should be obtained prior to empirical therapy; however, antibiotics should not be delayed if there is an inability to perform an LP. If imaging is required prior to the LP, blood cultures should be sent and antibiotics started, prior to a computed tomography (CT) scan. Interpretation of CSF in children who received prior antibiotics is complicated. In meningococcal meningitis, CSF can rapidly become sterile, often within 1–2 hours, and most commonly with a single dose of therapy. Sterilization of the CSF in *S. pneumoniae* meningitis may also occur within a few hours. In these cases, PCR is useful in identifying causative bacteria.

DIFFERENTIAL DIAGNOSIS

Many disorders other than meningitis and encephalitis may show signs of meningeal irritation and increased intracranial pressure, including trauma, hemorrhage, rheumatic diseases, and malignancies. Seizures can be associated with central nervous system (CNS) infection or can be the sequelae of brain edema, cerebral infarction or hemorrhage, or vasculitis.

TABLE 100.2 Cerebrospinal Fluid Findings in Various Central Nervous System Disorders

CONDITION	PRESSURE (CM H ₂ O)	LEUKOCYTES (CELLS/μL)	PROTEIN (mg/dL)/ GLUCOSE (mg/dL)	COMMENTS
Normal	10–20	<5; 60–70% lymphocytes, 30–40% monocytes, 1–3% neutrophils	20–45/>50% of serum glucose	WBC up to 10–20 cells/μL can be normal in neonates
Acute bacterial meningitis	Usually elevated (>25)	>100; usually thousands; PMNs predominate	100–500/usually <40 or <40% of serum glucose	Organisms may be seen on Gram stain and recovered by culture
Partially treated bacterial meningitis	Normal or elevated	1–10,000; PMNs usual but mononuclear cells may predominate if pretreated for extended period	>100/depressed or normal	Pretreatment may render CSF sterile, but bacteria may be detected by PCR
Tuberculous meningitis	Usually elevated; may be low because of CSF block in advanced stages	10–500; PMNs early but lymphocytes and monocytes predominate later	100–500; may be higher in presence of CSF block/ usually <50	Acid-fast smear and culture or mycobacteria PCR may be positive. Adenine deaminase can be used to aid in the diagnosis
Fungal	Usually elevated	10–500; PMNs early; mononuclear cells predominate later	20–500/usually <50	Organisms may be seen on smear, in culture, or by India ink preparation, and antigen may be positive in cryptococcal disease
Viral meningitis or meningoencephalitis	Normal or slightly elevated	10–1,000; PMNs early; mononuclear cells predominate later	<50/normal or depressed	Viruses may be detected by PCR
Abscess (parameningeal infection)	Normal or elevated	0–100 PMNs unless rupture into CSF	20–200/normal	Profile may be completely normal

CSF, Cerebrospinal fluid; PCR, polymerase chain reaction; PMNs, polymorphonuclear leukocytes.

TREATMENT

Treatment of bacterial meningitis focuses on sterilization of the CSF by antibiotics (Table 100.3) and maintenance of adequate cerebral and systemic perfusion. Due to increasing *S. pneumoniae* resistance, an empiric third-generation cephalosporin plus vancomycin should be administered until culture results and antibiotic susceptibility testing are available. Ceftriaxone, cefepime, or ceftriaxone are also adequate to treat *N. meningitidis*, *H. influenzae*, and some *E. coli*. For infants younger than 2 months of age, ampicillin is added to cover the possibility of *Listeria monocytogenes*. Duration of treatment is 5–7 days for *N. meningitidis*, 7–10 days for *H. influenzae*, and 10–14 days

for *S. pneumoniae*. Meningitis caused by gram-negative bacilli should generally be treated a minimum of 21 days or 14 days beyond the first negative CSF culture, whichever is longer.

Dexamethasone as **adjunctive therapy** initiated just before or concurrently with the first dose of antibiotics significantly diminishes the incidence of hearing loss resulting from *H. influenzae* meningitis. The role of adjuvant steroids for diminishing neurologic sequelae and mortality for pneumococcal and meningococcal meningitis in children is less clear.

Supportive therapy involves treatment of dehydration, shock, disseminated intravascular coagulation, syndrome of inappropriate antidiuretic hormone (SIADH), seizures, increased intracranial pressure, apnea, arrhythmias, and coma. Adequate cerebral perfusion must be maintained in the presence of cerebral edema.

TABLE 100.3 Initial Antimicrobial Therapy by Age for Presumed Bacterial Meningitis

AGE	RECOMMENDED TREATMENT	ALTERNATIVE TREATMENTS
Newborns (0–28 days)	Ceftazidime plus ampicillin with or without gentamicin	Ampicillin plus gentamicin
Infants and toddlers (1 mo to 4yr)	Ceftriaxone plus vancomycin	Cefepime plus vancomycin
Children and adolescents (5–13yr) and adults	Ceftriaxone plus vancomycin	Cefepime plus vancomycin

COMPLICATIONS AND PROGNOSIS

SIADH may complicate meningitis and necessitates monitoring of urine output and fluid administration. Persistent fever is common during treatment but also may be related to ineffective treatment or immune complex-mediated pericardial or joint effusions, thrombophlebitis, drug fever, or nosocomial infection. A repeat LP after 48 hours of therapy should be considered for those whose condition has not improved or has worsened, gram-negative meningitis, and for those who received adjunct steroids, which can interfere with the ability to monitor clinical response. CNS imaging should be considered in children who demonstrate focal neurologic signs or

symptoms, or persistently positive CSF cultures. CT with contrast, or magnetic resonance imaging (MRI), is used to detect subdural effusions with *S. pneumoniae* and *H. influenzae* meningitis or brain abscess associated with gram-negative organisms. *Citrobacter koseri* produces neonatal meningitis with a high incidence of brain abscess formation. Neurosurgery should be consulted to consider drainage if a brain abscess is present.

With current management, the mortality rate for bacterial meningitis in children remains significant, up to 15% depending on the organism. Morbidity and mortality are highest with *S. pneumoniae*. Of survivors, up to 30% have sequelae, including deafness, seizures, blindness, paresis, ataxia, or hydrocephalus. All patients with meningitis should have a hearing evaluation before discharge and at follow-up. Learning disabilities and behavioral problems may be more subtle, long-term consequences of infection. Careful developmental follow-up is important. Poor prognosis is associated with young age, long duration of illness before effective antibiotic therapy, seizures, coma at presentation, shock, low or absent CSF white blood cell count in the presence of visible bacteria on CSF Gram stain, and immunocompromised status.

Rarely, relapse may occur 3–14 days after treatment, possibly from parameningeal foci or resistant organisms. Recurrence may indicate an underlying immunologic or anatomic defect that predisposes the patient to meningitis.

PREVENTION

Routine immunizations against *H. influenzae* and *S. pneumoniae* are recommended for children beginning at 2 months of age. Quadrivalent vaccines against *N. meningitidis* (serotypes A, C, Y, and W-135) are recommended at age 11 or 12 years with a booster dose at 16 years, and for children older than 2 months who are at high risk of infection, including functional asplenia, complement deficiencies, and travelers to or residents of hyperendemic areas. A newer vaccine against *N. meningitidis* serotype B is currently recommended for high-risk patients 10 years and older. **Chemoprophylaxis** with rifampin, ciprofloxacin, azithromycin, or ceftriaxone to eradicate the carrier state and decrease transmission is recommended both for index cases with *N. meningitidis* and for their close contacts. For invasive *H. influenzae* type B, prophylaxis consists of rifampin.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 101

Encephalitis

ETIOLOGY

Encephalitis is an inflammatory process of the brain parenchyma, which usually presents with fever, headache, and mental status changes. Encephalitis is a challenging diagnosis in many aspects, as determining its etiology is difficult and treatment options are quite limited. The term

meningoencephalitis is used when meningeal inflammation is also present. Encephalitis is usually an acute infectious process, but it also may be a postinfectious, autoimmune part of a systemic disorder or the result of an indolent viral infection. Encephalitis may be diffuse or localized. Organisms cause encephalitis by one of two mechanisms: (1) direct infection of the brain parenchyma via an extension of meningitis, secondary to viremia, or retrograde spread via peripheral nerves or (2) a postinfectious, immune-mediated response in the central nervous system (CNS) that usually begins several days to weeks after clinical manifestations of the infection.

Viruses are the principal infectious causes of acute infectious encephalitis (Table 101.1). The most common viral causes of encephalitis in the United States are enteroviruses, arboviruses, and herpesviruses. HIV is also an important cause of subacute encephalitis in children and adolescents and may present as an acute febrile illness, but more commonly it is insidious in onset (see Chapter 125). Other less common viral causes of encephalitis include measles, JC virus, lymphocytic choriomeningitis virus (LCMV), rabies, influenza, and Japanese encephalitis. Numerous other infectious etiologies for encephalitis are possible in the appropriate setting, including prion diseases (e.g., Creutzfeldt-Jakob disease) and parasites such as amoeba and *Baylisascaris*, *Bartonella henselae*, *Mycobacterium tuberculosis*, *Plasmodium falciparum*, and *Mycoplasma pneumoniae*. Encephalitis also may result from metabolic, toxic, and neoplastic disorders. In many cases, the cause remains unknown.

Acute disseminated encephalomyelitis (ADEM) is the abrupt development of multiple neurologic signs related to an inflammatory, demyelinating disorder of the brain and spinal cord. ADEM can follow childhood viral infections (such as

TABLE 101.1 Causes of Acute Infectious Encephalitis

VIRUSES	BACTERIA
Enteroviruses	<i>Borrelia burgdorferi</i> (Lyme disease)
Parechoviruses	
Herpes simplex viruses (types 1 and 2)	<i>Bartonella henselae</i> (cat-scratch disease)
EBV	<i>Mycoplasma pneumoniae</i>
Arboviruses (West Nile virus, St. Louis, Japanese, LaCrosse, Powassan, and equine encephalitis viruses)	<i>Rickettsia rickettsii</i> (Rocky Mountain spotted fever)
Cytomegalovirus	PARASITES
Human immunodeficiency virus	<i>Plasmodium falciparum</i>
Rabies virus	<i>Naegleria fowleri</i>
LCMV	<i>Acanthamoeba</i> spp. <i>Baylisascaris</i>
VZV	FUNGI
Influenza virus	<i>Cryptococcus neoformans</i>
Mumps virus	<i>Coccidioides</i> species
Measles virus	<i>Histoplasma capsulatum</i>

EBV, Epstein-Barr virus; LCMV, lymphocytic choriomeningitis virus; VZV, varicella-zoster virus.

measles and chickenpox) or vaccinations and can clinically resemble multiple sclerosis.

Autoimmune encephalitis is a relatively common cause of encephalitis and is associated with specific autoantibodies directed to brain antigens, such as anti-N-methyl-D-aspartate receptor and antimyelin oligodendrocyte glycoprotein antibodies. The presentation is often subacute with psychological manifestations, cortical dysfunction, movement disorders, autonomic dysfunction, and seizures.

EPIDEMIOLOGY

Arboviral and enteroviral encephalitides characteristically appear in clusters or epidemics that occur from midsummer to early fall, although sporadic cases of enteroviral encephalitis occur throughout the year. Herpesviruses and other infectious agents account for additional sporadic cases throughout the year.

Arboviruses tend to be limited to certain geographic areas, reflecting the reservoir and mosquito vector. In North America, West Nile virus and La Crosse encephalitis occur in the summertime, resulting in a range of manifestations from asymptomatic infection to severe neurologic involvement. La Crosse virus is found in the Midwest and southeastern United States, whereas West Nile virus is more disseminated across the country. The principal vectors for West Nile virus are *Culex* mosquitoes, and a broad range of birds serves as its major reservoir.

Herpes simplex virus (HSV) encephalitis can occur in neonates with or without skin lesions via perinatal or postnatal transmission. Beyond the neonatal period, HSV encephalitis can result from primary or recurrent infection with HSV type 1. In the immunocompromised host, other herpes viruses, such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), human herpesvirus 6 (HHV-6), and varicella-zoster virus (VZV), as well as *Toxoplasma gondii* and JC viruses can reactivate and cause encephalitis. Fungal infections of the CNS are rare but can also cause disease in this patient population.

CLINICAL MANIFESTATIONS

Acute infectious encephalitis may be preceded by a prodrome of several days of nonspecific symptoms, such as sore throat, fever, headache, and abdominal complaints followed by the characteristic symptoms of progressive lethargy, behavioral changes, and neurologic deficits. Seizures are common at presentation. Children with encephalitis also may have a maculopapular rash and severe complications, such as fulminant coma, transverse myelitis, anterior horn cell disease, or peripheral neuropathy.

Neonates with HSV encephalitis can present with fever, lethargy, and/or seizures. Vesicular skin lesions typical of cutaneous infection may or may not be present.

DIFFERENTIAL DIAGNOSIS

The diagnosis is established presumptively by the presence of characteristic neurologic signs, typical epidemiologic findings, and evidence of infection by cerebrospinal fluid (CSF) analysis, electroencephalogram (EEG), and brain imaging techniques. Encephalitis may result from infections with bacteria, *Mycoplasma*, *Rickettsia*, fungi, and parasites, and from many

noninfectious diseases, including autoimmune, inflammatory, metabolic diseases (encephalopathy), such as Reye syndrome, hypoglycemia, collagen vascular disorders, drugs, hypertension, and malignancies.

Elucidating a careful history, including immunization record, travel to endemic regions, animal exposures, and geographic and social risk factors, may help to establish the etiology of encephalitis in a patient. If the patient is known to be or found to be immunocompromised, the differential diagnosis must be broadened accordingly.

LABORATORY AND IMAGING STUDIES

The diagnosis of viral encephalitis is supported by examination of the CSF, which typically shows a lymphocytic pleocytosis, a slight elevation in protein content, and a normal glucose level. The CSF occasionally may be normal. Extreme elevations of protein and reductions of glucose suggest tuberculosis, cryptococcal infection, or meningeal carcinomatosis. Blood can be sent for a complete blood count with differential and culture, as well as autoimmune encephalitis antibodies, liver function tests, and infectious serologies.

Neuroimaging studies are often required prior to a lumbar puncture (LP) in these children as they generally have altered mental status. Magnetic resonance imaging (MRI) is generally the study of choice in the diagnosis of encephalitis; however, computed tomography (CT) may be used to exclude contraindications to LP or if MRI is unavailable. Brain imaging may be normal or may show diffuse cerebral swelling of the parenchyma or focal abnormalities. EEG is abnormal and can show diffuse, slow wave activity, although focal changes may be present. A temporal lobe focus on EEG or brain imaging is a characteristic feature of HSV infection.

Serum and CSF testing may help determine an infectious etiology for encephalitis. Depending on the risk factors, serologic studies should be obtained for arboviruses (including West Nile virus, if indicated by the patient risk factors), HIV, EBV, *M. pneumoniae*, *B. henselae*, and Lyme disease. Additional serologic testing for less common pathogens should be performed as indicated by the travel, social, or medical history. In most cases of viral encephalitis, the virus is difficult to isolate from the CSF. Polymerase chain reaction (PCR) tests for HSV, enteroviruses, mycoplasma, West Nile virus, and other viruses are available and can be sent. Viral cultures of stool or throat may also be obtained though they have less utility than rapid multiplex PCR testing. CSF viral culture is not recommended. Even with extensive testing and the use of PCR assays, the cause of encephalitis remains undetermined in one third of cases. Both blood and CSF should be sent to detect brain-specific antibodies present in approximately 95% of patients with autoimmune encephalitis.

Brain biopsy is seldom performed and is generally recommended only if the etiology remains unknown and a patient continues to deteriorate. Rabies encephalitis and prion-related diseases (Creutzfeldt-Jakob disease and kuru) may be routinely diagnosed by culture or pathologic examination of brain biopsy tissue. Brain tissue can be sent for pathology, culture, and PCR testing and may be helpful to identify arbovirus and enterovirus infections, tuberculosis, fungal infections, and noninfectious illnesses, particularly primary CNS vasculopathies and malignancies.

TREATMENT

With the exception of HSV, VZV, CMV, HHV-6, and HIV, there is no specific therapy for viral encephalitis. Management is supportive and frequently requires intensive care unit admission to facilitate aggressive therapy for seizures, timely detection of electrolyte abnormalities, and, when necessary, airway monitoring and protection or reduction of increased intracranial pressure and maintenance of adequate cerebral perfusion pressure.

Intravenous acyclovir is the treatment of choice for HSV and VZV infections. CMV disease is treated with ganciclovir in immunocompromised patients. HHV-6 encephalitis in patients who are post-bone marrow transplant can also be treated with ganciclovir or foscarnet. HIV infections may be treated with a combination of antiretroviral agents. *M. pneumoniae* infections may be treated with doxycycline, fluoroquinolones, or macrolides, although the clinical value of treating encephalitis associated with *Mycoplasma* disease is uncertain.

ADEM has been treated with high-dose intravenous corticosteroids, but it is unclear whether improved outcomes reflect milder cases recognized by MRI, fewer cases caused by measles (which can cause severe ADEM), or improved supportive care. Autoimmune encephalitis has been treated with steroids, intravenous immunoglobulin, and rituximab.

COMPLICATIONS AND PROGNOSIS

Among survivors, symptoms usually resolve over several days to 2–3 weeks. Although most patients with epidemic forms of infectious encephalitis (St. Louis, California, West Nile, and enterovirus infections) in the United States recover without sequelae, severe cases leading to death or substantial neurologic sequelae can occur with virtually any of these neurotropic viruses. Sequelae can include paresis or spasticity, cognitive impairment, weakness, ataxia, and recurrent seizures. Most patients gradually recover some or all of their function. The overall mortality for infectious encephalitis is low, depending on the etiology.

Disease caused by HSV, Eastern equine encephalitis, or *M. pneumoniae* is associated with a worse prognosis, especially in children younger than 1 year of age or with coma. Rabies, with very rare exceptions, is fatal.

Relapses of ADEM occur in 14%, usually within 1 year with the same or new clinical signs. Recurrences of ADEM may represent the onset of multiple sclerosis in childhood.

PREVENTION

The best prevention for arboviral encephalitis is to avoid mosquito-borne or tick-borne exposures and to remove ticks carefully (see [Chapter 122](#)). There are no vaccines in use in the United States for the prevention of arboviral infection or for enteroviruses except for poliomyelitis. There are no specific preventive measures for HSV encephalitis except for cesarean section for mothers with active genital lesions (see [Chapter 65](#)). Rabies can be prevented by pre-exposure or post-exposure vaccination. Influenza encephalitis can be prevented by use of influenza vaccination. Reye syndrome can be prevented by avoiding use of aspirin or aspirin-containing compounds for children with fever as well as use of varicella and influenza vaccines.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 102

The Common Cold

ETIOLOGY

Upper respiratory tract infection (URI), also known as “the common cold,” is a self-limited viral process with prominent symptoms of rhinorrhea and nasal congestion, absent or mild fever, and few systemic manifestations. URIs are the most common cause of human disease and are often a cause of missed work or school, as well as visits to primary care pediatricians. Young children are at highest risk for frequent URI due to their lack of immunity from previous infection and close contact with others who frequently shed virus.

The viruses most commonly associated with colds are rhinoviruses. Other viruses that cause URIs include respiratory syncytial virus (RSV), human metapneumovirus, coronaviruses, coxsackieviruses, influenza, parainfluenza, and adenoviruses. Viral infection of nasal epithelium causes an acute inflammatory response with mucosal infiltration by inflammatory cells and release of cytokines. The host inflammatory response is partly responsible for many of the symptoms.

EPIDEMIOLOGY

URIs occur throughout the year with peak incidence from fall through late spring, reflecting the seasonal prevalence of viral pathogens and confined habitation during colder months. Young children have an average of seven to eight viral infections each year. The number decreases with age, to two to three colds each year by adulthood. Children in out-of-home day care during the first year of life have 50% more URIs than children cared for at home only. With preschool attendance, it is not unusual for children to experience one infection/month of the respiratory virus season. This difference diminishes during subsequent years in day care.

CLINICAL MANIFESTATIONS

URI symptoms typically develop 1–3 days after viral infection and include nasal congestion, rhinorrhea, sore or scratchy throat, and occasional nonproductive cough. Fever, although uncommon in adults, may occur in infants and young children. Symptoms usually persist for approximately 5–7 days, although it can be longer in preschool-aged children. Constitutional symptoms such as fever, myalgia, and headaches generally are present only early in the illness. Respiratory symptoms tend to persist for the duration of the illness. There is often a change in the color or consistency of nasal secretions, which is not necessarily indicative of sinusitis or bacterial superinfection. Examination of the nasal mucosa may reveal swollen, erythematous nasal turbinates.

LABORATORY AND IMAGING STUDIES

Laboratory studies often are not helpful. A nasopharyngeal swab for respiratory virus polymerase chain reaction (PCR) is often obtained in the inpatient setting in immunocompromised patients or for infection prevention reasons. Skin testing, specific immunoglobulin E (IgE) testing, or a **nasal smear** for eosinophils are not routinely performed but may be useful in the evaluation for allergic rhinitis (see [Chapter 79](#)).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of URI includes allergic rhinitis, foreign body (especially with unilateral nasal discharge), sinusitis, pertussis, and pharyngitis. Allergic rhinitis is characterized by absence of fever; eosinophils in the nasal discharge; and other manifestations, such as allergic shiners, nasal polyps, a transverse crease on the nasal bridge, and pale, edematous, nasal turbinate mucosa. Other rare causes of chronic rhinorrhea are choanal atresia or stenosis, cerebrospinal fluid fistula, diphtheria, tumor, congenital syphilis (with *snuffles*), nasopharyngeal malignancy, and granulomatosis with polyangiitis.

TREATMENT

There is no specific therapy for URIs. Antibacterial therapy is not beneficial and instead may cause harm. Management consists of symptomatic therapies. Antihistamines and decongestants are not recommended for children younger than 6 years of age because of adverse effects and lack of benefits. Similarly, cough suppressants and expectorants have not been shown to be beneficial. Vitamin C and inhalation of warm, humidified air are no more effective than placebo. The benefit of zinc lozenges or sprays has been inconsistent in children.

COMPLICATIONS AND PROGNOSIS

Otitis media is the most common complication and occurs in about 5% of children with a URI (see [Chapter 105](#)). Other complications include bacterial sinusitis, which should be considered if rhinorrhea or daytime cough persists without improvement for at least 10–14 days or if severe signs of sinus involvement develop, such as high fever for more than 3 days, facial pain, or facial swelling (see [Chapter 104](#)). Viral infections may lead to exacerbation of asthma and may result in inappropriate antibiotic treatment. In immunocompromised patients viral URIs can progress to lower respiratory tract infections and cause more severe disease.

PREVENTION

There are no proven methods for prevention of colds other than good handwashing and avoiding contact with infected persons. No significant effect of vitamin C or Echinacea for prevention of URIs has been confirmed.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

CHAPTER 103

Pharyngitis

ETIOLOGY

Many infectious agents can cause pharyngitis (Table 103.1), viruses being the most common. **Group A streptococcus** (*Streptococcus pyogenes*) is the most common important

TABLE 103.1 Major Microbial Causes of Acute Pharyngitis

AGENT	SYNDROME OR DISEASE	ESTIMATED PROPORTION OF ALL PHARYNGITIS (%)
BACTERIAL		
Group A streptococcus (<i>Streptococcus pyogenes</i>)	Pharyngitis, tonsillitis, scarlet fever	15–30
Group C and G streptococcus	Pharyngitis, tonsillitis	1–5
<i>Arcanobacterium haemolyticum</i>	Pharyngitis (scarlet fever–like syndrome)	0.5–3
<i>Fusobacterium necrophorum</i>	Lemierre syndrome	Unknown
<i>Mycoplasma pneumoniae</i>	Pharyngitis, pneumonia	Unknown
Other (e.g., <i>Neisseria gonorrhoeae</i> , <i>Corynebacterium diphtheriae</i> , <i>Francisella tularensis</i>)	Pharyngitis, laryngitis, tularemia	<5
VIRAL		
Rhinoviruses (>100 types)	URI	20
Coronaviruses (>4 types, including COVID-19)	URI, acute respiratory distress	>5
Adenoviruses (types 3, 4, 7, 14, 21)	Pharyngoconjunctival fever, acute respiratory disease	5
Herpes simplex viruses (types 1 and 2)	Gingivitis, stomatitis, pharyngitis	4
Parainfluenza viruses (types 1–4)	URI, croup	2
Influenza viruses (types A and B)	Influenza	2
Epstein-Barr virus	Mononucleosis	Unknown
Cytomegalovirus	Mononucleosis	Unknown
Coxsackie virus	Herpangina, hand, foot and mouth disease	Unknown
Unknown		40

URI, Upper respiratory tract infection.

Modified from Hayden GF, Hendley JO, Gwaltney JM Jr. Management of the ambulatory patient with a sore throat. *Curr Clin Top Infect Dis.* 1988;9:62–75.

bacterial cause of pharyngitis. Other bacterial organisms less often associated with pharyngitis include groups C and G streptococci (also β -hemolytic) and rarely *Arcanobacterium haemolyticum* (β -hemolytic, gram-positive rod) and *Francisella tularensis* (gram-negative coccobacillus and cause of tularemia). *Chlamydia pneumoniae* is associated with lower respiratory disease but can also cause sore throat. *Mycoplasma pneumoniae* is associated with atypical pneumonia and may cause mild pharyngitis without distinguishing clinical manifestations. *Neisseria gonorrhoeae* should be considered in a sexually active adolescent or adult with pharyngitis. Other bacteria, including *Staphylococcus aureus*, *Haemophilus influenzae*, and *S. pneumoniae*, are cultured frequently from the throats of children, but their role in causing pharyngitis is unclear.

Many viruses cause acute pharyngitis. Some viruses, such as adenoviruses, are more likely than others to cause pharyngitis as a prominent symptom, whereas other viruses, such as rhinoviruses, are more likely to cause pharyngitis as a minor part of an illness that primarily features other symptoms, such as rhinorrhea or cough. Epstein-Barr virus (EBV), enteroviruses (herpangina), herpes simplex virus (HSV), and primary HIV infection can also produce pharyngitis.

EPIDEMIOLOGY

Sore throat is the primary symptom in approximately one third of upper respiratory tract illnesses. Streptococcal pharyngitis is relatively uncommon before 2–3 years of age, but the incidence increases in young school-age children and then declines in late adolescence and adulthood. Streptococcal pharyngitis occurs throughout the year in temperate climates. The illness often spreads to siblings and classmates. Viral infections generally spread via close contact with an infected person and peak during winter and spring. EBV or cytomegalovirus-related **mononucleosis** (see [Chapter 99](#)) can feature pharyngitis as a prominent symptom and is most common in adolescents and young adults.

CLINICAL MANIFESTATIONS

Pharyngeal inflammation causes cough, sore throat, dysphagia, and fever. If involvement of the tonsils is prominent, the term **tonsillitis** or **tonsillopharyngitis** is often used.

The onset of streptococcal pharyngitis is often rapid and associated with prominent sore throat and moderate to high fever. Headache, nausea, vomiting, and abdominal pain are frequent. In a typical, florid case, the pharynx is distinctly red. The tonsils are enlarged and may be covered with a yellow, blood-tinged exudate. There may be petechiae on the soft palate and posterior pharynx, and the uvula may be red, stippled, and swollen. Anterior cervical lymph nodes are enlarged and tender to touch. However, some children present with only mild pharyngeal erythema without tonsillar exudate or cervical lymphadenitis. Compared with classic streptococcal pharyngitis, the onset of viral pharyngitis is typically more gradual, and symptoms more often include rhinorrhea, cough, and diarrhea. Conjunctivitis, coryza, or oral ulcerations also suggest a viral etiology. The diagnosis of streptococcal pharyngitis cannot be made on clinical features alone.

In addition to sore throat and fever, some patients with streptococcal pharyngitis exhibit the stigmata of **scarlet fever**:

circumoral pallor, strawberry tongue, and a fine diffuse erythematous macular-papular rash. The tongue initially has a white coating, but red and edematous lingual papillae later project through this coating, producing a **white strawberry tongue**. When the white coating peels off, the resulting **red strawberry tongue** is beefy red with prominent papillae. Patients infected with *A. haemolyticum* may present with similar findings.

Gingivostomatitis is characteristic of HSV type 1. **Herpangina** is an enteroviral infection with sudden onset of high fever, vomiting, headache, malaise, myalgia, poor intake, drooling, sore throat, and dysphagia. The oral lesions of herpangina may be nonspecific, but classically there are one or more small, tender, papular, or pinpoint vesicular lesions on an erythematous base scattered over the soft palate, uvula, and tongue. These vesicles enlarge from 1–4 mm over 3–4 days, rupture, and produce small, punched-out ulcers that persist for several days. Similar lesions may be seen in hand-foot-and-mouth disease caused by coxsackieviruses.

LABORATORY EVALUATION

The principal challenge is to distinguish pharyngitis caused by group A streptococcus from pharyngitis caused by viral organisms. A rapid streptococcal antigen test, a throat culture, or both should be performed to improve diagnostic precision and to identify children most likely to benefit from antibiotic therapy. Antigen-based rapid diagnostic tests for streptococcal pharyngitis have excellent specificity of 95–99%. However, the sensitivity of these rapid tests varies, and negative rapid tests should be confirmed by a throat culture or polymerase chain reaction (PCR) as these are the definitive diagnostic tests to establish the presence of streptococcal pharyngitis. However, as many as 20% of positive cultures in children represent chronic **streptococcal carriage** and not acute pharyngitis.

The predictive values of white blood cell count, erythrocyte sedimentation rate, and C-reactive protein are not sufficient to distinguish streptococcal from nonstreptococcal pharyngitis, and these tests are not routinely recommended. The white blood cell count in patients with infectious mononucleosis usually shows a predominance of atypical lymphocytes.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of infectious pharyngitis includes other local infections of the oral cavity, retropharyngeal abscesses (*S. aureus*, streptococci, anaerobes), diphtheria (if unimmunized), peritonsillar abscesses (streptococci, anaerobes, or, rarely, *S. aureus*), and epiglottitis. In addition, neutropenic mucositis (leukemia, aplastic anemia), thrush (candidiasis secondary to T-cell immune deficiency), autoimmune ulceration (systemic lupus erythematosus, Behçet disease), and Kawasaki disease may cause pharyngitis. Pharyngitis can be a feature of the acute retrovirus syndrome associated with primary HIV infection (see [Chapter 125](#)).

Vincent angina or **trench mouth** refers to a virulent form of anaerobic gingivitis and pharyngitis; gray pseudomembranes are found on the tonsils. **Lemierre syndrome** is acute pharyngitis complicated by suppurative thrombophlebitis of the internal jugular vein and septic pulmonary emboli. It primarily occurs in adolescents and is caused by *Fusobacterium necrophorum* (obligate anaerobic gram-negative bacilli).

Ludwig angina is a mixed anaerobic bacterial cellulitis of the submandibular and sublingual regions. It is typically due to spreading from an abscess of the second or third mandibular molar. It also has been associated with tongue piercing. A propensity for rapid spread, glottic and lingual swelling, and consequent airway obstruction makes prompt intervention imperative.

A syndrome of **periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA)** is a rare cause of recurrent fever in children. The fevers begin at a young age (usually <5 years). Episodes last approximately 5 days, with a mean of 28 days between episodes. Episodes are shorter with oral prednisone and do not respond to nonsteroidal anti-inflammatory drugs or antibiotics. Long-term sequelae do not develop.

TREATMENT

Even if untreated, most episodes of streptococcal pharyngitis resolve uneventfully over a few days. Early antimicrobial therapy accelerates clinical recovery by 24–48 hours. The major benefit of antimicrobial therapy is the prevention of acute rheumatic fever (see [Chapter 146](#)). Because the latent (incubation) period of **acute rheumatic fever** is relatively long (1–3 weeks), treatment instituted within 9 days of illness onset is virtually 100% successful in preventing rheumatic fever. Treatment begun after this period, although less than 100% successful, has some preventive value. Therefore antibiotic therapy should be started promptly in children with a positive rapid antigen test, throat culture, or PCR for group A streptococcus or a diagnosis of scarlet fever. In addition, a child who has symptomatic pharyngitis and a history of rheumatic fever, or a recent family history of rheumatic fever, or whose sibling has documented streptococcal infection should be treated.

A variety of antimicrobial agents can be used to treat streptococcal pharyngitis ([Table 103.2](#)). Penicillin or amoxicillin remain first-line therapy. Ten days of treatment is

recommended to prevent rheumatic fever. Intramuscular penicillin G can be used for children who cannot tolerate oral therapy. Cephalosporins have superior pharyngeal bacterial eradication rates compared to penicillin; however, they are only recommended as an alternative option. Five days of azithromycin is also an alternate treatment option for group A streptococcal pharyngitis, although rates of resistance to azithromycin are higher than those to penicillins. Test of cure for patients who respond clinically to treatment is not required. Children with recurrent episodes of group A streptococcal pharyngitis pose a problem, but true treatment failure is rare. Recurrent infection may represent nonadherence, chronic streptococcal carriage in the setting of a viral pharyngitis, or reinfection. A second course of treatment can be administered. Amoxicillin-clavulanate or clindamycin can be effective for eliminating streptococcal carriage.

Specific antiviral therapy is unavailable for most cases of viral pharyngitis. Patients with primary herpetic gingivostomatitis benefit from early treatment with oral acyclovir.

COMPLICATIONS AND PROGNOSIS

Pharyngitis caused by streptococci or respiratory viruses usually resolves completely. The complications of group A streptococcal pharyngitis include local suppurative complications, such as parapharyngeal abscess and other infections of the deep fascial spaces of the neck, and nonsuppurative complications, such as acute rheumatic fever and acute postinfectious glomerulonephritis. Viral upper respiratory tract infections, including infections caused by influenza A, adenoviruses, parainfluenza type 3, and rhinoviruses, may predispose the patient to bacterial middle ear infections.

PREVENTION

Antimicrobial prophylaxis with daily oral penicillin V prevents recurrent streptococcal infections and is recommended following an episode of acute rheumatic fever to prevent recurrences.

PEARLS FOR PRACTITIONERS

See *Infectious Diseases: Pearls for Practitioners* at the end of this section.

TABLE 103.2 Antimicrobial Treatment of Group A Streptococcal Pharyngitis	
Oral penicillin V (2–3 times daily for 10 days)	250–500 mg/dose × 10 days
Intramuscular benzathine penicillin G—for children ≤27 kg:	600,000 U; for larger children and adults: 1.2 million U, given as a single dose
Oral amoxicillin as a single daily dose (50 mg/kg; maximum, 1000–1200 mg)	× 10 days
<i>For persons allergic to penicillin:</i>	
Cephalexin 25 mg/kg/dose BID, maximum dose 500 mg/dose	× 10 days
Clindamycin 6–7 mg/kg/dose TID, maximum dose 300 mg/dose	× 10 days
<i>For persons allergic to β-lactams:</i>	
Azithromycin, children: 12 mg/kg (maximum: 500 mg/dose) on day 1 followed by 6 mg/kg/dose (maximum: 250 mg/dose) OD	on days 2 through 5

BID, Twice daily; OD, once daily; TID, three times daily.

CHAPTER 104

Sinusitis

ETIOLOGY

Sinusitis is a suppurative infection of the paranasal sinuses and most commonly occurs as a complication of an upper respiratory tract infection (URI). Only the maxillary and ethmoid sinuses are present at birth, whereas the sphenoid sinuses are present by 5 years of age. Frontal sinuses begin to develop at 7 years of age and are not completely developed until adolescence. The ostia draining the sinuses are narrow (1–3 mm) and drain into the middle meatus in the **ostiomeatal complex**. The mucociliary system maintains the sinuses as normally sterile.

Indwelling nasogastric and nasotracheal tubes predispose to nosocomial sinusitis.

Obstruction to mucociliary flow, such as mucosal edema resulting from a URI, impedes sinus drainage and predisposes to bacterial proliferation. The bacterial causes of most cases of acute sinusitis are *Streptococcus pneumoniae*, nontypable *Haemophilus influenzae*, and *Moraxella catarrhalis*. *Staphylococcus aureus* and anaerobes emerge as important pathogens in subacute and chronic sinusitis. Fungal sinusitis can occur in immunocompromised patients, especially those with prolonged and/or profound neutropenia.

EPIDEMIOLOGY

The true incidence of sinusitis is unknown. In addition to predisposing URI, other risk factors include allergic rhinitis, cystic fibrosis, immunodeficiency, HIV infection, nasogastric or nasotracheal intubation, primary ciliary dyskinesia, nasal polyps, and nasal foreign body.

CLINICAL MANIFESTATIONS
