Childhood growth patterns and adult height are the result of interactions between genetic and environmental factors. Since Francis Galton's famous study in 1885, it has been known that a child's height is strongly correlated with the height of his or her parents. Later large-scale studies focusing on height variability between twins showed that environmental factors have greater importance during early childhood, whereas genetic factors have a more decisive influence on the height of adolescents and adults.⁷² Recently, the specific genes that control normal height variation have begun to be elucidated by genome-wide association studies (GWAS), which search for statistical associations between adult height and single nucleotide polymorphisms. These studies have identified common allelic variants (usually with a minor allele frequency >5%) that individually exert only a small phenotypic effect, but together determine much of the variability of height.⁷³ This approach was used to identify variants in more than 700 loci that have a significant influence on height. Each of these variants is responsible for approximately 1 mm in height variability per allele and in combination, explain approximately 25% of the heritability in adult height.^{74,75} In addition, 83 lower-frequency coding variants (minor allele frequency ≤1%) have been identified as being responsible for up to 2 cm of height per allele.⁷⁶

Clinical Evaluation of Growth

Measurement

Accurate measurement is the critical cornerstone of all growth evaluations. Although it is often dismissed as simple (after all, how many parents track their kids' growth on a wall in their homes?), two factors make it in fact challenging. First, because growth is defined as the change in length or height over a certain period of time, the two measurements at each end of that time interval must be performed according to identical technique; any deviations by one or the other measurer can introduce artifactual microaccelerations or microdecelerations into the calculated growth that become amplified errors when the velocity is annualized for analysis (Box 11.1). Second, intrinsic to identical technique is correct positioning each and every time, which can be challenging with an infant or child who is fidgety, anxious, bored, developmentally unable to understand or execute the instructions, or physically challenged in achieving and maintaining the correct position (e.g., because

of hypotonia, hypertonia, contractures, balance issues, leg length asymmetry, malformations, injury, or illness). Further compounding the difficulty in maintaining identical technique each and every time are both personnel issues (the same child is commonly measured by different staff members at serial visits because of the time that has lapsed or different locations of care) and equipment issues (which must be calibrated regularly and used appropriately). A final source of error can occur at the recording stage, when the measurement is entered into the medical record, such as transposing digits, other typographical error, or inadvertently recording the measurement in inches or centimeters when it had been measured in the other unit.

Standing height should be measured with a wall-mounted stadiometer. The child should be standing erect against the wall or backboard with shoes off, any interfering hair accessories removed, and the head in the Frankfurt plane (the lower margins of the orbits and the upper margins of the ear canals all lying in the same horizontal plane), that is, looking straight ahead. The head plate, which is lowered on top of the head for the measurement reading, must be firmly fixed such that it is perpendicular to the wall or backboard. Flip-up horizontal bars (floppy arms) on weighing scales, frequently used to measure height, are subject to great errors because of the child's slumping posture and considerable variation in the angle of the horizontal bar.

Recumbent length is similarly measured for infants and toddlers using a recumbent length board, composed of a firm platform, a fixed head plate, and a moveable footplate for reading the measurement. Two people are required for accurate length measurement: one to hold the head in the Frankfurt plane, looking straight up, and the second to keep the knees straight and bring the measuring board to the feet, which must also be secured perpendicular at the ankles. Many practitioners, measuring infants unassisted, lie the patient on the paper covering the examining table, mark off with a pen on the paper the positions of the head and feet, remove the patient, and then use a measuring tape to quantify the distance between the two pen markings. This common technique is highly inaccurate because of incorrect positioning of the infant, movement and crumpling of the paper, and failure to get perpendicular markings by the pen.

Despite well-established, generally accepted protocols for measuring children, studies have shown that it is frequently done improperly.^{77,78} Observation of 55 US primary care practices (44 pediatric, 11 family practice) found measurements were considered accurate (defined as ≤0.5 cm) only 30% of the time, and differed from measurements of the same children by the study investigators by an average of 1.3 cm.⁷⁹ Because the average error exceeded the difference between normal (5 cm/year) and subnormal (4 cm/year) growth velocities, measurement error likely contributes to both inappropriate investigation and/or subspecialist referrals of normally growing children and missed detection of true growth problems in others. However, this is readily corrected through training. Randomization of these same 55 practices to educational intervention and control groups found that measurement accuracy rates rose persistently in the intervention group at 3 months (55% vs. 37% in the control group) and 6 months (70% vs. 34% in the control group) later.⁷⁹ Although many busy primary care practices measure patients only once, triplicate measurements are taken (with the average recorded) as a means

BOX 11.1 Annualized Growth Velocity

$$\text{Annualized growth velocity (units/yr)} = \frac{(\text{height at time 2 minus height at time 1}) \times 12 \text{ months}}{\# \text{ months between times 1 and 2}}$$

of improving accuracy when precision is key (e.g., for children undergoing growth evaluations and treatment in endocrine clinics or participating in research studies).

With the proper equipment, experienced personnel, and a cooperative child, the standing height percentile can be assessed with considerable accuracy. In contrast, even with good measurement technique, the error in short-term growth velocity assessment is problematic.⁷⁷ The relative error (absolute error divided by the measurement) is far greater for growth velocity than for height primarily because the denominator for the growth velocity (the small difference between two successive measurements) is so much smaller than the denominator for the height. For example, for a 5-year-old child with an observed height at the third percentile, the 95% confidence interval spans the second to fourth percentile but the confidence interval for a 12-month height velocity spans the eighth to 52nd percentiles.⁷⁷ As a result, even with 1-year growth velocity, children can easily be misclassified as having a normal versus abnormal growth velocity.⁷⁷ Trying to measure growth velocity over periods less than a full year results in a relative measurement error that is even greater. Growth velocity, measured over a year, was found to have little diagnostic validity to identify children with isolated idiopathic GH deficiency or Turner syndrome.⁸⁰ Height velocity had to be measured over a 3-year period to achieve acceptable validity.⁸⁰ Thus overreliance on calculated growth velocity may be misleading. However, it is important for the clinician to identify children with poor height and/or weight gain, which can indicate an important underlying disorder. As an alternative to calculated growth velocities, declines in height and/or weight percentiles on a standard growth chart can provide valuable clues to a diminished growth rate.⁷⁷

Growth Charts

Because normal growth follows a predictable pattern, growth charts are constructed depicting this pattern as sequential centile curves showing the distribution of selected body measurements (usually length or height, weight, and weight-for-length or body mass index [BMI]) in children of a given country. Growth is fastest during the fetal period and gradually slows during infancy, with an approximate length increase of 25 cm over the first year of life and 10 to 15 cm over the second year. During infancy, children commonly cross length centiles (physiological rechanneling) as they transition from prenatal to postnatal growth determinants; maternal and pregnancy health and nutrition have a major impact on the former, whereas the latter normally aligns with the child's genetic height potential. After the second birthday, the linear growth rate continues to decline, but more gradually, and shifting centile channels is abnormal. With the onset of puberty, statural growth accelerates, resulting in the pubertal growth spurt, after which the decline in linear growth rate resumes, causing height gain to gradually grind to a halt. However, attainment of adult body composition continues in the transition period that follows.

The population selected for reference is important when judgments are made about the height and growth of an individual. Multiple growth charts have been constructed for US children in past decades, differing in the racial and socioeconomic composition of the reference populations upon which they were based. Growth charts for children of other countries are likewise available, reflecting the different height distributions of the local populations. The most recent and currently recommended US growth charts, published in 2000 by the Centers for Disease Control and Prevention (CDC; available at https://www.cdc.gov/growthcharts/cdc_charts.htm), are based on several cross-sectional data sources and introduced US pediatric

BMI charts. Because the CDC and other national charts are used for clinical judgment despite being reference charts (i.e., observationally describing how children in the populations grow), the World Health Organization (WHO) set out to create growth standard charts (i.e., depicting how healthy children *should* grow). The 2006 WHO growth charts (available at: https://www.cdc.gov/growthcharts/who_charts.htm) are based on longitudinal measurements from birth to age 2 years of 882 children from six different countries, representing racial diversity yet growing under "ideal" conditions, and cross-sectional data on other children after age 2 years. Thus the CDC recommends use of the 2006 WHO growth charts under age 2 years and the 2000 CDC growth charts after age 2 years in assessing growth of US children.⁸¹ One important distinction is that the WHO charts are based on breastfed infants versus the mostly formula-fed infants of the CDC charts, resulting in differently shaped weight curves that can alter the perceived rates of failure to thrive depending on the feeding modality of the infants assessed clinically.

Two special categories of growth charts are also helpful. Velocity charts plot annual increments rather than height (distance) and are tempo adjusted, allowing for the variation in timing and intensity of the adolescent growth spurt. These charts may be helpful to assess the growth patterns of children with slower or more rapid tempo of maturation ("early and late bloomers"), whose variations are effectively lost in the cross-sectional height charts that average growth across peers in different developmental periods.⁸² One limitation to such longitudinal growth charts is that their data were derived from relatively small, nonrepresentative population samples recorded a long time ago. A second limitation is that the large relative error in growth velocity measurements, discussed earlier, creates both uncertainty in the individual child's data and also in the reference data upon which the growth velocity charts were based. Thus based on studies of measurement error, Voss and colleagues concluded, "Although velocity charts are attractive in concept, they seem to be no more discriminating than height charts in practice, and may be clinically deceptive unless interpreted with great care."⁷⁷ Alternatively, growth charts that show height, rather than growth velocity, but are based on longitudinal data, may be helpful for children with slow or rapid tempo of maturation.⁸²

The second special category of growth charts includes specific charts for children with particular genetic syndromes.⁸³ These charts are used in essentially the same way as the charts for normal children. Deviation of growth from the appropriate disease-related growth curve suggests the possibility of a second underlying problem, such as acquired hypothyroidism in a patient with Down or Turner syndrome.

Body Proportions

The skeleton does not grow proportionally. The upper-to-lower body segment ratio starts at 1.7 at birth, indicating a trunk considerably longer than the lower extremities. However, after birth, the lower extremities grow more rapidly than the trunk, and the ratio drops to approximately 1.0 by 10 years of age. Early cessation of linear growth, such as that which occurs in precocious puberty, results in persistently childlike proportions (short limbs compared with the trunk), whereas prolonged growth, such as occurs in hypogonadism, creates a long-limbed habitus.⁸⁴ Limb to trunk proportions can be assessed by three different techniques, all incorporating standing height measurement for comparison. For the upper-to-lower segment ratio, the lower body segment is measured from the upper border of the pubic symphysis to the floor while the patient is standing straight. This lower segment length is subtracted from the standing height to determine the upper segment length and

then divided by the lower segment length to determine the ratio, which can be compared with reference data.⁸⁵ The second technique measures the arm span (between the tips of the middle fingers with the arms fully extended perpendicular to the torso, again with the child standing straight against the wall) for comparison with the standing height. Normally arm span is less than standing height before age 8 years, equal to height at ages 8 to 12 years, and greater than height above age 12 years.⁸⁵ The third technique measures the sitting height, which is divided by the standing height to yield the sitting

height index. The sitting height index is sensitive for detecting disproportionate growth of the trunk (vertebrae) versus the lower extremities and can be used to screen for specific causes of disproportionate short stature, such as SHOX deficiency and hypochondroplasia.⁸⁶ Excellent reference data are available from NHANES III^{87,88} (Table 11.2).

Disproportions can occur not only between the limbs and trunk but also in specific limb segments, categorizing patients into specific diagnostic groups. Rhizomelia refers to disproportionate shortening of the proximal limbs (humerus and

femur), *mezomelia* to disproportionately shortened middle portion of the limbs (radius/ulna and tibia/fibula), and *acromelia* to disproportionately shortened distal limbs (hands and feet). Thus every child who presents with a growth problem should be evaluated for disproportionality because this information helps to narrow the differential diagnosis, including the possibility of skeletal dysplasias.⁸⁹

Skeletal Maturation

Normal variation in rates of maturation among children and adolescents impacts growth prognosis, as children with more time to grow can achieve taller adult heights. An anteroposterior (AP) radiograph of the nondominant hand and wrist is used to determine the child's bone age as a quantitative determination of somatic maturation. The bone age assesses the degree to which the skeleton has ossified. In the human embryo, the skeleton first forms out of cartilage, and then later the cartilage is remodeled into bone. This process continues throughout childhood. In the long bones, this ossification begins as a primary ossification center in the middle of the bone shaft and then spreads outward. Later, secondary ossification centers form in the epiphyses and also spread outward. However, the primary and secondary ossification centers remain separated during childhood by a thin layer of cartilage, termed the *growth plate*, which is responsible for bone elongation and therefore height gain. In adolescence, as growth comes to a halt, the growth plate itself is finally ossified, an event termed *epiphyseal fusion*, leaving cartilage only at the articular surface. Because bone is more radiopaque than cartilage or soft tissues, a radiograph of the left hand and wrist reveals how far along the ossification has proceeded in an individual child. The image is then compared with published standards (Greulich and Pyle⁹⁰ or Tanner-Whitehouse [TW]⁹¹). There are separate sets of standards for boys and girls. If, for example, a patient's bone age image is most similar to the standard for a 9-year-old child, then the patient is said to have a bone age of 9 years. Recently, an automated method to determine bone age has been developed.⁹²

Just like other auxological measures, bone ages have normal ranges, based on age and gender. The normal ranges define the normal variance between bone age and chronological age of a child. Discordance among skeletal centers, with maturity levels differing between bone groups, can be a normal variant. Because bone age assignment is such a subjective measure, it is prudent for pediatric endocrinologists to make their own readings rather than simply rely on radiologists' reports. This will eliminate interreader variability between repeated studies, thereby improving the validity of longitudinally following bone age progression in a child.

The bone age mirrors the tempo of physical development of the child, particularly reflecting the progression of growth plate senescence, and indicates the remaining growth potential. Knee films can be used instead at very young ages when hand/wrist films are not yet informative because of developmentally appropriate lack of ossification. The bone age is also more closely associated than the chronological age with the timing of central puberty in some situations, for example, boys with congenital adrenal hyperplasia, familial male-limited precocious puberty, and idiopathic short stature.⁹³ However, surprisingly, the bone age does not predict pubertal onset better than does chronological age in normal children.^{94,95}

Even before obtaining a bone age, a clinician can surmise a child's rate of maturation by examining their teeth; the degree of dental maturation tends to correlate with skeletal maturation (i.e., delayed dentition can imply delayed bone age).⁹⁶

Skeletal maturation, like skeletal growth, is highly regulated by endocrine, nutritional, and genetic factors. In general,

BOX 11.2 Gender Adjusted Midparental Height Formulae

For males: [(mother's height + 13 cm^a) + father's height] divided by 2
For females: [(father's height - 13 cm^a) + mother's height] divided by 2

^aFor English units, 5 inches can be added or subtracted instead of 13 cm.

factors that positively regulate linear growth, such as thyroid hormone, GH, estrogen, and nutritional intake, also positively regulate skeletal maturation, whereas factors that negatively regulate growth, such as glucocorticoids in high concentration, also negatively regulate skeletal maturation.

Prediction of Adult Height

Adult height predictions are used to try to determine which children are growing toward a normal adult height. The "normal" range for adult height can be defined by the outer centiles demarcated on the country's growth chart, recognizing that the centiles selected for this purpose (e.g., 5th and 95th or 3rd and 97th) are arbitrarily chosen.

Because height is a highly heritable trait, a more specific target can be established from the heights of the child's biological parents. It is important to measure the parents' heights rather than rely on self-reports, which are often inaccurate. The two parents' heights can be combined using the formulae for gender-adjusted midparental height (Box 11.2), which adjust for the 13-cm (5-inch) difference between the mean adult male and female heights, and provide the midparental height ± 2 SD (1 SD would be about 5 cm, or 2 inches) as the "normal" adult height range for their offspring. However, the adjusted midparental height assumes that the child's height is inherited from the parents in a polygenic fashion, with multiple inherited polymorphisms contributing to the child's height. It does not apply to monogenic conditions. If, for example, one of the two parents is short because of a heterozygous mutation in *SHOX* and the other parent is of normal height, the offspring will tend to be either short, like the affected parent, or of normal stature, like the unaffected parent, not halfway in between. Even for polygenic inheritance, empirical data indicate that children of short parents tend not to be as short as their parents and tall children tend not to be as tall as their parents. For example, when the midparental height is -2 SD, the children's heights tend to be closer to -1 SD.⁹⁷

The simplest approach to adult height prediction is to assume that the child's height centile will remain fairly constant until adulthood. However, this method is not accurate and may fail if the child has an advanced or delayed bone age, a condition that affects growth, or an early or late timing of puberty.

There are three popular methods for predicting adult height that take skeletal maturation (i.e., bone age) into account, and all are gender specific. The most commonly used of the three methods, the Bayley-Pinneau prediction tables from 1952,⁹⁸ uses longitudinal data derived from healthy US children living in Cleveland to estimate the fraction of growth remaining at each bone age (by the Greulich-Pyle method⁹⁰). Adult height is predicted by combining the child's bone age with the height measured at the time of the radiographic study. The prediction tables and the prediction error are provided in the Greulich and Pyle Atlas.⁹⁰ The Greulich and Pyle bone age (read either manually or with an automated system) can also be used in a more sophisticated mathematical prediction model (currently available online), which appears to have a slightly greater accuracy than the Greulich and Pyle tables in children with idiopathic

short stature.⁹² The TW method, derived from British children, uses TW standards for bone age assessment, in which each bone in the hand and wrist is assessed individually.⁹¹ In addition to the bone age and measured height, this method factors in chronological age, parental heights, and in girls, the occurrence of menarche. The third method for predicting adult height is the Roche-Wainer-Thissen (RWT) method.⁹⁹ This method takes into account the weight or nutritional status of the child and uses recumbent length instead of standing height (calculated as 1.25 cm greater than standing height). The five predictor variables in the RWT method are recumbent length, weight, bone age, chronological age, and parental heights. An additional method of height prediction has more recently been developed that uses more sophisticated mathematical methods and may show better accuracy than previous methods. It is currently available online.⁹²

Unfortunately, even using bone age, height predictions are not highly accurate. The prediction error is considerable but does decrease with age. For example, using the Bailey-Pinneau tables for girls, the prediction can err for a 9-year-old child by approximately 7.4 cm or 3 inches (2 SD of measurement error), and by approximately 3 cm or 1.2 inches for a 13-year-old child. Furthermore, these prediction methods and the associated error estimates are based on data from healthy children. There may be systematic errors in the setting of illness or in idiopathic short stature. For example, these methods overpredict adult height in untreated precocious puberty, Turner syndrome, and primordial short stature.¹⁰⁰ Sources of inaccuracy in adult height prediction include the inaccuracy of the bone age estimation itself, the inability to predict pubertal onset and tempo, and the difficulty taking into account effects of disease. A small difference in bone age determination can lead to a great difference in adult height prediction, especially during the pubertal growth spurt. A computer simulation, comparison study of three methods for adult height prediction—Bailey-Pinneau, RWT, and Khamis-Roche (calculates adult height without bone age from the child's height, weight, and midparental height, using gender and age-specific coefficients)¹⁰¹—found poor overall agreement among the three methods ($\kappa = 0.21$ for boys and negative for girls) in predicting adult height under the 1.2nd percentile (the threshold for the US Food and Drug Administration [FDA]-approved indication of growth hormone treatment for idiopathic short stature).¹⁰² It is important for both clinicians and patient-families to understand the considerable limitations of height prediction.

Inheritance of Stature

Much of the normal variability of height between individuals is caused by a polygenic influence. Multiple genetic variants, both common and rare, each having a small or moderate effect on linear growth, combine to determine the individual's height.^{74,76} However, short or tall stature, especially when severe or associated with other abnormalities, can also be primarily monogenic, that is, caused by a single variant that has a strong effect on linear growth. These monogenic causes may be identified because they follow classic Mendelian inheritance patterns,¹⁰³ usually autosomal dominant or autosomal recessive and less often X-linked. Clinically, the inheritance pattern is investigated by eliciting a careful family history of the heights of the extended family members, which can be visualized with a written pedigree. For a more detailed discussion, see section on Diagnostic Approach to the Patient with Short Stature later in this chapter. When the pedigree suggests a polygenic inheritance pattern, the clinician can calculate the adjusted midparental height, which provides an estimate of the likely adult height of the child, based on the

heights of the two parents. This topic is discussed in more detail in a previous section of this chapter: Clinical Evaluation of Growth—Prediction of Adult Height

DISORDERS OF CHILDHOOD GROWTH

Many disorders affect childhood growth, particularly decreasing growth to cause short stature. Many of the major causes are discussed later. However, the list is not exhaustive. An extensive, organized list can also be found within the International Classification of Pediatric Endocrine Diagnoses (ICPED, <http://www.icped.org/>).¹⁰⁴

Short Stature

Short stature results from decreased growth plate chondrogenesis. The decreased chondrogenesis can be caused by factors intrinsic to the growth plate (primary growth impairment) or can be secondary to factors elsewhere in the body that secondarily affect growth plate chondrocytes (secondary growth impairment) (Fig. 11.4).

Primary growth plate impairment can involve abnormalities in paracrine signaling, cartilage matrix, or intracellular factors. In some conditions, the defect in growth plate chondrogenesis causes bones to be not only short but also malformed, in which case the condition is called a *skeletal dysplasia* or, more precisely, a *chondrodysplasia*, for example, ACH. Often, genetic defects that affect the growth plate also affect the development of other tissues, leading to a syndrome that includes not only short stature but also other congenital anomalies and organ dysfunction, for example, NS or pseudohypoparathyroidism 1A.

Secondary growth impairment can involve nutritional deficiencies, endocrine abnormalities, inflammatory disorders, and extracellular fluid abnormalities. Often these disorders are caused by a defect in some organ system other than the skeleton, such as the kidneys, pituitary, thyroid, or immune system. These disorders occurring elsewhere in the body then lead to an abnormal concentration of some molecules that are needed for normal growth plate chondrocyte function. These molecules can include steroid or polypeptide hormones, proinflammatory cytokines, or small molecules, such as phosphate or hydrogen ion.

Both primary and secondary growth impairment can be monogenic, oligogenic, polygenic, or nongenetic. Some conditions affect fetal growth, and thus the child is born small for gestational age. Other conditions affect only postnatal growth so that the child is born at a size appropriate for gestation age, and the short stature develops subsequently. Yet other conditions affect both prenatal and postnatal growth.

Causes of Short Stature

Secondary Growth Impairment.

Nutritional Deficiencies. Adequate nutrition is required to support optimal statural growth, and there is often a lag between weight deceleration/acceleration and height deceleration/acceleration. Malnutrition can result from insufficient dietary intake, malabsorption or some other gastrointestinal process, or a combination of the two.

Malnutrition is the most common cause of poor growth globally, with insufficient dietary intake (total calorie and/or protein-calorie malnutrition) often related to food insecurity and poverty.^{105,106} Malnutrition is also common in higher socioeconomic communities, when energy demands (e.g., increased because of illness, sports or activities) are not met by intake (e.g., because of unstructured meals, picky eating, fear

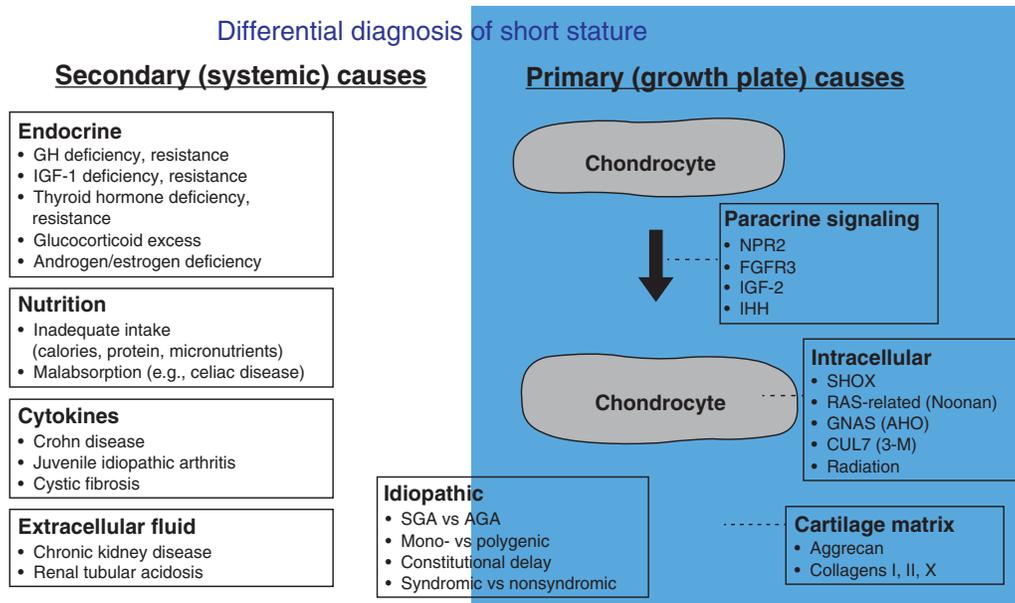

Fig. 11.4 The differential diagnosis of short stature. Short stature is caused by decreased growth plate chondrogenesis, which can result either from a local abnormality, within the growth plate itself, or a systemic abnormality, which then secondarily affects growth plate chondrocytes. The local causes include defects in autocrine/paracrine signaling, cartilage matrix, and intracellular regulatory systems. The systemic causes include endocrine, nutritional, cytokine, and extracellular fluid abnormalities. Idiopathic short stature is likely to be highly heterogeneous in etiology and include both systemic and local mechanisms. For each category, the diagram shows some examples of specific disorders and genes involved but does not present a complete list of known causes.

of obesity).¹⁰⁷ Decreased nutrient intake can result from oropharyngeal malformations (e.g., Pierre Robin sequence, cleft lip/palate), abnormal oral-motor function (e.g., pervasive developmental delay), as well as loss of appetite because of certain medications (e.g., stimulants for treatment of attention deficit hyperactivity disorder or chemotherapeutic agents). Eating disorders (e.g., anorexia nervosa) involve disturbed eating behaviors related to an altered body image or food avoidance because of phobias or sensory aspects of food.¹⁰⁸ Malabsorption can also cause malnutrition, and disorders such as celiac disease, IBD, or cystic fibrosis can present as isolated growth failure.^{109–111} Bone age and puberty are often delayed.

In addition to malnutrition, deficiency of certain micronutrients can impair statural growth. The frequent occurrence of concurrent deficiencies complicates the research and literature on any isolated micronutrient. Although iron deficiency is often found in children with nutritional growth stunting and should be corrected, multiple metaanalyses and systematic reviews of randomized controlled intervention trials of iron supplementation showed that iron therapy had no significant effect on growth in iron-replete children.¹¹² In contrast, human growth retardation (and male hypogonadism) from zinc deficiency was first reported by Prasad and colleagues in 1963,¹¹³ and several, but not all, systematic reviews show height and/or weight increase from zinc supplementation in children.¹¹² Zinc ion is required for activity of over 300 enzymes (zinc metalloenzymes), including DNA polymerase, ribonucleic acid (RNA) polymerase and thymidine kinase, which are important for nucleic acid and protein synthesis and cell division. Bone contains large amounts of zinc where it plays an important role in skeletal development, and zinc deficiency reduces IGF-1 production, cellular IGF-1 responsiveness, and growth response to GH treatment of children who are GH deficient.^{114,115}

Careful assessment of weight and height progression will identify children who are not gaining weight and growing

appropriately. Taking a detailed dietary history is essential to establishing this diagnosis, such as a 3-day diet diary for analysis of any macro- or micronutrient deficits. Treatment is, of course, nutritional repletion, which can involve patient-family education, behavior modification, dietary supplements and in severe cases, tube feedings, as well as treatment of any underlying gastrointestinal issues. However, it is important to have in mind, that several conditions that cause short stature are associated with low BMI (or have low BMI as a component of their phenotype), such as Silver-Russell syndrome (SRS), NS, and Bloom syndrome.

Endocrine Deficiencies

Growth Hormone Deficiency/Insensitivity.

Disorders of GH/IGF axis comprise a large and heterogeneous group of conditions with distinct phenotypes (Table 11.3). Clinical and hormonal evaluations are usually the cornerstones of diagnoses of these disorders.

Growth Hormone Deficiency. GH deficiency is a rare disorder with a prevalence of approximately 1 in 4000 during childhood. GH deficiency may be isolated (IGHD) or combined with other hormone deficiencies, when it is known as combined or multiple pituitary hormone deficiency (CPHD/MPHD). The condition may be congenital or acquired (Table 11.4).¹¹⁶ Early diagnosis and treatment is critical to ensure optimal final height outcomes. The diagnosis of GH deficiency is based on a combination of auxology, exclusion of other pathology leading to short stature, biochemical investigation of the GH-IGF-1 axis, and imaging of the hypothalamopituitary area.⁸⁰ More recently, a molecular diagnosis may be sought in those with “idiopathic” GH deficiency or MPH (see Table 11.1); however, the majority of patients with IGH deficiency or with CPHD remain to be explained in terms of etiology. Before evaluation of the GH-IGF-1 axis, other diagnoses, such as familial short stature, hypothyroidism, Turner syndrome, celiac disease, chronic illness,

TABLE 11.3 Phenotype Caused by Growth Hormone-Insulin-Like Growth Factor Axis Genetic Defects

	Gene	Inheritance	Growth Pattern	Hormone Measurement			Additional Features
				GH	IGF-1	IGFBP-3	
GH deficiency	multiple	AR/AD	varying severity/ postnatal	↓ to ↓↓↓	↓ to ↓↓↓	↓ to ↓↓↓	Midline defects, deficiency of other pituitary hormones
Bioinactive GH	<i>GH1</i>	AR/AD	varying severity/ postnatal	↑↑	↓↓	↓↓	Growth and IGF-1 improve after exogenous GH
GH insensitivity (GHI)	<i>GHR</i>	AR > AD	severe/postnatal	NI to ↑↑	↓ to ↓↓↓	↓ to ↓↓↓	Growth and IGF-1 do not improve after exogenous GH. Low GHBP in 70% of cases
GHI associated with immune dysfunction	<i>STAT5b</i>	AR > AD	severe/postnatal	↑↑	↓↓	↓↓	GHI phenotype with immune dysfunction and elevated PRL
Ternary complex defects	<i>IGFALS</i>	AR	mild/postnatal	NI to ↑	↓↓	↓↓↓	Laboratory abnormality disproportionate to mild short stature, (IGFBP-3 lower than IGF1 concentrations)
IGF1 defects	<i>PAPPA2</i>	AR	varying severity	↑↑	↑↑↑	↑↑↑	Mild microcephaly. Low free IGF-1 ^a
	<i>IGF1</i>	AR/AD	severe/pre- and postnatal	↑↑	↓↓↓↓	NI or ↑	Microcephaly, sensorineural deafness, developmental delay, intellectual disability
IGF2 defects	<i>IGF2</i>	ADp	severe/pre- and postnatal	NI or ↑	NI or ↑	NI or ↑	Phenotype resembling Silver Russell syndrome and low IGF-2 concentrations ^a
Bioinactive IGF-1	<i>IGF1</i>	AR	severe/pre- and postnatal	↑↑	↑↑↑↑	NI	Microcephaly, sensorineural deafness, developmental delay, intellectual disability, insulin resistance ^a
IGF insensitivity	<i>IGF1R</i>	AD > AR	varying severity/pre- and postnatal	NI to ↑↑	NI to ↑↑	NI to ↑↑	Variable clinical findings in the dominant forms. Microcephaly, developmental delay and intellectual disability may be present

^aPhenotype based on a limited number of patients/families.

The listed characteristics are typical of the associated disorders but may be absent in some children with these conditions. ↑, Increase; ↓, decrease; AD, autosomal dominant; ADp, autosomal dominant with paternal transmission; AR, autosomal recessive; GH, growth hormone; IGF, insulin-like growth factor; IGFBP, insulin-like growth factor binding protein; NI, normal; PRL, prolactin.

TABLE 11.4 Congenital and Acquired Causes of Growth Hormone Deficiency

1. CONGENITAL
- Genetic (see Table 11.2)
- Associated with structural defects of the brain
• Agenesis of the corpus callosum
• Septo-optic dysplasia
• Holoprosencephaly
• Encephalocele
• Hydrocephalus
- Associated with midline facial defects
• Cleft lip/palate,
• Single central incisor
• Cornelia de Lange Syndrome
• CHARGE syndrome
2. ACQUIRED CAUSES
Tumors in and around pituitary area, e.g., craniopharyngioma, germinoma
Metastatic tumors
Cystic lesions
Radiotherapy
Chemotherapy
Brain trauma
Inflammation/Infection, e.g., sarcoidosis, Langerhans cell histiocytosis, tuberculosis meningitis
Infiltration
Pituitary infarction
Psychosocial deprivation

such as Crohn disease or renal failure, and skeletal dysplasias should be excluded. Consensus guidelines on the diagnosis of GH deficiency in childhood were published in 2000,¹¹⁷ (<https://doi.org/10.1210/jcem.85.11.6984>) and suggest investigation into the following scenarios:

- 1) Severe short stature, defined as a height more than 3 SD below the mean.
- 2) Height more than 1.5 SD below the midparental height.
- 3) Height more than 2 SD below the mean and a height velocity over 1 year more than 1 SD below the mean for chronological age, or a decrease in height SD of more than 0.5 over 1 year in children over the age of 2 years.
- 4) In the absence of short stature, a height velocity more than 2 SD below the mean over 1 year or more than -1.5 SD sustained over 2 years, which may occur in GH deficiency presenting in infancy or in organic acquired GH deficiency.
- 5) Signs indicative of an intracranial lesion.
- 6) Signs of MPHID.
- 7) Neonatal symptoms and signs of GH deficiency.

The presentation in the neonatal period can include hypoglycemia, prolonged conjugated hyperbilirubinemia (usually with associated ACTH deficiency), and micropenis. Birth size is typically within the normal range, although there may be a reduction of approximately 10%, which occurs typically late in pregnancy. Growth velocity is reduced during the first year of life in children with severe GH deficiency with growth failure

manifesting by 6 months of age, but the phenotype evolves after 1 year of age in those with milder GH deficiency. The earliest manifestations are a reduction in height velocity followed by a reduction in height SDS adjusted for mean parental height SDS. The child's height SDS will ultimately fall below -2 SD, the time taken depending on the severity and duration of GH deficiency. A child with severe GH deficiency often has midface hypoplasia, hypotonia, a high-pitched voice, immature appearance, delayed dentition, thin sparse hair, slow nail growth, and truncal adiposity. GH deficiency is also associated with effects on cognition. In mice with GH deficiency, reduced spatial learning and memory has been reported whereas in untreated children with GH deficiency IQ, verbal comprehension and processing speed are reduced. In children and adults, the neurocognitive defects in GH deficiency are improved by GH therapy. With prompt recombinant human GH (rhGH) treatment, the outlook for final height is excellent. Other hormone deficiencies may require treatment; in particular those with structural abnormalities of the hypothalamopituitary region are more likely to evolve and develop other hormone deficiencies.

Causes of growth hormone deficiency.

Congenital disorders of hypothalamic development. Hypothalamopituitary dysfunction can arise from congenital malformations of the brain or hypothalamus or of the pituitary gland. Anencephaly results in a pituitary gland that is small or abnormally formed and frequently ectopic. Holoprosencephaly, resulting from abnormal midline development of the embryonic brain, is also typically associated with hypothalamic insufficiency. The clinical spectrum of holoprosencephaly can range from cyclopia to hypertelorism, accompanied by absence of the philtrum or nasal septum and midline clefts of the palate or lip. In these situations, the classic endocrine feature is diabetes insipidus (DI), often accompanied by GH, thyroid-stimulating hormone (TSH), and ACTH deficiencies.

Debate continues as to whether the incidence of GH deficiency is increased in cases of simple clefts of the lip and/or palate alone. Clearly, children with clefts who are growing abnormally require further evaluation, and both GH deficiency and CPHDs are more frequent in this cohort. SOD is a rare, congenital, heterogeneous anomaly with a prevalence ranging from 6.3 to 10.9 per 100,000.^{118,119} The condition is defined by the presence of any two of three features: midline forebrain defects, such as absence of the septum pellucidum and/or corpus callosum; optic nerve hypoplasia (ONH); and hypopituitarism caused by hypothalamopituitary maldevelopment. De Morsier, in 1956, described the postmortem findings of ONH and agenesis of the septum pellucidum and coined the term *SOD*, also known as *De Morsier syndrome*. Approximately 30% of patients with SOD manifest the complete clinical triad, 62% of patients have some degree of hypopituitarism, and 60% have an absent septum pellucidum.¹²⁰ The condition is equally prevalent in males and females. ONH may be unilateral or bilateral and may be the first presenting feature, with the later onset of endocrine dysfunction. Bilateral ONH is more common (88% as compared with 12% unilateral cases). In addition, there appears to be little correlation between the size of the optic nerve and its visual function. Neuroradiological abnormalities are present in up to 75% to 80% of patients with ONH. Pituitary hypoplasia may manifest as endocrine deficits varying from isolated GH deficiency to panhypopituitarism. There has been some suggestion that abnormalities of the septum pellucidum and hypothalamopituitary axis on neuroimaging can predict the severity of endocrine dysfunction. A decrease in growth rate because of GH deficiency is the most common feature, with hypoglycemia and polyuria and polydipsia being less common. Either sexual precocity or failure to develop in puberty may occur. Abnormal

hypothalamic neuroanatomy or function and DI may be a feature. The endocrinopathy evolves with a progressive loss of endocrine function over time. The most common endocrinopathy is GH deficiency followed by TSH and ACTH deficiency. Gonadotropin secretion may be retained in the face of other pituitary hormone deficiencies. Neurological deficit is common, but not invariably so, and deficits range from global retardation to focal deficits, such as epilepsy or hemiparesis. Other neuroanatomic abnormalities include cavum septum pellucidum, cerebellar hypoplasia, schizencephaly, and aplasia of the fornix. An association between SOD and other congenital anomalies, such as digital abnormalities, is not uncommon.

The etiology of SOD has remained largely unknown until recently. Both genetic and environmental factors have been implicated in the etiology of the condition.^{121,122} Mutations in genes implicated in forebrain, eye, and pituitary development account for a small number of patients with SOD, and these genes include *HESX1*, *SOX2*, *OTX2*, and *TCF7L1*.^{1,123} Environmental agents, such as viral infections, vascular or degenerative changes, and exposure to alcohol or drugs have also been implicated in the etiology of SOD. The condition presents more commonly in children born to younger mothers and clusters in geographic areas with a high frequency of teenage pregnancies. The overall frequency of genetic mutations in SOD has, however, been low suggesting that mutations in other known or unknown genes may contribute to this complex disorder.

Recently, the Sonic Hedgehog (SHH) signaling pathway has been implicated in more complex disorders of pituitary development. Mutations within SHH are associated with holoprosencephaly.¹²⁴ Gli transcription factors are involved in hedgehog signal transduction, and heterozygous loss-of-function mutations in *GLI2* have been identified in patients with holoprosencephaly.¹²⁵ Phenotypic penetrance is variable. In several affected individuals with *GLI2* mutations, pituitary gland function was abnormal, accompanied by variable craniofacial abnormalities. Other features included postaxial polydactyly, single nares, single central incisor, and partial agenesis of the corpus callosum. More recently, mutations in *GLI2* have been associated with hypopituitarism in the absence of any midline defects.¹²⁶

SOX2 and *SOX3* are members of the SOX (SRY-related high mobility group [HMG] box) family of transcription factors and are early markers of progenitor cells; their expression is down-regulated as cells differentiate. Initially *SOX2* mutations had been associated with bilateral anophthalmia, severe microphthalmia, learning difficulties, esophageal atresia, and genital abnormalities. However, further phenotypic characterization has revealed the presence of anterior pituitary hypoplasia, hypogonadotrophic hypogonadism, and variable GH deficiency, often with accompanying phenotypes, such as hippocampal abnormalities, corpus callosum agenesis, esophageal atresia, hypothalamic hamartoma, and sensorineural hearing loss.^{127,128} Although, in the majority of patients, the magnetic resonance imaging (MRI) reveals a small anterior pituitary, in occasional cases, the pituitary is enlarged and remains so for years.¹²⁹

Normal hypothalamopituitary development is critically dependent upon the dosage of *SOX3*; over- or underdosage can lead to hypopituitarism or infundibular hypoplasia. In humans, *SOX3* duplications or mutations are associated with variable phenotypes, including either IGHD or panhypopituitarism. There is variable developmental delay, and MRI usually reveals a small anterior pituitary, an ectopic/undescended posterior pituitary, and dysgenesis of the corpus callosum.¹³⁰ Deletion of *SOX3* has recently been associated with a persistent craniopharyngeal canal in association with hypopituitarism.

Trauma of the brain and/or hypothalamus. Traumatic brain injury (TBI) has been recognized as a cause of acquired hypopituitarism in a number of adult studies. Data on pediatric patients are still sporadic, but there is a growing awareness that hypopituitarism after TBI is underdiagnosed with possible negative effects on growth and development.¹³¹ Although the pituitary gland is protected within the sella turcica, the rich vascular network of the hypothalamus and pituitary and the structure of the pituitary stalk make it vulnerable to the effects of traumatic brain injury. The hypothalamus and pituitary have a complex vascular supply consisting of long hypophyseal vessels and a rich network of portal capillaries that surround the pituitary and infundibulum. The pathophysiology of hypopituitarism related to TBI is not clearly defined, but it is thought that it is the result of direct trauma or of vascular injury resulting in ischemia and infarction. This is supported by the anatomic findings of autopsies following head trauma, which include anterior lobe necrosis, pituitary fibrosis, hemorrhage, infarction, or necrosis of the pituitary stalk.¹³²

It is of note that the peripheral layer of anterior pituitary cells, under the capsule, receive arterial blood from the capsule and not from the system of portal veins, and this may explain why these cells and those in a small area adjacent to the posterior lobe are the only surviving cells in cases of pure anterior lobe necrosis.¹³³ Somatotrope cells are located in the wings of the pituitary gland, their vascular supply comes from portal vessels, and they are vulnerable to the disruption of blood supply after head injury. On the other hand, ACTH and TSH secreting cells are located in the medial portion of the pituitary and receive blood supply from portal vessels and the anterior pituitary artery. This may explain why GH deficiency is the most common deficiency seen after TBI. Hormone deficiencies may be identified in the first days to weeks posttrauma (acute phase) or may develop over time (late effect). As there is overlap between the symptoms and signs of hypopituitarism and those of neurological-psychological sequelae of TBI, it is possible that late-evolving or partial deficiencies can remain undiagnosed for years. It is not surprising, therefore that, in different studies, the time to diagnosis ranges from 1 to 40 years. It would appear that the majority of patients show a degree of pituitary hormone dysfunction in the first days after TBI (53%–76%); there is, however, wide variation in the reported hormone responses, which reflects the differences in patient selection and time of testing. All anterior pituitary hormones can be affected. Pituitary hormone deficiencies presenting in the acute phase are usually transient, but they may persist or appear and evolve over time. In adults, the incidence of permanent hypopituitarism ranges between 23% and 69% depending on the study. The GH axis is the most frequently affected (10%–33%), followed by the gonadal (8%–23%), adrenal (5%–23%), and thyroid (2%–22%) axes. The prevalence of permanent DI varies between 0% and 6%.^{134–137}

Until recently, there were only sporadic reports of hypopituitarism following TBI in children, but prospective studies designed to better characterize this disorder in the pediatric and adolescent population are in progress. The incidence of hypopituitarism is reported to range from 10% to 60% and, although this is lower in children as compared with adults, it is not uncommon.^{138–140} In general, the long-term outcome of TBI seems to be more favorable in children. Patients with hypopituitarism after head injury may have no clinical signs and symptoms suggestive of this disorder and prompt diagnosis requires a high degree of suspicion. A consensus guideline on the screening of patients post-TBI suggests that all patients who had TBI, regardless of its severity, should undergo baseline endocrine evaluation 3 and 12 months after the event or discharge from intensive treatment unit.¹⁴¹ For children and adolescents, an

algorithm for endocrine assessment and follow-up has also been suggested.¹³¹ However, a recent study has reported that permanent hypopituitarism is uncommon after severe brain injury in young children when stringent clinical criteria for pituitary insufficiency are used. Routine testing of pituitary function, as suggested for adults, may not be necessary in children and may lead to a high number of abnormal test results.

Perinatal trauma to the brain, hypothalamus, pituitary stalk, or anterior pituitary may result in isolated GH deficiency or in multiple deficiencies of the anterior pituitary, as may child abuse. Many published series of patients with GH deficiency indicate an increased incidence of birth trauma, such as breech deliveries, extensive use of forceps, prolonged labor, or abrupt delivery. Debate continues as to whether GH deficiency is the consequence of difficult delivery or merely reflects the perinatal consequences of fetal pituitary insufficiency.

Inflammation and infiltration of the brain and/or hypothalamus. Inflammation of the brain (meningitis or encephalitis resulting from bacterial, viral, or fungal infections) may result in hypothalamic/pituitary insufficiency, with most cases being reported as isolated case reports. Despite the bias in the selection of cases, the incidence of endocrine deficiencies likely depends on the virulence of the infectious organism, the severity and localization of the disease, and the immune status of the host. In a study of 19 adult patients who were investigated 10 to 56 months following CNS infection, 21% had ACTH deficiency and 11% had gonadotropin deficiency, whereas there was no GH deficiency or DI reported.¹⁴² Hypopituitarism has been reported following infection by a variety of agents, including group B streptococcus, *Haemophilus influenzae*, and *Mycobacterium tuberculosis*. The hypothalamus and/or pituitary may also be involved in sarcoidosis. Sarcoidosis is a multisystem granulomatous disease of unknown etiology, which clinically affects the CNS in 5% to 10% of cases.¹⁴³ The effects of sarcoidosis on the hypothalamopituitary axis are the result of infiltration by granulomatous tissue. On MRI, the lesion may infiltrate the hypothalamus and pituitary and cause thickening of the pituitary stalk, and it usually enhances with gadolinium. The most frequently reported endocrine abnormality is DI, which is reported in 25% to 50% of patients with neurosarcoidosis.^{143,144} This is followed by hyperprolactinemia although anterior pituitary dysfunction with hypogonadism has also been reported.¹⁴⁵ Sarcoidosis of the nervous system has a poor prognosis, but long-term remissions have been reported with high-dose intravenous pulse methylprednisolone therapy. Hormonal defects of less than 1-year duration may respond to steroid treatment, but longer standing deficits usually persist.¹⁴⁵

Hypophysitis is an inflammation of the pituitary gland that can be either primary or secondary and can result from infection, systemic disease, or irritation from adjacent lesions. This inflammatory process mimics, clinically and radiologically, tumors of the pituitary area. There are three histological types of primary hypophysitis: lymphocytic, granulomatous, and xanthomatous. Lymphocytic hypophysitis is the most common type; it involves the anterior pituitary and may infiltrate the infundibulum and posterior lobe. Lymphocytic hypophysitis occurs mainly in young women and is associated with pregnancy or the presence of autoimmune diseases, including Hashimoto thyroiditis, Graves disease, type I diabetes, and systemic lupus erythematosus.¹⁴⁶ There are rare case reports of hypophysitis in children and adolescents, and, in most cases, diagnosis has been made only after biopsy and histological examination, although in clinical practice, this is rarely performed. In many cases, hypophysitis presented with DI and hypopituitarism and preceded the diagnosis of an intracranial tumor, such as germinoma. In other cases, it can present with

DI and hypogonadotropic hypogonadism. Once the diagnosis is established, management is generally conservative, unless there are signs of increased intracranial pressure or optic nerve compression.

Langerhans cell histiocytosis (LCH) is characterized by clonal proliferation and accumulation of abnormal dendritic cells that can affect either a single site or many systems causing multiorgan dysfunction.¹⁴⁷ In children, the median age of diagnosis ranges between 1.8 and 3.4 years. LCH infiltrates the hypothalamopituitary area in 15% to 35% of patients with subsequent development of at least one pituitary hormone deficiency.¹⁴⁸ In a multicenter French national study of 589 pediatric patients with LCH, 145 patients (25%) had pituitary dysfunction. In 60 patients, pituitary involvement was already present at the time of diagnosis and in 20 of them it was the first manifestation of the disease. Patients at high risk of pituitary involvement seem to be those with multisystem disease involving skull and facial bones, mastoid, sinuses, and mucous membranes (i.e., gums, ear, nose, and throat region). Furthermore, compared with patients without pituitary involvement, patients with pituitary involvement have a higher rate of relapse (10% at 5 years vs. 4.8% at 5 years), and a higher incidence of neurodegenerative LCH.¹⁴⁹

DI is the most frequently reported permanent consequence of LCH and the most common endocrinopathy; almost all patients with pituitary involvement have DI, which usually presents early in the course of the disease, within the first 3 to 5 years, and occasionally may precede the diagnosis of LCH. Children with LCH and DI may also have anterior pituitary hormone deficiencies, with most deficits developing in the 6 years after the diagnosis of DI. The second most common endocrinopathy is GH deficiency, which occurs in 14% of all patients with LCH and in more than 40% of patients who have pituitary involvement.¹⁴⁸ In the vast majority of patients, GH deficiency is associated with DI, with a median interval of 2.9 to 3.5 years between the diagnosis of DI and development of GH deficiency.^{150,151} Isolated GH deficiency, or the association of GH deficiency with other anterior pituitary hormone deficiencies, occurs less commonly.

Pituitary MRI findings in patients with LCH include thickening of the pituitary stalk, suggestive of the infiltrative process, enhancing changes in the pituitary gland and hypothalamus, and absence of the bright signal of the posterior pituitary in T1-weighted images, caused by the loss of the phospholipid-rich antidiuretic hormone secretory granules. The latter is an invariable feature of patients who develop DI.^{152,153} Although, at the time of diagnosis of DI, 75% show a thickened pituitary stalk, only 24% have persistent stalk thickening after 5 years. These changes are variable and do not correlate with treatment or with clinical recovery as DI persists in all cases. The role of MRI in predicting the development of anterior hormone deficiencies is uncertain. It has been reported that patients who will become GH deficient are more likely to have a smaller anterior pituitary, while the size of the stalk and posterior pituitary are not significantly different.

Long-term follow-up of patients with LCH has shown that the already established hormone deficiencies cannot be reversed by treatment.

Tumors of the brain and/or hypothalamus. Tumors of the CNS are a major cause of hypothalamic insufficiency. This is especially true for midline brain tumors, such as germinomas, meningiomas, gliomas, colloid cysts of the third ventricle, ependymomas, and gliomas of the optic nerve. Although metastasis from extracranial carcinomas is rarely found in children, hypothalamic insufficiency may result from local extension of craniopharyngeal carcinoma or Hodgkin disease of the nasopharynx. Pituitary adenomas represent less than 3% of supratentorial tumors in childhood and about 3.5% to

6% of all surgically treated pediatric pituitary tumors. In most cases, they are hormonally active, arising from any of the five cell types of the anterior pituitary, and may produce prolactin (prolactinomas, 52%), ACTH leading to Cushing disease (corticotropinomas 33.3%), GH (somatotropinomas 8%), or more rarely TSH (thyrotropinomas). Nonfunctioning pituitary adenomas are rare in children (2.7%) compared with adults where they represent almost 20% of pituitary adenomas. Although the majority of childhood pituitary adenomas are prolactinomas presenting in adolescence, corticotropinomas are the most common tumors in prepubertal children.¹⁵⁴ Pituitary adenomas occur in isolation or may be part of a genetic syndrome, such as multiple endocrine neoplasia type 1 (MEN1), McCune-Albright syndrome (MAS), or Carney Complex. Their pathogenesis is not clear but there is increasing evidence that dysregulation in hormone receptor signaling, changes in molecules that regulate cell cycle or are important for adhesion to extracellular matrix, as well as changes in growth factors, may be implicated.¹⁵⁵ Their clinical presentation results from pituitary hormone hypersecretion or deficiencies, disruption of growth and sexual maturation, and pressure effects. On MRI, pituitary adenomas show slow uptake of gadolinium and appear as hypoenhancing lesions that may displace the pituitary stalk.

Optic gliomas. Tumors of the optic pathway represent 4% to 6% of all pediatric intracranial tumors and among these the most common are optic gliomas (65%). Most optic gliomas are low-grade lesions with favorable prognosis if treated optimally. Gliomas confined to the optic nerve have a predilection for females (60%–70%) and are associated with neurofibromatosis type 1 (NF-1) in more than half of cases, whereas 38% are sporadic. Children with sporadic gliomas were more likely to manifest increased intracranial pressure, decreased visual activity, and more commonly documented endocrine complications. The most frequent symptoms at presentation are visual defects (diminished vision, optic atrophy, strabismus, nystagmus, proptosis), ataxia, and precocious puberty. Because of their close anatomic relation to the hypothalamus and pituitary, dysregulation of the hypothalamopituitary axis is common and is caused either by the tumor itself or secondary to treatment. Premature sexual maturation is a frequently presenting symptom whereas the most common defect following cranial irradiation is GH deficiency.¹⁵⁶ NF-1-associated optic gliomas can also cause GH excess and excessive growth.¹⁵⁷

Cystic lesions. Cystic lesions in the pituitary area include Rathke's cleft cysts, arachnoidal cysts, and cystic adenomas and craniopharyngiomas. Rathke's cleft cysts are benign cystic remnants of Rathke's pouch. They are usually small (<5 mm), asymptomatic, and are found in almost 20% of routine autopsies.¹⁵⁸ They consist of well-differentiated columnar or cuboidal epithelial cells and the content of the cyst varies. Rathke's cleft cysts can grow gradually and become symptomatic, especially if they have suprasellar extension. Symptoms include headache, visual defects, and pituitary dysfunction ranging from increased prolactin to pituitary hormone deficiencies. Differential diagnosis from other cystic lesions in the area is not always easy, as on MRI the cyst fluid shows variable signal intensities and therefore cysts can appear as hypo- or hyperdense. Almost 50% of Rathke's cleft cysts show rim enhancement. Recurrence of the cyst after treatment is rare (2 of 14 patients in one series) and it is recommended that treatment should include both fluid drainage and cyst wall removal to avoid relapse.

Arachnoid cysts consist of a collection of cerebrospinal fluid (CSF)-like fluid surrounded by a wall made of arachnoid structures. They are mainly suprasellar, with only rare cases being intrasellar. Suprasellar cysts are usually diagnosed following nonendocrine symptoms, such as neurological deficits,

macrocephaly, and visual symptoms. Because of the proximity of the lesion to the hypothalamopituitary area, arachnoid cysts may cause central precocious puberty, amenorrhea, and hyperprolactinemia, in addition to thyrotropin, ACTH, or GH deficiency.

Craniopharyngiomas may result in hypothalamic dysfunction (discussed later).

Irradiation of the brain and/or hypothalamus. Cranial irradiation represents an important cause of hypothalamic/pituitary dysfunction. Irradiation may directly impair hypothalamic and pituitary function, and it is not always easy to discriminate between damage at each of these levels. In addition, thyroidal and gonadal function may also be directly affected if total body irradiation or craniospinal irradiation is administered. The degree of pituitary impairment is related to the dose of radiation received. Low doses typically result in isolated GH deficiency. With higher doses, multiple pituitary hormone deficiencies are observed. Two to 5 years after irradiation, 100% of children receiving more than 3000 cGy over 3 weeks to the hypothalamic-pituitary axis showed subnormal GH responses to insulin-provocative tests.

The degree of pituitary deficiency observed increases with time since irradiation. Children who test normally at 1-year postirradiation may still develop pituitary deficiencies at later times. Even when serum GH concentrations after provocative testing are normal, measures of spontaneous GH secretion may indicate an impairment. As little as 1800 cGy has been shown to affect spontaneous GH secretion in pubertal children.

Decreased GH secretion may be further complicated by the impact of irradiation on spinal growth, which can result in short stature and skeletal disproportion. Surprisingly, cranial irradiation can also result in precocious puberty—with the consequence that epiphyseal fusion occurs at an earlier age than is ideal from the perspective of maximizing growth. GnRH analogues may be used to delay pubertal progression. The endocrinologist observing the child who has received craniospinal irradiation must consider these three factors: evolving hypopituitarism, decreased spinal growth potential, and early puberty and premature epiphyseal fusion. Care must be taken to maximize the growth potential of the patient without causing skeletal disproportion and without delaying puberty excessively or allowing growth to terminate too early.

Genetic abnormalities resulting in combined pituitary hormone deficiency. The molecular basis of SOD and other midline conditions has been previously discussed.

Recessive mutations in *LHX3* have been identified in several consanguineous families, in addition to a single patient who was found to be compound heterozygous for two missense mutations within the gene. These patients usually present with multiple anterior pituitary hormone deficits, including ACTH deficiency, which was initially thought to be spared.¹⁵⁹ Pituitary morphology is variable between patients with *LHX3* mutations: most patients have a hypoplastic anterior pituitary with a normal posterior pituitary and midline structures^{1,6} conversely, an enlarged anterior pituitary has also been reported in a patient that was not evident in a previous MRI scan performed 10 years earlier.¹⁶⁰ In addition, a patient with a hypointense lesion in the anterior pituitary consistent with a microadenoma has also been described.¹⁶¹ The majority of patients with *LHX3* mutations reported to date have also exhibited a short rigid cervical spine with limited neck rotation and trunk movement. Again, the skeletal phenotypes can vary, and a single patient with normal neck rotation and no other syndromic features has been reported. In addition, most patients with *LHX3* mutations manifest sensorineural deafness,¹⁵⁹ the severity of which is also highly variable and can range from profound to very mild and may be missed in some cases. A direct role may be implicated here because *LHX3* is expressed in specific regions

of the inner ear in a pattern highly conserved between humans and mice, and it is likely to have a role in cochlea hair cell development.¹⁵⁹

Heterozygous mutations in *LHX4* have also been reported, with all patients exhibiting GH deficiency and associated short stature on presentation, again with variable additional endocrine deficits and extrapituitary abnormalities. Initially, a heterozygous intronic mutation that abolishes normal splicing of *LHX4* was reported by Machinis and colleagues¹⁶² in a three-generation family segregating in a dominant and fully penetrant manner. The probands presented with short stature and were found to be GH, TSH, and ACTH deficient, with anterior pituitary hypoplasia, an undescended posterior pituitary, and absent pituitary stalk on MRI. Other affected family members presented with short stature associated with IGHD and a normal posterior pituitary. Additional manifestations included a poorly formed sella turcica and pointed cerebellar tonsils. Several mutations have been subsequently described and are clearly variable in terms of penetrance and phenotype. Recently, a novel homozygous mutation in *LHX4* was associated with a severe recessive phenotype leading to a lethal form of hypopituitarism, suggesting that the variable penetrance observed in the majority of heterozygous mutations may indicate the presence of a second genetic abnormality that has not been detected to date.

The gene encoding *PROP1* is involved in the early determination and differentiation of multiple anterior pituitary cell lineages. Abnormalities of *PROP1* result in CPHD, characterized by variable degrees of deficiency of GH, prolactin, TSH, follicle-stimulating hormone (FSH), luteinizing hormone (LH), and occasionally ACTH. The first mutations in *PROP1* were identified in human patients with hypopituitarism characterized by GH, TSH, and prolactin (PRL) deficiencies in addition to reduced gonadotrophins and failure to enter spontaneous puberty.¹⁶³ Subsequently, *PROP1* mutations have been identified in patients from over 21 different countries, implicating *PROP1* mutations as the most common genetic cause of CPHD accounting for approximately 50% of familial cases, although the incidence in sporadic cases is much lower.¹⁶⁴ Affected individuals exhibit recessive inheritance, and the majority of mutations identified involve the DNA binding homeodomain. The mutations in *PROP1* identified to date include nonsense, missense, frameshift, intronic, and deletion mutations. The majority of the mutations are predicted to result in complete loss of function by ablating DNA binding and transcriptional activation, although some missense mutations retain partial activity. By far the most common mutation, accounting for 50% to 72% of all familial *PROP1* mutations in multiple unrelated families, is a 2-bp deletion within exon 2 resulting in a frameshift (often referred to as *p.S109X*). This mutation likely represents a mutational hot spot within the gene, rather than a common founder mutation, and combined with the c.150delA mutation, accounts for more than 90% of all known *PROP1* mutations.^{1,6}

Homozygosity for mutations in *PROP1* is typically associated with a deficit of GH, TSH, PRL, and gonadotrophins, although the time of onset and severity of hormone deficiency varies. Most patients present with early-onset GH deficiency and growth retardation; however, normal growth in early childhood has been reported in a patient who attained normal final height without GH replacement therapy. Patients may present with gonadotropin deficiency with the evolution of other hormone deficiencies later in life. TSH deficiency is also highly variable and has been reported as the initial presenting symptom in some cases, whereas other patients show delayed onset. The frequency of ACTH deficiency increases with age. Most patients exhibit normal ACTH and cortisol concentrations in early life; however, patients as young as 6 years have been described with

cortisol deficiency, emphasizing the necessity for complete and continuing clinical assessment of patients with *PRO1* mutations. The spectrum of human gonadotropin deficiency is extremely variable in patients with *PRO1* mutations, ranging from early hypogonadism with a micropenis and undescended testes and complete lack of pubertal development to spontaneous, albeit often delayed, onset of puberty with subsequent deficiency of gonadotropins, requiring hormone replacement therapy.

The pituitary morphology in patients with *PRO1* mutations is unpredictable; most cases show a hypoplastic or normal-sized anterior pituitary gland on imaging, with a normal pituitary stalk and posterior lobe, although some reports have documented an enlarged anterior gland. Longitudinal analyses of anterior pituitary size over time have revealed that several patients with an enlarged anterior gland at initial scanning in childhood show spontaneous regression and involution, so that MRI in older patients often demonstrates anterior pituitary hypoplasia, although the size of the pituitary can wax and wane during this time.¹⁶⁴ The pituitary enlargement consists of a mass lesion interposed between the anterior and posterior lobes, possibly originating from the intermediate lobe or Rathke's pouch remnant in the cleft, although the underlying mechanism for the mass remains unknown.

The evolving nature of hormone insufficiencies in patients with *PRO1* mutations suggests a progressive decline in the anterior pituitary axis, so such patients require regular monitoring for the development of hormone deficits that may not be apparent on initial presentation. The highly variable nature of the phenotype associated with *PRO1* mutations, even between siblings within the same family carrying identical mutations, again implicates unidentified genetic modifiers playing a role in the severity and onset of disease pathogenesis.

POU1F1 is the human homologue of the mouse gene *Pit1* and encodes a transcription factor involved in the activation of *GH* and *PRL* genes, regulation of the TSH- β promoter, and specification, proliferation, and survival of the corresponding cell lineages. Mutations within *POU1F1* (*PIT1*) (reviewed in¹⁶⁵) are generally associated with *GH*, *PRL*, and *TSH* deficiencies with variable anterior pituitary hypoplasia. Deficiencies of *GH* and *PRL* are generally complete and present early in life, whereas *TSH* deficiency can be highly variable. The majority of cases present with early *TSH* deficiency; however, in some cases, hypothyroidism occurs later in childhood. MRI of patients with *POU1F1* mutations demonstrates a small or normal-sized anterior pituitary gland with a normal posterior pituitary and infundibulum, but with no extrapituitary abnormalities. More than 28 different mutations in *POU1F1* have been described to date; the majority of these show recessive inheritance, including a complete gene deletion, as well as splice site mutations, whereas a small number are dominant mutations. Of these, the amino acid substitution p.R271W is the most frequent, having been identified in several unrelated patients from a variety of different ethnic backgrounds. The p.R271W substitution results in production of a protein that remains capable of binding to DNA but acts as a dominant negative inhibitor of transcription.

Studies of *POU1F1* in CPHD patient cohorts suggest that the incidence of mutations in cases of sporadic CPHD is quite low (approximately 3%–6%), whereas the incidence among familial patients with hypopituitarism is much greater (25%). Overall, screening studies suggest that abnormalities of *POU1F1* are a less common cause of CPHD than are abnormalities of the *PRO1* gene.¹

Haploinsufficiency of the homeobox gene *RIEG* results in Rieger syndrome, an autosomal-dominant disorder that involves abnormal development of the anterior chamber of

the eye, teeth, and umbilicus—with an occasional association with *GH* deficiency.

Genetic abnormalities of GH production and/or secretion resulting in isolated GH deficiency. It has been reported that up to 30% of patients with *IGH* deficiency have an affected parent or sibling. In addition to combined pituitary hormone deficiency, such as that caused by abnormalities of *PRO1* and *POU1F1* described previously,¹¹⁶ four Mendelian forms of *IGH* deficiency have been reported.

Isolated GHDIA results from deletions (6.7- 7.0- 7.6-, and 45-kb deletions have been reported) or mutations of the *GH1* gene that totally block *GH* synthesis or secretion. Transmission of isolated GHDIA is autosomal recessive, and patients have profound congenital *GH* deficiency. Because *GH* has never been produced by the patient, even in fetal life, patients are immunologically intolerant of *GH* and typically develop anti-*GH* antibodies when treated with pituitary-derived or recombinant DNA-derived *GH*, although development of growth-attenuating antibodies appears to be less frequent with the newer synthetic *GH* preparations.

When antibodies prevent a patient from responding to *GH*, recombinant (rh)IGF-1 therapy should be considered. The less severe form of autosomal-recessive *GH* deficiency (isolated GHDIB) is likely to also be the result of mutations or rearrangements of *GH1*, presumably resulting in a *GH* molecule that retains some function but is perhaps unstable. In addition, mutations in *GHRHR* also lead to GHD1B. To date, however, most patients with presumed isolated GHDIB have not demonstrated an alteration of *GH1* and *GHRHR* and the cause of their *GH* deficiency remains unclear. These patients generally respond well to *GH* therapy, and development of clinically significant anti-*GH* antibodies is unusual.

Isolated GHDII is transmitted as an autosomal dominant. Such patients usually have abnormalities of *GH1* that function in a dominant negative manner. The most common causes of this disorder appear to be splice site and intronic mutations that inactivate the 5'-splice donor site of intron 3, resulting in skipping of exon 3 with generation of the 17.5-kDa isoform of *GH* that exerts a dominant-negative effect on the secretion of the 22-kDa molecule. Transgenic mice that overexpress the 17.5-kDa isoform have a defect in the maturation of the *GH*-containing secretory vesicles and display anterior pituitary hypoplasia with the development of other hormone deficiencies. The 17.5-kDa isoform is retained in the endoplasmic reticulum, misfolded, and disrupts the secretory pathway. Similar mutations identified in humans are also associated with GHDII and an evolving endocrinopathy.¹¹⁶

Missense mutations that affect *GH* secretion and/or action can also cause autosomal dominant IDH deficiency. Patients with the p.Arg183His mutation have impaired release of *GH* as, at the cellular level, the secretory granules that contain the mutant Arg183His protein are not exocytosed as effectively as those containing the wild-type hormone.¹⁶⁶ Other mutations (for example, p.Pro89Leu) can cause more profound and early disturbances in the secretory pathway by alteration of the orientation of the *GH* helices and an effect on the correct folding of the molecule.

Patients with autosomal dominant *IGH* deficiency show considerable variation in the severity of *GH* deficiency. They present with low but detectable serum *GH* concentrations, variable height deficit, and can show anterior pituitary hypoplasia on MRI (38%–50%).^{167,168} Data on pedigrees with the Arg183His or e3+1G>A mutations highlight the fact that patients with the same mutation can vary considerably in height (≤ -4 SDS to normal) and even attain normal adult height without treatment. Patients with splice site mutations are thought to be more severely affected than those with missense mutations¹⁶⁹; however, patients with the IvS3+1 or

IvS3+2 splice site or the p.Pro89Leu mutations can develop additional pituitary hormone deficiencies, including ACTH, prolactin, TSH, or gonadotropin deficiency.¹⁷⁰ This evolving phenotype is unpredictable and dictates the need for lifelong follow-up of affected individuals. Another intriguing observation is that, even in patients with a genetic cause (for example, p.Glu32Ala), GH deficiency seems to reverse when they are retested at the end of growth, in the transition period before transfer from pediatric to adult services. However, this effect is temporary, and is observed in patients tested at the time of transition, and who should not be discharged from follow-up.

No convincing cases of mutations of the *GHRH* gene in humans have been identified. Abnormalities of the gene for the *GHRHR*, on the other hand, have been found in a number of pedigrees. *GHRHR* is a seven transmembrane domain receptor. Its expression requires the presence of the *POU1F1*. Homozygous or compound heterozygous mutations have been reported in *GHRHR* (missense, nonsense, splice site, deletions, or regulatory mutations) leading to type IB IGH deficiency. *GHRHR* mutations are identified in about 10% of patients with familial recessive IGH deficiency,¹⁷¹ and in about 3% of a selected cohort of patients IGH deficiency.¹⁷² Mutations are more likely to be identified in consanguineous pedigrees or patients from certain ethnic backgrounds, such as from the Indian subcontinent and Brazil.

Children with mutations in *GHRHR* have severe GH deficiency and short stature, but midfacial hypoplasia, neonatal hypoglycemia, and microphallus, as found in those with recessive *GHI* mutations, are rare. The anterior pituitary may rarely be normal; in the majority it is hypoplastic. The posterior pituitary and the pituitary stalk are normal. Partial loss of function mutations may be associated with a relatively mild GH deficiency phenotype. Overall, mutations in genes regulating GH secretion are rarely identified, suggesting that novel genes remain to be identified.¹⁷³

Isolated *GHDIII* is transmitted in an X-linked manner. Little is known about the etiology of this condition, although rare mutations in *SOX3* can be associated with IGHD with or without learning difficulties.

Congenital abnormalities of the pituitary. A number of reports have described the association of “idiopathic” GH deficiency with an ectopic neurohypophysis. MRI findings have been described in several series of patients with idiopathic GH deficiency. Abrahams and colleagues studied 35 patients with idiopathic GH deficiency and found that those with MRI findings could be divided into two groups: 43% had an ectopic neurohypophysis (neurohypophysis located near the median eminence), absent infundibulum, and an absence of the normal posterior pituitary bright spot, and 43% had a small anterior pituitary as an isolated finding or combined with an ectopic neurohypophysis.¹⁷⁴ All in all, an ectopic neurohypophysis was found in 87% of cases with multiple pituitary hormone deficiencies but in only 10% of cases with IGH deficiency.

In other studies, however, high-resolution MRI findings of one or more of the following have been suggested to be sensitive and/or specific indicators of hypopituitarism: a small anterior pituitary, attenuated pituitary stalk, and ectopic posterior pituitary. In one study, pituitary abnormalities were found in 80% of patients with IGH deficiency and 93% with MPHD. In patients whose peak GH concentration was less than 3 ng/mL, 90% had abnormal MRI findings—compared with 39% of those with GH concentrations 3 ng/mL or more.¹⁷⁵ In another study, the stalk was abnormal in 90% of patients with IGHD and was absent in 96% of patients with MPHD.¹⁷⁶ Thus MRI abnormalities are common in children with IGH deficiency and MPHD and are closely associated with the severity of GH deficiency. Patients with structural abnormalities will need lifelong follow-up in adulthood owing to the risk of

developing other pituitary hormone deficiencies. Patients with an ectopic posterior pituitary, however, can also show reversal of their GH deficiency on retesting at the time of transition from pediatric to adult services or in adulthood.^{177,178}

Tumors involving the pituitary. Many of the tumors that affect hypothalamic function also directly impact pituitary secretion of GH. In particular, craniopharyngiomas comprise a major cause of pituitary insufficiency. These tumors arise from remnants of Rathke’s pouch, the diverticulum of the roof of the embryonic oral cavity that normally gives rise to the anterior pituitary. Some consider this tumor a congenital malformation because it is believed to be present at birth, gradually growing over the ensuing years and decades.^{179–181} The tumor arises from rests of squamous cells at the junction of the adenohypophysis and neurohypophysis. As it enlarges, it forms a cyst that contains degenerated cells and it may calcify but does not undergo malignant degeneration. In children, they represent 5% to 15% of intracranial tumors and are the most common neoplasm of the hypothalamopituitary area, accounting for up to 80% of tumors in this location. Their incidence in the United States is 1.3 per million per year and almost 28% affect children younger than 14 years. There is a bimodal peak in incidence: the first peak occurs in children between 5 and 14 years and the second peak in adults older than 50 years. They can, however, be diagnosed at any age and have even been reported in the neonatal period.

At presentation, most craniopharyngiomas have a combined intra- and suprasellar location (74.2%) and almost half have hypothalamic involvement (51.6%). A smaller percentage is exclusively suprasellar (22.6%) or confined within the sella turcica (6%–3%). Almost one-third invade the floor of the third ventricle and may cause obstructive hydrocephalus.¹⁸² In pediatric patients, craniopharyngiomas are predominantly cystic (56.7%), multicystic (16.7%), predominantly solid (13.3%), purely solid (10%), or purely cystic (3.3%). The cystic fluid is viscous and rich in cholesterol and the incidence of calcification is much higher in children (83.3%) compared with adults.¹⁸³

There are two main histological types: the most common is the adamantinomatous type and consists of epithelial neoplastic cells that resemble those found in lesions of the jaw. The papillary type is much rarer and is found almost exclusively in adults. Although craniopharyngiomas are histologically benign, they can extend from their initial site, develop papillae, and invade vital surrounding tissues, including the hypothalamus and optic chiasm. This attachment makes their complete excision difficult, if not impossible, and contributes to tumor recurrence and morbidity.

Craniopharyngiomas are typically sporadic tumors. There have been, however, rare case reports of affected family members suggesting recessive inheritance. Overactivation of the *Wnt* signaling pathway appears to play a role in craniopharyngioma development; activating mutations in beta-catenin, a downstream component of the *Wnt* signaling pathway, have been identified in adamantinomatous craniopharyngiomas.¹⁸⁴

Clinical signs and symptoms of craniopharyngiomas can arise at any age, from infancy to adulthood, but most typically in midchildhood. The most common presentation is with symptoms of increased intracranial pressure (up to 75%), such as headaches, vomiting, or oculomotor abnormalities. Impaired vision is common. Visual field defects may result from compression of the optic chiasm, and papilledema or optic atrophy may be observed. Visual and olfactory hallucinations have been reported, as have seizures and dementia.

It is estimated that 70% to 80% of children have evidence of endocrine deficiencies at presentation and that growth failure is observed in 32% to 52% of children before diagnosis. Low concentrations of IGF-1 have been reported in 80% of children at time of diagnosis. GH deficiency is the most common

hormone deficiency, documented in 75% to 100% of those tested before treatment. It is followed by ACTH (20%–70%) and TSH (3%–30%) deficiencies. Compression of the pituitary stalk or damage to hypothalamic dopaminergic neurons results in elevated PRL concentrations, observed in 8% to 20% of children at diagnosis. The incidence of DI at presentation varies between 10% and 29% of patients, depending on the study. In adolescence in particular, craniopharyngiomas may present with delayed puberty or pubertal arrest. Rare presentations include precocious puberty and syndrome of inappropriate anti-diuretic hormone secretion.

Lateral skull films often demonstrate enlargement or distortion of the sella turcica, frequently accompanied by suprasellar calcification(s). Nevertheless, some children with craniopharyngiomas will have normal plain films, and alternative radiological techniques are recommended. Computed tomography (CT) is a sensitive technique for identification of small amounts of calcification or cystic abnormalities. MRI is probably the most sensitive technique. Craniopharyngiomas appear as mass lesions in the sellar and/or suprasellar area that may extend to the hypothalamus and invade the third ventricle. Adamantinomatous craniopharyngiomas are predominantly cystic and the cystic portion of the lesion appears hyperintense in T1 and T2 images. The solid part of the tumor shows areas of high and low signal intensity that represent areas of calcification and hemosiderin deposits. In the majority of cases (58%–76%), the size of craniopharyngiomas, as estimated by MRI or CT, has been reported to be 2 to 4 cm, whereas it is smaller than 2 cm in 4% to 28% cases and more than 4 cm in 14% to 20%.

The management of craniopharyngiomas is complex, controversial, and it is best achieved by a multidisciplinary approach. Aims of the treatment are to relieve acute signs and symptoms of compression (raised intracranial pressure, threatening visual failure); to preserve hypothalamic function, thus reducing later morbidity and mortality; and to provide long-term control and prevent recurrence. What has been evident from different studies is that the extent of surgical resection is probably the most important factor that influences the recurrence of craniopharyngioma. In patients who had surgery only, the 10-year recurrence free survival rate was 83% after total removal, 50.5% after subtotal removal and 15.6% after partial removal. Tumor recurrence usually occurs in the first 5 years and is relatively rare thereafter. However, even after complete resection confirmed radiologically, relapses occur in up to 15% to 25% of patients. In older series, however, when patients were treated with radical and repeated surgical resections, mortality was high (25%–50%) and hypothalamic, visual, and cognitive morbidity occurred in the vast majority (75%), especially in craniopharyngiomas with suprasellar or retrochiasmatic extension.¹⁸⁵

Guidelines for the multidisciplinary management of children with craniopharyngioma have recently been published.^{186,187} It is now suggested that patients can be categorized into two risk groups with respect to management and prognosis. The good risk group includes older children with small tumors (2–4 cm) and no hypothalamic syndrome or hydrocephalus. Younger children, with larger tumors (>2–4 cm) and hypothalamic syndrome or hydrocephalus are in the poor risk group. Complete radical resection, with or without adjuvant radiotherapy, is suggested for the good risk group, whereas limited surgery and immediate or delayed radiotherapy is the treatment of choice for the poor risk group. The recent availability of proton beam therapy is a valuable addition to the therapeutic armamentarium.¹⁸⁸

Idiopathic pituitary growth hormone deficiency. As discussed previously, many of the disease processes that affect hypothalamic regulation of GH secretion also impact pituitary function. Given current diagnostic limitations, it is not always possible to completely discriminate between hypothalamic and pituitary

dysfunction. Furthermore, it is likely that many cases of so-called idiopathic GH deficiency will be found to have a molecular basis for the disorder. Indeed, in the past 5 years we have seen an explosion of information concerning genes critically involved in pituitary somatotrope differentiation and function.

At this time, however, a clear cause for pituitary GH deficiency is often not identified—hence the term *idiopathic*. An incidence of pituitary GH deficiency in 1:60,000 live births was reported from the United Kingdom. A more recent survey of 48,000 Scottish schoolchildren has indicated an incidence as high as 1:4000, whereas the best estimate available in the United States population is at least 1:3480.

It is likely, however, that childhood GH deficiency is an overdiagnosed condition. In particular, the diagnosis of later onset idiopathic IGH deficiency should always be questioned. Although one may argue that destructive or inflammatory lesions of the hypothalamus or pituitary may only affect GH secretion, that IGH deficiency caused by a mild mutation/deletion of the *GHRHR* gene or *GHI* gene may appear late, or that CPHD may first present with what appears to be IGH deficiency, such circumstances appear to be rare. In the absence of anatomic abnormalities evident on imaging studies and/or biochemical evidence of CPHD, the diagnosis of acquired isolated idiopathic GH deficiency demands careful and thorough documentation. Indeed, recent data suggest that retesting of such patients may be associated with an early reversal of the diagnosis.^{189,190} The overdiagnosis of GH deficiency likely arises from the poor specificity of provocative GH testing, particularly in prepubertal children.^{191–193}

Bioinactive growth hormone. A small number of patients with a defect in the *GHI* gene that generates a biologically inactive but immunoreactive GH molecule have been reported.^{194,195} These patients have a common phenotype and are characterized by severe short stature (usually height SDS <−3) and very low concentrations of IGF-1 and IGFBP-3, but normal or elevated GH concentrations (basal or after a stimulation test). Patients may present with mild clinical characteristics, such as prominent forehead and saddle nose, that are typical of GHI. Contrary to what would be expected in a patient with GHI, these patients showed some improvement in growth rate and IGF-1 levels with exogenous GH treatment. Missense mutations in *GHI*, which are inherited in an autosomal dominant or recessive fashion, generate a mutated GH that is capable of binding to the receptor, but cannot properly activate signal transduction by the GHR.

Growth hormone insensitivity.

GHI is a genetic disorder that is defined as the inability to respond to endogenous and exogenous GH with appropriate growth and metabolic effects. The classical form of GHI, also known as *Laron syndrome*, is characterized by severe short stature that manifests postnatally and is associated with dysmorphic features, such as craniofacial disproportion with a relatively small face, depressed nasal bridge, high-pitched voice, truncal obesity, and micropenis, a phenotype similar to that seen in patients with complete congenital GH deficiency (Fig. 11.5).¹⁹⁶ Typically, GHI patients show very low concentrations of IGF-1, IGFBP-3, and ALS, but elevated basal and stimulated GH concentrations. In most cases, GHI is caused by a fully penetrant autosomal recessive mutation in the *GHR*. The majority of these mutations are located in exons that encode the extracellular domain of *GHR* and disrupt the ligand-binding domain and/or impair transport of the receptor to the plasma membrane.¹⁹⁷ For these reasons, patients with classic GHI often show low or undetectable GHBP levels because GHBP is generated by proteolytic cleavage of the extracellular GHR domain. However, mutations elsewhere in the

Fig. 11.5 Phenotype of a patient with severe growth hormone deficiency or insensitivity: frontal bossing, depressed nasal bridge, midfacial hypoplasia, and truncal obesity.

GHR gene may result in normal or elevated GHBP concentrations.¹⁹⁸

After characterization of complete forms of GHI, several cases with a milder or otherwise atypical GHI phenotype were described.^{197,199} The clinical spectrum of partial GHI may vary between patients with typical laboratory findings of GHI who lack classic facial and dysmorphic features associated with Laron syndrome, and patients who are initially classified as having ISS. Usually, partial GHI patients are heterozygous for dominant-negative *GHR* mutations or present a biallelic defect involving hypomorphic *GHR* mutations.¹⁹⁹ Some residual *GHR* activity is retained in both situations, which causes a variety of partial phenotypes. In addition, GHBP is frequently detectable, and even elevated, in some patients with partial GHI.

Usually the diagnosis of patients with severe GHI is not difficult, and molecular studies add little other information to the clinical assessment. Conversely, the absence of a typical phenotype raises a challenge for establishing the diagnosis of partial GHI; hence the use of genetic studies that analyze *GHR* is a valuable molecular diagnostic tool.²⁰⁰

It is noteworthy that GH pharmacogenetic studies have suggested that a single *GHR* polymorphism, the presence or absence of *GHR*-exon 3, was associated with a small but significant modulation of growth response during recombinant human GH therapy.^{201,202} In addition, a whole-genome association study has demonstrated that a *GHR* nonsense variant, which causes severe GHI in the homozygous state, results in a reduction of 4.2 cm in height in heterozygotes,²⁰³ indicating

that *GHR* variants also play an important role in height variability in a polygenic model.

Growth Hormone Insensitivity Associated With Immune Dysfunction. There is a distinct group of patients with GHI that exhibit an associated immune dysfunction, mainly characterized by lymphocytic interstitial pneumonia, eczema, and autoimmune disease.²¹ These patients harbor biallelic mutations in the *STAT5B* gene. Patients with biallelic *STAT5B* defects have a hormonal profile similar to patients with homozygous defects in *GHR*. *STAT5B* is a critical molecule involved in *GHR* signal transduction, mediating the growth-promoting actions of the *GHR*. The immune dysregulation resulting from *STAT5B* mutations can be explained by the fact that other molecules use the *STAT5B* signaling pathway, including some ILs. The defect in IL-2 action is particularly important because this IL participates in the activation of T lymphocytes and in the development of regulatory T lymphocytes.²⁰⁴ Elevated concentrations of PRL are a distinctive feature of biallelic *STAT5B* mutations, because *STAT5B* signaling is required for negative feedback of PRL production. Such patients also show moderate lymphopenia, with a marked reduction of natural killer and T cells, featuring a notable impairment in T-regulatory cells, which contribute to mucosal immunity and host defense against intracellular pathogens.²¹ Individuals carrying heterozygous loss-of-function *STAT5B* mutations have a reduced height (approximately 3.9 cm) and lower IGF-1 and IGFBP-3 levels than noncarrier controls.²⁰⁵ Although these individuals are usually within the normal height range, this finding supports the hypothesis that heterozygosity of rare pathogenic variants contributes to normal height heritability.⁷⁶

Recently, patients carrying dominant-negative heterozygous *STAT5B* variants were reported to have postnatal growth failure, eczema, and elevated immunoglobulin E but not severe immune disease,²⁰⁶ expanding the range of clinical and genetic presentations associated with aberrant *STAT5B* genotypes. Moreover, there are some reports of patients with partial GHI and immune dysfunction who harbor *STAT3* gain-of-function variants that are associated with diminished *STAT5B* transcriptional activity.²⁰⁷

Insulin-Like Growth Factor-1 Deficiency/Resistance.

Acid-Labile Subunit Deficiency. Homozygous defects in the gene encoding the insulin-like growth factor acid-labile subunit (*IGFALS*) cause severe ALS deficiency and an absence of ternary complex formation (IGFs/ALS/IGFBP-3).²⁰⁸ Patients with ALS deficiency are characterized by mild to moderate short stature, undetectable or very low serum concentrations of ALS, and very low serum concentrations of IGF-1 and IGFBP-3, with IGFBP-3 being more affected than IGF-1. Some of these patients also present with variable reduction in birth size, delayed onset of puberty, variable degrees of insulin insensitivity, and/or low bone mineral density. It was assumed that growth restriction in these patients is mild, despite the marked reduction in IGF-1 and IGFBP-3 concentrations, because the relative preservation of circulating free IGF-1 concentrations²⁰⁹ and/or expression of locally produced IGF-1.²⁰⁸ *IGFALS* defects are autosomal recessive traits and patients can be either homozygous or compound heterozygous for ALS mutations. Heterozygous carriers have a mild reduction in height (approximately 1 SDS) in relation to their noncarrier relatives.¹⁹⁹

Defects in the Proteolytic Cleavage of IGFBPs (*PAPPA2* Gene). *PAPPA2* is a protease highly specific for cleavage of IGFBP-3 and -5. Cleavage of these IGFBPs releases IGF-1 from the ternary complex (IGFBP-3 and ALS) and allows free IGF-1 to act on target tissues. To date, only two families have been reported with homozygous mutations in the *PAPPA2* gene.²⁸ Affected members of these families had an increased amount of IGF-1 bound in ternary complexes and decreased free or bioactive IGF-1. These patients were clinically characterized

by progressive growth failure, microcephaly, and thin bones. They also had a marked elevation of total IGF-1, IGF-2, IGFBP-3, IGFBP-5, and ALS concentrations, but low free IGF-1. GH is also elevated in these patients, probably because of decreased negative feedback caused by the reduction in free IGF-1.

Primary Insulin-Like Growth Factor Deficiency.

IGF1 defects. A small number of patients with pathogenic variants in *IGF1* have been described to date,^{58,210} approximately half of whom harbor homozygous variants and an autosomal recessive inheritance pattern. These patients are characterized by severe intrauterine and postnatal growth failure, microcephaly, sensorineural deafness, variable intellectual deficits, and reduction in vertebral bone mass. Patients show undetectable concentrations of IGF-1 and elevated basal and stimulated GH concentrations but have normal concentrations of IGFBP-3 and ALS. Insulin resistance has also been observed in these patients (secondary to GH excess), as well as partial gonadal dysfunction and obesity. Patients homozygous for less disruptive *IGF1* mutations⁵⁸ or harboring heterozygous *IGF1* mutations²¹⁰ have significantly short stature, with or without microcephaly or intellectual disability, and low or low-normal IGF-1 concentrations. This milder clinical presentation, particularly in patients with heterozygous *IGF1* variants, makes diagnosis difficult without molecular genetic investigations.

Bioinactive Insulin-Like Growth Factor-1. There is a report describing a patient homozygous for an *IGF1* mutation that results in formation of an immunoreactive but biologically inactive polypeptide.²¹¹ This abnormal IGF-1 molecule is the product of a missense variant in the *IGF1* gene and has a 90-fold reduced affinity for its receptor. In this study, the affected patient showed severe pre- and postnatal growth failure, microcephaly, sensorineural deafness, intellectual disability, and osteoporosis, a phenotype very similar to that seen in patients with severe IGF-1 deficiency. GH concentrations were very elevated in response to insulin-induced hypoglycemia and IGF-1 was also markedly elevated.

Insulin-Like Growth Factor Insensitivity. IGF1R defects have been identified in patients born small for gestational age (SGA) who did not show catch-up growth.²¹² Patients with biallelic (homozygous or compound heterozygous) *IGF1R* mutations have a homogeneous clinical phenotype that is similar to the phenotype of patients with homozygous *IGF1* mutations. In contrast with the rarity of biallelic *IGF1* and *IGF1R* mutations, heterozygous *IGF1R* variants are relatively frequent and manifest considerable clinical variability. The extent of growth restriction is variable as are the degrees of delay in psychomotor and mental development with absence or presence of microcephaly. Patients with *IGF1R* mutations also show delayed bone age and IGF-1, IGFBP-3, and GH concentrations that range from normal to high.²¹²

There are also reports of patients with abnormalities in chromosome 15, in which the *IGF1R* gene is deleted. Phenotypes displayed by these patients depend upon the type and extent of the abnormality. As a rule, patients with biallelic *IGF1R* defects or heterozygous nonsense mutations have a more severe clinical presentation than patients heterozygous for missense mutations, reflecting a spectrum related to the residual activity of IGF-1.²¹² Up to 2% of children born SGA without catch-up growth may have heterozygous defects in *IGF1R*.²¹³ *IGF1R* haploinsufficiency has been observed even among patients born at an appropriate size for gestational age, and is usually classified as idiopathic short stature.²¹⁴ Because of significant clinical variability, diagnosis of IGF insensitivity based only on clinical and laboratory findings is not possible, reinforcing the importance of molecular genetic diagnosis for these patients.

Hypothyroidism and Thyroid Hormone Resistance.

Hypothyroidism. Many of the clinical features characteristic of adult myxedema are lacking in pediatric patients with acquired hypothyroidism. Although it is widely believed that the most common and prominent manifestation of chronic acquired hypothyroidism is growth failure,²¹⁵ several studies have shown that growth failure is often a relatively uncommon manifestation of hypothyroidism, as the diagnosis is usually made relatively early, before significant growth failure sets in.^{216,217} Hypothyroidism may present with short stature, excess weight gain, and a suboptimal growth velocity. Classical features, such as constipation, dry skin, hair loss, delayed deep tendon reflexes and coarse facies may be either absent or mild. Postnatal growth retardation may also be observed in the infant with congenital hypothyroidism, but the development of newborn screening programs for hypothyroidism have generally resulted in prompt diagnosis and treatment of such patients in the Western world. In acquired hypothyroidism, growth retardation may take several years to become clinically evident. However, once present, growth failure is typically severe and progressive.

Although chronic hypothyroidism is generally characterized by delayed puberty, precocious puberty and even premature menarche can occur in hypothyroid children—an entity called *VanWyk-Grumbach syndrome*. However, in males, the testes are usually enlarged with relatively minimal virilization possibly because of predominant FSH secretion. In some females with severe primary hypothyroidism, large recurrent ovarian cysts may manifest. Skeletal age is usually markedly delayed.

Confirmation of the diagnosis of primary hypothyroidism is usually straightforward. Serum concentrations of free thyroxine (FT4) are reduced, and TSH concentrations are elevated. The presence of antithyroid antibodies is consistent with a diagnosis of Hashimoto thyroiditis, the most common cause of acquired hypothyroidism in the Western world. Isolated secondary and tertiary hypothyroidism, caused by TSH and thyroid-releasing hormone deficiency (respectively), are very rare causes of acquired hypothyroidism.

Replacement therapy with levothyroxine is associated with a period of rapid catch-up growth. Despite this gratifying response, however, accelerated growth often does not result in restoration of full growth potential—largely because of the rapid increase in skeletal age during the first 18 months of treatment, often with rapid progression through puberty. In the study of Rivkees and associates, children with severe growth retardation caused by long-standing hypothyroidism, who were treated at an initial mean chronological age of 11 years, had adult heights approximately 2 SD below the means for sex. These final heights were significantly lower than midparental heights or initial predicted adult heights based on data of Bayley and Pinneau. The deficit in adult stature correlated significantly with the duration of hypothyroidism before initiation of treatment.

Thyroid Hormone Resistance.

RTHbeta. TR β -mediated resistance to thyroid hormone (RTH) in humans has an incidence of approximately 1 in 40,000 and arises because of point mutations in the *TRHB* gene,²¹⁸ which encodes thyroid hormone receptor beta (TR β). Individuals with RTH β exhibit a characteristic biochemical profile (raised FT4, free triiodothyronine [FT3] with unsuppressed TSH) because of refractoriness within the TR β dependent negative feedback signaling system, which regulates the hypothalamopituitary-thyroid axis. This results in the axis equilibrating around a new higher “set point” with elevated FT4 and FT3 concentrations.

Clinical manifestations of RTH β are highly variable and the majority of individuals are relatively asymptomatic. Associated clinical features may be attributable to differential TR isoform expression in different organs such that tissues predominantly

expressing TR β (liver, kidney, hypothalamus, pituitary) exhibit resistance to thyroid hormone, whereas tissues expressing predominantly TR α (skeletal and cardiac muscle, bone, brain), remain sensitive to the elevated circulating concentrations of thyroid hormones and so may exhibit relative thyrotoxicosis. Thus RTH subjects have increased heart rate compared with euthyroid controls, which may reflect the predominance of TR α in myocardium, and increased resting energy expenditure probably mediated by the predominance of TR α in skeletal muscle. Children with RTH β may present with growth retardation or failure to thrive and attention deficit hyperactivity disorder may also be present. Goiter is also common.

Rarely, homozygous *THRB* point mutations or deletions have been described in association with a more severe phenotype including marked intellectual impairment, hearing loss, dysmorphic features (bird-like facies, pigeon breast, winged scapulae), deaf-mutism, and color blindness.²¹⁹

RTH α . RTH occurs as a result of heterozygous, dominant negative, loss-of-function mutations in the *THRA* gene,²²⁰ which encodes thyroid hormone receptor alpha (TR α). It presents with tissue-specific hypothyroidism in tissues predominantly expressing the TR α isoform and near-normal thyroid function tests because TR α is the predominant isoform regulating thyroid hormone negative feedback in the hypothalamus and pituitary gland. Patients may exhibit characteristic broad facies with hypertelorism, a flattened nose, prominent tongue, and thick lips and are macrocephalic, perhaps because of delayed fontanelle closure. An excessive number of skin tags have been noted in many cases.²¹⁹

Growth retardation is often prominent, in keeping with the crucial role of TR α for normal skeletal maturation and is commonly predominantly lower segmental. Radiological features of skeletal dysplasia in affected children may include wormian bones (disordered, intramembranous ossification), epiphyseal dysgenesis (disordered, endochondral ossification), and delayed dentition.^{220–223} Constipation is common and may be severe.

TR α is the predominant TR isoform in brain and affected individuals usually exhibit neurocognitive deficits, including delayed milestones (motor, speech) in childhood, impaired motor coordination and slow initiation of movement, manifesting as dyspraxia or broad-based gait, and slow speech. IQ is variably reduced.

The most common biochemical abnormalities include low/low-normal T4 and high/ high-normal T3 concentrations, a subnormal T4/T3 ratio, and variably reduced reverse T3, which may reflect altered metabolism of thyroid hormones.

Levothyroxine therapy has been beneficial in some childhood cases, improving growth, alleviating constipation, and improving motor development and wellbeing. TSH concentrations suppress readily on treatment with elevation of FT3 to supraphysiological levels, which does raise the possibility that chronic excess TH exposure in thyroxine-treated RTH patients might lead to unwanted toxicities in normal TR α -containing tissues, such as liver or bone.

Glucocorticoid Excess (Cushing Syndrome).

Glucocorticoid excess has a profound effect on skeletal growth whether the cause of Cushing syndrome is hypersecretion of ACTH, a primary adrenal tumor, or glucocorticoid therapy. Glucocorticoids appear to slow growth primarily through a direct action on the growth plate.²²⁴ GH secretion is typically normal and serum concentrations of IGF peptides and IGF-BPs are not generally affected. This concept also explains the observation that treatment with GH cannot completely overcome the growth inhibiting effects of excess glucocorticoids.

If the glucocorticoid excess resolves, catch-up growth occurs but is often not complete such that the adult height may be diminished.²²⁵ The longer the duration and the greater the intensity of glucocorticoid excess, the less likely the patient will

experience complete catch-up growth. It is therefore important to limit exposure to excess glucocorticoids as much as the underlying condition being treated will allow. The characteristic signs of Cushing syndrome (such as truncal obesity, decreased muscle mass, striae, easy bruising, thin skin, hypertension, and osteoporosis) are well known. Adrenal tumors secreting large amounts of glucocorticoids frequently also produce excess androgens, which may mask the growth inhibitory effects of glucocorticoids, but also advance skeletal maturation.

Children with Cushing syndrome may lack many of the clinical signs and symptoms associated with the disorder in adults and may present primarily with an acceleration in weight gain accompanied by a deceleration in linear growth. Thus a growth chart showing increasing weight percentiles and decreasing height percentiles suggests Cushing syndrome. In contrast, exogenous obesity is associated with normal or even accelerated skeletal growth.

Sex Steroid Exposure.

Both premature and excess sex steroid exposure, as well as delayed puberty may impact the height of a child.

Premature/Excess Sex Steroid Exposure.

Causes include premature sexual maturation because of gonadotrophin-dependent and -independent causes, adrenal hyperandrogenism because of adrenarache, virilizing adrenal tumors or congenital adrenal hyperplasia (CAH), ovarian and testicular tumors, and human chorionic gonadotropin hormone-producing tumors. Excess production of sex steroids will lead to an increase in growth rate with tall stature initially, later followed by early fusion of epiphyses and eventual short stature. For example, undertreatment or late diagnosis of CAH results in rapid growth with initial tall stature, with early growth cessation and epiphyseal fusion and short stature in adulthood. Estrogen accelerates linear growth in part by stimulating GH secretion, but estrogen also acts on the growth plate to accelerate growth plate senescence and thus decrease the remaining growth potential.^{226,227} Androgen appears to have a direct, stimulatory effect on growth at the growth plate.³⁹

Delayed Puberty.

Pubertal delay because of constitutional delay of growth and puberty is one of the most common causes of short stature in the peripubertal years. This is a variant of normal puberty that appears to be more common in males and is characterized by delayed maturation of the hypothalamic-pituitary-gonadal (HPG) axis with a consequent lack of gonadal sex steroid secretion and sexual development. Short stature with reduced GH secretion, a delayed skeletal age, and a low concentration of IGF-1 may be associated with a reduced growth velocity, as GH secretion is highly dependent on sex steroid production during adolescence. The condition is benign and self-limiting but may be associated with considerable psychological distress and poor self-esteem.

Inflammatory Disorders.

Chronic inflammatory disorders, such as JIA, IBD, and cystic fibrosis, can impair linear growth causing short stature. The underlying mechanisms are probably complex; the growth impairment may be mediated by proinflammatory cytokines, including TNF- α , IL-1-beta, and IL-6, undernutrition, and glucocorticoid therapy and may involve both direct effects on growth plate chondrocytes and indirect effects mediated by endocrine abnormalities⁵¹ (see previous sections on Regulation Of Linear Growth, Cytokine Regulation of Linear Growth, Nutritional Regulation of Linear Growth, and Glucocorticoids).

JIA is a heterogeneous group of disorders, which, as the name implies, share the common features of persistent joint inflammation, onset in childhood, and a poorly understood etiology. Categories of JIA differ in their clinical presentation, including number of joints involved, systemic inflammatory

manifestations, and the presence of psoriasis.²²⁸ Treatments include nonsteroidal antiinflammatory drugs, intraarticular and systemic glucocorticoids, methotrexate, and a variety of anticytokine therapies. Impaired linear growth is more common in systemic and polyarticular JIA but may also occur in oligoarticular JIA.²²⁸ Short stature is uncommon at initial clinical presentation but becomes more frequent in subsequent years.²²⁹ Adult height can be adversely affected. Decreased circulating IGF-1 is reported in slowly growing children with JIA.²²⁸ Decreased GH has also been reported, but the interpretation of these findings is less straightforward and could be complicated by glucocorticoid treatment and poor test specificity.²²⁸ Small randomized trials suggest that GH treatment increases growth rate²²⁸ and may increase adult height.²³⁰ Larger, long-term, controlled studies in specific JIA subtypes are needed to establish efficacy and safety.²²⁸ It is hoped that recent advances in antiinflammatory treatment will improve long-term outcomes, including stature.

IBD includes ulcerative colitis, in which the inflammation is limited to the mucosal layer of the colon, and Crohn disease, in which the inflammation is transmural and can involve any part of the gastrointestinal tract. Significant growth impairment is more common in Crohn disease. Some children may present to medical attention with poor growth as the predominant manifestation, rather than marked symptoms of gastrointestinal disease.²³¹ Screening laboratory tests, such as hemoglobin, platelet count, albumin, C-reactive protein (CRP), and erythrocyte sedimentation rate are often, but not always, abnormal at presentation.²³² Effects on adult height are mild in most patients.^{228,233} The mechanisms underlying the decreased growth may involve nutritional deficiencies, inflammation, and glucocorticoid therapy. Circulating IGF-1 concentrations can be decreased.²³⁴ Decreased GH has also been reported, but the interpretation is complicated by poor test specificity. Randomized short-term trials suggest that GH treatment can increase the linear growth rate.^{235,236} Long-term trials are needed to determine safety and efficacy.

Disorders Involving Abnormal Extracellular Fluid and/or Failure of Specific Organ Systems.

Abnormalities in a variety of organ systems, such as the kidney, liver, heart, and lungs can impair childhood growth. Many of these disorders affect the content of the extracellular fluid, an aqueous solution that contains many different solutes including inorganic ions, nutrients, proteins, dissolved gases, and metabolic waste. Abnormalities in the extracellular fluid can slow linear growth both through direct effects on growth plate chondrogenesis and indirect effects involving nutritional and endocrine factors.

In children with chronic kidney disease, short stature is common, and adult height is often affected.²³⁷ Short stature is more prevalent with more severe renal impairment and with earlier age of onset.^{238,239} The etiology is thought to be multifactorial. Poor nutritional intake caused by anorexia often contributes to the growth failure, as can glucocorticoid use.²³⁹ There is evidence that the mechanisms can include GH insensitivity and decreased IGF bioavailability because of increased concentrations of IGF-BPs.^{240,241} In children with chronic kidney disease, approaches to address the growth impairment include improving nutritional intake, optimizing dialysis, and, when possible, minimizing glucocorticoid use.^{238,239} Recombinant GH treatment increases growth rate in children with chronic renal insufficiency and is used therapeutically in select patients^{237,238} (see section on Treatment of Short Stature).

Short stature also occurs in children with renal tubular acidosis. In these disorders, hyperchloremic metabolic acidosis results from impaired acid excretion by the kidney. Impaired linear growth is seen both in distal and proximal renal tubular acidosis.^{242,243}

Decreased linear growth is also found in children with hyperphosphatemia, including those with X-lined hypophosphatemic rickets, which involves elevated FGF-23 concentrations²⁴⁴ and also hereditary hypophosphatemic rickets with hypercalciuria, which is caused by defective renal sodium-phosphate cotransporters.²⁴⁵ In these disorders, the growth plates show abnormalities typical of rickets. There is evidence that low phosphate concentrations in the extracellular fluid directly impair growth plate chondrocyte differentiation, contributing to the abnormal linear growth.²⁴⁶

Congenital heart disease frequently impairs childhood growth.²⁴⁷ Growth impairment occurs both in cyanotic and noncyanotic disorders. Undernutrition, involving both anorexia and increased nutritional needs, is thought to be a major contributing factor.²⁴⁷⁻²⁴⁹

Psychosocial Deprivation.

Psychosocial deprivation growth failure is a disorder of growth associated with emotional deprivation and/or a pathological environment that disrupts normal parent-child attachment. It can affect children of all ages; failure to thrive is usually seen in infancy, whereas toddlers and older children are frequently depressed and often manifest bizarre behaviors surrounding food and eating (such as drinking from toilets and dish pans, eating from garbage cans and pets' dishes, and binging). Delayed statural growth and puberty, growth arrest lines in long bones, and temporary widening of cranial sutures have been reported.²⁵⁰ Although malnutrition is commonly associated, there is some evidence suggesting that psychosocial deprivation may cause growth stunting despite an adequate supply of nutrients. For example, Widdowson described two German orphanages run by women of opposite personalities. Despite similar dietary intakes, children under the care of the unpleasant, aggressive, nonnurturing woman did not thrive, whereas those under the care of the woman with opposite personality traits grew well.²⁵¹

Suppressed GH secretion, not related to disturbed sleep, has been reported in some cases,²⁵² but this finding is confounded by the poor specificity of GH testing.¹⁹¹ The hallmark of this condition is reversibility of the growth stunting and GH secretory abnormalities (when found) upon removal from the hostile environment and placement into a nurturing one.²⁵²⁻²⁵⁴ Lower serum concentrations of certain neuroendocrine markers (melatonin, serotonin, β -endorphins, and adrenocorticotrophic hormone) were found in children with social deprivation, particularly those with growth failure, than in controls or children with failure to thrive.²⁵⁵

Early placement of children suffering from social deprivation into a nurturing environment is critical not only for recovery of height and weight gain, but also for cognitive improvement, and catch-up in height serves as a positive predictor of cognitive recovery.²⁵⁶ A study of socially deprived Romanian children randomized to foster versus ongoing institutional care, age 5 to 32 months at baseline, found a mean increase of 12.6 points (SD, 4.7 points) in verbal IQ for each incremental increase of 1 SD in height Z-score between baseline and 42 months.²⁵⁶ Even with growth recovery, children who had suffered early deprivation may still face persistent abnormalities of the hypothalamic-pituitary-adrenal system; early puberty; increased risk of metabolic syndrome in adulthood; and cognitive, behavioral, and emotional sequelae.²⁵⁷

Primary Growth Impairment.

Disorders Involving Autocrine/Paracrine Factors.

Growth plate chondrocytes secrete multiple factors that act locally in a paracrine fashion on nearby chondrocytes and an autocrine fashion on the secreting cell. These factors, many of which are polypeptides, serve to coordinate the proliferation and differentiation of cells in the different zones of the growth plate (see section on Autocrine/Paracrine Regulation of Linear

Growth earlier). Consequently, mutations in genes that are involved in this local intercellular communication can impair growth plate chondrogenesis, causing short stature, or sometimes enhance growth plate chondrogenesis, causing tall stature. If the abnormal growth plate chondrogenesis affects not only bone length but also bone shape, malformation ensues, and the condition is termed a *chondrodysplasia*.⁵³ The discussion that follows provides some examples of growth disorders related to paracrine signaling defects, focusing especially on those that can present as isolated short stature without an obvious chondrodysplasia.

Disorders Involving Insulin-Like Growth Factor-2. *IGF2* is an imprinted gene that is paternally expressed prenatally and, in several tissues, postnatally. DNA hypomethylation in the region of the *IGF2* gene results in reduced paternal *IGF2* expression and presents clinically as SRS (see section on Imprinting Disorders—Silver-Russell syndrome for details), which affects both pre- and postnatal growth in humans.²⁵⁸ Recently, several patients with pathogenic *IGF2* gene variants associated with intrauterine and postnatal growth restriction were described.²⁵⁹ Typically, only those who inherited the variant through paternal transmission were affected, a finding consistent with the imprinting of the *IGF2* gene. These patients also had clinical signs compatible with SRS, such as low birth weight with normal head circumference, triangular face, and micrognathia. Some patients presented with delayed psychomotor development. Hormonally, the patients had low concentrations of IGF-2, but normal to elevated IGF-1, IGFBP-3, and GH concentrations. It has also been suggested that heterozygous pathogenic variants in *HMGA2* and *PLAG1* genes can cause similar phenotypes. *PLAG1* activates *IGF2* through a promoter and *HMGA2* is an upstream regulator of *PLAG1*. Both genes were associated with growth abnormalities in mice models and in GWAS metaanalyses of height in humans.²⁶⁰

Disorders Involving C-Type Natriuretic Peptide Signaling. C-type natriuretic peptide (CNP) acts on its receptor, NPR2 (also called *NPRB* and *GC-B*) to stimulate growth plate chondrogenesis. Consequently, mutations in either the ligand or the receptor can impair linear growth. Biallelic (homozygous or compound heterozygous), loss-of-function mutations in *NPR2* cause a chondrodysplasia with short stature, termed *acromesomelic dysplasia, Maroteaux type*. Monoallelic (heterozygous) loss-of-function mutations in *NPR2* can present as isolated short stature, often with an increased sitting to standing height ratio.²⁶¹ Similarly, heterozygous mutations in *NPPC*, which encodes CNP, cause autosomal dominant short stature with a tendency to small hands.²⁶²

Conversely, gain-of-function mutations in *NPR2* can cause tall stature that may be accompanied by scoliosis, arachnodactyly, and particularly long great toes.⁵⁴ Overexpression of CNP appears to cause a similar phenotype.²⁶³

Disorders Involving Fibroblast Growth Factor Signaling. FGFs, acting through *FGFR3*, negatively regulate growth plate chondrogenesis. Consequently, gain-of-function mutations in *FGFR3* impair linear growth. The severity of the phenotype varies depending on the mutation, including (in decreasing order of severity) thanatophoric dysplasia, ACH, and hypochondroplasia, all of which include short stature that disproportionately affects the extremities as compared with the trunk.

ACH is the most common chondrodysplasia. The vast majority of patients with ACH have the same point mutation in *FGFR3* because of a high mutation rate at that base pair. It is inherited in an autosomal dominant fashion, but, because of the high mutation rate, most cases are sporadic, arising from de novo mutations. ACH results in rhizomelic short limbs, a large head, and midface hypoplasia.²⁶⁴ Impaired growth of

the foramen magnum can result in cervical cord compression, which can be lethal.

Hypochondroplasia has a milder phenotype than ACH and can present with short stature, brachydactyly, large head, and limited elbow extension.²⁶⁵ Diagnosis involves clinical features, radiological skeletal features, and molecular genetic testing. Some patients with clinical and radiological features of hypochondroplasia may not have mutations in *FGFR3*, indicating locus heterogeneity.²⁶⁵

Milder gain-of-function mutations have been reported to present as proportionate short stature.⁵⁵

Conversely, monoallelic, loss-of-function mutations cause tall stature with camptodactyly, arachnodactyly, scoliosis, and hearing loss, termed *CATSHL syndrome*.^{56,266}

Disorders Involving Parathyroid Hormone-Related Protein and Indian Hedgehog Signaling. PTHrP and IHH form a local negative feedback loop in the growth plate that controls chondrocyte proliferation and particularly hypertrophy. PTHrP acts through PTH1R, the same receptor that PTH acts through. Interestingly both loss-of-function and gain-of-function mutations in PTH1R impair growth plate chondrogenesis, causing skeletal dysplasias—Blomstrand lethal chondrodysplasia and Jansen metaphyseal chondrodysplasia, respectively.⁶⁰

PTH1R is a seven-transmembrane-domain receptor, which signals in part through Gs-alpha. Heterozygous mutations in *GNAS*, the gene encoding Gs-alpha, cause Albright hereditary osteodystrophy (AHO), which is characterized by short stature, subcutaneous ossifications, and variable brachydactyly (particularly with shortened distal phalanges and fifth, fourth and third metacarpals).²⁶⁷ The short stature develops with age because of early slowing and cessation of linear growth, accompanied by an advanced radiograph bone age and early epiphyseal closure. AHO occurs with either paternal or maternal inheritance of the mutation. When the heterozygous mutations in *GNAS* is inherited on the maternal allele, the AHO findings can be accompanied by resistance to PTH, gonadotropins, TSH, and GHRH, as well as obesity as part of pseudohypoparathyroidism 1A (PHP1a). These additional features occur with maternal inheritance because *GNAS* is imprinted, such that it is normally preferentially expressed by the maternal allele in some tissues. The role of GH treatment in PHP1a is under investigation.²⁶⁷ When the mutation is paternally inherited, the patient shows only AHO, a condition termed *pseudopseudohypoparathyroidism (PPHP)*. Mutations in protein kinase cyclic adenosine monophosphate-dependent type I regulatory subunit alpha (PRKAR1A), which lies downstream in Gs-alpha signaling, cause acrodysostosis which has features similar to AHO and PHP1a.²⁶⁸

Heterozygous mutations in *IHH* cause autosomal dominant short stature as part of brachydactyly type A1²⁶⁹ or can cause short stature with nonspecific skeletal abnormalities. The latter condition is characterized by mild disproportionate short stature often with shortening of the middle phalanx of the fifth finger but not classic features of brachydactyly type A1.⁶¹

Disorders Involving Cartilage Extracellular Matrix. Growth plate chondrocytes secrete a cartilage matrix, which is composed of many different proteins, including multiple types of collagen, and proteoglycans. Mutations in genes encoding these proteins and proteoglycans can impair growth plate chondrogenesis and therefore linear growth. The clinical manifestation can be a chondrodysplasia. For example, *COL10A1* encodes collagen X, which is a major component of the growth plate cartilage matrix, and heterozygous mutations in *COL10A1* cause metaphyseal chondrodysplasia, Schmid type. Similarly, heterozygous mutations in cartilage oligomeric matrix protein can present as pseudoachondroplasia or the milder multiple epiphyseal dysplasia-1, both of which cause short stature.

Mutations in genes encoding components of the cartilage extracellular matrix may also have a milder phenotype, presenting, not as a chondrodysplasia, but instead as short stature without an obvious chondrodysplasia. For example, *ACAN* encodes aggrecan, a proteoglycan that is an important component of cartilage matrix. Homozygous mutations can cause a severe chondrodysplasia with extreme short stature termed *spondyloepimetaphyseal dysplasia*, aggrecan type. Heterozygous mutations can cause a milder skeletal dysplasia or can present clinically as isolated short stature without obvious signs of a chondrodysplasia.²⁷⁰ The condition can be inherited as an autosomal dominant trait. Typically, the bone age is advanced, and growth cessation occurs at an early age. Affected family members may develop early-onset osteoarthritis and intervertebral disc disease because of the cartilage matrix abnormality.

Disorders Involving Intracellular Factors and/or Fundamental Cellular Processes

Genetic defects in several intracellular pathways or fundamental cellular processes result in a large and heterogeneous group of short stature syndromes. These syndromes often show distinct phenotypes reflecting multiple mechanisms of growth impairment, some of which are not completely elucidated.²⁷¹ A discussion of representative disorders in this category, chosen for their frequency or importance as models of disease, is included in this text, but bear in mind that this is a large group of disorders that includes hundreds of distinct conditions.

Defects in *SHOX*. The *SHOX* is located inside the pseudoautosomal region 1 (PAR1) of the sex chromosomes X and Y. Genes located within PAR1 escape X-inactivation; hence two copies of *SHOX* are expressed in both males and females. *SHOX* encodes a transcription factor that is required for normal limb development and growth plate function, especially for the forearm and lower legs.²⁷² Monosomy of chromosome X, in patients with Turner syndrome, leads to *SHOX* haploinsufficiency and partially explains the short stature and some of the skeletal features observed in these patients (*cubitus valgus* and the bowing and shortening of forearms and lower legs) (see [Chapter 17 on Turner syndrome](#) for details). Furthermore, heterozygous mutation in *SHOX* coding or regulatory regions cause *SHOX* haploinsufficiency and is associated with a spectrum of short stature phenotypes, including Leri-Weill dyschondrosteosis (LWD) and short stature without any specific skeletal features. LWD is a dominant inherited skeletal dysplasia that is characterized by disproportionate short stature, mesomelic limb shortening, and Madelung deformity ([Fig. 11.6](#)). In addition, LWD patients often have a high-arched palate, *cubitus valgus*, *genu varum*, muscular hypertrophy, and a tendency to have an increased BMI. Heterozygous *SHOX* defects are identified in 70% to 90% of patients with LWD and in 2% to 15% of children classified as idiopathic short stature. Homozygous *SHOX* defects are associated with Langer mesomelic dysplasia, which is a rare and severe form of short-limb dwarfism. The estimated prevalence of *SHOX* deficiency is 1:1000, and for this reason, it is considered one of the main monogenic causes of short stature.

The chromosomal location of *SHOX*, in a region with a high number of repeat sequences, is predisposed to deletions, which are responsible for 80% of cases of *SHOX* haploinsufficiency. Most of the remaining 20% are caused by single nucleotide mutations. Molecular genetic investigation of a *SHOX* defect is indicated in patients and families with LWD and in children classified as ISS because molecular diagnosis of *SHOX* defects permits the identification of the etiology of short stature. Such diagnoses have therapeutic implications because hGH treatment is effective in improving adult height.²⁷³ Both phenotypes, LWD and ISS, can be observed among affected members of the same family; for this reason the presence of

Fig. 11.6 Madelung deformity observed in patients with Leri-Weill dyschondrosteosis associated with *SHOX* haploinsufficiency: presence of dorsal subluxation of the distal radioulnar joint. X-ray image of hand and wrist with triangularization of the distal radial epiphysis; “V-shaped” proximal carpal row (or pyramidalization) and early epiphyseal growth arrest in the medial part of the distal radius, resulting in bowing of distal radius.

a relative with LWD in a family with autosomal dominant short stature increases the probability of a *SHOX* defect. In addition, the presence of disproportionate short stature, evidenced by a sitting height index (sitting height/total height) SDS over 2, without evidence of skeletal dysplasia, is a simple and useful tool for selecting ISS children for *SHOX* molecular genetic screening.⁸⁶ Because the sensitivity of the sitting height index is greater in adults than children, it is also useful to measure the sitting height index of short parents of a short child.

Noonan Syndrome and the *RAS*opathies. NS is a relatively common genetic disorder, with an estimated prevalence of 1 in 1000 to 1 in 2500 live births with an equal male and female prevalence.²⁷⁴ It has an autosomal dominant inheritance pattern, with near complete penetrance and marked clinical heterogeneity. Approximately one-third of patients diagnosed with NS have an affected parent, with the remainder of patients harboring de novo mutations. NS is characterized by distinctive facial dysmorphic features ([Fig. 11.7](#)), congenital heart defects (most commonly pulmonary valve stenosis, hypertrophic cardiomyopathy, and septal defects), chest wall abnormalities (*pectus carinatum* and/or *excavatum*), and growth retardation. Patients with NS may also show mild to moderate developmental delays, learning disabilities, kyphoscoliosis, and lymphedema, frequent easy bruising, and bleeding tendency. Individuals with NS have a mildly increased risk of developing malignancies (mostly juvenile myelomonocytic leukemia, other myeloproliferative disorders, and brain tumors) during childhood.²⁷⁵ Unilateral or bilateral cryptorchidism is frequently observed in affected boys. Although birth weight and length are usually within normal ranges, most infants with NS have feeding difficulties that can lead to failure to thrive.

Fig. 11.7 Facial features of a patient with Noonan syndrome. The same patient is shown, first at the age of 8 years (left) and 17 years (right). Typical characteristics of Noonan syndrome are observed: mild hypertelorism, ptosis, downslanting palpebral fissures, low-set posteriorly rotated ears, and *pectus excavatum*.

Growth retardation develops after birth and is accompanied by reduced IGF-1 concentrations, but usually normal GH secretion,²⁷⁶ although GHD has been described in some patients. Boys and girls with NS typically have delayed onset of puberty, which results in a prolonged adolescent growth period. Mean adult height for patients with NS is approximately -2 SDS,²⁷⁷ and it was recently recognized that patients with NS show a lean body phenotype and resist weight gain during childhood and adult life.^{276,277}

Mutations in more than 15 genes acting in the RAS/MAPK pathway cause NS, as well as other rare syndromes with characteristics that overlap with NS, including cardiofaciocutaneous syndrome, Costello syndrome, NS with multiple lentiginos (formerly called *LEOPARD syndrome*), and Noonan-like syndrome with loose anagen hair.²⁷⁶ These syndromes represent a group of genetic conditions known collectively as *RASopathies*. The molecular defects associated with NS and other *RASopathies* lead to RAS/MAPK pathway hyperactivation, which is responsible for the pleiotropic effects observed in these disorders.

Diagnosis of NS should primarily be based on clinical findings. Classical facial features or typical cardiac malformation generally trigger a suspicion for NS, especially when associated with developmental delay and/or short stature. The molecular diagnosis of NS can be established by a multigene panel or whole exome sequencing (WES).²⁷⁸ Serial single-gene testing can be considered if panel testing is not feasible and should start with protein-tyrosine phosphatase nonreceptor-type 11 (*PTPN11*) sequencing because 40% of NS patients harbor heterozygous pathogenic variants in this gene. *PTPN11* pathogenic variants are more likely to be found when pulmonary stenosis is present, and mutations at codons 61, 71, 72, and 76 are associated with juvenile myelomonocytic leukemia.²⁷⁸ It is noteworthy that several studies investigating children with idiopathic short stature by multiple gene-targeted sequencing identified patients who were heterozygous for pathogenic variants in *PTPN11*, reflecting the mildest end of the clinical spectrum of NS.²⁷⁹

Disorders of *GNAS* Inactivation. Guanine-nucleotide binding protein (G protein) subunit alpha S (Gs-alpha) is a key protein that mediates the intracellular signaling of many hormone receptors by activation of adenylyl cyclase. Gs-alpha is one of the transcripts generated from the *GNAS* locus, a complex, imprinted locus that produces multiple transcripts using alternative promoters and alternative splicing. Gs-alpha shows biallelic expression in most cells (e.g., chondrocytes), but in some cells (e.g., pituitary somatotropes, proximal renal tubular cells, thyroid epithelial cells, gonadal cells), it is preferentially expressed from the maternal allele.²⁸⁰

Heterozygous inactivation of *GNAS* is responsible for two main phenotypes: PHP and PPHP.²⁶⁷ Patients with PHP show

resistance to PTH in proximal renal tubular cells and consequent hypocalcemia and hyperphosphatemia, despite high PTH concentrations. Resistance to other hormones can be observed, mainly TSH, gonadotropins, and GHRH. In addition, patients with PHP can also present with early-onset obesity and cognitive impairment. PHP can be caused by inactive mutations in *GNAS* coding regions on the maternal allele (PHP1a) or epimutation (e.g., abnormal methylation patterns), which decrease the expression of maternal Gs-alpha (PHP1b).²⁶⁷ Short stature with skeletal involvement is present in patients with PHP1a and PPHP, because of a decrease in PTHrP action through the PTH receptor (PTH1R) resulting from Gs-alpha deficiency. Patients with PPHP carry mutations in the paternal *GNAS* allele and hence do not show PTH resistance in renal tubular cells where the maternal allele is expressed. The skeletal phenotype observed in patients with PHP1a and PPHP is termed *AHO*. *AHO* is characterized by a rounded face, short stature, premature closure of growth plates, brachydactyly, and ectopic ossifications.²⁶⁷

In most children with PHP1a and PPHP the height percentile declines with age, and the bone age is usually advanced.²⁶⁷ Consequently, most patients with PHP1a and with PPHP have short stature by the time of adulthood. In both conditions, resistance to PTHrP in the growth plate likely plays an important role, and, in PHP1a, GHRH resistance may also contribute. In contrast, most patients with PHP1b are of normal stature.

It is recommended that molecular diagnosis of *AHO* should include DNA sequencing, followed by copy number variation (CNV) analysis of the *GNAS* locus for patients with PHP and PPHP. Methylation analysis of the *GNAS* locus is recommended for PHP patients with negative genetic test results.^{267,268}

3-M Syndrome. 3-M syndrome is an autosomal recessive disorder characterized by pre- and postnatal growth retardation, normal head circumference, facial dysmorphism (round face with a large forehead, hypoplastic midface, full eyebrows, short nose with anteverted nares, prominent mouth, and pointed chin), mild skeletal changes (short neck, hyperlordosis, tall vertebral bodies, and prominent heels), and normal intelligence.^{281,282} Hypogonadism and hypospadias have been reported in some male patients. To date, biallelic loss-of-function mutations in three genes (*CUL7*, *OBSL1*, or *CCDC8*) have been implicated in 3-M syndrome, but it is expected that mutations of other genes within the same pathway might be involved in patients with no identified molecular defect. *CUL7* is a ubiquitin ligase and is involved in the degradation of a number of proteins, such as p53, which regulate the cell cycle, IGF-1 signaling, and chondrocyte proliferation. 3-M syndrome is part of the differential diagnosis of SRS (see section on Imprinting Disorders—Silver-Russell Syndrome for details),

and should be considered in patients with typical skeletal findings and/or with consanguineous parents. Molecular diagnosis of 3-M syndrome is preferably established by multigene panel or WES because of genetic heterogeneity.²⁸³

DNA Damage Repair Syndromes. As a group, DNA damage repair syndromes are characterized by genetic instability, growth failure, intellectual disability, increased risk of cancer, and features of accelerated aging.²⁸⁴ These are rare conditions, but Bloom syndrome²⁸⁵ and Fanconi anemia²⁸⁶ are two important differential diagnoses for children born SGA that do not show catch-up growth. Both are autosomal recessive disorders associated with prenatal onset of growth retardation and microcephaly. Bloom syndrome is classically associated with telangiectatic erythema of the midface in a butterfly distribution, with photosensitivity and signs of immunodeficiency (i.e., increased susceptibility to pneumonia, bronchiectasis, and chronic lung disease). Fanconi anemia should be suspected when patients have a thumb deformity (hypoplasia or aplasia), and signs of bone marrow failure (anemia, neutropenia, and/or thrombocytopenia). In addition to growth impairment and low BMI, both conditions are also associated with other endocrine abnormalities. Hypergonadotropic hypogonadism is commonly observed in both conditions. In addition, patients with Fanconi anemia are also at markedly increased risk for diabetes mellitus, dyslipidemia, and thyroid dysfunction.²⁸⁶ Diagnosis of both Bloom syndrome and Fanconi anemia can be established through a specialized cytogenetic test for chromosomal abnormalities or by molecular genetic testing for biallelic pathogenic variants in an associated gene.^{287,288}

Primordial Dwarfisms. Primordial dwarfism is the term for a group of disorders characterized by extreme, global pre- and postnatal growth failure, marked microcephaly, and varying degrees of intellectual disability.^{289,290} It comprises rare recessive genetic diseases, such as Seckel syndrome, microcephalic osteodysplastic primordial dwarfism (MOPD), and Meier-Gorlin syndrome. Each of these syndromes has specific clinical features and is caused by defects in specific genes. The genetic defects associated with these syndromes compromise cell division and include abnormalities in genes that participate in fundamental cellular processes.²⁹⁰ For example, Seckel syndrome type I is caused by defects in the *ATR* gene, a master regulator of a DNA damage response signaling cascade, which is an essential regulator of genomic integrity. MOPD type II is caused by defects in the pericentrin gene (*PCNT*), which encodes a core centrosomal protein that is essential for mitotic spindle formation.

Imprinting Disorders.

Imprinting disorders are a group of congenital disorders caused by molecular changes that affect imprinted chromosomal regions and genes.²⁹¹ Imprinting is an epigenetic phenomenon in which genes are expressed in a parent-of-origin-specific manner—either expressed from the maternal or the paternal allele, not biparentally. Genomic imprinting involves DNA or histone methylation that does not alter the genetic code. Although imprinted genes may undergo mutations that affect protein function (e.g., see *IGF2* defects), in addition, their expression can be affected epigenetic changes, including alterations in DNA methylation (epigenetic mutation or epimutation) or inheritance of both alleles from the same parent (uniparental disomy).²⁹¹ SRS, Temple syndrome, and Prader-Willi syndrome (PWS) are examples of growth disorders that involve imprinted genes and can be caused by epimutations.

Silver-Russell Syndrome. SRS is a well-recognized cause of pre- and postnatal growth retardation. Typical patients are born SGA with preserved head circumference (relative macrocephaly) and do not undergo spontaneous catch-up growth in

Fig. 11.8 Phenotype of a patient with Silver-Russell syndrome: low-body mass index, triangular-shaped face, and a broad forehead with relative macrocephaly.

postnatal life (height SDS < -2 after the second year of life). In addition, patients with SRS usually have protruding foreheads, feeding difficulties with low body mass indices, and body asymmetry (Fig. 11.8).²⁵⁸ Other common features observed in patients with SRS are triangular face, micrognathia, crowded or irregular teeth, fifth finger clinodactyly, low muscle mass, and excessive sweating; males may also exhibit hypospadias. Hypoglycemia may also be a feature and necessitate overnight feeding.

SRS is often caused by imprinting abnormalities involving the chromosomal region 11p15.5.²⁹² This locus contains the *IGF2* gene, which is expressed exclusively from the paternal allele during fetal life in most embryonic tissues. Hypomethylation of the *H19/IGF2* differentially methylated region is identified in 40% to 60% of patients with SRS, whereas only 1% of patients carry CNVs in this region. Interestingly, patients with 11p15.5 epimutation frequently have multilocus imprinting disturbances, although the clinical significance of this phenomenon remains unclear.²⁵⁸ Maternal uniparental disomy involving this region [UPD(11p)m], although possible, has rarely been described. All these molecular defects lead to a decrease in paternal *IGF2* expression, which contributes to growth restriction. Less than 10% of patients with SRS carry maternal UPD of an imprinted locus on chromosome 7 [UPD(7q)m] that harbors two imprinted genes: one maternally expressed, *GRB10* (7p12.1), and another paternally expressed *MEST* (7q32).^{258,291}

There is extensive overlap in clinical phenotypes associated with SRS-related (epi)genotypes. Body asymmetry, fifth finger clinodactyly, congenital anomalies, and marked prenatal growth impairment are more frequently observed in patients with 11p15.5 hypomethylation, whereas neurocognitive problems are more frequent in patients with UPD(7q)m.^{258,293} Molecular tests are useful to confirm clinical diagnoses and are usually assessed by methylation-specific multiplex ligation-mediated polymerase chain reaction (PCR) amplification (MS-MLPA), which is cost-effective and enables parallel analysis of copy number and DNA methylation.²⁵⁸ Molecular karyotype analysis (single nucleotide polymorphism [SNP]-array or comparative genomic hybridization [CGH]-array) should be carried out in patients in which the diagnosis of SRS is considered but mUPD7 and 11p15 hypomethylation have been excluded.²⁵⁸

Prader-Willi Syndrome. PWS is an imprinting disorder characterized by neonatal hypotonia, failure to thrive in early infancy,

global developmental delay, short stature, and rapid-onset obesity during childhood with high body fat mass and low muscle mass.^{294,295} Patients typically also have some degree of intellectual disability, behavioral disorders, and small hands and feet. Patients with PWS have an increased incidence of sleep apnea and sudden death. In addition, PWS is associated with hypothalamic dysfunction causing hypogonadotropic hypogonadism, reduced GH secretion, and an increased risk of central adrenal insufficiency.^{294,295}

PWS is caused by a lack of expression of paternally inherited genes in the region of chromosome 15q11.2-q13.^{295,296} Several genes in this locus that contribute to the PWS phenotype are expressed exclusively from the paternal allele. The majority of patients (70%) have a deletion of the paternal allele, whereas one-quarter have maternal uniparental disomy [UPD(15q)m]. Imprinting defects that silence paternal genes in the PWS locus have also been observed in PWS patients but are less common.^{295,296} Although a DNA methylation analysis by MS-MLPA that is consistent with PWS is sufficient for diagnosis, identification of the underlying genetic mechanism is necessary for appropriate genetic counseling.²⁹⁶

Evidence that GH deficiency may contribute to the short stature and body composition abnormalities in PWS has motivated clinical trials of GH therapy for this disorder. These trials suggest that GH treatment of children with PWS increases linear growth, lean body mass, physical function, and decreases fat mass. As a result, GH treatment for PWS was approved by the FDA. However, final height may be compromised because of the relatively frequent occurrence of premature adrenarche. Because children with PWS are at increased risk of sleep apnea and sudden death and the possibility that GH might exacerbate this risk, clinical and polysomnographic evaluation for sleep-related disordered breathing is recommended.

Temple Syndrome. Temple syndrome is an imprinting disorder that is considered in the differential diagnosis of SRS and PWS because of phenotypic overlaps.²⁹⁷ It is mainly caused by maternal uniparental disomy of chromosome 14 [UPD(14)m] but can also be caused by epimutation and/or microdeletion affecting a paternal imprinting region on chromosome 14q32.2. Typical patients with Temple syndrome are born SGA with relative macrocephaly and do not experience catch-up growth during childhood. These individuals usually show hypotonia and feeding difficulties during infancy but develop truncal obesity later in childhood. Other features that overlap with SRS or PWS include frontal bossing, prominent forehead, small hands and feet, and mild intellectual disability. Precocious puberty and metabolic abnormalities, such as overweight/obesity, early-onset glucose intolerance/type 2 diabetes, and hyperlipidemia, are important distinguishing characteristics of patients with Temple syndrome.²⁹⁸ These metabolic associations are attributed to haploinsufficiency of *DLK1*, a paternally expressed gene located at 14q32.2, which acts as a negative modulator of adipocyte differentiation.

Chromosomal Abnormalities and Copy Number Variation. Chromosomal abnormalities constitute a well-established cause of growth disorders that was first identified after the development of classical cytogenetic techniques, such as karyotyping.²⁹⁹ Karyotyping allowed for identification of the molecular basis of Turner and Down syndromes as complete or partial X monosomy and trisomy of chromosome 21, respectively. The knowledge derived from these pioneering studies was responsible for inclusion of genetic testing in the routine evaluation of children with growth disturbance. It is accepted that karyotyping should be ordered in any female with unexplained growth failure.³⁰⁰ The clinical features of Turner syndrome are described in Chapter 17.

After the development of fluorescence in-situ hybridization and array-based techniques, it became feasible to identify an

increasing number of small, unbalanced structural rearrangements that are below the resolution limit of the light microscope. These submicroscopic deletions and duplications involve a single gene or can involve a set of genes in close proximity and thus can cause contiguous gene syndromes. The patients' phenotype is determined by the combination of phenotypes associated with each gene present in the unbalanced chromosome segment. There are numerous examples of contiguous gene syndromes associated with growth disorders,²⁷¹ such as Williams-Beuren syndrome, caused by 7q11.23del, and DiGeorge syndrome, caused by 22q11.2del. The prevalence of pathogenic CNV in children with short stature of unknown etiology reportedly ranges from 10.4% to 15.5%, being more frequent in patients with developmental delay, intellectual disability, or additional major malformations.³⁰¹ However, both in research studies and in clinical practice, it is often difficult to determine whether a particular CNV is pathogenic or benign and coincidental.

Idiopathic Growth Impairment. Often children present to an endocrinologist with short stature of postnatal onset, and an etiology cannot be identified. In these idiopathic conditions, there are clues that the underlying unknown etiologies are likely to be extremely diverse. Some idiopathic short stature is inherited in a pattern that suggests a polygenic inheritance, whereas others show a monogenic recessive or monogenic dominant pattern. Some short stature is proportionate, affecting different bones in the body similarly, whereas some is disproportionate, often with growth of the extremities affected more than growth of the spine. In some children, the child appears completely healthy and normal whereas other children have dysmorphic features, developmental delay, or other health problems, suggesting that an underlying genetic change may affect more than just growth plate chondrocytes. In some children with idiopathic short stature, the weight is affected more than the height, suggesting that the decreased linear growth is secondary to decreased nutrition, perhaps involving reduced appetite.³⁰² In some children with short stature of unknown etiology, body length was already below normal at birth, suggesting that linear growth was impaired in the fetus. In other children, the birth size was normal, and the short stature developed at some point during childhood, suggesting that the linear growth impairment only became manifest in postnatal life.

What might be the etiologies? We can speculate that the etiology of the decreased growth plate chondrogenesis in these children may fall into the same categories as the known etiologies of short stature. Some may be endocrine, for example, GH or IGF-1 effects that are too subtle to be detected by our current tests. Others may involve local paracrine/autocrine signaling systems, cartilage matrix, or intracellular regulatory mechanisms. Some may be mild forms of known skeletal dysplasias or dysmorphic syndromes, but with manifestations too subtle for clinical recognition. Others are likely caused by genes whose effect on growth plate chondrogenesis is currently unknown.

Following traditional classification schemes, short stature of postnatal onset and short stature of prenatal onset are discussed separately in the following sections.

Idiopathic Short Stature of Postnatal Onset, Including Constitutional Delay. In many children with short stature of postnatal onset, the etiology cannot be determined despite a careful medical history, physical examination, and laboratory studies. In some of these children, both parents, the siblings, and other family members are short, suggesting a polygenic inheritance. Presumably, these children have inherited multiple sequence variants each of which has a mild, negative effect on linear growth. Some of these variants are likely to be common polymorphisms that have been identified by recent GWAS.⁷⁴

In other children, the short stature appears to be inherited primarily from one parent, and a careful family history suggests an autosomal dominant inheritance. In these children, the short stature primarily arises from a single genetic variant. Some dominant causes, such as mutations in *SHOX* or *NPR2* are known, but it is likely that there are many monogenic causes yet to be discovered.

Some children with short stature show a marked delay in physical maturation, with a delayed bone age, a delayed onset of puberty, and continuation of linear growth to a later age than other children. Professor James Tanner, a pioneer in the field of childhood growth, used the musical term *tempo* to describe this overall pace of maturation, which varies between different children. The term *constitutional delay* of growth and puberty is used to describe children with a delayed tempo. This term can conflate two conditions—constitutional delay that has a clinical onset at puberty and constitutional delay that has a clinical onset in early childhood.

Some children have a delay of pubertal onset in which the primary cause appears to be a delay in the activation of the HPG. Often there are other family members with a similar delay in pubertal activation and sometimes family members with hypogonadotropic hypogonadism. These children typically grow normally in the prepubertal years. After the normal age of pubertal onset, a transient delay in sex steroid secretion in these children causes their linear growth percentile to decrease. This decrease in percentile results in part from the fact that other children undergo a pubertal growth spurt, causing the normal percentile curves to pull away from the delayed child. However, even if one ignores the upward deflection of the normal range, the linear growth rate of the child with delayed puberty tends to decline from his or her prior prepubertal rate, presumably because of progressive growth plate senescence without the countervailing accelerating effect of sex steroids. In these children, once puberty starts at a late age, a pubertal growth spurt occurs. Although the magnitude of the pubertal growth spurt is typically diminished compared with a child with earlier pubertal onset, the overall prolonged period of growth allows for a normal or even tall adult stature.

In other children with constitutional delay the delay appears to have a prepubertal onset. These children are short throughout childhood and have a delayed bone age even before puberty. Some of these children may be short in childhood but, because of the delayed cessation of growth in adolescence, will end up at a normal adult height. In other children with this form of constitutional delay, the adult stature may be somewhat low. In these children, a primary lesion affecting the HPG axis could not account for the condition. One possible contributing factor to explain the decreased growth, bone age delay, and pubertal delay is diminished appetite.³⁰²

Short Stature of Unknown Etiology and of Prenatal Onset. In some children with short stature, body size was already diminished at birth, that is, the child was born SGA. Various definitions of SGA have been used. However, a consensus statement defines SGA by a weight and/or length less than -2 SDS.³⁰³ A history of being born SGA indicates a process that diminishes fetal growth because of fetal, placental, or maternal abnormalities. Fetal causes include genetic disorders (such as single gene defects, imprinting defects, deletions/duplications, and aneuploidy—see discussions earlier in chapter), fetal infection (such as cytomegalovirus and toxoplasmosis), and multiple gestations. Placental causes include confined placental mosaicism, abruptio placenta, placenta previa, and other conditions associated with uteroplacental insufficiency. Maternal causes include preeclampsia; hypertension; pregestational diabetes mellitus; and systemic maternal renal, cardiac, pulmonary, hematological, and rheumatological disorders, as well as maternal use of alcohol

or cigarettes. However, in many infants born SGA, the underlying etiology remains unknown.³⁰⁴

If the SGA child continues to fall further away from the normal range postnatally, then the underlying etiology likely involves a fundamental process that affects both fetal and postnatal growth, for example, some chondrodysplasias. Genetic disorders that cause both marked fetal and postnatal growth impairment are referred to as *primordial dwarfisms*. Typically, the growth impairment affects multiple tissues, including the CNS, resulting in a relatively small head size. Often, in addition to diminished growth, there are congenital anomalies. This category is heterogeneous and includes recognized genetic syndromes, such as Seckel syndrome, microcephalic osteodysplastic primordial dwarfism types I and II, and Meier-Gorlin syndrome.³⁰⁵ Multiple genetic defects have been identified, involving fundamental cellular functions, for example, DNA replication, DNA repair, RNA splicing, and centrosome formation.²⁹⁰ SRS is characterized by decreased fetal and postnatal growth, which can affect body size asymmetrically. A triangular-shaped face, prominent forehead, and specific minor anomalies are often found (see Primary Growth Impairment—Imprinting Disorders earlier).

However, in most children born SGA, the growth rate after birth exceeds normal, causing catch-up growth. Much of this catch-up growth occurs during the first year of life and approximately 90% of term SGA children attain a stature greater than -2 SDS by 2 years of age.³⁰³ However, the adult height of individuals born SGA is decreased by approximately 1 SDS compared with the normal population.³⁰³ Catch-up growth tends to be more gradual and less complete in preterm SGA children. For children born SGA whose height fails to catch up into the normal range, treatment with recombinant GH increases linear growth and is approved for this use in both the United States and Europe.

There is evidence that individuals born SGA tend to show more insulin resistance and adiposity than those born at normal size. The effects appear to be greater in those who were SGA but gained weight rapidly during the first 3 months of life.³⁰⁶ There is also evidence that girls born SGA have a tendency to earlier menarche, although usually still within the normal range, and are also more likely to have premature adrenarche,³⁰³ although not all studies support these conclusions.³⁰⁷

Diagnostic Approach to the Patient With Short Stature

Although short stature itself is not a disease, growth failure can be a sensitive sign of an underlying health problem. The diagnostic evaluation should first try to distinguish healthy variant from pathological growth patterns and, for the latter, identify the underlying cause and treat them accordingly.

Time Course. The onset of growth faltering can be a very helpful clue for narrowing the differential diagnosis. To ascertain the time course accurately, the clinician must have the child's growth records available, both for length/height and weight, preferably beginning at birth. Because these records are of such value to the diagnostic evaluation, the parents should be urged to obtain a complete set. If the data are not already plotted on appropriate length/height and weight growth charts, the clinician should do so. The clinician then visually evaluates the overall pattern of growth to determine when the growth rate was subnormal, that is, when the child's height or weight was crossing percentiles downward. Often the growth curve will show some irregularities resulting from measurement error, and the experienced clinician learns to smooth the data in the mind's eye.

If the child's height and/or weight were subnormal at birth (SGA), the implication is that the growth rate was below

normal in utero and therefore that a condition interfering with growth was already present in fetal life. If the growth curves then show recovery after birth, the overall pattern suggests a condition that was present in utero but then resolved, such as a maternal or placental disorder. In contrast, if the SGA child continues to show slow growth postnatally, the pattern suggests an intrinsic growth problem, such as a genetic syndrome or skeletal dysplasia.³⁰⁸ Similarly, defects in IGF-1 action, including *IGF-1* gene defects, *IGF1R* gene defects, as well as *IGF-2* gene defects and SRS, cause combined pre- and postnatal growth failure. If the child is born at a normal size but then grows slowly during early postnatal life, the clinician should suspect a congenital disorder that affects postnatal but not fetal growth, including congenital GH deficiency or GH insensitivity syndrome. Onset of growth faltering during childhood suggests an acquired problem, for example, IBD, a tumor causing pituitary dysfunction, or a medication that interferes with growth. The astute clinician can sometimes find a correspondence between the onset of slow growth on the growth chart and some event in the child's history, such as starting a growth-suppressing medication or the onset of an illness. Such a temporal correspondence suggests a causal relationship. Onset of growth slowing during adolescence may also result from delayed puberty.

Inheritance Pattern. A careful family history, ideally including the heights of parents, siblings, grandparents, aunts, uncles, and cousins, can be highly informative. Traditionally, the family history is used to categorize the short stature as either familial or nonfamilial. However, this categorization is confusing in terms of the underlying genetic etiology. Familial short stature conflates monogenic short stature (primarily because of a mutation in a single gene, either dominant or recessive) and oligo/polygenic short stature. Nonfamilial short stature, despite the label, can still be genetic (see later).

Therefore it is more helpful to use the pedigree to help distinguish monogenic (primarily autosomal dominant and autosomal recessive) causes of short stature from oligo/polygenic causes. In some cases, the short stature appears to be inherited from an affected parent and an affected grandparent, suggesting a dominantly inherited defect, for example *SHOX* deficiency or a heterozygous *NPR2* mutation. Less often, short stature occurs in two affected siblings with unaffected parents, suggesting a recessive disorder, such as GH insensitivity syndrome or 3-M syndrome. In other cases, the child is uncharacteristically short compared with all the other family members. This apparently sporadic short stature could be caused by an acquired problem or by a genetic defect that is autosomal recessive, de novo dominant, or (if the patient is male) X-linked recessive. If the parents are of truly midnormal stature or even tall, the condition is less likely to be polygenic. In other families, multiple family members are short, in a pattern that cannot be explained by a monogenic inheritance, suggesting an oligogenic or polygenic inheritance. These conditions are generally benign.

In practice, the pedigree may not clearly distinguish between a monogenic and polygenic inheritance, in part because of assortative mating, that is, the tendency of short individuals to mate with other short individuals. As a result, families may have components of both monogenic and oligo/polygenic short stature. When there is a wide spread in parental heights, a child may take after one or the other parent's height channel rather than the calculated average, and with random assortment of genes at each and every conception, it is impossible to predict a priori which parent that is.

Careful Medical History and Physical Examination. With the differential so broad, a careful and comprehensive history is critically important. Multigenerational history of adult heights and pubertal timing, as well as diseases that run in

the family, is needed to set the stage. The family history should identify family members with delayed puberty, which would suggest constitutional delay of growth and puberty, as well as those with early puberty, which can also be a heritable factor affecting a child's growth pattern. In addition, the clinician should ask about family history of medical illnesses that have a hereditary component and might affect growth, such as hypothyroidism.

Prenatal and birth history, particularly birth weight and length and gestational age, help identify conditions that affect fetal growth. Detailed questioning should be used to screen for subtle symptoms of systemic illnesses, for example, gastrointestinal disease, CNS tumors, GH deficiency or other pituitary disease, hypothyroidism, Cushing syndrome, and eating disorders. Medications should be ascertained. History of neonatal jaundice or hypoglycemia, CNS malformations (especially SOD and holoprosencephaly), history of head trauma or neurological insult, and history of neoplasia, especially when treated with cranial irradiation, should raise suspicion for possible GH deficiency. For adolescents, the age of thelarche, pubarche, menarche, and voice change, as appropriate, are needed to place the growth pattern within the context of pubertal timing. Social and nutritional histories sometimes make the diagnosis.

The physical examination serves particularly to screen for dysmorphic syndromes and systemic illnesses. The clinician should look carefully for dysmorphic features that might point to a syndrome, such as Silver-Russell, Turner, Noonan, Down, Prader-Willi, or Williams syndrome, or *SHOX* haploinsufficiency. Comprehensive physical examination should include funduscopy, visual fields by confrontation, and thyroid palpation. GH deficiency may be associated with midline defects (especially central maxillary incisor), nystagmus (presenting sign of SOD), and papilledema, and in boys, micropenis, mid-face hypoplasia, abdominal adiposity, and high-pitched voice. Similarly, signs of hypothyroidism should be sought.

Evaluation of dental age may provide insight into a child's skeletal maturation. There are wide variations in the time of eruption of primary and secondary teeth, which may be affected by local and environmental factors, such as jaw size, position of the unerupted teeth, and premature loss of deciduous teeth. Children with GH deficiency or untreated hypothyroidism usually have significantly delayed dentition or abnormal teeth (hypodontia, usually of the maxillary incisors). Mild delays in dental progress may occur in constitutional growth delay. Delays in dentition are often associated with delayed closure of the fontanels and delayed bone age.

Anthropometrics. Accurate anthropometric measurements should be performed (see section on Measurement earlier in this chapter) including height, weight, head circumference, arm span, and sitting height or lower segment. Abnormal body proportions can be a valuable clue for the diagnosis of a chondrodysplasia. Many chondrodysplasias affect the growth plates of the extremities more than those of the vertebrae, resulting in an increased sitting height index, increased upper-to-lower segment ratio, and short arm span compared with the height. Conversely, a disproportionately short trunk can reflect conditions that adversely affect the vertebrae, such as scoliosis, spinal irradiation, or certain chondrodysplasias. When disproportionate short stature is suspected, further measurements of the various limb segments should also be made to distinguish rhizomelic, mesomelic, and acromelic conditions. The diagnosis of a specific chondrodysplasia can often be made by expert interpretation of skeletal radiographs complemented with specific biochemical and genetic tests that target the specific causal mutations.⁸⁹

The relative gain in weight compared with gain in height is important to consider in every child undergoing a growth

BOX 11.3 Body Mass Index

$$\text{Body mass index (BMI)} = \frac{\text{weight (kg)}}{(\text{height in meters})^2}$$

evaluation, even those without any gastrointestinal symptomatology, to exclude a nutritional cause of growth faltering. BMI (Box 11.3) is calculated for children over age 2 years, and weight-for-length can be used from birth to age 5 years; both are plotted on their respective growth charts (available at https://www.cdc.gov/growthcharts/cdc_charts.htm). Although BMI or weight-for-length “below the curves” is an obvious sign of severe malnutrition, growth faltering can result from milder cases of malnutrition that plot within the “normal” ranges. Drop across major centiles of BMI or weight-for-length and/or a drop in weight-for-age centiles that precedes the drop in height-for-age centiles should alert to a possible underlying nutritional problem. In contrast, when the height is affected similarly to the weight or more than the weight (resulting in a normal to mildly increased BMI), one should suspect disorders in which the growth plates are affected more than the growth of other tissues, for example, GH deficiency, hypothyroidism, and chondrodysplasias. When the height percentile decreases but the weight percentile increases, glucocorticoid excess should be considered.

Prenatal malnutrition can result in a birth size characterized by SGA or IUGR. Infants exposed to early fetal malnutrition have low birth weight and are symmetrically small (proportionate IUGR). Undernutrition in late pregnancy results in an asymmetrically growth-restricted infant whose head circumference is preserved by a physiological adaptation (brain-sparing phenomenon).

Bone Age. Although the bone age is helpful in assessing a patient’s growth potential, it provides only limited information as to the underlying cause of the short stature. A bone age can be delayed because of constitutional delay, many systemic or endocrine diseases impairing growth, chronic glucocorticoid treatment, or malnutrition. A bone age consistent with the chronological age can occur in polygenic familial short stature, some monogenic causes of isolated short stature, some syndromic causes, and some chondrodysplasias. An advanced bone age, which occurs uncommonly in children with short stature, points to specific genetic disorders, such as heterozygous *ACAN* mutations, *AHO*, and *SHOX* deficiency.

Screening Laboratory Investigations. Not all children with short stature need a screening laboratory investigation. For example, in a child who has been growing steadily just below and parallel to the lower limit of normal for stature, who appears otherwise healthy in the medical history and physical examination, and who has a pedigree suggesting polygenic short stature, the yield of laboratory investigation would be very low. A second example would be a child with a condition, such as a genetic syndrome, that readily explains the short stature. However, when the pattern of growth, medical history, physical examination, or pedigree are concerning for an occult pathological etiology (see sections on Time Course, Inheritance Pattern, Careful Medical History and Physical Examination, and Anthropometrics), then a laboratory investigation may be warranted.³⁰⁹

Recommended laboratory screening tests may include a complete blood count, erythrocyte sedimentation rate, creatinine, glucose, electrolytes, bicarbonate, liver function tests, calcium, phosphate, albumin, celiac screen, FT4, TSH, IGF-1 and, in younger children, IGFBP-3.^{309,310} A karyotype or microarray

should be performed in girls with unexplained short stature to exclude a diagnosis of Turner syndrome³¹¹ and in short boys with associated genital abnormalities. A radiograph of the left hand and wrist should be obtained for a bone age evaluation by an expert to estimate the remaining growth potential. Malformations on this radiograph may sometimes point to a skeletal dysplasia. An advanced bone age in a child with short stature suggests specific genetic etiologies, such as *ACAN* mutations.²⁷⁰ A skeletal survey should be considered in children with suspicion for a skeletal dysplasia, such as those with disproportion or those with a family history of disproportionate short stature.

There is evidence that such laboratory screening approaches have a low yield in a population of children below the third percentile for height, negative history, review of systems, and normal physical examination,³¹² again emphasizing that these laboratory tests can be reasonably omitted in some children, as discussed earlier.

Measurement of Insulin-Like Growth Factor-1 Concentrations in Growth Disorders. Serum IGF-1 concentrations are greatly influenced by chronological age, degree of sexual maturation, and nutritional status.³¹³ As a result, use of normative values based on both age and pubertal stage is critical. For example, using a normal range for Tanner I children is problematic because normal IGF-1 concentrations rise substantially with age even before puberty. Conversely, using the normal range for 14-year-old boys as normative data for a prepubertal patient of that age is also problematic because the patient will have lower IGF-1 concentrations because of lower sex steroids. Therefore a practical approach is to use age-specific normative data for children of prepubertal age and to use pubertal stage-specific normative data for children of pubertal age.

Serum IGF-1 concentrations are commonly used as a screening test for GH deficiency. This use is based on the well-established physiological observation that GH stimulates circulating IGF-1 concentrations. Consequently, IGF-1 concentrations are, on average, lower in children with GH deficiency than in normal children or children with non-GH-deficient short stature. However, there is extensive overlap between the serum IGF-1 concentration in GH-deficient and non-deficient children both because GH-deficient children can have serum IGF-1 within the lower portion of the normal range and because non-GH-deficient children with short stature can have serum IGF-1 below the normal range. Thus serum IGF-1 appears to show both incomplete sensitivity and specificity for GH deficiency.^{314–316} However, studies in this area are complicated to interpret because we do not have a gold standard test for GH deficiency, but instead rely on provocative GH tests, which are also problematic (see section Follow-Up Laboratories and Imaging later). As a practical matter, serum IGF-1 concentrations may help direct the evaluation toward or away from GH deficiency but should be interpreted with caution. Low IGF-1 concentrations can also be seen in other conditions, for example, malnutrition, GH insensitivity, *IGF1* mutations, and ALS deficiency. High IGF-1 concentrations can occur in some causes of short stature, for example, *IGF1R* mutations, in which the IGF-1 concentrations tend to be above the average for age unless the patient is malnourished, and *PAPPA2* mutations.

Because GH stimulates not only IGF-1 but also IGFBP-3 production, serum IGFBP-3 can similarly be used as a screening test for GH deficiency. Blum and associates³¹³ have suggested that radioimmunoassay determination of serum concentrations of IGFBP-3 might be more specific (but less sensitive) than IGF-1 assays in the diagnosis of GH deficiency and may be useful in young children in whom the normal concentrations of IGF-1 are low and therefore difficult to distinguish from GH deficiency.

Follow-Up Laboratories and Imaging. After screening laboratories (random blood draw) narrow the differential diagnosis, follow-up functional testing may be needed. The most commonly performed functional tests are provocative GH tests (also called *GH stimulation tests*) to diagnose GH deficiency. Because of its pulsatile secretion during deep sleep, random GH levels are generally uninformative except in the neonatal period, before the sleep entrainment develops.³¹⁷ Measurement of circulating concentrations of IGF-1 and IGFBP-3 may be helpful but are generally not definitive, as discussed earlier. Thus a group of provocative (stimulation) tests has been developed in which GH concentrations are serially measured via an in-dwelling intravenous catheter after administration of pharmacological agents identified as GH secretagogues (Table 11.5). These tests should be performed in the fasting

TABLE 11.5 Provocative Growth Hormone Tests Used to Diagnose Growth Hormone Deficiency

Stimulus	Dosage and procedure	Sampling for GH, min
Exercise	Forced climbing of steps Cycle ergometer, 2 W/kg BW (10 min)	0, 15–20 after start
Arginine HCl	0.5 g/kg BW (max, 30 g) (infused IV 10% arginine HCl in 0.9% NaCl at a constant rate over 30 min)	–30, 0, 15, 30, 45, 60, 90, 120
Ornithine HCl	12g/m ² BSA (infused IV 6.25% ornithine HCl in 0.9% NaCl at a constant rate over 30 min)	–30, 0, 15, 30, 45, 60, 90, 120
Insulin (regular)	0.1–0.05 IU/kg BW IV	–30, 0, 15, 30, 45, 60, 90, 120
Arginine HCl-insulin	See arginine test (insulin is injected [see earlier] 60 min after administration of arginine)	–30, 0, 15, 30, 45, 60, 80, 90, 105, 120, 150
Clonidine (2-[2,6-dichlorophenyl] amino-2-imidazoline)	0.15 mg/m ² BSA orally	–30, 0, 30, 60, 90, 120, 150
Glucagon	0.03 mg/kg BW (IM or SC) (may be combined with propranolol, 0.75 mg/kg BW orally 2 h before glucagon)	0, 60, 90, 120, 150, 180
L-Dopa (L-3,4-dihydroxyphenylalanine)	< 15 kg BW: 125 mg <35 kg BW: 250 mg >35 kg BW: 500 mg (taken orally)	–30, 0, 30, 60, 90, 120
GHRH (1–40) (1–44) (1–29)NH ₂	1 g/kg BW IV bolus	–30, 0, 15, 30, 45, 60, 90, 120

BSA, Body surface area; BW, body weight; GHRH, GH-releasing hormone. IM, intramuscular; IV, intravenously; SC, subcutaneously. From Ranke MB. Diagnosis of GH Deficiency and GH Stimulation Tests. In: Ranke MB, ed. *Diagnostics of Endocrine Function in Children and Adolescents*. 3rd Ed. Basel, Switzerland: Karger; 2007:107–128. Table 3.

state and hypothyroidism, if present, should be corrected before testing. Because of the high frequency of false “failure” results on any provocative test, a conventional standard has developed that diagnosis of GH deficiency requires inadequate peak GH concentrations on two different provocative GH tests (which can be performed in sequence on the same day). The generally accepted diagnostic GH threshold is 10 mcg/L.

Unfortunately, even the combination of two provocative GH tests, as commonly performed, has poor test specificity. Marin and colleagues performed provocative GH testing (exercise and arginine-insulin) on normal children and found that the majority of prepubertal, healthy children had a peak GH response less than 10 mcg/L on all three tests. The lower limit of the normal range was approximately 2 mcg/L. These data suggest that GH stimulation testing results in a very large number of false positive diagnoses.¹⁹¹ The test specificity improved with increasing Tanner pubertal stage. There is also evidence that GH response and therefore test specificity decreases with BMI, even within the normal BMI range¹⁹³ and children with obesity have particularly low GH concentrations. Overdiagnosis of GH deficiency has potential adverse consequences, including the psychological effects of incorrectly labeling a child as having a disease, the triggering of additional testing, such as pituitary MRI and pituitary function tests, a failure to pursue other testing to find the actual cause of growth failure, and taking away the family’s ability to make an informed decision about whether to use GH treatment in a child with non-GH-deficient short stature. The latter concern may be partially addressed by informing the family about the high rate of false positive stimulation tests. The poor specificity of provocative GH tests in children also may explain why isolated childhood GH deficiency frequently is not confirmed when the patient is retested as a young adult.^{318,189}

Sex steroid priming before provocative GH testing augments the ability of the secretagogues to elicit a GH response and improves test specificity. In the study by Marin and colleagues cited earlier, when prepubertal children received estrogen priming before the provocative GH testing and when a diagnostic threshold of 7 mcg/L was used, then provocative GH test showed acceptable specificity.¹⁹¹ Similar studies suggest that estrogen priming improves specificity while retaining adequate sensitivity, but test sensitivity is difficult to assess, particularly for partial GH deficiency, because we lack a gold standard for the diagnosis to which other tests can be compared.¹⁹² In studies supporting estrogen priming, priming was used even in young children; even though high estrogen concentrations are nonphysiological at a young age, the estrogen served as a useful adjunctive pharmacological stimulus. Despite these data, GH stimulation testing is commonly performed without sex steroid priming.

Because of the significant limitations of provocative GH tests, the Pediatric Endocrine Society Guidelines for GH treatment recommended “against reliance on GH provocative test results as the sole diagnostic criterion of GH deficiency,”³¹⁹ but rather suggested that the test results should be interpreted in the context of the patient’s growth pattern, risk factors for GH deficiency, and other diagnostic test results, such as IGF-1 and IGFBP-3 concentrations, bone age, and pituitary imaging (see later).

Similar logic was used in creating the IGF-1 generation test to diagnose primary IGF-1 deficiency (PIGFD). In this case, GH is used as the secretagogue, and the serum IGF-1 response is measured to identify those patients whose low random IGF-1 concentration results from GH insensitivity. Such patients would be expected to similarly fail to increase their IGF-1 production (and hence, growth) in response to GH therapy and might be better served with recombinant IGF-1 treatment instead. However, this test too is fraught with limitations; although multiple test protocols have been proposed, no

standard IGF-1 generation test protocol with a highly sensitive and specific IGF-1 threshold has been established.³¹⁹

MRI of the pituitary, with and without contrast, is standard of care for all patients diagnosed with GH deficiency. The goal is to screen for pituitary malformations and for neoplasms. However, the majority of cases of IGH deficiency remain idiopathic, in part because imaging can capture only gross structural defects, whereas GH deficiency can arise from cellular and molecular defects that cannot be visualized by MRI. In addition, the likely high rate of false positive diagnoses of GH deficiency may contribute to the low yield of findings on imaging. In patients with GH deficiency, additional pituitary hormone deficiencies should be sought.

Genetic Testing. Genetic tests are being progressively introduced into clinical practice for investigating patients with growth disorders. Current genetic testing is primarily able to identify the etiology only in children with monogenic, not polygenic, growth disorders. Patients with severe short stature (height SDS < -3), from consanguineous parents or families with clear autosomal dominant short stature, with evidence of a skeletal dysplasia or with a complex phenotype (syndromic condition) are more likely to have a monogenic genetic condition.¹⁰³ Even in children with monogenic growth disorders, genetic testing often fails to uncover the etiology. This frequent failure occurs in part because the genetic etiology of growth disorders is highly heterogeneous and many of the involved genes remain to be discovered. In addition, the genetic testing may reveal a variant in a gene known to be responsible for the growth disorder, but there may not be sufficient evidence to determine whether that particular variant is pathogenic.

There are three main scenarios in which a genetic test for children with short stature should be requested (Fig. 11.9). The first is when there is a clinical suspicion of a specific genetic condition in a patient. In this situation, genetic tests serve to confirm a suspected diagnosis. A molecular confirmation of the diagnosis has a more obvious impact on genetic counseling and patient care when the phenotype does not allow an unambiguous diagnosis. For example, for a 2-year-old patient with a phenotype typical of ACH, the genetic test could be postponed. In contrast, for a patient at the same age that is suspected to have NF-1, but who does not fulfill the diagnostic criteria because of their young age, a positive genetic test could evince valuable information, with immediate consequences in the follow-up evaluation. In patients with a recognizable condition that is caused primarily by mutations in a single gene, sequencing that single candidate gene is feasible. However, in

conditions with genetic heterogeneity or involving large genes, the use of a targeted sequencing panel or exome sequencing may be preferable.

The second scenario involves patients with syndromic phenotypes that do not fit any recognized condition. For these patients, molecular genetic investigation using a genome approach, such as by molecular karyotyping (SNP array or array-CGH)³⁰¹ and/or WES^{103,320} can identify a causative genetic variant in a significant number of cases.

The third scenario applies to patients with isolated short stature, in other words, to healthy children with height SDS < -2 and normal laboratory and radiological investigation. Certainly, this scenario comprises the majority of children evaluated for growth impairment. Many of these children have parents with short stature, supporting the presence of a genetic factor in their height. It has long been thought that such children have a polygenic etiology,^{76,321} but recent studies have demonstrated several monogenic causes in patients initially classified as ISS³²² (Table 11.6). A proportion of these children are on the mild end of the phenotypic spectrum of a known syndromic disorder associated with short stature,³²³ such as NS. Furthermore, numerous studies have associated specific genes mainly involved in growth plate regulation, such as *SHOX*,⁸⁶ *ACAN*,²⁷⁰ *NPR2*,^{54,324} *NPPC*,²⁶² and *IHH*,⁶¹ which result in isolated short stature phenotypes. Patients with short stature caused by defects in these genes may also show nonspecific radiological findings (Fig. 11.10), such as advanced bone age or abnormalities in the metacarpals or phalanges. Each of these genes accounts for a small fraction of short stature cases ($\leq 1\%$ – 2%), but may be significantly higher in cases of familial short stature.³²⁴ In children with ISS, the absence of specific clinical findings makes recognition difficult without a molecular genetic study and makes the candidate gene approach impracticable. For these reasons, a multiple-gene testing approach using next-generation sequencing is preferable for investigation of ISS. The choice to use WES or gene-panel analysis depends on the availability of facilities and cost-benefit evaluations.³²⁵ Even when using WES, analysis should prioritize genes already associated with the isolated short stature phenotype and genes associated with syndromic conditions that exhibit well-documented phenotypic variability (see Table 11.6). Although a conclusive diagnosis cannot be made for most patients with ISS after broad genetic investigation, a positive result will have a significant impact for patients and their families.³²⁶ It is expected that molecular genetic screening using a panel of genes or exome analysis will become increasingly valuable in the diagnostic evaluation of children with isolated short stature^{322,326} because, over time,

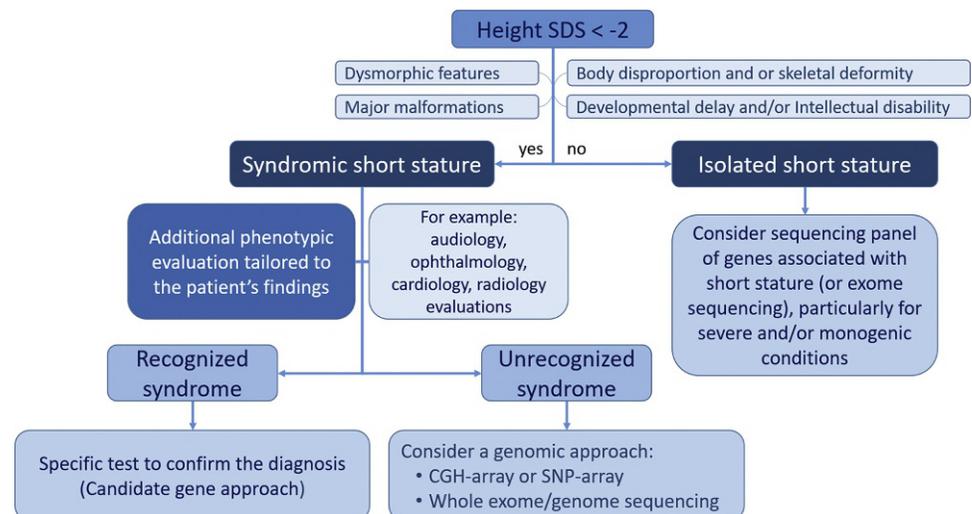

Fig. 11.9 Overview of the molecular genetic investigation of children with short stature.

TABLE 11.6 Genes Associated With Isolated Short Stature Phenotype, Usually Initially Classified as Idiopathic Short Stature

Gene	Inheritance Pattern	Frequency ^a	Evidence of Association ^b	Observation	Ref
GENES INVOLVED IN GH-IGFs AXIS					
<i>GH1</i>	AD	NA	Limited		386
<i>GHSR</i>	AD/AR	NA	Limited	It may be associated with GH deficiency in the same family	13
<i>GHR</i>	AD	NA	Limited	Mild GH insensitivity phenotype (Low IGF-1 and GHBP levels)	387
<i>STAT5B</i>	AD	NA	Limited	Mild GH insensitivity phenotype with eczema	206
<i>IGFALS</i>	AR	NA	Strong	Severe IGF-1 and IGFBP-3 deficiency out of proportion to the mild height deficit	388
<i>IGF1</i>	AD	NA	Limited		210
<i>IGF1R</i>	AD	NA	Moderate	Majority born SGA and elevated IGF-1 concentrations either basal or during rhGH therapy	389
<i>PAPPA2</i>	AR	NA	Limited	Elevated IGF-1 and IGFBP-3 concentrations	28
GENES INVOLVED IN GROWTH PLATE DEVELOPMENT					
<i>SHOX</i>	AD	1%–16%	Strong	Mild body disproportion, sometimes with family members with typical LWD	390
<i>ACAN</i>	AD	1.4%–2.1%	Strong	Advanced bone age	391
<i>NPPC</i>	AD	NA	Limited	Mild brachydactyly	262
<i>NPR2</i>	AD	1.2%–3.4%	Strong	Short metacarpals in some patients	392
<i>FGFR3</i>	AD	NA	Limited	Normal body proportion in contrast with hypochondroplasia phenotype	55
<i>IHH</i>	AD	1.6%	Moderate	Shortening of middle phalanges of 2 nd and 5 th fingers in some patients	61
GENE INVOLVED IN RAS-MAPK PATHWAY					
<i>PTPN11</i>	AD	1.5%	Limited	Clinically unrecognized mild forms of Noonan syndrome	279

^aFrequency observed in studies that evaluated unselected children with isolated short stature (idiopathic short stature or nonsyndromic small for gestational age).

^bStrength of evidence that changes in this gene are associated with the isolated short stature phenotype³⁹³ (many of these genetic changes have been more clearly associated with syndromic short stature).

AD, Autosomal dominant; AR, autosomal recessive; GH, growth hormone; GHBP, GH binding protein; IGF, insulin-like growth factor; IGFBP, insulin-like growth factor binding protein; IHH, Indian hedgehog; LWD, Leri-Weill dyschondrosteosis; NA, not available; rhGH, recombinant human GH; SGA, small for gestational age.

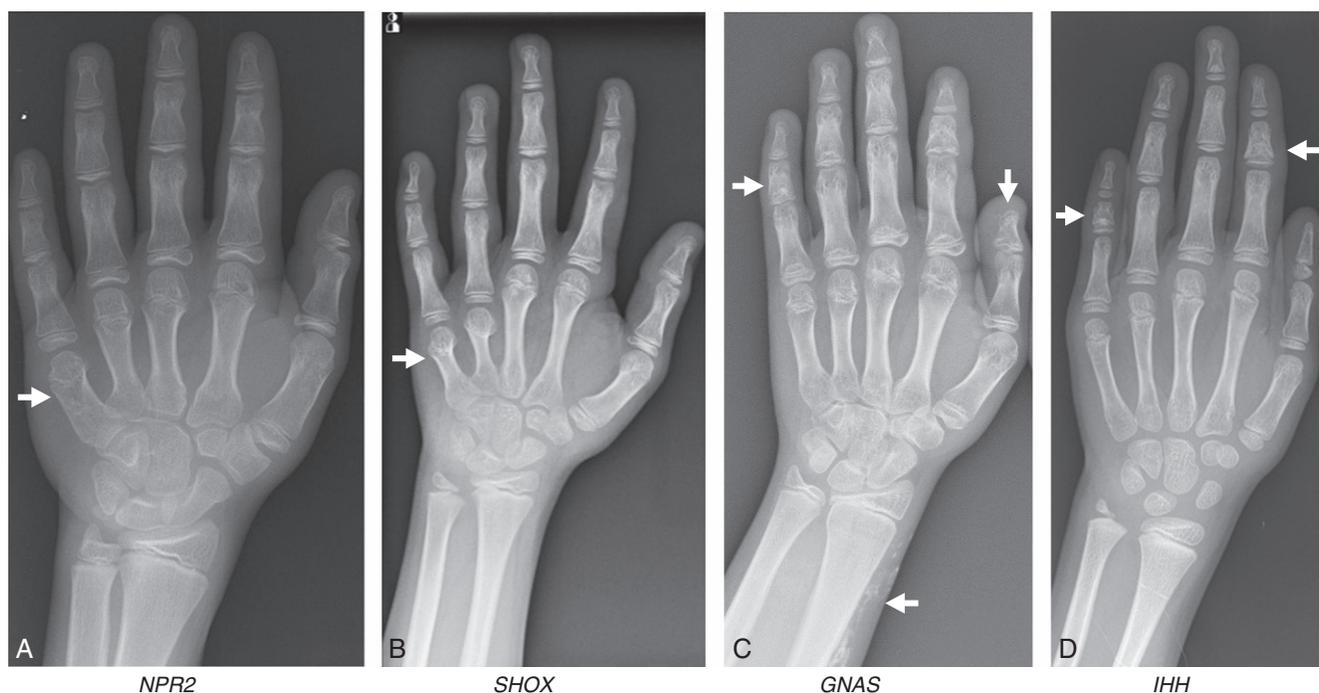

Fig. 11.10 Hand radiographs of children with short stature with nonspecific skeletal abnormalities associated with heterozygous variants in genes involved in growth plate development. A, Short metacarpals observed in some patients with natriuretic peptide receptor 2 (NPR2) variants; B, short fourth and fifth metacarpals in a patient with short stature homeobox (SHOX) haploinsufficiency; C, shortening of middle phalanges and distal phalanx of the thumb with the presence of subcutaneous ossifications in a patient with pseudopseudohypoparathyroidism because of guanine nucleotide binding protein(s) (GNAS) defect inherited from the father; and D, shortening of the middle phalanx of the second and fifth fingers with cone-shaped epiphyses associated with Indian hedgehog (IHH) gene defects.

additional causative genes and additional causative variants within known genes will be discovered and because the cost, coverage, and accuracy of the sequencing will improve.

Treatment of Short Stature

When a treatable cause of the short stature is uncovered, for example, celiac disease or hypothyroidism, there is usually little difficulty deciding on a plan to treat the underlying problem. Often, however, either the etiology remains unclear (idiopathic short stature) or the etiology is known but a specific treatment that specifically corrects the underlying etiology is not known. In these cases, the clinician and family may consider a nonspecific treatment to attempt to compensate for the underlying cause of diminished growth. Although multiple possible treatment approaches could potentially be used, the most common consideration is GH treatment.

Growth Hormone. hGH treatment of a patient with GH deficiency was first reported by Dr. Maurice Raben in 1958.³²⁷ He purified hGH from pituitary extracts from donor cadavers using hot glacial acetic acid, which retained GH but destroyed TSH, LH, and FSH. Soon thereafter, Wilhelmi developed another extraction method; he collected pituitaries in distilled water, froze them, and performed column extraction that yielded hGH, as well as other anterior pituitary hormones.³²⁸ Soon, national pituitary agencies were established in various countries to collect, extract, and dispense pituitary hGH for clinical use. About 400 pituitaries per year were needed to treat one child with hypopituitarism, so treatment was limited to the severest cases and dosing regimens were dictated by the limited hGH availability.³²⁹ The pituitary programs were terminated beginning in 1985 when Creutzfeldt-Jacob disease, a prion-mediated, progressive, and fatal spongiform encephalopathy, was diagnosed in patients who had previously received contaminated hGH extracted by the Wilhelmi method.³²⁹

Serendipitously, 1985 also saw the advent of GH production by recombinant DNA technology for clinical use; rhGH replaced pituitary hGH and has remained the sole source of GH treatment. Because the supply of rhGH was suddenly limitless—pharmaceutical companies could produce and sell as much as the market was willing to bear—the advent of rhGH not only increased the safety of GH treatment but opened the possibility to treating more patients with different indications at higher doses and for longer duration. rhGH use expanded from replacing GH deficiency (in patients with GH deficiency and PWS) to augmenting growth in patients who were GH replete but had other defects impairing their growth (Box 11.4). For example, GH treatment for ISS was approved by the FDA in 2003 for individuals with height below -2.25 SD (1.2 percentile), whose growth velocity would not be expected to allow attainment of an adult height in the normal range and whose diagnostic evaluation excluded other causes of growth failure that should be observed or treated by other means.³³⁰

Current rhGH treatment consists of nightly subcutaneous injections—subcutaneous because the polypeptide nature of rhGH precludes oral administration, and nightly, because most endogenous GH secretion occurs at night. Most rhGH manufacturers also created pen devices to facilitate administration by families. However, adherence with years of nightly injections remains challenging, and many companies have sought to develop long-acting rhGH preparations that may support long-term adherence via reduction in injection frequency; such preparations remain investigational.³³¹

Benefits. For children with GH deficiency, rhGH treatment provides both height and health benefits. Acceleration of statural growth is evident within the first few months of starting

BOX 11.4 Indications for Growth Hormone Treatment Approved by the US Food and Drug Administration

US FOOD AND DRUG ADMINISTRATION INDICATIONS WITH YEARS OF THEIR APPROVAL

Pediatric Indications

GH deficiency (1985)
Chronic renal insufficiency (1993)
Turner syndrome (1996)
Prader-Willi syndrome (2000)
Small-for-gestational age without catch-up growth (2001)
Idiopathic short stature (2003)
SHOX gene haploinsufficiency (2007)
Noonan syndrome (2008)

Adult Indications

HIV/AIDS-associated wasting (1996)
GH deficiency (1997)
Short bowel syndrome, dependent on parenteral nutrition (4-week course of GH) (2003)

AIDS, Acquired immunodeficiency syndrome; *GH*, growth hormone; *HIV*, human immunodeficiency virus.

rhGH treatment, with the greatest height velocities seen in the first year of treatment, slightly less in year 2, and slightly less still but persistent years 3 to the end of treatment. The increase in height velocity translates into an increase in height Z-score. Although historically individuals with untreated isolated GH deficiency had mean adult height Z-scores of -4.7 (range, -3.9 to -6),³³² those treated with rhGH commonly achieve adult heights in the normal range (i.e., less than 2 SD below the population mean and their midparental height). Patients with taller parents tend to have greater response to treatment than those with shorter parents, as do patients who are still prepubertal at initiation of treatment versus those already in puberty.³³³

In addition to height benefits, patients with GH deficiency derive health benefits from rhGH treatment owing to the effects of GH on lipid, protein, and glucose metabolism. Multiple studies have shown that rhGH treatment improves the decreased bone mineral density, decreased lean muscle mass, and increased fat mass seen in untreated children with GH deficiency. Although short-term studies showed a positive effect of rhGH treatment on left ventricular mass, data were inconsistent on cardiac performance measured by echocardiography (fractional shortening and left ventricular ejection fraction), vascular function (intimal media thickness at common carotid arteries), lipid profiles (although rhGH treatment lowers total and low-density lipoprotein cholesterol levels, data were inconsistent whether children with untreated GH deficiency had normal or abnormal profiles), and atherogenic indices.³¹⁹

For children receiving rhGH treatment who are not GH deficient (all indications except GH deficiency and Prader-Willi syndrome), benefits are limited to height only and even there, are often less dramatic than for children with GH deficiency.³³⁴ In a randomized controlled trial of children with ISS, approximately 6 years of GH treatment increased adult height by approximately 6 cm.³³⁵ Treatment responses vary widely, perhaps because ISS is such a heterogeneous categorization; some patients may experience no measurable increase in height Z-score. Furthermore, it is unclear whether the increase in height attributable to GH treatment has important psychological benefits.³³⁶ Thus it is important to counsel patients and their families accordingly before starting rhGH treatment, to

allow them to make an informed decision and to manage expectations.³¹⁹

Potential Adverse Effects. Potential adverse effects of rhGH treatment have been extensively reviewed recently by the Pediatric Endocrine Society^{319,337} and Growth Hormone Research Society,³³⁸ and results summarized herewith. The majority of safety data derive from postmarketing surveillance registries of rhGH, which were initially mandated by the FDA for all rhGH manufacturers for their respective products and then continued by the manufacturers themselves. Although these registries were well powered by their size (international scope and decades of data collection) to identify catastrophic or frequent adverse effects, there are some limitations. These include: (1) reliance on voluntary ascertainment for both occurrence and relatedness to rhGH treatment may lead to incomplete data capture, (2) on-treatment surveillance may miss any adverse effects that become manifest only after treatment has ended, (3) changes over time in rhGH dose and/or patient characteristics may alter the risk for adverse effects, and (4) lack of a valid control population precludes comparison to determine actual rhGH treatment effects on risk.

Adverse effects on rhGH treatment occur at low frequency (<3% of treated children) but are potentially serious and should be reviewed with patient-families before they decide to embark on treatment. Intracranial hypertension occurs at an estimated overall incidence of 28 per 100,000 treatment-years, generally during rhGH treatment initiation or dosage increases; it resolves with discontinuation of rhGH, after which rhGH may be restarted at half-dose and increased more gingerly. Slipped capital femoral epiphysis (SCFE) occurs at an estimated overall incidence of 73 per 100,000 treatment-years, with a median onset of 0.4 to 2.5 years after initiation of rhGH treatment, and requires surgical pinning of the capital femoral epiphysis to correct its malposition. Scoliosis progression can occur, especially in patient populations with higher baseline risk (PWS and Turner syndrome), and seems to result from rapid growth rather than rhGH per se.

Some apparent “adverse effects” of rhGH treatment actually reflect physiological GH actions. Physiological effects of GH on glucocorticoid metabolism (i.e., reducing hepatic 11 β -hydroxysteroid dehydrogenase 1-mediated conversion of inactive cortisone to active cortisol and increasing cytochrome P450 3A4-mediated cortisol catabolism) can unmask underlying adrenal insufficiency in those whose GH deficiency may be associated with MPHD. Likewise, by increasing peripheral deiodination of T4 to T3, rhGH can lower serum free T4 concentrations, which are often used to diagnose central hypothyroidism. GH physiologically decreases insulin sensitivity, and therefore rhGH treatment may induce glucose intolerance and manifest hyperglycemia in children with compromised insulin secretion or sensitivity, and lead to increased insulin requirement in children with diabetes mellitus already on insulin replacement. However, rhGH effects on insulin sensitivity occur only during treatment, with a return to baseline upon termination of rhGH treatment.

Risk of neoplasia with rhGH treatment has been a longstanding concern, based partly on indirect evidence. For example, IGF-1 promotes growth and metastases of various malignant cells in experimental models, and higher circulating IGF-1 concentrations are epidemiologically associated with increased risk of premenopausal breast cancer, colon cancer, and possibly prostate cancer.³³⁷ Epidemiological studies have suggested an increased risk of certain malignancies in patients with acromegaly,³³⁷ whereas individuals with Laron syndrome (GH insensitivity) seem protected against developing cancer.³³⁹

Surveillance studies generally have not found an increased risk for new malignancies in otherwise healthy children with

no prior history of cancer and no known predisposition to cancer. For patients with known tumor predisposition because of genetic or other medical conditions, data are insufficient to determine whether rhGH treatment further increases that risk. Published guidelines are generally based on retrospective data because randomized controlled trials have not been conducted. Per recent guidelines, rhGH treatment is contraindicated in patients with active malignancy, but pediatric cancer survivors who have completed cancer therapy and are without signs of active neoplastic disease may be candidates for rhGH treatment. rhGH treatment has not been found to raise their intrinsic risk of recurrence. Although rhGH treatment has been associated with a small early increase in the overall risk for subsequent primary neoplasms, subsequent studies found the risk related to irradiation rather than rhGH treatment.^{340,341} These studies of cancer risk are uncontrolled and retrospective, and thus the risks remain uncertain. Although few data are available to guide the appropriate interval between completion of cancer therapy and initiation of rhGH treatment, a standard waiting period of 12 months to establish “successful therapy” of the primary lesion has been recommended but can be altered depending on individual patient circumstances. Despite being histologically nonmalignant, craniopharyngiomas have a high rate of recurrence or progression after resection and are sometimes treated with irradiation, thereby increasing the patient’s risk to develop subsequent primary neoplasms. Craniopharyngiomas are commonly associated with GH deficiency, and there are no data to suggest treating them differently than malignant tumors with regard to observation periods before initiating rhGH treatment.

Long-term posttreatment risks are still poorly known because: (1) rhGH has only been available since 1985, and therefore the oldest treated patients are now in their 40s or early 50s; (2) the postmarketing surveillance registries lose track of patients once they stop treatment with that particular brand of rhGH; (3) studies designed to answer such questions require sufficient size and duration of follow-up; and (4) well-matched control groups are lacking. The ongoing multicenter “Safety and Appropriateness of Growth hormone treatments in Europe” (SAGhE) study was created to assess mortality and morbidity in adults in eight European countries (Belgium, France, Germany, Italy, the Netherlands, Sweden, Switzerland and the United Kingdom [England, Wales, and Scotland]) who had been treated in childhood with rhGH (not pituitary hGH) for approved indications. This industry-independent, cohort study compared 24,232 previously rhGH-treated patients, after an average 17.1 years of follow-up, with expected rates from national and local population data.³⁴² Early conflicting data from preliminary subgroup analyses were reviewed in the aforementioned society papers.^{319,337,338} Two additional SAGhE analyses were reported subsequently. For patients in the entire consortium who had received rhGH treatment for “isolated growth failure” (i.e., isolated GH deficiency, ISS, or SGA), cancer risk was not raised overall nor site specifically. However, for patients who did not have “isolated growth failure,” analyses found increased incidence of bone and bladder cancers and, with longer duration of follow-up, Hodgkin lymphoma in those without previous cancer, and increased cancer mortality risk associated with increasing rhGH daily dose for patients treated after previous cancer.³⁴³ Analysis of a five-country SAGhE cohort of 10,403 patients found a raised risk of meningioma related to previous irradiation for an underlying malignancy, but not to rhGH treatment.³⁴⁰ These studies are subject to inherent limitations, including the lack of a well-matched control group and the insufficient length of follow-up to fully assess the risk of the common malignancies (e.g., breast and colon cancer) that are statistically associated with IGF-1

concentrations and occur primarily in later adulthood. Further study is required.

Beyond the aforementioned considerations, which apply to all pediatric patients receiving rhGH treatment, there are additional risks pertaining to special populations. Patients with PWS have an underlying risk for both central and obstructive sleep apnea (OSA), sometimes leading to sudden death. Both GH and IGF-1 can stimulate adenotonsillar growth and might thereby exacerbate OSA. Thus polysomnography before initiating rhGH treatment and monitoring during rhGH treatment is recommended for patients with PWS. For those who develop OSA, rhGH treatment should be interrupted until their respiratory status can be stabilized by surgery (adenoidectomy and/or tonsillectomy, when appropriate) or continuous positive airway pressure. Another special population consists of critically ill patients in the intensive care setting. Increased mortality was observed with rhGH treatment in two placebo-controlled clinical trials in non-GH-deficient adult patients with acute critical illness because of complications following open-heart surgery, abdominal surgery or multiple accidental trauma, or those with acute respiratory failure. The safety of continuing rhGH treatment in pediatric patients receiving replacement doses for approved indications who concurrently develop these illnesses has not been established, and so potential benefits of rhGH treatment continuation should be weighed against potential risks.

On-Treatment Monitoring. During treatment, patients must be monitored at least every 6 months with auxological measurements, Tanner staging, and measurement of IGF-1 concentrations. IGF-1 concentrations provide information regarding treatment adherence and individual responsiveness to rhGH dose changes. Despite a lack of direct evidence, maintaining IGF-1 concentrations within age- and gender-specific normal ranges seems prudent.^{319,338} Soliciting a history of new or worsening headache, visual disturbance, or the presence of papilledema on funduscopic examination should prompt further evaluation for intracranial hypertension, and a history of hip pain or gait disturbance should elicit an evaluation for SCFE. Serial spinal examinations should be performed to screen for scoliosis. Assessment of cortisol and thyroid hormone sufficiency in patients whose GH deficiency may be related to MPHD and screening hemoglobin A1c in patients at risk for disturbed carbohydrate metabolism are warranted.^{319,338}

Treatment with rhGH at pediatric doses should not continue beyond epiphyseal fusion, lest acromegalic changes (e.g., disproportionate enlargement of the hands, feet, jaw, and tongue) be induced. When growth velocity drops to 2 to 2.5 cm/year, a bone age radiograph should be obtained to confirm epiphyseal fusion.³¹⁹ However, after a brief interruption in treatment, reassessment for adult GH deficiency can result in continued treatment for adult GH deficiency (with lower doses designed for the metabolic and body composition benefits outlined earlier). However, upon retesting, the majority of patients with isolated, idiopathic pediatric GH deficiency do not meet criteria for adult GH deficiency and do not require further treatment.

Shared Decision-Making Process. For children with non-GH-deficient short stature, the decision to treat with GH is difficult, in part because so many gaps remain in our understanding of the benefits and risks. The treatment of ISS with GH has been particularly controversial. As recommended by the latest guidelines for GH treatment by the Pediatric Endocrine Society, "In the USA, for children who meet FDA criteria, we suggest a shared decision-making approach to pursuing GH treatment for a child with ISS. The decision can be made on a case-by-case basis after assessment of physical and psychological burdens, and discussion of risks and benefits. We recommend against the routine use of GH in every child with height SDS (HtSDS) ≤ -2.25 ."³¹⁹

Several factors underlie this approach.³³⁰ Many patient-families seek evaluation and treatment of short stature out of concerns for psychosocial adaptation, both currently in childhood and projected into adulthood.³⁴⁴ However, evidence is limited to support either notion, that height is associated with psychological wellbeing and quality of life or that GH treatment improves this.³⁴⁵ Further, although GH treatment has been shown to increase the mean height of treated cohorts of patients with ISS, individual responses are highly variable, including some who do not increase their height SDS. With the same height meaning different things to different people, the variable responsiveness to treatment, and different perceptions of treatment burden, the risk-benefit consideration of GH treatment is a highly personal one.

Several markers of social success, including professional and mating, have been associated with tallness in males.^{115,345} Thus social pressures for tallness seem to affect males more than females and this leads to bias, conscious or subconscious, among parents seeking medical care for short children, among primary care clinicians who decide whether to pursue diagnostic testing and/or subspecialist referral, and among endocrinologists who prescribe GH treatment. The end result is that boys outnumbered girls in US pediatric GH registries 2:1 for all indications and 3:1 for ISS (the most socially driven indication) even though the prevalence of height below -2.25 SD (the FDA approved cut-off for GH treatment of ISS) did not differ by gender in a large, regional pediatric primary care population.³⁴⁶ Likewise, racial/ethnic disparities also have been observed in US pediatric GH registries.³⁴⁷ It behooves clinicians to be mindful of these tendencies, so that abnormal growth patterns are recognized and evaluated equally for all children as a potential sign of an underlying health problem.

Insulin-like Growth Factor-1. rhIGF-1 is available for treating patients with growth failure because of decreased IGF-1 concentrations that would not respond to GH treatment. It is used to treat severe primary IGF-1 deficiency because of GH insensitivity syndrome (Laron syndrome, caused by mutation in the GHR), *STAT5b* gene mutation, and *IGF1* gene mutations. In addition, rhIGF-1 is used to treat *GHI* gene deletion when patients have developed neutralizing antibodies that render further rhGH treatment ineffective. For unexplained severe PIGFD, where the degree of GH responsiveness is unclear, a trial of rhGH is recommended before turning to rhIGF-1 treatment.³¹⁹ rhGH treatment of patients with GH deficiency induces a greater growth response than rhIGF-1 treatment of patients with PIGFD, perhaps because of IGF-1-independent actions of GH at the growth plate, which the latter cannot replace. Further, rhGH treatment induces IGFBP-3, as well as IGF-1, making it more physiological than rhIGF-1 treatment, requires only once daily injections (versus twice daily injections of rhIGF-1), and does not cause hypoglycemia as does the latter (see later).

The most common cause of low IGF-1 concentrations in children and adolescents with growth stunting is undernutrition.³⁴⁸ A careful dietary history and inspection of the weight and BMI curves are important to screen for this possibility. For children with suspected undernutrition, nutritional intervention is the appropriate treatment rather than hormonal therapy. rhIGF-1 treatment is also not a standard treatment for children with a low IGF-1 concentration because of chronic systemic illness or children with mildly low IGF-1 concentrations associated with ISS or constitutional delay.

When indicated, rhIGF-1 treatment is administered as twice daily subcutaneous injections of 80 to 120 mcg/kg (also given outside the United States as 150–180 mcg/kg once daily injections). Hypoglycemia occurs in 42% of patients during their course of rhIGF-1 treatment, and although most

episodes are mild or moderate, severe hypoglycemic reactions (loss of consciousness, seizure) can occur.³¹⁹ Thus for safety, patient-families need to be educated about this risk, rhIGF-1 should be administered 20 minutes after a carbohydrate-containing meal or snack and withheld if the patient is not going to eat, and vigilance increased during intercurrent illnesses, including home glucometer use. rhIGF-1 treatment can also lead to hypertrophy of the tonsils and adenoids, hypersensitivity and allergic reactions, and reactions to the benzyl alcohol component of the diluent. Other potential adverse effects of rhIGF-1 treatment are similar to those of rhGH treatment.³¹⁹

Sex Steroids. Treatment with estrogens accelerates linear growth, causing a transient growth spurt, but also accelerates growth plate senescence, causing an earlier termination of linear growth. In general, the latter effect predominates, so that adult height is decreased. Treatment with aromatizable androgens can have similar effects because the androgens are converted to estrogens by the enzyme aromatase. However, treatment with nonaromatizable androgens, which cannot be converted to estrogens, may accelerate linear growth with less acceleration of growth plate senescence. Of nonaromatizable androgens, the best studied is oxandrolone. Oxandrolone treatment has been shown to increase adult height modestly in girls with Turner syndrome (see Chapter 17 on Turner syndrome for details). Oxandrolone increases linear growth rate in boys with constitutional delay of growth; however, no adequately powered, long-term, randomized controlled trials have evaluated the effect on adult height.^{349,350}

Gonadotropin Releasing Hormone Agonists. GnRH agonist treatment produces a highly effective, reversible suppression of the pituitary-gonadal axis. In a pubertal child, sex steroid production is greatly diminished, slowing both linear growth and growth plate senescence. In some situations at least, the latter effect predominates, resulting in a greater adult height. Although no long-term well-controlled trials are available, it is generally believed that GnRH agonist treatment in children with central precocious puberty diminishes the impairment in adult height³⁴⁹; (see Chapters 16 and 18 on Puberty and Its Disorders in the Female and Male, respectively, for details). In short adolescents with a normally timed puberty, GnRH treatment for 3.5 years, in a randomized controlled trial, initially slowed growth but also slowed bone age progression and allowed linear growth to continue longer; the net effect was an increase in adult height by approximately 4 cm.^{65,349} Potential adverse effects include decreased bone mineral density, as well as the psychological consequences of pubertal delay and of decreased stature during adolescence. Delivery options include regular intramuscular injections or an implantable device that must be removed or replaced approximately annually. This treatment is not approved by the FDA for children with short stature and a normally timed puberty and is used less frequently than GH treatment.

Aromatase Inhibitors. As noted earlier, estrogens transiently accelerate linear growth, but also accelerate growth plate senescence, causing an earlier termination of linear growth, and the net effect is generally a decrease in adult height. In men with estrogen deficiency resulting from biallelic mutations in the aromatase gene, the normal deceleration and cessation of linear growth in mid- to late adolescence is delayed, allowing for slow but persistent linear growth well into young adulthood resulting in tall stature.³⁵¹ Similar effects have been reported in estrogen resistance because of biallelic mutation in the estrogen receptor-alpha gene.³⁵¹ These observations suggest that pharmacological blockade of estrogen production with aromatase inhibitors during male adolescence might delay skeletal maturation and prolong linear growth, resulting in a greater adult

height. In principle, this treatment might have an advantage over GnRH agonist treatment by allowing the normal effects of androgen during male adolescence.

Randomized controlled trials of the aromatase inhibitor anastrozole or the more potent letrozole have been conducted in boys with short stature and in boys with constitutional delay. However, these studies have not been powered or were not analyzed to definitively assess the effect on adult height.^{352,353} In addition, questions about safety remain, some of which are suggested by the phenotype of aromatase-deficient men, including possible adverse effects on spermatogenesis, bone mineral density, lipids, insulin sensitivity, cognitive functions, and prostate growth. In addition, testosterone concentrations can rise to supraphysiological levels and vertebral deformities have been reported. Because of unanswered questions regarding efficacy and safety, aromatase inhibitors are not approved by the FDA for treatment of short stature and current guidelines by the US Pediatric Endocrine Society urge caution in the use of these agents outside of controlled clinical trials.³⁵⁴

C-Type Natriuretic Peptide Agonists for Achondroplasia.

ACH is the most common human skeletal dysplasia and is caused by a gain-of-function mutation in *FGFR3* that leads to excessive signaling in the MAPK pathway. Overactive MAPK signaling leads to impaired proliferation and terminal differentiation of chondrocytes and impaired synthesis of the extracellular matrix in the growth plate.⁵⁴ The binding of CNP to its receptor, NPR-B, generates cyclic guanosine monophosphate that activates cGKII, which inhibits the activation of MAPK pathway. Animal models of ACH have demonstrated that CNP overexpression rescues the impaired bone growth phenotype caused by *FGFR3* activation. This evidence suggests that CNP could be a potential therapy for ACH. Several clinical trials are in progress to evaluate the efficacy and safety of CNP analogues in children with ACH (www.clinicaltrials.gov).

Surgical Treatment. Based on distraction osteogenesis (i.e., osteotomy followed by a gradual rhythmic interruption of bone callus formation using an external fixation device, such as the Ilizarov frame), surgical leg lengthening was originally developed to correct length discrepancies or deformities. Bilateral leg lengthening surgery has been proposed as a treatment for some severe forms of short stature, especially those with shortening of limbs, for example, ACH.³⁵⁵ This technique can be applied to tibia and femoral lengthening alone or combined.^{355,356} The procedure is capable of promoting a significant total height gain (20 cm), but has a high frequency of complications and sequelae.³⁵⁵⁻³⁵⁷ Surgery can be performed in early childhood, but it is not recommended until the child is old enough to participate in the therapeutic decision. Although leg lengthening has the potential to bring better adaptability to patients with severe short stature, it is invasive and associated with a high risk of short- and long-term complications and is controversial among individuals with skeletal dysplasias (<https://www.lpaonline.org/>). For these reasons, the procedure should be performed in specialized centers and only on selected patients with severe short stature who have received adequate information about the procedure, risks, and consequences.

Tall Stature

A child may have a height above the normal range for many reasons. Often, the parents are also tall and the child's stature appears to be inherited as an oligogenic or polygenic trait. In these cases, the tall stature is considered a normal variation. Obesity is another common cause for stature above the normal range. However, there are also a large number of uncommon causes of tall stature, most of them genetic. Some

of these uncommon causes, such as Klinefelter syndrome, Beckwith-Wiedemann syndrome (BWS), Marfan syndrome, and GH excess have important health implications. Therefore in the child presenting with tall stature, a careful clinical evaluation is warranted.

Tall stature results from excessive growth plate chondrogenesis. This increased chondrogenesis can either arise from a primary cause within the growth plate chondrocytes themselves or can arise from a secondary cause, occurring elsewhere in the body and affecting the growth plate through a circulating, usually endocrine, factor.

Causes of Tall Stature

Secondary Growth Excess.

Endocrine Causes of Tall Stature

Growth Hormone/Insulin-Like Growth Factor-1 Excess. In children with increased growth rate but absence of pubertal signs, GH excess or hyperthyroidism should be considered. When the former occurs before epiphyseal fusion the result is rapid growth, metabolic changes similar to those observed in acromegalic patients, and elevated serum IGF-1 concentrations. GH concentrations may be elevated on an overnight GH profile, with no troughs detectable. Furthermore, serum GH concentrations are not suppressed by oral glucose administration during an oral glucose tolerance test. MRI may reveal a pituitary tumor in the form of a micro- or macroadenoma. Recent advances have revealed a genetic cause in a significant proportion of these patients. Somatic *GNAS1*, *PIK3CA*, and *USP8* mutations may be identified, or the tumor may occur as a component of syndromes, such as the MAS, the Carney complex, MEN 1 and Type 4, and *DICER* and *succinate dehydrogenase (SDH)*-related syndromes. Mutations in arylhydrocarbon-interacting protein (AIP) have been associated with familial pituitary adenomas (FIPA), and more recently, microduplications involving chromosome Xq26.3 have been associated with pituitary gigantism because of pituitary tumors as part of the X-linked acrogigantism (X-LAG) syndrome.

Familial Pituitary Adenomas. This condition is characterized by two or more cases of pituitary adenomas in a family in the absence of other associated tumors. Acromegaly/gigantism is associated with 54% of tumors, prolactinoma with 27%, nonfunctioning pituitary adenomas in 17%; prolactinoma and gigantism/acromegaly may occur in the same pedigree. *AIP* (a tumor suppressor gene) mutations are present in 15% to 30% of FIPA families, and in 20% of sporadic pediatric pituitary adenomas (PAs). The penetrance of PAs among *AIP* mutation-positive carriers is around 12% to 30%, suggesting the role of other disease modifiers. The mean age at diagnosis is 18 to 24 years; almost all *AIP* mutation positive cases were diagnosed by 40 years of age. *AIP* mutation-positive PAs are more likely to be macroadenomas (90%) and aggressive, needing multimodal therapy.

X-LAG Syndrome. This is associated with microduplications of Xq26.3 including the orphan G-protein-coupled receptor *GPR101*, which is significantly overexpressed in the pituitary of these patients. Mutations may be sporadic de novo, as well as familial germline Xq26.3 microduplications, and mutations may be mosaic. *GPR101* is also highly expressed in the hypothalamus and nucleus accumbens. Affected patients usually have gigantism of early onset, usually before the age of 5 years, and may have an increased appetite, acanthosis, coarse facial features, and excess sweating. There is a female preponderance, and the condition is associated with macroadenomas and somatotrope hyperplasia. Hyperprolactinaemia has been described in 85% of cases. *AIP* mutations account for 30% of pituitary gigantism, whereas X-LAG accounts for 10% cases.³⁵⁸

Sex Steroid Excess.

Early exposure to sex steroids causes growth acceleration in children. This early exposure can result from central precocious puberty; virilizing forms of congenital adrenal hyperplasia; ovarian cysts; or adrenal, testicular, or ovarian tumors; or exogenous sex steroids and other causes. Elevated estrogen concentrations accelerate skeletal maturation, including growth plate senescence, resulting in an advanced bone age, early cessation of growth, and early epiphyseal fusion. Because of this accelerated growth plate senescence and early growth cessation, the patient typically shows increased stature in childhood but decreased stature in adulthood. One of the goals of treating precocious puberty, whether central or peripheral, is to preserve adult height. In central precocious puberty treated with a GnRH analogue, the achieved adult height tends to be greater than the predicted adult height before treatment, modestly less than the predicted height at the end of treatment, and often modestly less than the midparental height, particularly if the treatment is not initiated soon after onset of puberty.³⁵⁹

Prolonged Growth Caused by Delayed Skeletal Maturation.

This comprises a heterogeneous group of diseases, including hypogonadism, aromatase deficiency, and estrogen resistance. In direct contrast to precocious puberty, these patients do not have a growth spurt because of the absence of, or resistance to, sex steroids. Growth rate is slow but, the deficiency in estrogen action also slows growth plate senescence, allowing these patients to keep growing into adulthood, developing tall stature with eunuchoid proportions (increased arm span and upper-to-lower segment ratio) only later in life. Consequently, untreated patients with hypogonadism may show normal stature in childhood, mildly short stature in early adolescence, and tall stature in adulthood.

Aromatase Deficiency. Aromatase deficiency is a rare disease with autosomal recessive inheritance. In males, the diagnosis is made later in adulthood, when there is tall stature, incomplete epiphyseal closure, eunuchoid proportions of the skeleton, osteoporosis, and obesity. Estrogen concentrations are low, whereas FSH, LH, and testosterone are slightly increased. The most intriguing features are the presence of steatohepatitis, insulin resistance with acanthosis nigricans, and high concentrations of triglycerides. The administration of low-dose estrogen allows completion of bone maturation after the complete closure of the epiphyses and thereafter leads to an increase in bone density. More than 30 mutations (point mutations, deletions and insertions) have been found in the gene *CYP19A1*, which encodes the P450 aromatase enzyme expressed in several tissues, such as gonad, brain, placental syncytiotrophoblast, breast, and adipose tissue, and catalyzes biosynthesis of estrogens from androgens.³⁶⁰

Estrogen Receptor α Deficiency. Rare cases of estrogen receptor α (*ER α*) deficiency have been reported with considerable phenotypic similarity to that of aromatase deficiency with tall stature and eunuchoid body proportions. The patients show continued linear growth into adulthood because of delayed skeletal maturation, osteoporosis, absent breast development with markedly elevated serum estrogen concentrations, and multicystic ovaries and amenorrhea in females. To date, the rare estrogen-resistant patients have had homozygous missense mutations in the *ER α* gene.^{361,362}

Thyrotoxicosis.

In hyperthyroidism, an increase in growth rate is associated with an advanced bone age, although stature and bone age are often still within the normal range.^{216,363} The diagnosis is made by measuring free T4 and TSH concentrations. The most common cause is Graves disease.

McCune-Albright Syndrome.

MAS is a rare cause of gonadotropin-independent precocious puberty, GH excess, and hyperthyroidism. It is a genetic

disorder caused by an activating mutation in the *GNAS* gene, which encodes the alpha subunit of the stimulatory G protein. The causative somatic mutation arises during embryogenesis and is distributed in a mosaic pattern. It is characterized as the triad of polyostotic fibrous dysplasia of bone, precocious puberty, and café-au-lait skin pigmentation. Moreover, other associated endocrinopathies have been recognized, including hyperthyroidism, GH excess, FGF23-mediated phosphate wasting, and hypercortisolism. Skin manifestations are common and are usually present at or shortly after birth. The café-au-lait spots typically have irregular margins giving them a “coast of Maine” appearance, and usually show an association with the midline of the body. In MAS, fibrous dysplasia of bone typically occurs at several sites (polyostotic), and commonly presents with fracture, deformity, and/or bone pain. Radiographs show characteristic expansive lesions with a “ground glass” appearance.

Other Endocrine Causes.

Familial glucocorticoid deficiency (FGD) is a condition characterized by resistance to ACTH. In addition to mutations in melanocortin receptor 2, several other causes have been identified. FGD is also associated with tall stature.³⁶⁴

Babies with congenital hyperinsulinemic hypoglycemia or those born to mothers with diabetes mellitus tend to be large for dates although they do not tend to be tall in the long term.

Nutritional Obesity.

Obesity has become the most common cause of tall stature. The growth chart is the most important diagnostic “test” in evaluating obesity; the endocrine causes of excessive weight gain and adiposity (glucocorticoid excess—both iatrogenic and endogenous Cushing syndrome, hypothyroidism, and GH deficiency) all tend to diminish statural growth, whereas nutritional (i.e., “exogenous”) obesity is associated with robust statural growth. Obesity also advances skeletal maturation, as evidenced by the bone age, and is associated with increased incidence of premature adrenarche and, in girls, early puberty. Thus although the height centiles of obese children typically exceed their midparental height centiles, these children typically stop growing younger such that adult height ends up at a centile lower than that followed in childhood, and thus obesity appears to have little effect on adult height.

Obesity has multiple effects on the GH/IGF-1 axis. Spontaneous GH secretion is reduced in both pulse frequency and amplitude, and lower amplitude secretion also can be evident on provocative GH testing.³⁴⁸ Despite the reduction in GH, circulating IGF-1 concentrations are similar to or, in some studies, higher in obese than in nonobese individuals. Some studies suggest that the amount of bioavailable IGF-1 is increased because of reductions in circulating IGFBP-1 and IGFBP-2 (IGFBP-3 remains unchanged). Circulating concentrations of GHBP also are increased.³⁴⁸

Perhaps the most extreme example is a phenomenon called *growth without GH*, whereby obese children can maintain normal growth velocity despite a clear absence of GH, such as from surgical resection of craniopharyngioma.³⁶⁵ Mechanisms implicated for maintaining their statural growth include insulin,^{365,366} leptin,³⁶⁶ sex hormones,³⁶⁶ and a growth-promoting adipokine, such as growth and differentiation factor 5.³⁶⁷

Primary Growth Excess.

In some children, the excessive growth plate chondrogenesis responsible for tall stature arises from a primary abnormality within the growth plate chondrocytes themselves. These primary causes include single gene defects that affect autocrine/paracrine signaling within the growth plate, cartilage extracellular matrix, or intracellular regulatory pathways. In other children, the underlying cause is not a single gene defect but rather another genetic abnormality, such as a chromosomal anomaly, a genetic CNV (deletion or duplication), or imprinting disorder.

Disorders Involving Autocrine/Paracrine Factors.

Fibroblast growth factor-3 (*FGFR3*) negatively regulates growth plate chondrogenesis. Consequently, as discussed earlier in the chapter, gain-of-function mutations in *FGFR3* impair growth plate chondrogenesis and can present clinically as a chondrodysplasia with short stature, such as hypochondroplasia or ACH. Other mutations in *FGFR3*, likely involving a loss of function, appear to cause excessive growth plate chondrogenesis, presenting clinically as tall stature with skeletal abnormalities.^{56,368}

CNP acts through NPR2 to stimulate growth plate chondrogenesis (see discussion earlier). As a result, loss-of-function mutations in NPR2 slow chondrogenesis to cause short stature. Conversely, gain-of-function mutations in NPR2 cause tall stature, associated with scoliosis and macrodactyly of the great toe.³⁶⁹

Simpson-Golabi-Behmel syndrome type 1 (SGBS1) is characterized by pre- and postnatal overgrowth, distinctive facies, intellectual disability, and a variety of congenital anomalies. It is X-linked and can be caused by mutations in *GPC3* or 4. The glypicans encoded by these genes are cell surface heparan sulfate proteoglycans. There is evidence that glypicans are involved in BMP, FGF, hedgehog (HH), and wingless-integrated (WNT) signaling.

Disorders Involving Cartilage Extracellular Matrix/Fluid.

Fibrillin-1 (*FBN1*) is a major component of microfibrils, which are found extracellularly in connective tissues. Some heterozygous mutations in *FBN1* cause Marfan syndrome, which is inherited in an autosomal dominant fashion and has multiple skeletal, ocular, and cardiovascular manifestations. Skeletal abnormalities include tall stature with disproportionately long limbs and digits, as well as pectus excavatum or carinatum and scoliosis. Eye findings include myopia and ectopia lentis. Cardiovascular manifestations include aortic root enlargement with a high risk of aortic dissection.³⁷⁰ Other mutations in *FBN1* can cause acromelic dysplasias, which are characterized by short stature with disproportionate shortening of the distal limbs.

Homocystinuria caused by cystathionine β -synthase deficiency shows some similarities to Marfan syndrome. It can affect the skeleton, causing tall stature with disproportionately long extremities, scoliosis, and pectus excavatum.³⁷¹ Other manifestations include myopia and ectopia lentis, thromboembolism, and developmental delay.³⁷¹ There is evidence that the excessive linear growth is caused by high extracellular concentrations of homocysteine.³⁷²

Disorders Involving Intracellular Factors.

Klinefelter syndrome is a relatively common chromosomal disorder that is usually associated with a 47,XXY karyotype, sometimes with mosaicism. The classical features include a male with tall stature with relatively long lower extremities, small testes usually with azoospermia, and gynecomastia (see Chapter 18 on Puberty and Its Disorders in the Male for details).³⁷³ The tall stature and increased lower leg length is thought to be caused by increased copy number of *SHOX*, a transcription factor that appears to be important for growth plate function. *SHOX* is located in a pseudoautosomal region on the X and Y chromosomes and escapes X inactivation. Therefore normal males and females have two active copies of *SHOX*, whereas girls with Turner syndrome have only one copy, causing short stature, and boys with Klinefelter syndrome have three active copies, causing tall stature.³⁷³

Mutations in genes that affect epigenetic modifications can cause overgrowth. Sotos syndrome is characterized by overgrowth, which is typically of prenatal onset. The overgrowth affects the limbs more than the spine and is accompanied by macrocephaly and advanced bone age. In addition, there are characteristic facial features and variable developmental delay. It can be caused by heterozygous mutations in *NSD1*, which encodes a histone methyltransferase and therefore affects epigenetic control of gene expression. Malan syndrome, which is

also termed *Sotos syndrome 2*, is a similar disorder that is characterized by overgrowth, macrocephaly, characteristic facies, and developmental delay and is caused by mutations in gene nuclear factor I X (*NFIX*).³⁷⁴ Mutations in *NFIX* can also cause Marshall-Smith syndrome, which can include tall stature with advanced bone age, intellectual disability, and distinctive facies.

Weaver syndrome has features similar to Sotos syndrome, including tall stature, advanced bone age, characteristic facies, and variable intellectual disability. It can be caused by mutations in *EZH2*, *EED*, or *SUZ12*, which participate in the PRC2 protein complex and are involved in histone methylation, an epigenetic modification. A similar overgrowth syndrome is caused by heterozygous mutations in *DNMT3a*, which encodes a DNA methyltransferase that affects DNA methylation.

BWS manifests as overgrowth, typically both pre- and post-natal, which can disproportionately affect different tissues resulting in macroglossia and hemihypertrophy. Patients have an increased risk of abdominal wall defects at birth, hyperinsulinism, and embryonal tumors. BWS can be caused by genetic or epigenetic abnormalities in a cluster of imprinted genes in the 11p15.5–11p15.4 region. Often, there is abnormal DNA methylation in this region and abnormal expression of the imprinted genes, *CDKN1C* (a cell cycle inhibitor) and *IGF2* (a paracrine growth factor).³⁷⁵

Perlman syndrome is an overgrowth syndrome similar to BWS but inherited in an autosomal recessive fashion. It is caused by mutations in *DIS3L2*, which is thought to be involved in messenger RNA degradation.

Idiopathic Growth Excess. The majority of healthy tall children with no apparent cause of growth excess will be classified as idiopathic tall stature, including familial tall stature and constitutional advance in growth and adolescence.³⁷⁶ Both are diagnoses of exclusion and the most common diagnoses among people with tall stature. Children with familial tall stature usually maintain growth at approximately the same high percentile and reach an adult height within their target range. Constitutional advance in growth is characterized by a developmental pattern opposite to constitutional delay of growth. It can be associated, although not exclusively, with obesity. These patients show accelerated growth with advanced bone age and relatively early puberty, usually resulting in normal adult height. In this group of children with isolated tall stature, it is very unusual to identify a monogenic cause for overgrowth. The growth pattern and height of these children is probably explained by the combination of several common variants in a typical polygenic effect. However, the ability to predict tall stature using polymorphisms identified in GWAS height is limited.³⁷⁷

Diagnostic Approach to the Patient With Tall Stature

Although we can define tall stature as a height SDS over 2, in the absence of other symptoms and signs, the large majority of tall children and adolescents are healthy and have familial tall stature or constitutional advance in growth.³⁷⁶ In addition, tall stature has a wider social acceptance than short stature and secondary conditions resulting in overgrowth are infrequent. For these reasons, more restricted referral criteria are usually used to improve the identification of pathological overgrowth conditions and thereby reduce unnecessary testing. Patients with more severe tall stature, those with height significantly above the mean parental height or who cross upward through percentiles during childhood and/or puberty are significantly more likely to have tall stature caused by a specific pathological condition and require clinical investigation. Furthermore, presence of intellectual disability, macrocephaly, or dysmorphic features can indicate a syndromic tall stature condition (in general with a genetic basis). In children with tall stature and these additional features, a more detailed evaluation for genetic syndromes should be considered.

The main differential diagnoses of children with tall stature are precocious exposure to sex steroids, supernumerary sex chromosome aneuploidies (e.g., Klinefelter syndrome), growth hormone excess (i.e., pituitary gigantism), BWS, Marfan syndrome, Sotos syndrome, Weaver syndrome, and other rare genetic conditions (see section on Causes of Tall Stature earlier). Despite the complexity and multiplicity of potential causes for tall stature, several diagnoses can be obtained from a carefully documented medical history and a comprehensive physical examination (Table 11.7). Depending on specific clinical findings from the medical history and physical examination, special investigations are often required to confirm the initial clinical impression (Table 11.8).

Determination of growth patterns are a critical part of the medical history (Fig. 11.11). Tall children who cross percentiles upward should be investigated for precocious exposure to sex steroids, GH excess, and hyperthyroidism. On the other hand,

TABLE 11.7 Key Findings in the Medical History and Physical Examination of Children With Tall Stature

Key Findings	Disorders
Family history suggesting an autosomal recessive inheritance and/or presence of consanguinity	Homocystinuria, CATSHL syndrome
Family history suggesting an autosomal dominant inheritance of tall stature	Familial tall stature, Marfan syndrome, epiphyseal chondrodysplasia, Miura type (increase of signal by <i>CNP/NPR-B</i>)
Developmental delay, intellectual disability and behavior problems	Sotos, Weaver syndrome, homocystinuria, fragile X-chromosome, <i>DNMT3A</i> mutations, and others
Increased birth weight and length SDS for gestational age	Beckwith-Wiedemann, Sotos, Weaver syndromes, <i>IGF1R</i> duplications, and others
Head circumference SDS	Macrocephaly is observed in Sotos, Weaver, <i>DNMT3A</i> mutations, and fragile-X syndromes Microcephaly is observed in CATSHL syndrome
Presence of precocious secondary sexual characteristics	Precocious sex steroids exposure (precocious puberty, virilizing disorders)
Signs of hypogonadism (small testes, amenorrhea, underdevelopment of breast and body hair)	Several different causes; in males, mainly Klinefelter syndrome
Marfanoid habitus (arm span that exceeds the height, arachnodactyly and hyperlaxity)	Marfan, Sotos, homocystinuria, epiphyseal chondrodysplasia, Miura type
Macroductyly of the great toes	Epiphyseal chondrodysplasia, Miura type (increase of signal by <i>CNP/NPR-B</i>)
Body disproportion (arm span that exceeds the height and/or sitting height : total height SDS < -2)	Klinefelter syndrome
Dysmorphic facial features	Several syndromic forms of overgrowth conditions, each one with particular features
Severe kyphoscoliosis	CATSHL syndrome, epiphyseal chondrodysplasia, Miura type

The listed signs and symptoms are diagnostically helpful when present but may be absent in some children with the associated disorders. *CATSHL*, Camptodactyly, tall stature, and hearing loss syndrome (recessive *FGFR3* mutation); *CNP*, C-type natriuretic peptide; *NPR-B*, natriuretic peptide receptor B; *SDS*, standard deviation score.

TABLE 11.8 Complementary Diagnostic Tests That Can be Useful During Investigation of a Patient With Tall Stature

Examination	Objective
Wrist and hand x-ray for bone age determination	Advanced bone age is often observed in patients with Sotos syndrome, Weaver syndrome, Beckwith-Wiedemann syndrome, precocious sex steroids exposure, constitutional advance of growth, and obesity. Delayed bone age is observed in hypogonadism, aromatase deficiency, and estrogen resistance
Serum IGF-1, random GH and OGTT for GH suppression	Screening for GH excess
Serum TSH, free-T4	Screening for hyperthyroidism
LH, FSH, Testosterone/estradiol levels	For evaluation of precocious sex steroids exposure in presence of physical signs or hypogonadism
Serum homocysteine	Screening for homocystinuria mainly in patients with Marfanoid habitus, consanguineous parents and/or intellectual disability
Karyotype	Assessment of chromosome aberrations (i.e., Klinefelter syndrome, 47 XYY, 47 XXX) or CAIS
Echocardiogram	Assessment of aortic root dilation (i.e., Marfan syndrome)
Ophthalmological evaluation	Assessment of <i>ectopia lentis</i> (i.e., Marfan syndrome and homocystinuria)
<i>FBN1</i> sequence	To confirm or exclude the diagnosis of Marfan syndrome in patients with suggestive clinical findings
Molecular karyotype (SNP or CGH array)	To identify submicroscopic copy number variation (deletion or duplication), mainly in patients with unexplained developmental delay/intellectual disability, autism spectrum disorders, and/or multiple congenital anomalies
High-throughput sequence (whole exome or gene panel sequence)	To simultaneously investigate the presence of pathogenic variants in several genes associated with tall stature, especially in patients with high suspicion for genetic causes

CAIS, Complete androgen insensitivity; CGH, comparative genomic hybridization; FSH, follicle-stimulating hormone; GH, growth hormone; IGF-1, insulin-like growth factor-1; LH, luteinizing hormone; OGTT, oral glucose tolerance test; SNP, single nucleotide polymorphism; T4, thyroxine, TSH, thyroid-stimulating hormone.

children who are above 2 SD in height and remain in the same percentile and are compatible with the target height of their percentile suggest familial tall stature, in the absence of other positive findings. Sotos and Weaver syndromes should be considered particularly in children born large for gestational age that remain with height SDS above 2 and have associated macrocephaly and/or cognitive impairment.³⁷⁸ BWS should be investigated in children with pre- and postnatal overgrowth associated with neonatal hypoglycemia, macroglossia, omphalocele, umbilical hernia, and/or a history of an embryonal tumor (e.g., Wilms tumor, hepatoblastoma, neuroblastoma, rhabdomyosarcoma).³⁷⁹ Disproportionately tall stature (long

legs, arm span that exceeds the height, and/or sitting height: total height SDS < -2), small testes, gynecomastia, learning disability, and/or increased gonadotropin concentrations suggest Klinefelter syndrome.³⁸⁰ Tall children with personal or family histories of ectopia lentis (subluxation of the lenses) or aortic root dilation should be investigated for Marfan syndrome.³⁸¹ Finally, there are children whose height is within the reference range during childhood, but who have prolonged growth beyond adolescence resulting in a height SDS above 2 in adulthood,³⁷⁶ a pattern which can result from impaired estrogen production or action.

Genetic tests are important to confirm diagnostic hypotheses and also to investigate patients with syndromic overgrowth of unknown cause. Because of the heterogeneity of genes that can cause pathological tall stature, the large size of some genes and the rarity of these conditions, a multigene strategy using next-generation sequencing (exome sequencing or targeted panel sequencing) may be more efficient than targeted sequencing of a single candidate gene.³⁷⁶ Moreover, molecular karyotyping (CGH or SNP microarrays) is also a useful tool to investigate patients with overgrowth associated with developmental delay, intellectual disability, or autism spectrum disorders.

Treatment of Tall Stature

Treatment for Growth Hormone Excess. The treatment for pituitary gigantism can be complex, and includes medical therapy using somatostatin analogues, which result in biochemical cure in 70% with tumor shrinkage in 75%. Cabergoline can also be tried and is particularly effective in patients with tumors secreting both GH and prolactin. The GH antagonist, Pegvisomant, can also be used although it does not cause tumor shrinkage. Transsphenoidal resection of the tumor is associated with biochemical cure in 75% to 95%. Radiotherapy is used in resistant cases, but may be associated with complications including hypopituitarism, visual impairment, and possibly secondary tumors.

Treatment for Other Endocrine Causes of Tall Stature. When tall stature is caused by excess sex steroids or thyroid hormone, the underlying endocrine abnormality is usually treatable. The treatments for precocious puberty, congenital adrenal hyperplasia, and hyperthyroidism are discussed elsewhere.

Treatment for Nonendocrine Tall Stature. In general, tall stature that does not have a specific pathological etiology does not require treatment. However, tall stature in a child may cause anxiety to parents, who may then request treatment to cease growth progression. No evidence-based guideline has been created with respect to the selection of potential candidates for adult height reduction. Treatment decisions are often influenced by the predicted adult height, based on a radiograph of the nondominant hand and wrist. Typically, treatment is only considered for adolescents whose predicted adult height is more than 2.5 SD above the population mean. Unfortunately, the available methods to predict adult height, including the Bayley-Pinneau method and TW Mark 1 and 2 methods, have limited accuracy and, depending on the bone age, a tendency to overestimate adult height.³⁸²

Various types of treatment, either hormonal or surgical, have been used to reduce growth in children with tall stature.

One approach for an excessive height prediction that has been studied is to induce puberty early, thereby leading to early cessation of growth and early epiphyseal fusion, using testosterone in males and estrogens in females. However, this use of sex steroids has declined over the last 20 years, in part because of adverse treatment effects.³⁸³ In the short term, boys treated

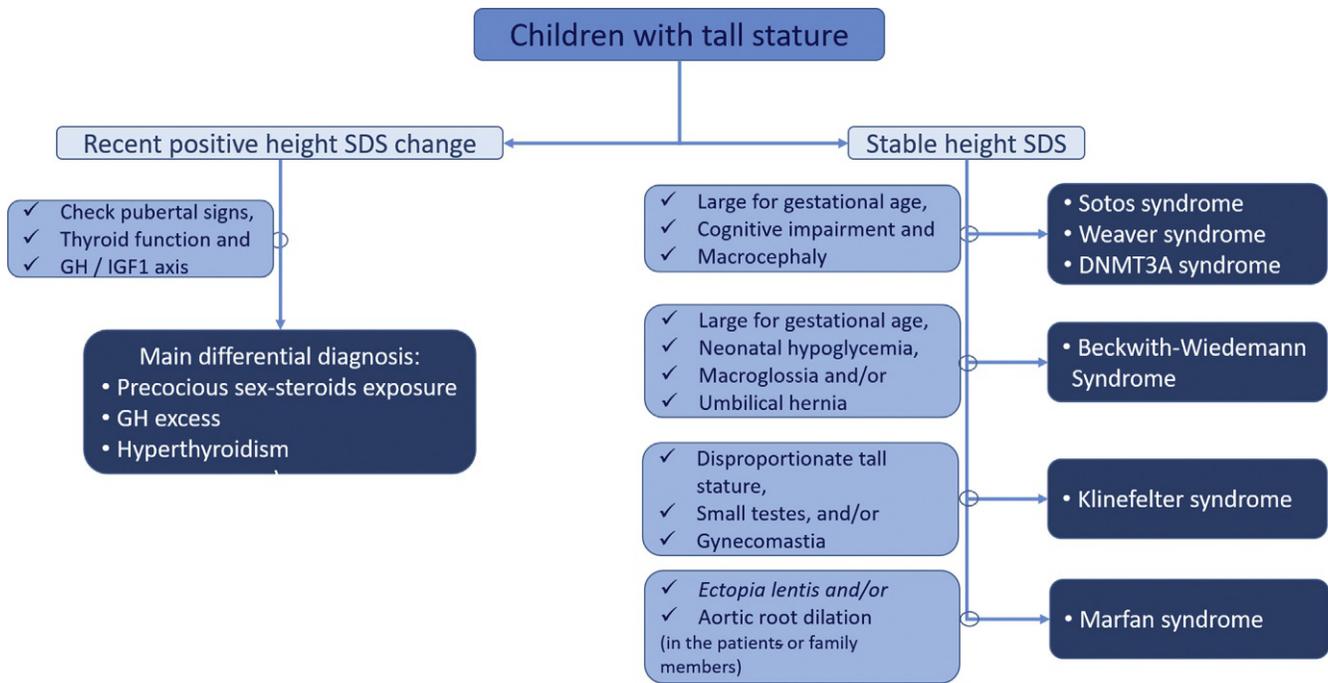

Fig. 11.11 Overview of investigation of children with tall stature.

with androgens may present with myalgia, acne, gynecomastia, and weight gain, whereas girls treated with high doses of estrogen may have weight gain, night cramps, galactorrhea, ovarian cysts, and predisposition to thrombosis. There is also evidence that tall women who were treated with high-dose estrogen are at risk of decreased fertility.³⁸⁴ Some have advocated inducing puberty by the use of more physiological doses of sex steroids before the tall child progresses into puberty as a means of reducing final adult height. There remains a significant amount of uncertainty regarding the efficacy of exogenous sex steroids in limiting final height, whether used as part of a high or lower dose strategy.

Nocturnal infusion of octreotide, a somatostatin analogue, has been reported to reduce GH secretion and height prediction in tall children. However, a more recent study showed that long-term treatment with a somatostatin analogue does not reduce final height in a manner sufficient to justify treatment in tall stature.³⁸⁵

The most common surgical procedure for reducing growth is bilateral percutaneous epiphysiodesis of the distal femur and proximal tibia and fibula. Epiphysiodesis is a surgical intervention for reducing final height by approximately 5 cm, which is typically performed at a bone age exceeding 12.5 years in girls with a stature of 170 cm and 14 years in boys with a stature more than 185 cm.³⁸³

INTRODUCTION

Maintenance of the tonicity of extracellular fluids within a very narrow range is crucial for proper cell function.¹ Extracellular osmolality regulates cell shape, as well as intracellular concentrations of ions and other osmolytes. Furthermore, proper extracellular ionic concentrations are necessary for the correct function of ion channels, action potentials, and other modes of intercellular communication. Extracellular fluid tonicity is regulated almost exclusively by the amount of water intake and excretion, whereas extracellular volume is regulated by the level of sodium chloride intake and excretion. In children and adults, normal blood tonicity is maintained over a 10-fold variation in water intake by a coordinated interaction among thirst, vasopressin, and renal systems. Dysfunction in any of these systems can result in abnormal regulation of blood osmolality, which if not properly recognized and treated may cause life-threatening dysfunction in neuronal and other cellular activities.

The posterior pituitary, or the neurohypophysis, secretes the nonapeptide hormones vasopressin (also termed *antidiuretic hormone [ADH]*) and oxytocin. Vasopressin controls water homeostasis, and oxytocin regulates smooth muscle contraction during parturition and lactation. Disorders of vasopressin secretion and action lead to clinically important derangements in water metabolism. In this chapter, the physiology of water and volume regulation is summarized, a symptom-based approach to the differential diagnosis of the diseases of water homeostasis is presented, and a review of the pathology and treatment of disorders involving these systems is provided.

PHYSIOLOGY OF OSMOTIC AND VOLUME REGULATION

The control of plasma tonicity and intravascular volume involves a complex integration of endocrine, neural, and paracrine pathways. Osmotic sensor and effector pathways control the regulation of vasopressin release and signal transduction, whereas volume homeostasis is determined largely through the action of the renin-angiotensin-aldosterone system, with contributions from both vasopressin and the natriuretic peptide family. An improved understanding of the anatomic structures and molecules involved has developed through recent molecular biologic and physiologic studies.

Osmotic Sensor and Effector Pathways

Vasopressin and Oxytocin Biochemistry

Vasopressin and oxytocin are evolutionarily-related peptides (paralogs), having arisen from gene duplication of a phylogenetically common molecule approximately 450 million years ago.² Both peptides consist of a 6-amino-acid disulfide ring, plus a 3-amino-acid tail, with amidation of the carboxy terminus.³ As early as 1895, a potent biologic principle—consisting of vascular pressor activity, “birth quickening,” and milk secretory effects—was recognized in neurohypophyseal extracts.⁴ The sequences of the individual peptides with pressor and antidiuretic capacity (vasopressin) and oxytocic capacity were determined by du Vigneaud and colleagues during the mid-1950s,³ culminating in the synthesis of each hormone in its biologically active form.^{5,6} In most mammals, vasopressin and oxytocin differ in only two amino acids—one substitution within the ring and one within the tail structure (Fig. 12.1). Exploration of the structure-function relationship of specific amino acids, within both vasopressin and oxytocin, has allowed characterization of molecules with important clinical use. Although the vasopressor activity was markedly diminished by the replacement of l-arginine with d-arginine at position 8 of the vasopressin molecule, the duration of action was prolonged, and the antidiuretic action enhanced by the amino-terminal deamidation, creating the analogue desmopressin (desamino-d-arginine vasopressin [dDAVP]) (see Fig. 12.1).⁷ Whereas the antidiuretic:pressor ratio for vasopressin is 1:1, this ratio for dDAVP is between 2000:1 and 3000:1. This difference is almost entirely caused by the differential binding of dDAVP to the V2 and V1 receptors (2054:1). dDAVP, with an antidiuretic potency between 2 times and 3 times that of its parent vasopressin,⁸ is now routinely used in clinical practice.

The association of vasopressin and oxytocin with specific proteins, the neurophysins, while stored in the neurohypophysis was apparent as early as 1900.⁹ Subsequent isolation and characterization of the neurophysins revealed two distinct forms, one type exclusively associated with vasopressin and the other exclusively associated with oxytocin.^{10,11} Both are single-polypeptide chains of molecular weight 10,000 daltons. Despite extensive biophysical characterization, including

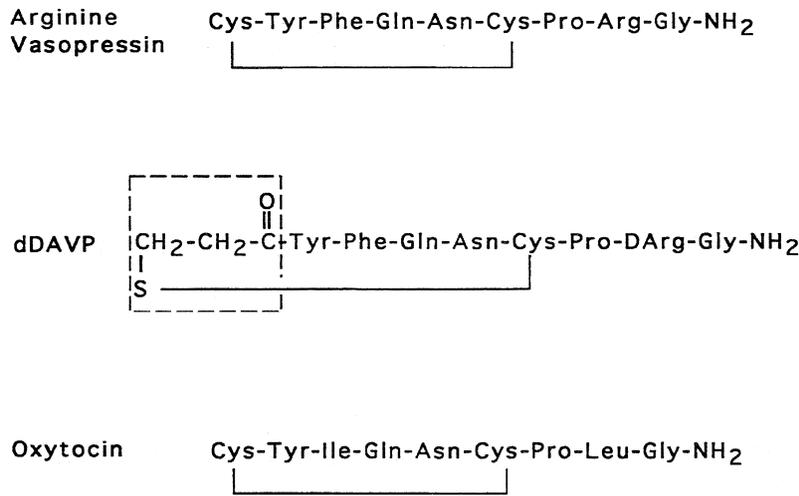

Fig. 12.1 Structures of vasopressin, desamino-d-arginine vasopressin (dDAVP), and oxytocin. In dDAVP, the deamidated cysteine is enclosed in the box.

crystallography of the oxytocin-neurophysin complex,^{12,13} the biologic function of the neurophysins remains unknown. Possible roles for the neurophysins include hormone stabilization against degradation during intracellular storage, more efficient packaging within secretory granules, enhancement of posttranslational processing by the proenzyme convertases, and hormone transport in blood. Recently, copeptin, a segment of vasopressin-associated neurophysin, has been developed as an indicator of vasopressin secretion.¹⁴

The common origin of vasopressin and its neurophysin from a single larger precursor was first proposed by Sachs and colleagues,¹⁵ who showed increased incorporation of 35S cysteine, infused into canine third ventricle, into vasopressin isolated from the hypothalamus compared with vasopressin isolated from the posterior pituitary. Isolation of the larger precursor from the hypothalamus, followed by trypsin

digestion, produced fragments of size similar to that of vasopressin and its neurophysin, with vasopressin immunoreactivity in the 1000-dalton component.¹⁷

Since 1990, molecular genetic analyses have enhanced the understanding of the synthesis, the processing, and the evolution of the vasopressin and oxytocin preprohormones. All mammalian vasopressin and oxytocin genes each consist of three exons (Fig. 12.2).¹⁸ The first exon encodes the 19-amino-acid signal peptide, followed by vasopressin or oxytocin nonapeptides. This is followed by a 3-amino-acid protease cleavage site, leading into the first nine amino acids of neurophysin II (for vasopressin) or neurophysin I (for oxytocin). After interruption of the coding region by an intron, exon 2 continues with neurophysin coding sequences. The third exon completes the sequence of the neurophysin and, for vasopressin only, is followed by coding information for an

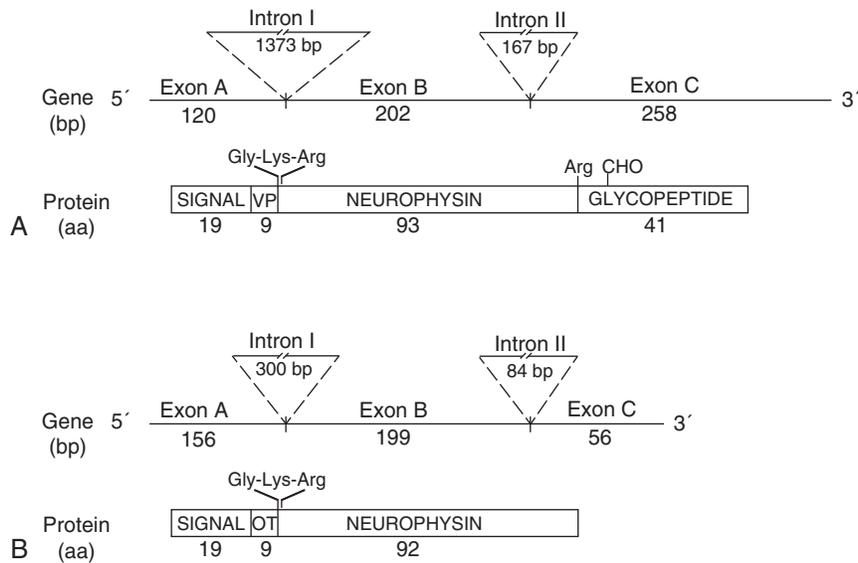

Fig. 12.2 Structure of the human genes and peptide products of vasopressin (VP) (A) and oxytocin (OT) (B). Shown are the sizes of exons and intron, in nucleotide base pairs (bp) and peptide products in amino acids (aa). Depicted are the amidation-dibasic cleavage signal (Gly-Lys-Arg) at the carboxy terminus of vasopressin and oxytocin, and the monobasic cleavage signal at the end of neurophysin. CHO, Carbohydrate; signal, signal peptide.

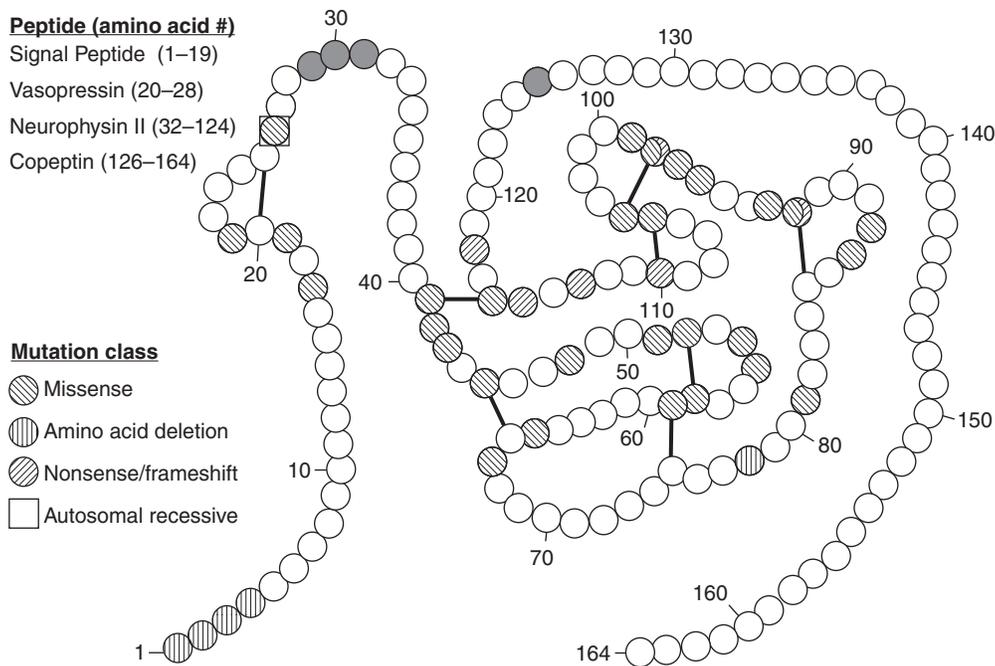

Fig. 12.3 Structure of preprovasopressin peptide and most frequent AVP mutations in central diabetes insipidus. The 164-amino-acid preprovasopressin peptide consists of signal peptide, vasopressin, neurophysin II, and copeptin. Vasopressin and neurophysin II are separated by three basic residues (gray), which serve as peptide cleavage and amidation sites. The 16 cysteines in preprovasopressin are connected by eight putative disulfide bridges, many of which are mutated in autosomal dominant diabetes insipidus. Amino acid mutations are classified as missense, deletion, or nonsense/frameshift. Most mutations are inherited with an autosomal dominant pattern, except at amino acid 26, which has an autosomal recessive pattern.

additional 39-amino-acid glycopeptide (copeptin) whose function is unclear. Preprovasopressin contains 16 cysteines, which likely participate in eight disulfide bridges that determine the tertiary structure of the protein (Fig. 12.3). One cysteine pair is present in vasopressin peptide, whereas the rest are in neurophysin.

In all mammalian species analyzed thus far, oxytocin and vasopressin genes are adjacent in chromosomal location (chromosome 20 in the human 19) and linked tail to tail, in opposite transcriptional orientation. In the human, they are separated by only 12 kb.¹⁹ This likely explains their origin from the ancient duplication of a common ancestral gene.²⁰ Whether this adjacent linkage is of regulatory significance is unclear.

Expression of vasopressin and oxytocin genes occurs in the hypothalamic paraventricular and supraoptic nuclei.¹ The magnocellular components of each of these nuclei are the primary neuronal populations involved in water balance, with vasopressin synthesized in these areas carried by means of axonal transport to the posterior pituitary, its primary site of storage and release into the systemic circulation (Fig. 12.4). The bilaterally paired hypothalamic paraventricular and supraoptic nuclei are separated from one another by relatively large distances (approximately 1 cm). Their axons course caudally, converge at the infundibulum, and terminate at different levels within the pituitary stalk and the posterior pituitary gland (see Fig. 12.4). Vasopressin is also synthesized in distinct parvocellular neurons of the paraventricular nucleus, where it has a role in modulation of hypothalamic-pituitary-adrenal axis activity. In this site, vasopressin is colocalized in cells that synthesize corticotropin-releasing hormone,^{21,22} and both are

secreted at the median eminence and carried through the hypothalamic-hypophyseal portal capillary system to the anterior pituitary, where together they act as the major regulators of adrenocorticotrophic hormone synthesis and release.²³ Vasopressin is also present in the hypothalamic suprachiasmatic nucleus, the circadian pacemaker of the body, where its function is unknown.

Regulation of Vasopressin Secretion and Thirst

Osmotic Regulation. The rate of secretion of vasopressin from the paraventricular and supraoptic nuclei is influenced by several physiologic variables, including plasma osmolality and intravascular volume, as well as nausea and a number of pharmacologic agents. The major osmotically active constituents of blood are sodium, chloride, and glucose (with insulin deficiency). Normal blood osmolality ranges between 280 and 290 mOsm/kg H₂O.

The work of Verney²⁴ first demonstrated the relationship of increased vasopressin release in response to increasing plasma osmolality, as altered by infusion of sodium chloride or sucrose. At that time, it was postulated that there existed intracranial sensors sensitive to changes in plasma osmolality. Multiple researchers have subsequently confirmed that plasma vasopressin concentration increases in response to increasing plasma tonicity, with the location of the osmosensor, likely to be within the circumventricular organ, neuronal nuclei surrounding the third ventricle, which lacks a blood-brain barrier.²⁵ The organ vasculosum of the lamina terminalis (OVLT) and the subfornical organ (SFO), areas of the preoptic hypothalamus outside the blood-brain barrier, are likely sites

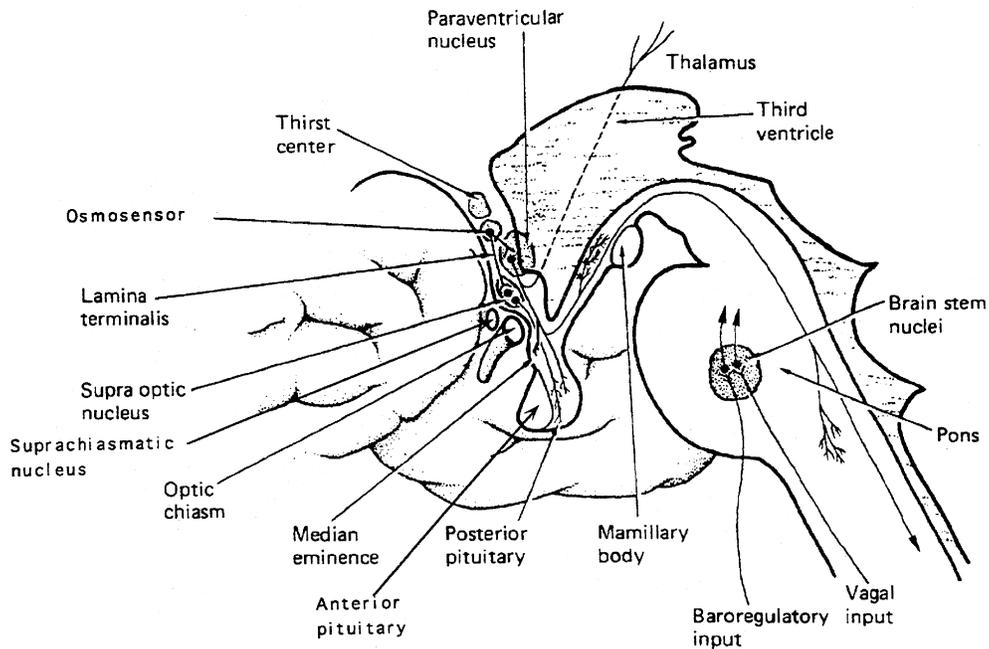

Fig. 12.4 Vasopressin cells in the hypothalamus. Diagram of vasopressin cell bodies in the supraoptic, paraventricular, and suprachiasmatic hypothalamic nuclei, and axonal termination in the posterior pituitary and median eminence. Because vasopressin axons terminate at different levels in the pituitary stalk and posterior pituitary, the amount of permanent cell loss, following neurosurgical insult, is determined by the highest level of damage, which will dictate the degree of vasopressin axon transection and retrograde neuronal degeneration. (Modified with permission from Baylis, P.H. (1989). Vasopressin and its neurophysin. In: Degroot, L.D. (ed). Endocrinology, 2nd ed. WB Saunders, Philadelphia, p. 213.)

of both osmosensing, because lesions of the OVLT result in impaired vasopressin secretion and hypernatremia.^{26,27} Also the site of action of angiotensin II, infused intracerebrally or peripherally, to produce vasopressin secretion and antidiuresis resides within the OVLT.^{28–30}

The pattern of secretion of vasopressin into blood has been characterized extensively in normal individuals and in those with abnormalities in water homeostasis. Normally, at a serum osmolality of less than 280 mOsm/kg, plasma vasopressin concentration is at or below 1 pg/mL, the lower limit of detection of most radioimmunoassays.³¹ Above 283 mOsm/kg—the normal threshold for vasopressin release—plasma vasopressin concentration increases in proportion to plasma osmolality, up to a maximum concentration of about 20 pg/mL at a blood osmolality of approximately 320 mOsm/kg (Fig. 12.5). The osmosensor can detect as little as a 1% change in blood osmolality. Plasma concentrations in excess of 5 pg/mL are also found with nausea, hypotension, hypovolemia, and insulin-induced hypoglycemia, but further increments in urine concentration do not occur, because peak antidiuretic effect is achieved at 5 pg/mL. The rate of increase of plasma vasopressin concentration, and thus the sensitivity of the osmosensor, exhibits substantial (as much as 10-fold) interindividual variation as plasma osmolality increases.³² The set-point for vasopressin secretion varies in a single individual, in relation to changes in volume status and hormonal environment (e.g., pregnancy³³) or glucocorticoid status.^{34,35} After the seventh week of gestation, osmotic thresholds for both vasopressin release and thirst are reduced by approximately 10 mOsm/kg (see Fig. 12.5), such that normal blood osmolality, during pregnancy, is approximately 273 mOsm/kg (serum sodium 135 mEq/L).^{33,35} Similarly, thresholds for vasopressin release and thirst during the luteal phase of the menstrual cycle are approximately 5 mOsm/kg lower than those in the follicular phase.^{36,37} Human chorionic gonadotropin, during pregnancy,³⁸ and luteinizing hormone, during the second half

of the menstrual cycle, may contribute to these changes in osmotic thresholds.

The sensation of thirst, a more integrated cortical activity, is determined by other anatomically distinct hypothalamic neurons, with afferents involving the ventromedial nucleus,³⁹ and subfornical organ.⁴⁰ The activation of the thirst mechanism is probably mediated by angiotensin II.⁴¹ Whether the osmosensor for thirst and vasopressin release are the same is not certain, although this is suggested by lesions in the anteroventral

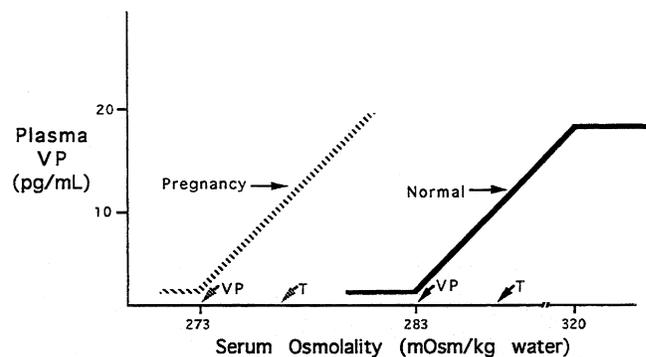

Fig. 12.5 Osmotic thresholds for vasopressin and thirst. The threshold for vasopressin release is below that for thirst. In nonpregnant persons there is linear increase in vasopressin (VP) release up to a serum osmolality of 320 mOsm/kg, after which no further increase occurs. In pregnancy, there is a decreased threshold for vasopressin release and thirst sensation, with no change in the sensitivity (slope) of the vasopressin-osmolality relationship. Vasopressin secretion in pregnancy presumably also plateaus at some level of hyperosmolality, although this has not been studied. Normal nonpregnant persons, solid line and arrows; pregnant women, dashed line and arrows. T, Threshold for thirst; VP, threshold for vasopressin secretion.

region of the third ventricle that abolish both thirst sensation and vasopressin release.⁴² It makes physiologic sense that the threshold for thirst (293 mOsm/kg) is approximately 10 mOsm/kg higher than that for vasopressin release⁴³ (see Fig. 12.5). Otherwise, during the development of hyperosmolality, the initial activation of thirst and water ingestion would result in polyuria, without activation of vasopressin release, causing a persistent diuretic state. Immediately after water ingestion, before a change in blood osmolality or volume, vasopressin concentration falls and thirst ceases.⁴⁴ The degree of suppression is directly related to the coldness⁴⁵ and volume⁴⁶ of the ingested fluid. Water that bypasses the pharynx does not have this effect.⁴⁷ The effect is probably mediated by chemoreceptors present in the oropharynx that project to the subfornical organ, which results in decreased thirst and vasopressin release.^{40,48,49} This "presystemic" regulation of thirst and vasopressin secretion, before osmolality changes, guards against both the rapid overdrinking of fluids after prior intense thirst, and reversal of anti-diuresis with the onset of water ingestion.

As noted earlier, water balance is regulated in two ways: (1) vasopressin secretion stimulates water reabsorption by the kidney, thereby reducing future water loss, and (2) thirst stimulates water ingestion, thereby restoring previous water loss. Ideally, these two systems work in parallel to efficiently regulate extracellular fluid tonicity (Fig. 12.6); however, each system by itself can maintain plasma osmolality in the near-normal range. For example, in the absence of vasopressin secretion but with free access to water, thirst drives water ingestion up to the 5 to 10 L/m² of urine output seen with vasopressin deficiency. Conversely, an intact vasopressin secretory system can compensate for some degree of disordered thirst regulation. When both vasopressin secretion and thirst are compromised, however, by either disease or iatrogenic means, there is great risk of the occurrence of life-threatening abnormalities in plasma osmolality.⁵⁰

Nonosmotic Regulation. Separate from osmotic regulation, vasopressin has been shown to be secreted in response to alterations in intravascular volume. Afferent baroreceptor pathways arising from the right and left atria and the aortic arch (carotid sinus) are stimulated by increasing intravascular

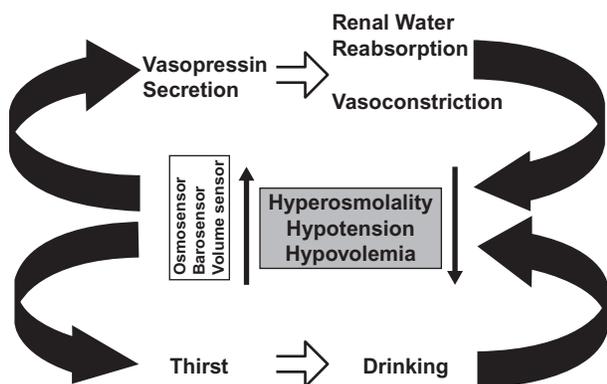

Fig. 12.6 Regulation of vasopressin secretion and serum osmolality. Hyperosmolality, hypovolemia, or hypotension are sensed by osmosensors, volume sensors, or barosensors, respectively. These stimulate both vasopressin secretion and thirst. Vasopressin, acting on the kidney causes increased reabsorption of water (antidiuresis) and acting on the vasculature, causes vasoconstriction. Thirst causes increased water ingestion. The results of these dual negative feedback loops cause a reduction in hyperosmolality or hypotension/hypovolemia. Additional stimuli for vasopressin secretion include nausea, hypoglycemia, and pain.

volume and stretch of vessel walls, and they send signals through the vagus and glossopharyngeal nerves, respectively, to the brain stem nucleus tractus solitarius. Noradrenergic fibers from the nucleus tractus solitarius synapse on the hypothalamic paraventricular nucleus and the supraoptic nucleus and, on stimulation, inhibit vasopressin secretion.⁵¹

The pattern of vasopressin secretion in response to volume, as opposed to osmotic stimuli, is markedly different (Fig. 12.7). Although minor changes in plasma osmolality

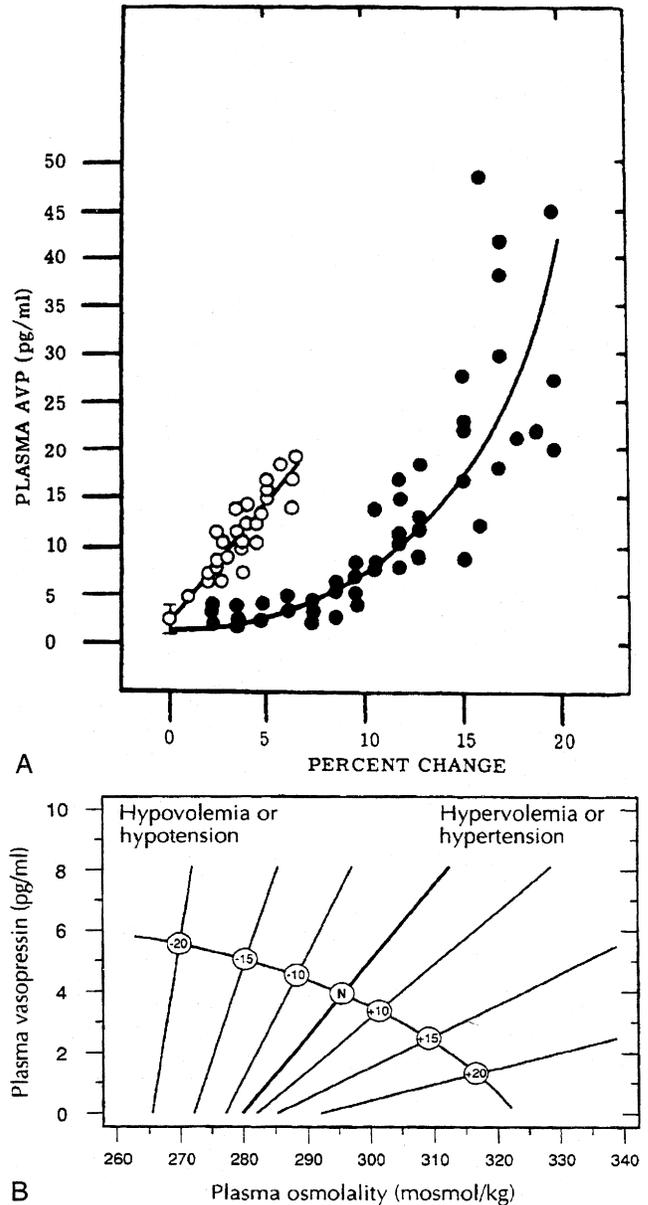

Fig. 12.7 Relationships between osmotic and nonosmotic stimuli for vasopressin release. A, Relationship of plasma vasopressin (AVP) concentration to the percent increase in blood osmolality (open circles) or decrease in blood volume (closed circles). B, Alteration of sensitivity of osmotic stimulation of vasopressin secretion by volume or pressure stimuli. (From Shaikh, Z.H.A., Taylor, H.C., Maroo, P.V., Llerena, L.A. (2000). Syndrome of inappropriate antidiuretic hormone secretion associated with lisinopril. *Ann Pharmacother*, 34, 176–179; van Laar, T., Lammers, G.-J., Roos, R.A.C., Gerritsen, J.J., Meinders, A.E. (1998). Antiparkinsonian drugs causing inappropriate antidiuretic hormone secretion. *Mov Disord*, 13, 176–178. With permission.)

above 280 mOsm/kg evoke linear increases in plasma vasopressin, substantial alteration in intravascular volume is required for alteration in vasopressin output.⁵² No change in vasopressin secretion is seen until blood volume decreases by approximately 8%. With intravascular volume deficits exceeding 8%, vasopressin concentration increases exponentially. Furthermore, osmotic and hemodynamic stimuli can interact in a mutually synergistic fashion, so that the response to either stimulus may be enhanced by the concomitant presence of the other (see Fig. 12.7). When blood volume or blood pressure decreases by approximately 25%, vasopressin concentrations are evident of 20- to 30-fold above normal, and vastly exceeding those required for maximal antidiuresis. Mice with deletion of the V1a vasopressin receptor gene, *Avpr1*, indicate that vasopressin acting through this receptor is required to maintain normal blood pressure, even at low concentrations of blood vasopressin.⁵³

Nausea, as evoked by apomorphine, motion sickness, or vasovagal reactions, is a very potent stimulus for vasopressin secretion. This effect is likely mediated by afferents from the area postrema of the brain stem and may result in vasopressin concentrations two to three orders of magnitude above basal levels. Nicotine is also a strong stimulus for vasopressin release.⁵⁴ These pathways probably do not involve osmotic or hemodynamic sensor systems, because blockade of the emetic stimulus, with dopamine or opioid antagonists, does not alter the vasopressin response to hypernatremia or hypovolemia.

Vasopressin secretion is inhibited by glucocorticoids; because of this, loss of negative regulation of vasopressin secretion occurs in the setting of primary or secondary glucocorticoid insufficiency.⁵⁵ The insertion of aquaporin-2 (AQP2) in the renal luminal membrane is stimulated by nitric oxide.⁵⁶ Glucocorticoids inhibit nitric oxide synthase,⁵⁷ thereby providing a mechanism by which they may facilitate free water clearance, by inhibiting nitric oxide-induced insertion of AQP2 into the luminal membrane. The effects of cortisol loss of both enhancing hypothalamic vasopressin production and directly impairing free water excretion are important considerations in the evaluation of the patient with hyponatremia, as is subsequently discussed.

Vasopressin Metabolism

Once in the circulation, vasopressin has a half-life of only 5 to 10 minutes, owing to its rapid degradation by a cysteine aminoterminal peptidase called *vasopressinase*. A synthetic analogue of vasopressin, desmopressin, is insensitive to aminoterminal degradation and thus has a much longer half-life of 8 to 24 hours. During pregnancy, the placenta secretes increased amounts of this vasopressinase,^{58,59} resulting in a 4-fold increase in the metabolic clearance rate of vasopressin.⁶⁰ Normal women compensate with an increase in vasopressin secretion, but women with preexisting deficits in vasopressin secretion or action,⁶¹ or those with increased concentrations of placental vasopressinase, associated with liver dysfunction⁶² or multiple gestations,⁶³ may develop diabetes insipidus in the last trimester, which resolves in the immediate postpartum period.⁶⁴ As expected, this form of diabetes insipidus responds to treatment with desmopressin but not with vasopressin.^{59,65,66}

Sites of Vasopressin Action

Vasopressin Receptors. Vasopressin, released from the posterior pituitary and the median eminence, affects the function of several tissue types by binding to members of a family of G protein-coupled cell surface receptors, which subsequently transduce ligand binding into alterations of intracellular

second messenger pathways. Biochemical and cell biologic studies have defined three receptor types, designated V1, V2, and V3 (or V1b). The major sites of V1 receptor expression are on vascular smooth muscle^{53,67} and hepatocytes,⁶⁸⁻⁷¹ where receptor activation results in vasoconstriction^{72,73} and glycogenolysis,⁷⁴ respectively. The latter activity may be augmented by stimulation of glucagon secretion from the pancreas.⁷⁴ The V1 receptor on platelets also stimulates platelet aggregation.⁷⁵ V1 receptor activation mobilizes intracellular calcium stores through phosphatidylinositol hydrolysis.^{73,76} Despite its initial characterization as a powerful pressor agent, the concentration of vasopressin needed to significantly increase blood pressure is several-fold higher than that required for maximal antidiuresis,⁷⁷ although substantial vasoconstriction in renal and splanchnic vasculature can occur at lower concentrations.⁷⁸ The cloning of the V1 receptor^{67,68,70} has greatly elucidated the relationship of the vasopressin (and oxytocin^{79,80}) receptors and, through sensitive in situ hybridization analysis, has further localized V1 expression to the liver and the vasculature of the renal medulla, as well as to many sites within the brain, including the hippocampus, the amygdala, the hypothalamus, and the brain stem.^{69,71} Compared with their normal counterparts, mice genetically modified to be deficient in the V1 receptor (V1a KO) have been found to have insulin resistance, increased hepatic glucose production, decreased hepatic glycogen content, and decreased aldosterone secretion, despite a lower plasma volume, lower basal blood pressure, greater degree of lipolysis, and impaired nuclear transport of the renal tubular mineralocorticoid receptor.⁸¹ The V3 (or V1b) receptor is present on corticotrophs in the anterior pituitary⁸² and acts through the phosphatidylinositol pathway⁸³ to increase adrenocorticotropic hormone secretion.⁸⁴ Its binding profile for vasopressin analogues resembles more closely that of the V1 than the V2 receptor. The structure of this receptor has been determined in humans by cloning of its complementary deoxyribonucleic acid (DNA).^{83,85} Its structure is similar to that of the V1 and oxytocin receptors, and it is expressed in the kidney, as well as in the pituitary. Mice with deletion of the V1b (V3) receptor gene (*V1bKO*) have been created and studied.^{86,87} As expected, they have defective activation of the pituitary-adrenal axis, following some acute and chronic stressors. Male *V1bKO* mice were also found to have decreased aggression and social motivation.⁸⁸

Modulation of water balance occurs through the action of vasopressin on V2 receptors, located primarily in the renal collecting tubule, along with other sites in the kidney, including the thick ascending limb of the loop of Henle and periglomerular tubules.⁸⁹ It is also present on vascular endothelial cells in some systemic vascular beds, where vasopressin stimulates vasodilation,⁹⁰ possibly through activation of nitric oxide synthase.⁹¹ Vasopressin also stimulates von Willebrand factor, factor VIIIa, and tissue plasminogen activator through V2-mediated actions. Because of this, desmopressin is used to improve the prolonged bleeding times characteristic of uremia, type I von Willebrand disease, and hemophilia.⁹² The V2 receptor consists of 370 amino acids encoding seven transmembrane domains characteristic of the G protein-coupled receptors.^{89,93} These transmembrane domains share approximately 60% sequence identity with the V1 receptor, but substantially less with other members of this family (Fig. 12.8). Unlike the V1 and V3 receptors, the V2 receptor acts through adenylate cyclase to increase intracellular cyclic adenosine monophosphate (AMP) concentration. The human V2 receptor gene is located on the long arm of the X chromosome (Xq28),⁹⁴ at the locus associated with congenital, X-linked vasopressin-resistant diabetes insipidus. Mice in which *V2R* has been deleted have a similar nephrogenic diabetes insipidus phenotype.⁹⁵

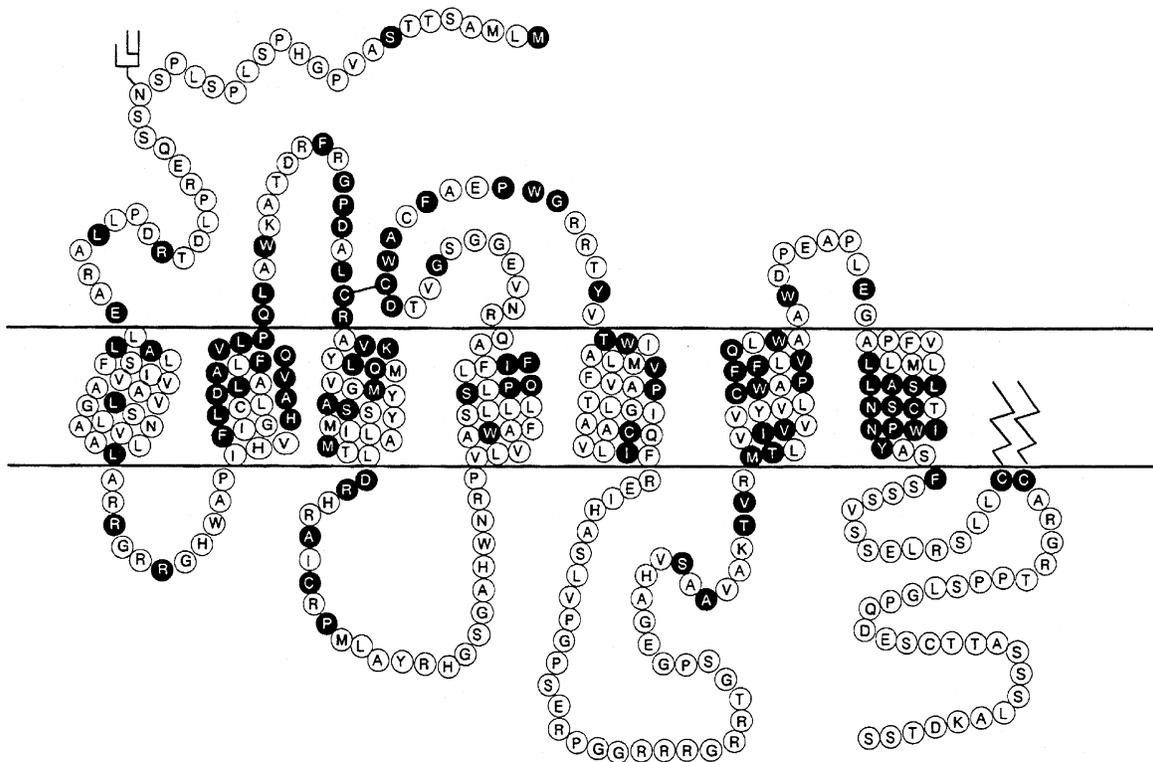

Fig. 12.8 Structure of the V1 and V2 vasopressin receptors, and the oxytocin receptor. Depicted, are predicted membrane topology, with the extracellular domain at the top of the figure and amino acids in the one-letter code. Amino acids in *open circles* encode the V1 receptor, whereas those in *black circles* are common to all three receptors. (Baylis, P.H. (1989). Vasopressin and its neurophysin. In: Degroot, L.J., ed. Endocrinology. 2nd ed. WB Saunders, Philadelphia, p. 213. With permission.)

Renal Cascade of Vasopressin Function. Vasopressin-induced increases in intracellular cyclic AMP, as mediated by the V2 receptor, triggers a complex pathway of events resulting in increased permeability of the collecting duct to water and efficient water transit across an otherwise minimally permeable epithelium (Fig. 12.9).¹ Activation of a cyclic AMP-dependent protein kinase imparts remodeling of cytoskeletal microtubules and microfilaments that culminate in the insertion of aggregates of water channels into the apical membrane.^{96,97} These mechanisms may involve a vesicle-associated membrane protein-2–like protein (VAMP-2), which also regulates synaptic vesicle activity in neuronal terminals,⁹⁸ and its associated receptor syntaxin-4.⁹⁹

Insertion of the water channels causes an up to 100-fold increase in water permeability of the apical membrane, allowing water movement along its osmotic gradient into the hypertonic inner medullary interstitium from the tubule lumen and excretion of a concentrated urine (see Fig. 12.9). The molecular analysis of the water channels has revealed a family of related proteins, designated aquaporins, that differ in their sites of expression and pattern of regulation.^{97,100} Each protein consists of a single polypeptide chain with six membrane-spanning domains (Fig. 12.10). Although functional as monomers, they form homotetramers in the plasma membrane.

AQP2 is expressed mostly within the kidney,¹⁰¹ primarily within the collecting duct.¹⁰² It is also expressed in the vas deferens, at least in the rat, although it is not regulated by vasopressin in this location.¹⁰³ Studies with immunoelectron microscopy have demonstrated large amounts of AQP2 in the apical plasma membrane and subapical vesicles of the collecting duct, consistent with the “membrane shuttling” model

of water channel aggregate insertion into the apical membrane after vasopressin stimulation.¹⁰³ Studies analyzing the mechanism by which AQP2 traffics to the apical plasma membrane have demonstrated that vasopressin-induced, protein kinase A–mediated serine phosphorylation at amino acid 256 is required for its exocytosis,¹⁰⁴ a process also requiring a heterotrimeric G protein of the G_i family.¹⁰⁵ In response to water restriction or desmopressin infusion in humans, the content of urinary AQP2 in both soluble and membrane-bound forms has been found to increase.¹⁰⁶ Mice with targeted deletion of the AQP2 gene have been made.¹⁰⁷ As expected, they have nephrogenic diabetes insipidus that is unresponsive to treatment with vasopressin.

Hypercalciuria is associated with polyuria despite adequate vasopressin levels. The activation by luminal calcium, of the calcium-sensing receptor (CaSR) on the apical membranes of the collecting duct cells of the kidney, is associated with resistance to vasopressin action.¹⁰⁸ The production of dilute urine when there is increased urinary concentration of calcium, has been hypothesized to be a protective mechanism to mitigate the risk of precipitation of calcium in the kidneys. Mechanisms by which the activation of the CaSR decreases AQP2 levels in the collecting duct cells include reduced synthesis of AQP2 by the generation of AQP2 targeting microribonucleic acid (miRNA), and the inactivation and degradation of AQP2 through ubiquitination and phosphorylation at serine261.^{109,110}

In addition to AQP2, different aquaporins appear to be involved in other aspects of renal water handling. In contrast to the apical localization of AQP2, aquaporin-3 and aquaporin-4 are expressed on the basolateral membrane of

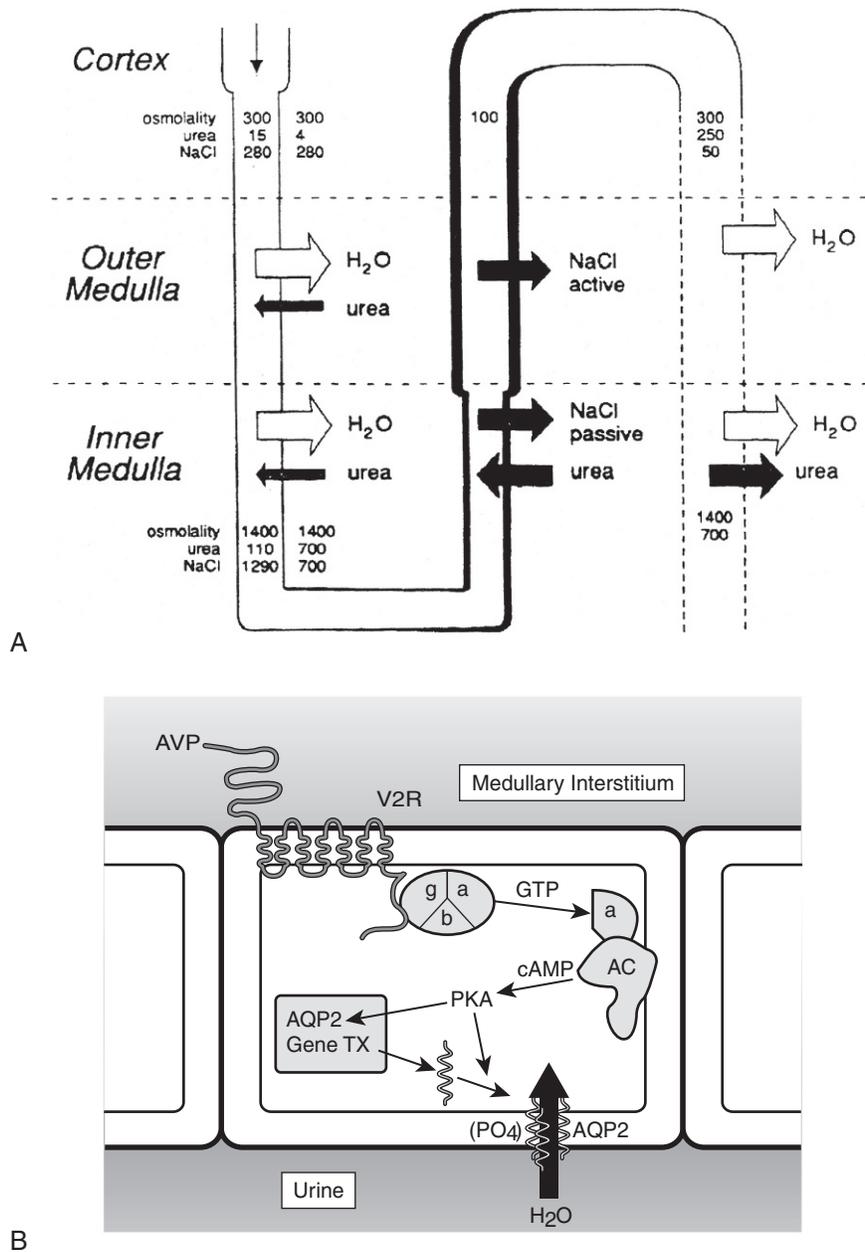

Fig. 12.9 Vasopressin action in the kidney. A, Solute and water handling in the kidney. B, Action of vasopressin in the collecting duct cell. Vasopressin (AVP) binds to the V2 receptor (V2R), causing the binding of guanosine triphosphate (GTP) to the stimulatory alpha G protein subunit (α). This activates adenylate cyclase (AC), resulting in an increase in cyclic adenosine monophosphate (cAMP) and activation of protein kinase A (PKA). The catalytic subunit of PKA, via phosphorylation of serine 256 of the water channel, aquaporin-2 (AQP2), causes aggregation of AQP2 homotetramers in membrane vesicles and their fusion with the collecting duct luminal membrane, resulting in an increase in water flow from the urine into the renal medullary interstitium. Demeclocycline, lithium, high calcium, and low potassium interfere with these processes, possibly at the level of cAMP generation and AQP2 synthesis or action. a, Gs alpha; b, Gs beta; g, Gs gamma. (A from van Laar, T., Lammers, G-J., Roos, R.A.C., Gerritsen, J.J., Meinders, A.E. (1998). Antiparkinsonian drugs causing inappropriate antidiuretic hormone secretion. *Mov Disord*, 13, 176–178. With permission.)

the collecting duct epithelium. They are involved in the flow of water and urea from the inside of the collecting duct cell into the extracellular renal medullary space. Mice made genetically deficient in aquaporin-4 demonstrate a mild urinary concentrating defect,¹¹¹ whereas those with deficiency of aquaporin-3 alone, or together with aquaporin-4, demonstrate more severely impaired urinary concentrating ability.¹¹² Mice made genetically deficient in aquaporin-1 demonstrate a urinary concentrating defect caused by decreased water permeability in the proximal tubule.¹¹³

Volume Sensor and Effector Pathways Renin-Angiotensin-Aldosterone System

In contrast to the vasopressin system, the classic, or peripheral, renin-angiotensin system primarily affects maintenance of intravascular volume as opposed to plasma tonicity. In addition to the well-established endocrine regulatory system, several local renin-angiotensin systems have emerged, with both autocrine and paracrine effects in their tissue of synthesis, whose regulation is independent of the classic system. Finally, brain and

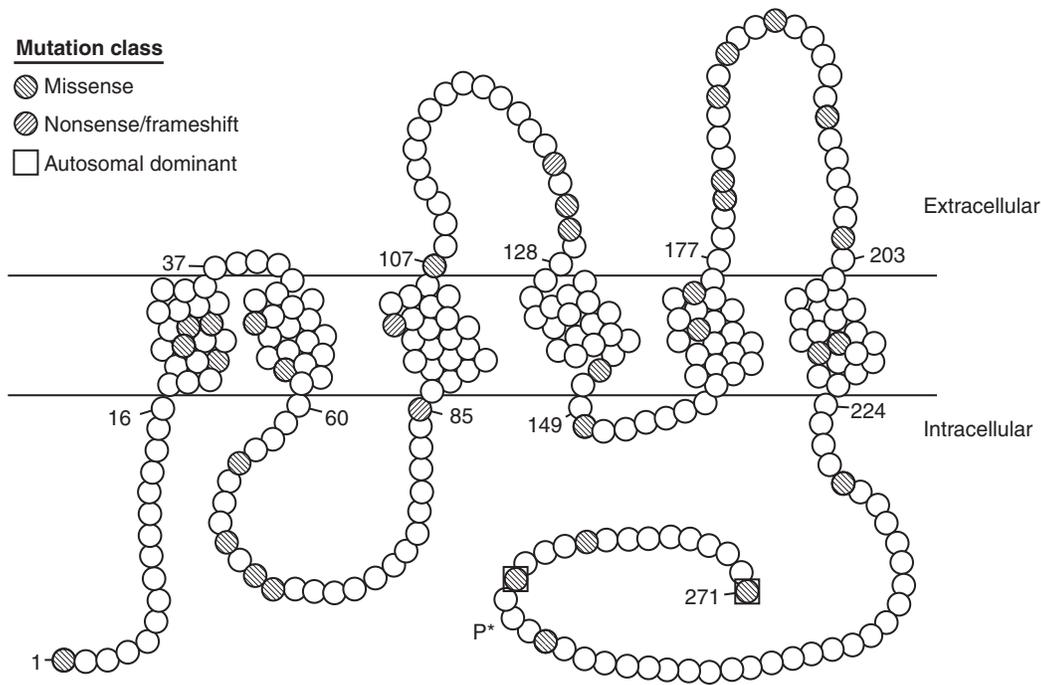

Fig. 12.10 Structure of the aquaporin-2 (AQP2) protein inserted into the luminal membrane of the distal tubule and AQP2 mutations that cause autosomal nephrogenic diabetes insipidus. Depicted, are predicted membrane topology, with the extracellular domain at the top of the figure. The 271-amino-acid protein consists of five transmembrane domains, four intracellular domains, and three extracellular domains. Amino acid mutations are classified as missense or nonsense/frameshift. Most mutations are transmitted with an autosomal recessive pattern, with autosomal dominant transmission noted by boxed amino acids. Vasopressin-dependent, protein kinase A-mediated phosphorylation of serine at amino acid 256 (P^{*}) is noted.

pituitary angiotensin systems involved in blood pressure, autonomic function, and fluid balance have been characterized with extensive interaction with the vasopressin system, and vasopressin has been found to play a role in the normal action of aldosterone on the renal tubular epithelium.¹¹⁴

Endocrine Renin-Angiotensin-Aldosterone System

Anatomy and Biochemistry. Renin, which is synthesized by the renal juxtaglomerular apparatus, is a proteolytic enzyme that catalyzes the cleavage of angiotensinogen, synthesized by hepatocytes, into the decapeptide angiotensin I. Angiotensin I possesses no intrinsic vasoreactive or mineralocorticoid secretagogue activity, but is efficiently cleaved by angiotensin-converting enzyme in the lungs, as well as other peripheral sites, to generate the octapeptide angiotensin II. Angiotensin II is further metabolized to the heptapeptide angiotensin III by removal of one amino-terminal amino acid. Angiotensin II possesses greater vasopressor activity and is present in approximately a 4-fold greater amount than angiotensin III. Angiotensins II and III possess equivalent mineralocorticoid secretory activity on the adrenal glomerulosa cells.

Angiotensin II and III act through cell surface receptors (AT₁) on the adrenal glomerulosa cells to activate the phospholipase C/protein kinase C pathway.¹¹⁵ This activation results in increased production of pregnenolone from cholesterol by side-chain cleavage enzyme (20,22-desmolase) and of aldosterone from corticosterone by the glomerulosa-specific corticosterone methyl oxidase I and II activities (18-hydroxylation and dehydrogenation, respectively).¹¹⁶ A distinct receptor subtype for angiotensin II and III, the AT₂ receptor, is not G protein coupled and is of unclear physiologic significance in the periphery,^{117–119} but may counteract AT₁ effects by inducing natriuresis.¹²⁰ Aldosterone, the primary and most potent endogenous mineralocorticoid released by the zona

glomerulosa, acts on target tissues expressing the nuclear mineralocorticoid (or type I glucocorticoid) receptor to promote sodium absorption and potassium excretion. For control of intravascular volume, the primary target of action of aldosterone is the distal nephron. Here, aldosterone increases synthesis of apical membrane sodium channels, mitochondrial enzymes involved in adenosine triphosphate production, and components of Na⁺, K⁺ adenosine triphosphatase to cause increased sodium reabsorption and potassium excretion.

Regulation of Secretion. Decreased intravascular volume as sensed by the renal juxtaglomerular apparatus results in release of renin.^{121,122} Increased plasma renin activity then allows increased conversion of angiotensinogen to angiotensin I, which in turn is converted peripherally to angiotensins II and III. Increased angiotensin II activity causes vasoconstriction and blood pressure elevation, whereas both angiotensins II and III stimulate aldosterone release from the zona glomerulosa and subsequent salt and water retention and potassium excretion by the distal tubule of the kidney. Conversely, expanded intravascular volume causes decreased renin output and less sodium and water resorption in the kidney, serving to decrease intravascular volume and restore homeostasis.

Changes in vascular volume are not the only regulators of the renin-angiotensin-aldosterone system. Serum potassium concentration directly modulates aldosterone release by the adrenal glomerulosa by its effects on plasma membrane potential and activation of voltage-gated calcium channels.¹²³ By membrane depolarization, increased serum potassium leads to increased aldosterone synthesis, which promotes renal potassium excretion, whereas low serum potassium reduces aldosterone synthesis and decreases urinary potassium losses. Pituitary adrenocorticotropic hormone and vasopressin act through their respective receptors on the glomerulosa cells to increase acute aldosterone secretion. These effects are of short

duration because long-term chronic infusions do not chronically elevate aldosterone concentrations. Direct inhibitors of aldosterone secretion, and thus promoters of natriuresis, include atrial natriuretic peptide (ANP),^{124,125} somatostatin,¹²⁶ and dopamine.¹²⁷

Local Renin-Angiotensin Systems

Anatomy and Biochemistry. In addition to the well-defined endocrine circuit, the components of the renin-angiotensin system have been found in a wide variety of tissues, including brain, pituitary, arterial wall, heart, ovary, kidney, and adrenal, where paracrine and autocrine regulatory functions^{122,128} have been postulated, undergoing regulation independent of the systemic counterpart. From the standpoint of regulation of water and volume homeostasis, the brain renin-angiotensin system merits further description. It has long been known that peripherally synthesized angiotensin II could increase blood pressure by effects on the brain outside the blood-brain barrier, at sites such as the OVLT, SFO, area postrema, and median eminence, as revealed by ligand-binding studies. Over the past decade, it has become clear that the complete system for generation of angiotensin II is present within the brain. Angiotensinogen has been localized to astrocytes by both immunohistochemical peptide localization and *in situ* hybridization analysis of messenger RNA. In contrast, renin has been found in high concentration in nerve terminals, with enhanced release on nerve depolarization. Angiotensin-converting enzyme has been found within vascular, choroid plexus, and neuronal components of the central nervous system, most notably the SFO and many hypothalamic nuclei, sites of endogenous angiotensin II receptor expression, primarily of the AT₁ subtype, as well as sites not expressing the angiotensin II receptor, such as the basal ganglia. The primary effector molecule, angiotensin II, has been localized specifically to neurons and subcellularly to synaptic vesicles. Two of the most significant sites include the circumventricular organs and the paraventricular nucleus of the hypothalamus. Within the paraventricular nucleus, angiotensin II immunoreactivity colocalizes with magnocellular vasopressin, whereas its receptors are within the parvocellular region of the paraventricular nucleus.

Regulation of Secretion. The forebrain angiotensin II pathway, of which the paraventricular nucleus is one component, and circumventricular organ angiotensin II pathway are important control centers for maintenance of osmotic and volume homeostasis. Increased concentration of peripheral angiotensin II, as would be expected in intravascular volume depletion, stimulates drinking behavior. This action of peripheral angiotensin II can be abolished by destruction of the OVLT or SFO, regions whose destruction has long been recognized as causing adipsia. Further effects of central angiotensin II action include augmentation of sodium appetite and stimulation of vasopressin release, all serving, as with peripheral angiotensin II, to restore intravascular volume and maintain blood pressure. The signal of hypovolemia is transduced through the vagal nerve from volume sensors to the brain stem and the region of the nucleus tractus solitarius. Efferents from these brain-stem centers project to the median preoptic nucleus and paraventricular nucleus, as does the forebrain angiotensin II pathway, where drinking and pressor effects, as well as vasopressin release, are elicited.

Separate pathways for vasopressin release mediate the response to either peripheral angiotensin II or purely osmotic stimulation of the osmosensors.¹²⁹ The release of vasopressin in response to osmotic stimulation is not increased by peripheral angiotensin II, and pure osmotic stimulation does not increase salt appetite. Central angiotensin II, in contrast, may function as a transmitter in the osmosensing circuit, leading to vasopressin release.

The Natriuretic Peptide System

In addition to the classic vasopressin and renin-angiotensin-aldosterone systems, the natriuretic peptide families of ligands and their receptors add further potential for modulation of salt and water balance. The interaction of the natriuretic peptide system occurs both in the central nervous system through effects on vasopressin secretion, and peripherally, through its ability to both directly promote natriuresis in the kidney and indirectly inhibit adrenal aldosterone production.

Anatomy and Biochemistry. ANP was initially discovered as a component of cardiac atrial muscle that was able to induce natriuresis, a decrease in blood pressure, and an increase in hematocrit when injected into rats.¹³⁰

The biologically active form of ANP consists of a 28-amino-acid peptide that includes a 17-amino-acid ring structure¹³¹ (Fig. 12.11). The primary sequence of the peptide has been conserved among mammalian species and, in addition to synthesis in cardiac atrial tissue,¹³² has been detected in brain, spinal cord, pituitary, and adrenal gland.^{133,134} Within the brain, ANP synthesis occurs at several critical neuroendocrine regulatory sites, including the periventricular, arcuate, anteroventral preoptic, and lateral hypothalamic nuclei. ANP is synthesized as a 151-amino-acid preprohormone and is stored as a 126-amino-acid prohormone after removal of the signal peptide sequence. Coupled with secretion of pro-ANP is its cleavage between amino acids 98 and 99 to yield the mature 28-amino-acid 99–126 fragment.

Subsequent investigation defined a second peptide from porcine brain with structural homology to ANP.¹³⁵ This peptide, designated brain natriuretic peptide (BNP), was later found to be secreted by the heart as well, in this case, from both ventricular and atrial tissue. Human BNP consists of a 32-amino-acid processed from a larger preprohormone¹³⁶ sharing a central ring structure with ANP (see Fig. 12.11), although it is less conserved between species than ANP.

A third member of this family, C-type natriuretic peptide (CNP), was also isolated from porcine brain.¹³⁷ In brain, CNP is the most abundant member of the natriuretic peptide family. Within the hypothalamus, specific sites of synthesis largely overlap sites of ANP expression. Little CNP can be detected in plasma, and in marked contrast to ANP and BNP, CNP does not increase in plasma in the setting of cardiac failure.¹³⁸ Outside the brain, CNP is synthesized in endothelial and vascular smooth muscle. In tissues capable of CNP gene expression, two forms of the peptide are produced, a 53-amino-acid peptide and a less abundant 22-amino-acid molecule (see Fig. 12.11).

Three distinct endogenous receptors exist for the natriuretic peptides. The first of these receptors isolated (natriuretic peptide receptor [NPR]-A or guanylyl cyclase [GC]-A) was cloned by virtue of its homology to sea urchin sperm guanylyl cyclase and was later found to have ANP and BNP as its normal ligands.¹³⁹ A second guanylyl cyclase type receptor (NPR-B) has substantial homology to NPR-A; however, it binds CNP with substantially greater affinity than ANP or BNP.¹⁴⁰ A third receptor (NPR-C¹⁴¹) does not possess guanylyl cyclase activity and probably functions to clear all three natriuretic peptides from the circulation.¹⁴² *In situ* hybridization studies using probes capable of distinguishing the different receptor types have revealed some interspecies discrepancy in distribution. The NPR-A receptor has been localized to kidney, adrenal, pituitary, brain, and heart in monkey, with NPR-B limited to adrenal, pituitary, and brain.¹⁴³ In rat, broad tissue distribution of both NPR-A and NPR-B has been described.¹⁴⁴ The NPR-C receptor has similarly been found in adrenal, heart, brain, and pituitary.¹⁴³

stimulates thirst.¹⁵⁴ The overall importance of the CNP central pathways in modulation of water balance in humans remains to be defined.

APPROACH TO THE PATIENT: DIFFERENTIAL DIAGNOSIS OF DISORDERS OF WATER METABOLISM

Hyponatremia (Fig. 12.12)

Hyponatremia (serum sodium <135 mEq/L) in children is usually associated with severe systemic disorders. It is most often caused by intravascular volume depletion or excessive salt loss and is also encountered with hypotonic fluid overload, especially in infants. Inappropriate vasopressin excess is one of the least common causes of hyponatremia in children, except after vasopressin administration for treatment of diabetes insipidus.

In evaluating the cause of hyponatremia, one should first determine whether the patient is dehydrated and hypovolemic. This is usually evident from the physical examination (decreased weight, skin turgor, central venous pressure) and laboratory data (high blood urea nitrogen, renin, aldosterone, uric acid). With a decrease in the glomerular filtration rate, proximal tubular reabsorption of sodium and water will be high, leading to a urinary sodium value often less than 10 mEq/L. Patients with decreased “effective” intravascular volume from congestive heart failure, cirrhosis, nephrotic syndrome, or lung disease will present with similar laboratory data, but will also have obvious signs of their underlying disease, which often includes peripheral edema. Patients with primary salt loss will also appear volume depleted. If the salt loss is from the kidney (e.g., diuretic therapy or polycystic kidney disease), the urine sodium level will be elevated, as may urine volume. Salt loss from other regions (e.g., the gut in gastroenteritis or the skin in cystic fibrosis) will cause urine sodium to be low, as in other forms of systemic dehydration. Cerebral salt wasting has been invoked to occur with central nervous system insults, and results in high serum ANP concentrations, leading

to high urine sodium and urine excretion and systemic dehydration.^{155–157} Its existence is controversial, and believed by many experts to be rare or not exist.^{158–162}

The syndrome of inappropriate antidiuresis (SIAD) exists when a primary elevation in vasopressin secretion or inappropriate activation of the vasopressin V2 receptor is the cause of hyponatremia.^{163,164} It is characterized by hyponatremia, an inappropriately concentrated urine (>100 mOsm/kg), normal or slightly elevated plasma volume, and a normal-to-high urine sodium (because of volume-induced suppression of aldosterone and elevation of ANP). Serum uric acid is low in patients with SIAD, whereas it is high in those with hyponatremia caused by systemic dehydration or other causes of decreased intravascular volume.¹⁶⁵ Measurement of plasma vasopressin is often not very useful because it is elevated in nearly all causes of hyponatremia, except for primary hypersecretion of ANP¹⁶⁶ or mutations in the vasopressin receptor that lead to its inappropriate activation. Because cortisol and thyroid deficiency cause hyponatremia by several mechanisms, discussed subsequently, they should be considered in all hyponatremic patients. Drug-induced hyponatremia should be considered in patients on potentially offending medications, as discussed later. In children with SIAD who do not have an obvious cause, a careful search for a tumor (thymoma, glioma, bronchial carcinoid) should be considered. Recently, the measurement of copeptin, coupled with hypertonic saline infusion, has been used to classify SIAD into different subtypes.¹⁶⁷

Polyuria, Polydipsia, and Hypernatremia (Fig. 12.13)

In children, it must first be determined whether pathologic polyuria or polydipsia (either exceeding 2 L/m²/day) is present. The following questions are asked: Is there a psychosocial reason for either polyuria or polydipsia? Can either be quantitated? Has either polyuria or polydipsia interfered with normal activities? Is nocturia or enuresis present? If so, does

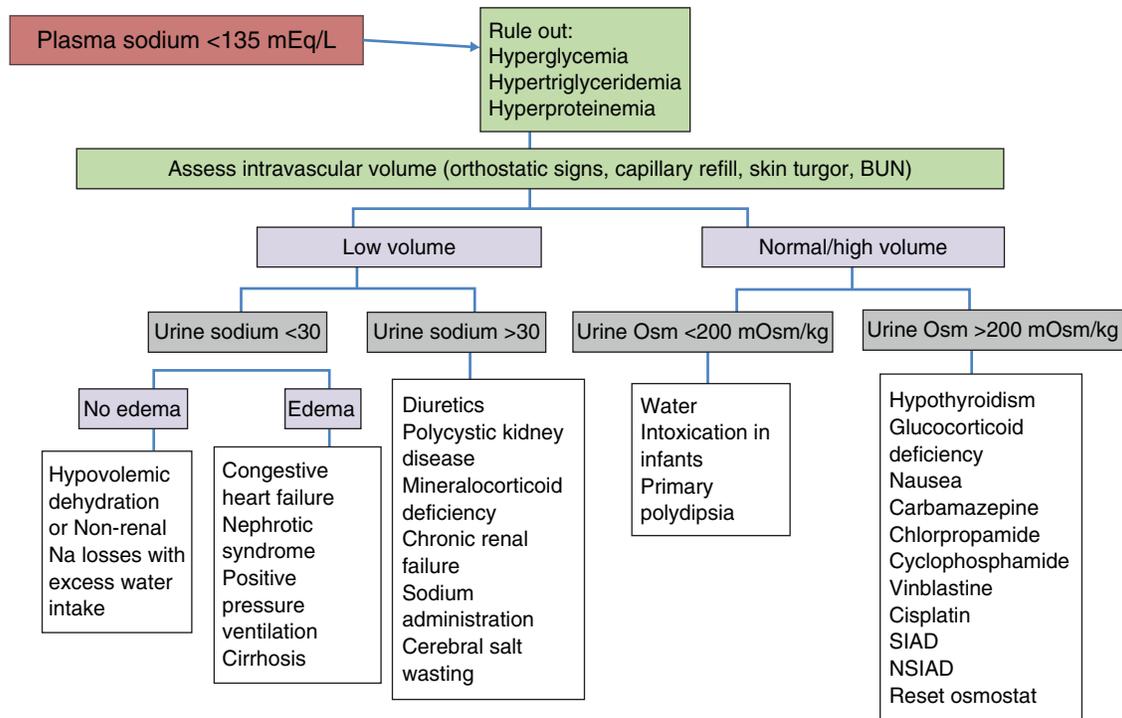

Fig. 12.12 Diagnostic algorithm for hyponatremia.

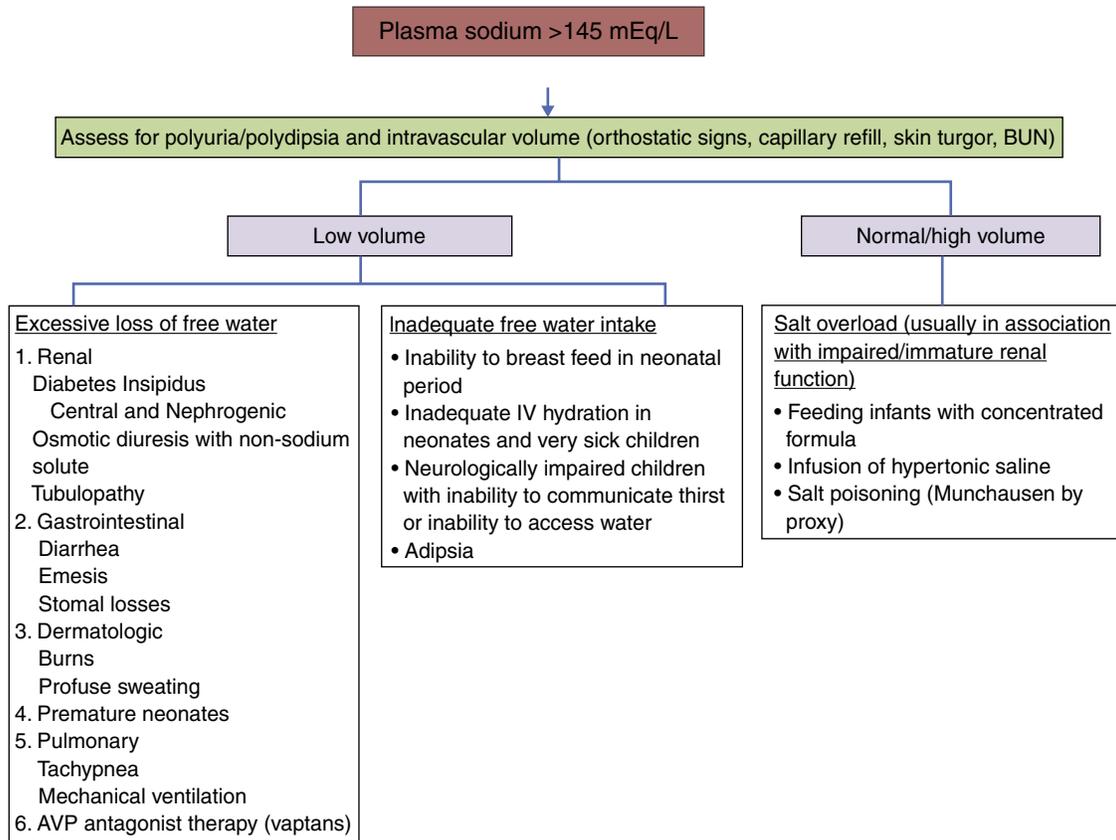

Fig. 12.13 Diagnostic algorithm for hypernatremia.

the patient also drink after nocturnal awakening? Does the history (including longitudinal growth data) or physical examination suggest other deficient or excessive endocrine secretion or an intracranial neoplasm?

If pathologic polyuria or polydipsia is present, the following should be obtained. In the outpatient setting: serum osmolality; serum concentrations of sodium, potassium, glucose, calcium, and blood urea nitrogen; and urinalysis, including measurement of urine osmolality, specific gravity, and glucose concentration. A serum osmolality greater than 300 mOsm/kg, with urine osmolality less than 300 mOsm/kg, establishes the diagnosis of diabetes insipidus. If serum osmolality is less than 270 mOsm/kg, or urine osmolality is greater than 600 mOsm/kg, the diagnosis of diabetes insipidus is unlikely. If, on initial screening, the patient has a serum osmolality less than 300 mOsm/kg, but the intake/output record at home suggests significant polyuria and polydipsia that cannot be attributed to primary polydipsia (i.e., the serum osmolality is greater than 270 mOsm/kg), the patient should undergo a water deprivation test to establish a diagnosis of diabetes insipidus and to differentiate central from nephrogenic causes.

After a maximally tolerated overnight fast (based on the outpatient history), the child is admitted to the outpatient testing center in the early morning of a day when an 8- to 10-hour test can be carried out, and the child is deprived of water.^{168,169} The physical signs and biochemical parameters shown in the accompanying protocol are measured (Fig. 12.14). If at any time during the test, the urine osmolality exceeds 1000 mOsm/kg, or 600 mOsm/kg and is stable over 1 hour, the patient does not have diabetes insipidus. If at any time the serum osmolality exceeds 300 mOsm/kg and the urine osmolality is less than 600 mOsm/kg, the patient has diabetes insipidus. If the serum osmolality is less than 300 mOsm/kg and

the urine osmolality is less than 600 mOsm/kg, the test should be continued unless vital signs disclose hypovolemia. This may be difficult in a young child who may not tolerate a long period of fasting.

A common error is to stop a test too soon, based on the amount of body weight lost, before either urine osmolality has plateaued above 600 mOsm/kg or a serum osmolality above 300 mOsm/kg has been achieved. Unless the serum osmolality increases above the threshold for vasopressin release, a lack of vasopressin action (as inferred by a nonconcentrated urine) cannot be deemed pathologic. As an alternative to water deprivation, hypertonic saline can be infused intravenously to raise serum osmolality above the threshold for vasopressin release.¹⁷⁰ If the diagnosis of diabetes insipidus is made, aqueous vasopressin (Pitressin, 1 U/m²) should be given subcutaneously. If the patient has central diabetes insipidus, urine volume should fall and osmolality should at least double during the next hour, compared with the value before vasopressin therapy. If there is less than a 2-fold increase in urine osmolality after vasopressin administration, the patient probably has nephrogenic diabetes insipidus. Desmopressin should not be used for this test, because it has been associated with water intoxication in small children in this setting.¹⁷¹ Patients with long-standing primary polydipsia may have mild nephrogenic diabetes insipidus because of dilution of their renal medullary interstitium. This should not be confused with primary nephrogenic diabetes insipidus, because patients with primary polydipsia should have a tendency toward hyponatremia, rather than hypernatremia, in the basal state. Moreover, this form of secondary nephrogenic diabetes insipidus will reverse after cessation of overdrinking. Patients with a family history of X-linked nephrogenic diabetes insipidus, or more rarely, autosomal recessive mutations in the AQP2 water

Water Deprivation Test

channel (most commonly but not always found in consanguineous families¹⁷²), can be evaluated for these disorders in the prenatal or perinatal period by DNA sequence analysis, thus allowing therapy to be initiated without delay.¹⁷³

The water deprivation test should be sufficient in most patients to establish the diagnosis of diabetes insipidus and to differentiate central from nephrogenic causes. Plasma

vasopressin concentrations may be obtained during the procedure (see Fig. 12.14), although they are rarely needed for diagnostic purposes in children.¹⁷⁴ They are particularly helpful in differentiating between partial central diabetes insipidus and nephrogenic diabetes insipidus, in that they are low in the former and high in the latter situation.¹⁷⁵ If urine osmolality concentrates normally, but only after serum osmolality is well

above 300 mOsm/kg, the patient may have an altered threshold for vasopressin release, also termed a *reset osmostat*. This may occur after head trauma, neurosurgery, or brain tumors.¹⁷⁶ More recently, an immunoassay for copeptin, the carboxy-terminus of the vasopressin precursor, has been developed, which may replace the measurement of vasopressin in the evaluation of diabetes insipidus.¹⁴ Copeptin is more stable than vasopressin, and blood concentrations of the two peptides are highly correlated.¹⁷⁷ Copeptin levels correlate well with vasopressin levels and show the same response as vasopressin levels to osmotic and to hemodynamic changes.¹⁷⁰

The diagnostic accuracy of using a copeptin cut-off value of 4.9 pmol/L (central diabetes insipidus if ≤ 4.9 pmol/L; primary polydipsia if > 4.9 pmol/L), after increasing the plasma sodium level to above 150 mmol/L with a bolus followed by an intravenous (IV) infusion of 3% saline, to differentiate between primary polydipsia, central diabetes insipidus and nephrogenic diabetes insipidus, was found to be significantly higher than that of the indirect water deprivation test (96.5% vs. 76.6%). The hypertonic saline infusion test correctly differentiated between partial diabetes insipidus and primary polyuria in 95.2% of the cases, in contrast to the 73.3% success rate with the use of the indirect water deprivation test in the same study.¹⁴ Nephrogenic diabetes insipidus could be diagnosed without the need for water deprivation, when the baseline copeptin level was greater than 21.4 pmol/L.¹⁷⁰

Magnetic resonance imaging (MRI) is not very helpful in distinguishing central diabetes insipidus from nephrogenic diabetes insipidus.¹⁷⁸ Normally, the posterior pituitary is seen as an area of enhanced brightness in T1-weighted images after administration of gadolinium.¹⁷⁹ The posterior pituitary "bright spot" is diminished or absent in both forms of diabetes insipidus, presumably because of decreased vasopressin synthesis in central, and increased vasopressin release in nephrogenic disease.^{180–182} In primary polydipsia, the bright spot is normal, probably because vasopressin accumulates in the posterior pituitary during chronic water ingestion,¹⁸² whereas it is decreased in SIAD, presumably because of increased vasopressin secretion.¹⁷⁸ Presence of hyperintensity upon T1-weighted MRI in the pituitary stalk, and its absence in the posterior pituitary region, has been associated with acute postneurosurgical diabetes insipidus.¹⁸³ Dynamic, fast-frame, MRI analysis has allowed estimation of blood flow to the posterior pituitary.¹⁸⁴ With this technique, both central and nephrogenic diabetes insipidus are associated with delayed enhancement in the area of the neurohypophysis.¹⁸⁵

In the inpatient postneurosurgical setting, central diabetes insipidus is likely if hyperosmolality (serum osmolality > 300 mOsm/kg) is associated with urine osmolality less than serum osmolality. One must beware of intraoperative fluid expansion with subsequent hypoosmolar polyuria masquerading as diabetes insipidus. Elevated copeptin levels within 24 hours after neurosurgery, in the hypothalamic-pituitary region, predict the unlikelihood of subsequent central diabetes insipidus, whereas low copeptin levels favor it.¹⁸⁶

SPECIFIC DISORDERS OF WATER METABOLISM

Hyponatremia With Normal Regulation of Vasopressin

Hyponatremia With Appropriate Decreased Secretion of Vasopressin

Increased Water Ingestion (Primary Polydipsia). In a hypoosmolar state with vasopressin secretion normally suppressed, the kidney can excrete urine with an osmolality as low as

50 mOsm/kg. Under these conditions, a daily solute load of 500 mOsm/m² could be excreted in 10 L/m² of urine per day. Neonates cannot dilute their urine to this degree and are prone to develop water intoxication at levels of water ingestion above 4 L/m²/day (approximately 60 mL/h in a newborn). This may happen when concentrated infant formula is diluted with excess water, either by accident or in a misguided attempt to make it last longer.¹⁸⁷ A primary increase in thirst, without apparent cause, leading to hyponatremia, has been reported in infants as young as 5 weeks of age.¹⁸⁸ In older children, with a normal kidney and the ability to suppress vasopressin secretion, hyponatremia does not occur unless water intake exceeds 10 L/m²/day, a feat that is almost impossible to accomplish. Long-standing ingestion of large volumes of water will decrease the hypertonicity within the renal medullary interstitium, which will impair water reabsorption and guard against water intoxication.¹⁸⁹ Hyponatremia will occur at lower rates of water ingestion when renal water clearance is impaired, either because of inappropriately elevated vasopressin secretion or for other reasons.

The rare patient in whom the osmotic thresholds for thirst and vasopressin release are reversed illustrates the importance of the normal relationship between these two responses to osmotic stimulation.¹⁹⁰ If thirst is activated below the threshold for vasopressin release, water intake and hypoosmolality will occur and suppress vasopressin secretion, leading to persistent polydipsia and polyuria. As long as daily fluid intake is less than 10 L/m², hyponatremia will not occur. Despite the presence of polyuria and polydipsia, this entity should not be confused with diabetes insipidus because of the absence of hypernatremia, although desmopressin treatment of such a patient may lower serum osmolality below the threshold for thirst, suppressing water ingestion and the consequent polyuria.

Decreased Renal Free Water Clearance. Adrenal insufficiency, either primary or secondary, has long been known to result in compromised free water excretion.^{34,191} The mechanisms by which glucocorticoids and mineralocorticoids modulate water diuresis have been the subject of substantial investigation. Some studies have demonstrated increased plasma vasopressin activity in the context of glucocorticoid insufficiency,^{192,193} consistent with more recent molecular biologic evidence that glucocorticoids inhibit transcription of the vasopressin gene.¹⁹⁴ Other investigators, however, have failed to detect vasopressin in plasma of patients with adrenal insufficiency and abnormal water clearance.¹⁹⁵ Consistent with vasopressin-independent actions of adrenal steroids on water metabolism, Brattleboro rats with hypothalamic diabetes insipidus manifest impaired excretion of a water load after adrenalectomy.¹⁹¹ In adrenalectomized Brattleboro rats, glucocorticoid administration restored urine flow rate but did not restore maximal urinary diluting capacity. Conversely, mineralocorticoid administration restored maximal urinary diluting capacity but not flow rate. Thus both mineralocorticoids and glucocorticoids are required for normal free water clearance. In part, these vasopressin-independent actions of mineralocorticoids and glucocorticoids have been attributed to the increased glomerular filtration rate arising from reexpansion of extracellular fluid volume (reduced owing to salt wasting) and improved cardiovascular tone, respectively.^{35,196,197} By restoring the glomerular filtration rate, more free water is delivered to the distal tubule for excretion. In addition, volume repletion reduces the nonosmotic stimuli for vasopressin release of volume depletion and hypotension. Recently, nitric oxide has been found to stimulate cyclic guanosine monophosphate-dependent membrane insertion of AQP2 into renal epithelial cells.¹⁹⁸ Because glucocorticoid has been shown to

inhibit endothelial nitric oxide synthase,¹⁹⁹ it is possible that under conditions of glucocorticoid deficiency, high levels of nitric oxide synthase result in elevated levels of endothelial nitric oxide in the renal vasculature, which in the distal renal tubule stimulate increased, vasopressin-independent, AQP2 activity and decreased free water clearance.

Direct effects of glucocorticoid or mineralocorticoid insufficiency on aquaporin expression and function have not been reported. In addition to impairing maximal renal diluting capacity, adrenal insufficiency compromises maximal urine-concentrating capacity.²⁰⁰ This effect has been shown to result from reduced tubular response to vasopressin.

Thyroid hormone is also required for normal free water clearance, and its deficiency likewise results in decreased renal water clearance and hyponatremia. Although some studies suggest that vasopressin mediates the hyponatremia of hypothyroidism because ethanol increases free water excretion in hypothyroid patients, this effect has not been found in other reports.²⁰¹ In addition, in severe hypothyroidism, hypovolemia is not present and hyponatremia is accompanied by appropriate suppression of vasopressin.²⁰² Similar to the consequences of isolated glucocorticoid deficiency described earlier, hypothyroidism impairs free water clearance more than maximal urine diluting capacity.²⁰³ This decrease in free water clearance may result from diminished glomerular filtration rate and delivery of free water to the diluting segment of distal nephron, as suggested by both animal²⁰⁴ and human studies.²⁰⁵

Given the often-subtle clinical findings associated with adrenal and thyroid deficiency, all patients with hyponatremia should be suspected of having these disease states and have appropriate diagnostic tests performed if indicated. Moreover, patients with coexisting adrenal failure and diabetes insipidus may have no symptoms of the latter until glucocorticoid therapy unmasks the need for vasopressin replacement.^{206,207} Similarly, resolution of diabetes insipidus in chronically polyuric and polydipsic patients may suggest inadequate glucocorticoid supplementation or noncompliance with glucocorticoid replacement.

Some drugs may cause hyponatremia by inhibiting renal water excretion without stimulating secretion of vasopressin

(Table 12.1), an action that could be called *nephrogenic SIAD*. In addition to augmenting vasopressin release, both carbamazepine^{208,209} and chlorpropamide^{210,211} increase the cellular response to vasopressin. Acetaminophen also increases the response of the kidney to vasopressin;²¹⁰ however, this has not been found to cause hyponatremia. High-dose cyclophosphamide treatment (15 to 20 mg/kg IV bolus) is often associated with hyponatremia, particularly when it is followed by a forced water diuresis to prevent hemorrhagic cystitis.^{212–214} Plasma vasopressin concentrations are normal, suggesting a direct effect of the drug to increase water resorption.²¹⁵ Similarly, vinblastine, independent of augmentation of plasma vasopressin concentration or vasopressin action,²¹⁶ and cisplatin^{217,218} cause hyponatremia. These drugs may damage the collecting duct tubular cells, which are normally highly impermeable to water, or may enhance AQP2 water channel activity and thereby increase water reabsorption down its osmotic gradient into the hypertonic renal interstitium.

Treatment. Hyponatremia caused by cortisol or thyroid hormone deficiency reverses promptly after institution of hormone replacement. Because the hyponatremia is often chronic, too rapid an increase in the serum sodium concentration should be avoided if possible, as will be discussed subsequently. When drugs that impair free water excretion must be used, water intake should be limited, as if the patient has SIAD, to 1 L/m²/24 h, using the regimen discussed.

Hyponatremia With Appropriate Increased Secretion of Vasopressin

Increased vasopressin secretion causing hyponatremia may be either an appropriate response or an inappropriate response to a pathologic state. Inappropriate secretion of vasopressin or V2 receptor activity (SIAD) is the much less common of the two entities.^{219,220} Whatever the cause, hyponatremia is a worrisome sign often associated with increased morbidity and mortality.²²¹

Systemic Dehydration. Systemic dehydration (water in excess of salt depletion) initially results in hypernatremia,

Proven actions of the drugs, if known, and whether the drugs have resulted in hyponatremia in humans, are indicated.

hyperosmolality, and activation of vasopressin secretion, as discussed earlier. In addition, the associated fall in the renal glomerular filtration rate results in an increase in proximal tubular sodium and water reabsorption, with a concomitant decrease in distal tubular water excretion. This limits the ability to form a dilute urine and, along with the associated stimulation of the renin-angiotensin-aldosterone system and suppression of ANP secretion, results in the excretion of urine that is very low in sodium. As dehydration progresses, hypovolemia and/or hypotension become major stimuli for vasopressin release, much more potent than hyperosmolality. This effect, by attempting to preserve volume, decreases free water clearance further and may lead to water retention and hyponatremia, especially if water replacement in excess of salt is given. Other nonosmotic factors may stimulate vasopressin release in a sick child, including pain, nausea, stress and specific conditions, such as pneumonia or meningitis. In many cases, hyponatremia caused by intravascular volume depletion is evident from physical and laboratory signs, such as decreased skin turgor, low central venous pressure, hemoconcentration, and elevated blood urea nitrogen levels. The diagnosis may be subtle, however. For example, patients with meningitis or pneumonia may present with hyponatremia, for which water restriction has been advocated in the belief that it is caused by central SIAD. Several studies have found that volume depletion, rather than SIAD, is often the cause of the hyponatremia,^{222–224} and that it resolves more readily when supplemental, rather than restricted, fluid and solute are administered.²²⁵ In patients with hyponatremia after head trauma, volume depletion rather than central SIAD is the cause in approximately one-half of cases.²²⁶ Similarly, many patients with gastroenteritis who present with mild hyponatremia and elevated plasma vasopressin levels²²⁷ have these on the basis of systemic dehydration rather than SIAD, and benefit from volume expansion rather than fluid restriction.²²⁸ More generally, most hospitalized pediatric patients with hyponatremia benefit from isotonic rather than hypotonic fluid replacement, suggesting that the underlying cause of the electrolyte disturbance is dehydration.^{229–231} Meta-analyses of several studies have revealed that the incidence of hyponatremia in hospitalized children that received hypotonic maintenance IV fluids was significantly higher than those that received isotonic maintenance IV fluids. As a result, the current guidelines for fluid management of hospitalized children recommend the use of isotonic IV fluids except in special clinical situations.²³²

Primary Loss of Sodium Chloride. Salt can be lost from the kidney, such as in patients with congenital polycystic kidney disease, acute interstitial nephritis, and chronic renal failure. Mineralocorticoid deficiency, pseudohypoaldosteronism (sometimes seen in children with urinary tract obstruction or infection), diuretic use, and gastrointestinal disease (usually gastroenteritis with diarrhea and/or vomiting) can also result in excess loss of sodium chloride. Hyponatremia can also result from salt loss in sweat in cystic fibrosis, although obstructive lung disease with elevation of plasma vasopressin probably plays a more prominent role, as has been discussed. With the onset of salt loss, any tendency toward hyponatremia will initially be countered by suppression of vasopressin and increased water excretion. With continuing salt loss, hypovolemia and/or hypotension ensues, causing nonosmotic stimulation of vasopressin. This, plus increased thirst, which leads to ingestion of hypotonic fluids with low solute content, results in hyponatremia. Weight loss is usually evident, as is the source of sodium wasting. If it is the kidney, it is accompanied by a rate of urine output and a urine sodium content greater than those associated with most other causes of hyponatremia, except a primary increase in ANP secretion.

Decreased Effective Plasma Volume. Congestive heart failure, cirrhosis, nephrotic syndrome, positive-pressure mechanical ventilation,²³³ severe burns,²³⁴ lung disease (bronchopulmonary dysplasia^{235–237} [in neonates]), cystic fibrosis with obstruction,^{238,239} and severe asthma^{240,241} are all characterized by a decrease in “effective” intravascular volume.^{201,242} This occurs because of impaired cardiac output, an inability to keep fluid within the vascular space, or impaired blood flow into the heart, respectively. As with systemic dehydration, in an attempt to preserve intravascular volume, water and salt excretion by the kidney are reduced; and decreased barosensor stimulation results in a compensatory, appropriate increase in vasopressin secretion, leading to an antidiuretic state and hyponatremia.²⁴³ Because of the associated stimulation of the renin-angiotensin-aldosterone system, these patients also have an increase in the total-body content of sodium chloride and may have peripheral edema, which distinguishes them from those with systemic dehydration. In patients with impaired cardiac output and elevated atrial volume (e.g., congestive heart failure or lung disease), ANP concentrations are elevated, which contributes to hyponatremia by promoting natriuresis.

Treatment. Patients with systemic dehydration and hypovolemia should be rehydrated with salt-containing fluids, such as normal saline or lactated Ringer’s solution. Because of activation of the renin-angiotensin-aldosterone system, the administered sodium will be avidly conserved and a water diuresis will quickly ensue, as volume is restored and vasopressin concentrations fall.²⁴⁴ Under these conditions, caution must be taken to prevent too rapid a correction of hyponatremia, which may itself result in brain damage.

Hyponatremia caused by a decrease in effective plasma volume from cardiac, hepatic, renal, or pulmonary dysfunction is more difficult to reverse. The most effective therapy is the least easily achieved: treatment of the underlying systemic disorder. Patients weaned from positive-pressure ventilation undergo a prompt water diuresis and resolution of hyponatremia, as cardiac output is restored and vasopressin concentrations fall. The only other effective route is to limit water intake to that required for the renal excretion of the obligate daily solute load of approximately 500 mOsm/m² and to replenish insensible losses. In a partial antidiuretic state with a urine osmolality of 750 mOsm/kg H₂O and insensible losses of 500 mL/m², oral intake would have to be limited to approximately 1200 mL/m²/day. Because of concomitant hyperaldosteronism, the dietary restriction of sodium chloride needed to control peripheral edema in patients with heart failure may reduce the daily solute load and further limit the amount of water that can be ingested without exacerbating hyponatremia. Hyponatremia in these settings is often slow to develop, rarely causes symptoms, and usually does not need treatment. If the serum sodium falls below 125 mEq/L, water restriction to 1 L/m²/day is usually effective in preventing a further decline. Because water retention in these disorders is a compensatory response to decreased intravascular volume, an attempt to reverse it with drugs, such as demeclocycline or specific V2 receptor antagonists (which induce nephrogenic diabetes insipidus as discussed subsequently) could result in worsening hypovolemia, with potentially dire consequences.²⁴⁵

In general, patients with hyponatremia caused by salt loss require ongoing supplementation with sodium chloride and fluids. Initially, IV replacement of urine volume with fluid containing sodium chloride (150 to 450 mEq/L depending on the degree of salt loss) may be necessary; oral salt supplementation may be required subsequently.¹⁶⁶ This treatment contrasts to that of SIAD, in which water restriction without sodium supplementation is the mainstay.

Precautions in the Emergency Treatment of Hyponatremia. Most children with hyponatremia develop the disorder gradually, are asymptomatic, and should be treated with water restriction alone. The development of acute hyponatremia, or a serum sodium concentration below 120 mEq/L, may be associated with lethargy, psychosis, coma, or generalized seizures, especially in younger children. Acute hyponatremia causes cell swelling owing to the entry of water into cells (Fig. 12.15), which can lead to neuronal dysfunction from alterations in the ionic environment or to cerebral herniation because of the encasement of the brain in the cranium. If present for more than 24 hours, cell swelling triggers a compensatory decrease in intracellular organic osmolytes, resulting in the partial restoration of normal cell volume in chronic hyponatremia.²⁴⁶

The proper emergency treatment of cerebral dysfunction depends on whether the hyponatremia is acute or chronic.^{247,248} In all cases, water restriction should be instituted. If hyponatremia is acute, and therefore probably not associated with a decrease in intracellular organic osmolyte concentration, rapid correction with hypertonic 3% sodium chloride, administered intravenously, may be indicated. As a general guide, this solution, given in the amount of 12 mL/kg, will result in an increase in serum sodium concentration of approximately 10 mEq/L. If hyponatremia is chronic, hypertonic saline treatment must be undertaken with caution, because it may result in both cell shrinkage (see Fig. 12.15) and the associated syndrome of central pontine myelinolysis.²⁴⁹ This syndrome, affecting the central portion of the basal pons, as well as other brain regions, is characterized by axonal demyelination, with sparing of neurons. It becomes evident within 24 to 48 hours after too rapid correction of hyponatremia, has a characteristic appearance by computed tomography and MRI, and often causes irreversible brain damage.²⁴⁹⁻²⁵¹ If hypertonic saline treatment is undertaken, the serum sodium concentration should be raised only high enough to cause an improvement in mental status, and in no case faster than 0.5 mEq/L/h or 12 mEq/L/day.^{247,249-251} In the case of systemic dehydration, the increase in serum sodium level may occur very rapidly using this regimen. The associated hyperaldosteronism will cause avid retention of the administered sodium, leading to rapid restoration of volume and suppression of vasopressin

secretion and resulting in a brisk water diuresis and an increase in the serum sodium concentration.²⁴⁴

Acute treatment of hyponatremia is more difficult in patients with decreased effective plasma volume. This is both because the underlying disorder makes it difficult to maintain the administered fluid within the intravascular space and because an associated increase in ANP promotes natriuresis and loss of the administered salt. Furthermore, patients with cardiac disease who are administered hypertonic saline may require concomitant treatment with a diuretic, such as furosemide, to prevent worsening of heart failure, which will also increase natriuresis.

Hyponatremia With Abnormal Regulation of Vasopressin

Hyponatremia With Inappropriate Increased Secretion of Vasopressin or Increased Vasopressin V2 Receptor Activity (Syndrome of Inappropriate Antidiuresis)

Causes of SIAD. SIAD is uncommon in children.^{219,220,252} It can occur with encephalitis, brain tumor,²⁵³ head trauma,^{226,254} brain malformations,²⁵⁵ in psychiatric disease,²⁵⁶ and in the postictal period after generalized seizures;²⁵⁷ after prolonged nausea;^{258,259} pneumonia;^{260,261} or acquired immunodeficiency syndrome.²⁶² Many drugs have been associated with impaired free water clearance as indicated in Table 12.1. Impaired free water clearance can result from alteration in vasopressin release, increased vasopressin effect at the same plasma vasopressin concentration, or vasopressin-independent changes in distal collecting tubule water permeability. Common drugs that have been shown to result in hyponatremia include carbamazepine,²⁰⁹ chlorpropamide,²⁶³ vinblastine,²¹⁶ vincristine,²⁶⁴ and tricyclic antidepressants.^{265,266} Newer sulfonylurea agents, including glyburide, are not associated with SIAD.²⁶⁷ Other rarer causes of SIAD in children are listed in Table 12.2. Although it has been believed to be the cause of hyponatremia associated with viral meningitis, volume depletion is more commonly the etiology.^{222,225} In contrast, the majority of children with tuberculous meningitis have hyponatremia

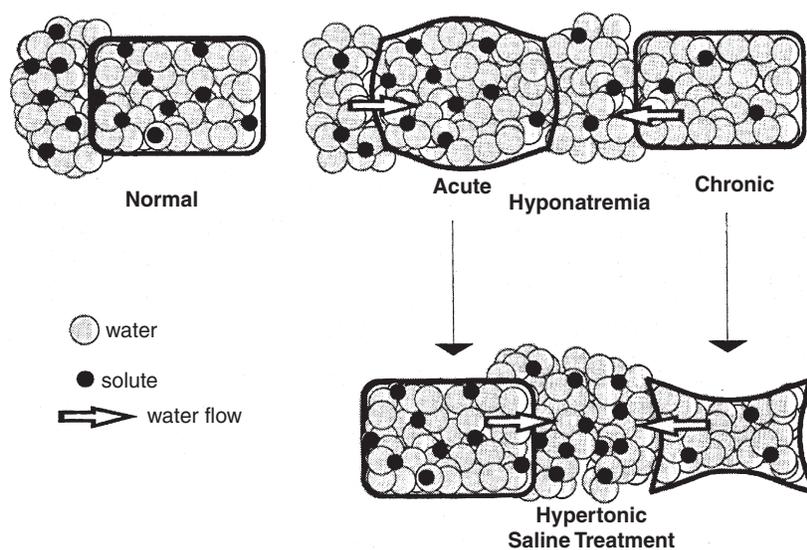

Fig. 12.15 Changes in organic osmolytes with hyponatremia and after its correction. Under normal conditions, osmotic balance exists between extracellular and intracellular compartments. With acute hyponatremia, water enters cells, causing cell swelling. After approximately 24 hours of continued hyponatremia, intracellular organic osmolytes decrease, restoring cell volume toward normal. Hypertonic saline treatment of acute hyponatremia results in restoration of normal cell volume, whereas the same treatment of chronic hyponatremia results in cell shrinkage. Large circle, water; closed smaller circle, solute; arrow, direction of water flow.

TABLE 12.2 Causes of Syndrome of Inappropriate Secretion of Vasopressin

Central Nervous System	Cancer	Infections	Pulmonary
Head trauma	Small cell of lung	Herpes zoster	Viral pneumonia
Subarachnoid hemorrhage	Duodenum	Respiratory syncytial virus	Bacterial pneumonia
Brain abscess	Pancreas	Tuberculosis	Abscess
Guillain-Barre syndrome	Thymoma	Aspergillosis	
Hydrocephalus	Bladder	Botulism	
Meningitis	Ureter		
	Lymphoma		
	Ewing sarcoma		

and SIAD (in one report attributed to cerebral salt wasting²⁶⁸), which predict more severe disease and poor outcome.^{269–271} SIAD is the cause of the hyponatremic second phase of the triple-phase response seen after hypothalamic-pituitary surgery. Hyponatremia with elevated vasopressin secretion is found in up to 35% of patients 1 week after transsphenoidal pituitary surgery.^{272,273} The mechanism is most likely retrograde neuronal degeneration with cell death and vasopressin release. Secondary adrenal insufficiency causing stimulation of vasopressin release²⁷⁴ may also play a role, because hyponatremia most commonly follows the removal of adrenocorticotropic hormone-secreting corticotroph adenomas.²⁷³ In the vast majority of children with SIAD, the cause is the excessive administration of vasopressin, whether to treat central diabetes insipidus,^{171,275} or less commonly, bleeding disorders²⁷⁶ (as has been discussed previously), or, most uncommonly, following dDAVP therapy for enuresis.

Two unrelated infants with mutations in the vasopressin V2 receptor that presented with severe hyponatremia in the first months of life heralded a new genetic cause of hyponatremia.²⁷⁷ These two infants had missense mutations at codon 137 that converted arginine to cysteine or leucine and led to constitutive activation of the V2 receptor with appropriately suppressed arginine vasopressin plasma concentration. This genetic disorder has been termed “*nephrogenic syndrome of inappropriate antidiuresis (NSIAD)*.” It remains unclear what portion of isolated early-onset chronic SIAD results from activating mutations of the V2 receptor, although the incidence is likely to be very low. Interestingly, this same codon is also the site of a loss-of-function mutation (R137H), which leads to X-linked nephrogenic diabetes insipidus.²⁷⁸ Over one dozen patients with NSIAD have been reported,^{279–281} including one patient presenting at the age of 38 years.²⁸²

Treatment of SIAD. Chronic SIAD is best treated by chronic oral fluid restriction. Under full vasopressin antidiuretic effect (urine osmolality of 1,000 mOsm/L), a normal daily obligate renal solute load of 500 mOsm/m² would be excreted in 500 mL/m² of water. This, plus a daily nonrenal water loss of 500 mL/m², would require that oral fluid intake be limited to 1000 mL/m²/day to avoid hyponatremia, as has been discussed more fully. In young children, this degree of fluid restriction may not provide adequate calories for growth. In this situation, the creation of nephrogenic diabetes insipidus may be indicated to allow sufficient fluid intake for normal growth.^{283–285} Lithium and demeclocycline were previously recommended to induce nephrogenic diabetes insipidus in this situation but are associated with significant toxicities, which limits their use in pediatric patients. Oral urea has been

effectively used to treat adult patients with chronic SIAD by virtue of its ability to induce an effective osmotic diuresis. This therapy was also demonstrated to be safe and effective in four children with chronic SIAD, including two with mutations in the vasopressin V2 receptor.^{279,280,285,286} Specific nonpeptide V2 receptor antagonists (vaptans) have also been developed for use in subacute or chronic SIAD caused by inappropriate increased vasopressin secretion.²⁸⁷ Their use is not US Food and Drug Administration (FDA) approved in children. Side effects include increased thirst, dry mouth, elevated hepatic transaminase levels, liver toxicity, and a significant overcorrection of hyponatremia. The aquaretic effects of the vaptans, after either parental or oral administration, have a rapid onset of action, exert peak effects within a few hours, and subside within 24 hours.^{43,164,288,289} In a large series of adult patients with euvolemic or hypervolemic hyponatremia resulting from cirrhosis, heart failure, or SIAD, these vasopressin receptor antagonists were effective in sustained elevation of serum sodium concentration. Another study in adults, limited to subjects with SIAD arising from inappropriate vasopressin secretion, demonstrated the efficacy of long-term treatment with an orally active vaptan, in conjunction with fluid restriction to 1.5 L per day.²⁹⁰ Substantial variability in the degree of serum sodium elevation was observed, however. This variability resulted from both interindividual differences in drug efficacy/disposition, and the failure to adequately restrict water consumption. The primary adverse effect from these agents is inflammation at infusion sites, although rises in serum sodium above rates recommended to prevent myelinolysis have also been found.⁴³ Very limited experience with vaptans has been reported in children,^{283–285,289,290} though they have been used to promote hydration during chemotherapy, with malignancy-associated SIAD.²⁹¹ These agents have not been effective in treating activating mutations of the V2 receptor,²⁹² although low-dose urea has been useful.²⁷⁹ Because the predictability of hypertonic saline administration for acute, severe forms of SIAD is greater than that of vaptans, hypertonic saline infusion for symptomatic hyponatremia because of inappropriate vasopressin secretion remains the recommended intervention.⁴³ Of note, some of these V2 receptor antagonists facilitate the proper transport of loss-of-function V2 receptor mutants to the cell surface.

Acute treatment of hyponatremia caused by SIAD is only indicated if cerebral dysfunction is present. In that case, treatment is dictated by the duration of hyponatremia and the extent of cerebral dysfunction. Because patients with SIAD have volume expansion, salt administration is not very effective in raising the serum sodium because it is rapidly excreted in the urine because of suppressed aldosterone and elevated ANP concentrations.

Hyponatremia With Inappropriate Decreased Secretion of Vasopressin, Caused by Increased Secretion of Atrial Natriuretic Peptide

Although ANP does not usually play a primary role in the pathogenesis of disorders of water metabolism, it may have an important secondary role.^{235,293–295} Patients with SIAD have elevated ANP concentrations, probably caused by hypervolemia, which may contribute to the elevated natriuresis of SIAD and which decrease as water intake is restricted.²⁹³ Likewise, the suppressed ANP concentrations found in central diabetes insipidus, probably caused by the associated hypovolemia, rise after dDAVP therapy.²⁹³ However, hyponatremia in some patients, primarily those with central nervous system disorders, including brain tumor, head trauma, hydrocephalus, neurosurgery, cerebral vascular accidents, and brain death, has been postulated to be caused by the primary hypersecretion of ANP.^{159,166,283–285,289,290,296,297} This syndrome, called *cerebral salt wasting*, is defined by hyponatremia accompanied by

elevated urinary sodium excretion (often more than 150 mEq/L), excessive urine output, hypovolemia, suppressed vasopressin, and elevated ANP concentrations (>20 pmol/L). Thus it is distinguished from SIAD, in which normal or decreased urine output, euvolemia, only modestly elevated urine sodium concentration, and elevated vasopressin concentration occur. Direct measurement of intravascular volume status with a central venous line is often helpful. The distinction is important because the therapies of the two disorders are markedly different. As noted previously, there is controversy regarding the prevalence of cerebral salt wasting,^{158–161} with most patients actually having either SIAD, dehydration, elevated glucocorticoids, or a combination of these. In patients in an intensive care setting, with the initial diagnosis of cerebral salt wasting, none of them upon further investigation were hypovolemic, one of the cardinal criteria of the syndrome.²⁹⁸

Treatment of Cerebral Salt Wasting. Treatment of patients with cerebral salt wasting consists of restoring intravascular volume with sodium chloride and water, as with the treatment of other causes of systemic dehydration. The underlying cause of the disorder, which is usually caused by acute brain injury, should also be treated if possible. A common error is to replace sodium with IV normal saline in the setting of hyperosmolar urine. If urine osmolality is higher than that of the infused saline, hyponatremia may worsen. Instead, saline hypertonic to urine, or enteral sodium chloride, should be used to avoid this issue.

Other Causes of True and Factitious Hyponatremia

True hyponatremia is associated with hyperglycemia, which causes the influx of water into the intravascular space. Serum sodium will decrease by around 1.6 mEq/L for every 100 mg/dL increment in blood glucose above 100 mg/dL. Glucose is not ordinarily an osmotically active agent, and does not stimulate vasopressin release, probably because it is able to equilibrate freely across plasma membranes. However, in the presence of insulin deficiency and hyperglycemia, glucose acts as an osmotic agent, presumably because its normal intracellular access to osmosensor sites is prevented.²⁹⁹ Under these circumstances, an osmotic gradient exists, and this stimulates vasopressin release. In diabetic ketoacidosis, this, together with the hypovolemia caused by the osmotic diuresis secondary to glycosuria, results in marked stimulation of vasopressin secretion.^{300–303} Rapid correction of hyponatremia may follow soon after the institution of fluid and insulin therapy. Whether this contributes to the pathogenesis of cerebral edema, occasionally seen following treatment of diabetic ketoacidosis, is not known. Elevated concentrations of triglycerides may cause factitious hyponatremia, as can obtaining a blood sample downstream from an IV infusion of hypotonic fluid.

Hypernatremia With Inappropriate Decreased Vasopressin Secretion or Action

Central Diabetes Insipidus

Central (hypothalamic, neurohypophyseal, neurogenic, or vasopressin-sensitive) diabetes insipidus can be caused by disorders of vasopressin gene structure; syndromes that result in loss of vasopressinergic neurons; accidental or surgical trauma to vasopressin neurons; congenital anatomical hypothalamic or pituitary defects; neoplasms; infiltrative, autoimmune, and infectious diseases affecting vasopressin neurons or fiber tracts; and increased metabolism of vasopressin.^{304,305} The etiology of central diabetes insipidus is not apparent in anywhere between 9% and 55% of children and young adults in different

series published in the literature.^{306–309} Long-term surveillance can identify an underlying cause that is not apparent at the time of initial diagnosis, sometimes after as long as 21 years.³¹⁰

Genetic Causes. Familial, autosomal dominant central diabetes insipidus is manifest within the first half of the first decade of life.^{311–317} Vasopressin secretion, initially normal, gradually declines until diabetes insipidus of variable severity ensues.³¹⁸ Patients respond well to vasopressin replacement therapy. The disease has a high degree of penetrance, but may be of variable severity within a family,³¹⁹ and may spontaneously improve in middle age.^{319,320} Vasopressin-containing neurons are absent from the magnocellular paraventricular neurons,³²¹ but present in parvocellular regions.³²² Several different oligonucleotide mutations in the vasopressin structural gene have been found to cause the disease.³²³ To date, there have been over 75 mutations detected in the coding region of the vasopressin gene, with the majority being missense mutations in or around cysteines (see Fig. 12.3).³²⁴ Most mutations are in the neurophysin portion of the vasopressin precursor, except for five in either the signal peptide or vasopressin peptide regions of the gene. This suggests that mutant neurophysin has a deleterious function, possibly being misfolded and blocking the proper intracellular sorting or packaging of vasopressin into secretory granules (see later). There are no disease-causing mutations in the copeptin region of the vasopressin precursor. This suggests either that this region has a low mutation rate, that it does not serve a critical function in vasopressin biology, or mutations in it are not disruptive to cellular health.

A family with a missense mutation within the vasopressin peptide region (Proline→Leucine at amino acid 7) of the gene, causing markedly reduced biological activity, was reported.³²⁵ The disease in this family is transmitted with an autosomal recessive pattern. This indicates that haploinsufficiency is not the basis for the autosomal dominant nature of the disease in families with the more common mutations in the neurophysin region of the gene. Another patient with autosomal recessive central diabetes insipidus presented at a young age (5 months), with compound heterozygous mutations in both copies of *AVP*, one inherited from each normal parent, again indicating that only one functioning copy is required for normal physiology.³²⁶

On the other hand, with autosomal dominant familial central diabetes insipidus, the abnormal gene product may interfere with the processing and secretion of the product of the normal allele,³²⁷ or cause neuronal degeneration and cell death.³²⁸ In support of this, mutant vasopressin precursors impair the secretion of the normal protein in cell models,³²⁷ and in a transgenic mouse model of the disease, a progressive loss of hypothalamic vasopressin-containing neurons occurs as the mice develop diabetes insipidus.³²⁹ Heterozygous mice with a mutation (C67X) in the vasopressin gene known to cause autosomal dominant familial neurohypophyseal diabetes insipidus in humans, developed diabetes insipidus by 2 months of age. They were found to have retention of the precursor of vasopressin within the neurons and the induction of an endoplasmic reticulum chaperone protein (BiP).³³⁰ However, humans presenting at less than 1 year of life with central diabetes insipidus are less likely to have autosomal dominant central diabetes insipidus, and more likely to have a structural brain defect.

Vasopressin deficiency is also found in the DIDMOAD syndrome, consisting of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness.^{313,331–335} The gene for this syndrome complex, also known as *Wolfram syndrome*, was localized to human chromosome 4p16 by polymorphic linkage analysis. The *Wolfram syndrome* gene, *WFS1*, encodes an 890-amino-acid tetrameric transmembrane protein that primarily localizes

to the endoplasmic reticulum. It is thought to function as a calcium channel or regulator of a calcium channel.^{336–342} Patients with mutations in proconvertase *PCSK1*, required for cleavage of the vasopressin precursor into mature vasopressin and neurophysin, have multiple endocrinopathies including central diabetes insipidus.³⁴³

Trauma. The axons of vasopressin-containing magnocellular neurons extend uninterrupted to the posterior pituitary over a distance of approximately 10 mm. Trauma to the base of the brain can cause swelling around or severance of these axons, resulting in either transient or permanent diabetes insipidus.³⁴⁴ Permanent diabetes insipidus can occur after seemingly minor trauma. Approximately one-half of patients with fractures of the sella turcica will develop permanent diabetes insipidus,³⁴⁵ which may be delayed as long as 1 month following the trauma, during which time neurons of severed axons may undergo retrograde degeneration.³⁴⁶ Septic shock³⁴⁷ and postpartum hemorrhage, associated with pituitary infarction (Sheehan syndrome),^{348,349} may involve the posterior pituitary with varying degrees of diabetes insipidus. Diabetes insipidus is never associated with cranial irradiation of the hypothalamic-pituitary region, although this treatment can cause deficits in all of the hypothalamic releasing hormones carried by the portal-hypophyseal system to the anterior pituitary. Because vasopressin is carried directly to the posterior pituitary via magnocellular axonal transport, it may be that radiation affects hypothalamic releasing hormone function by interruption of the portal-hypophyseal circulation, which is absent from the vasopressin circuitry.

Neurosurgical Intervention. One of the most common causes of central diabetes insipidus is the neurosurgical destruction of vasopressin neurons following pituitary-hypothalamic surgery. It is important to distinguish polyuria associated with the onset of acute postsurgical central diabetes insipidus from polyuria caused by the normal diuresis of fluids given during surgery. In both cases, the urine may be very dilute and of high volume, exceeding 200 mL/m²/h. However, in the former case, serum osmolality will be high, whereas in the latter case it will be normal. A careful examination of the intraoperative record should also help distinguish between these two possibilities. Vasopressin axons traveling from the hypothalamus to the posterior pituitary terminate at various levels within the stalk and gland (see Fig. 12.4). Because surgical interruption of these axons can result in retrograde degeneration of hypothalamic neurons, lesions closer to the hypothalamus will affect more neurons and cause greater permanent loss of hormone secretion. Not infrequently, a “triple phase” response is seen.³⁵⁰ Although the exact incidence of this phenomenon remains unknown, in a small study, nearly one in three children who underwent surgery for a craniopharyngioma developed it.³⁵¹ Following surgery, an initial phase of transient diabetes insipidus is observed, lasting 1.5 to 2 days, and possibly caused by edema in the area interfering with normal vasopressin secretion. If significant vasopressin cell destruction has occurred, this is often followed by a second phase of SIAD, which may last up to 10 days, and is caused by the unregulated release of vasopressin by dying neurons. A third phase of permanent diabetes insipidus may follow if more than 90% of vasopressin cells are destroyed. Usually, a marked degree of SIAD in the second phase portends significant permanent diabetes insipidus in the final phase of this response. In patients with coexisting vasopressin and cortisol deficits (e.g., in combined anterior and posterior hypopituitarism, following neurosurgical treatment of craniopharyngioma), symptoms of diabetes insipidus may be masked because cortisol deficiency impairs renal free water clearance, as discussed subsequently. In such cases, institution of

glucocorticoid therapy alone may precipitate polyuria, leading to the diagnosis of diabetes insipidus.

Congenital Anatomic Defects. Midline brain anatomic abnormalities, such as septo-optic dysplasia with agenesis of the corpus callosum,³⁵² the Kabuki syndrome,³⁵³ holoprosencephaly,³⁵⁴ and familial pituitary hypoplasia with absent stalk³⁵⁵ may be associated with central diabetes insipidus.^{255,356} These patients need not have external evidence of craniofacial abnormalities.³⁵⁴ Central diabetes insipidus caused by midline brain abnormalities is often accompanied by defects in thirst perception,^{352,356} suggesting that a common osmosensor may control both vasopressin release and thirst perception. Some patients with suspected defects in osmosensor function but with intact vasopressin neurons may have recumbent diabetes insipidus, with baroreceptor-mediated release of vasopressin, while upright, and vasopressin-deficient polyuria, while supine.³⁵⁷

Neoplasms. Several important clinical implications follow from knowledge of the anatomy of the vasopressin system. Because hypothalamic vasopressin neurons are distributed over a large area within the hypothalamus, tumors that cause diabetes insipidus must either be very large or infiltrative or be strategically located at the point of convergence of the hypothalamo-neurohypophyseal axonal tract in the infundibulum. Germinomas and pinealomas typically arise near the base of the hypothalamus where vasopressin axons converge before their entry into the posterior pituitary, and for this reason, are among the most common primary brain tumors associated with diabetes insipidus.³⁵⁸ Germinomas causing the disease can be very small^{359,360} and undetectable by MRI for several years following the onset of polyuria.³⁶¹ For this reason, quantitative measurement of the beta subunit of human chorionic gonadotropin, often secreted by germinomas and pinealomas, and regularly repeated MRI scans should be performed in children with idiopathic or unexplained diabetes insipidus. Empty sella syndrome, possibly caused by unrecognized pituitary infarction, can be associated with diabetes insipidus in children.³⁶² Craniopharyngiomas and optic gliomas can also cause central diabetes insipidus when very large, although this is more often a postoperative complication of the treatment for these tumors.³⁶⁸ Hematologic malignancies can cause diabetes insipidus. In some cases, such as with acute myelocytic leukemia, the cause is infiltration of the pituitary stalk and sella.^{363–365} However, more than 30 patients with monosomy or deletion of chromosome 7 associated with acute blast transformation of myelodysplastic syndrome presented with central diabetes insipidus,^{366–373} without evidence of infiltration of the posterior pituitary by neoplastic cells, leaving the cause of the diabetes insipidus unresolved.

Infiltrative, Autoimmune, and Infectious Diseases.

Langerhans cell histiocytosis and lymphocytic hypophysitis are the most common types of infiltrative disorders causing central diabetes insipidus. Approximately 10% of patients with histiocytosis will have diabetes insipidus. These patients tend to have more serious, multisystem disease for longer periods of time than those without diabetes insipidus,^{374,375} and anterior pituitary deficits often accompany posterior pituitary deficiency.³⁷⁶ MRI characteristically shows thickening of the pituitary stalk.³⁷⁷ One report suggests that in patients with Langerhans cell histiocytosis, radiation treatment to the pituitary region within 14 days of onset of symptoms of diabetes insipidus may result in return of vasopressin function in more than one-third of affected patients.³⁷⁸

Lymphocytic infundibuloneurohypophysitis may account for over one-half of patients with “idiopathic” central diabetes insipidus.^{379,380} This entity may be associated with other

autoimmune diseases.³⁸¹ Image analysis discloses an enlarged pituitary and thickened stalk,^{379,382} and biopsy of the posterior pituitary reveals lymphocytic infiltration of the gland, stalk, and magnocellular hypothalamic nuclei.³⁸³ A necrotizing form of this entity has been described, which also causes anterior pituitary failure and responds to steroid treatment.³⁸⁴ Diabetes insipidus can also be associated with pulmonary granulomatous diseases,³⁸⁵ including sarcoidosis.³⁸⁶ The use of checkpoint inhibitors as anticancer immunotherapy causes an autoimmune hypophysitis that can not only result in anterior pituitary dysfunction, but also central diabetes insipidus, which may be reversible upon discontinuation of the drug.^{387,388}

Whether antibody-mediated destruction of vasopressin cells occurs is controversial. Over one-half of patients with central diabetes insipidus of a nontraumatic cause have antibodies directed against vasopressin-containing cells,³⁸⁹ and patients with other autoimmune diseases have such antibodies without evidence of diabetes insipidus.³⁹⁰ Many patients with central diabetes insipidus also have antivasopressin peptide antibodies, although their appearance usually follows institution of vasopressin treatment.³⁹¹ It is very possible that antibodies directed against vasopressin-containing cells or vasopressin are not pathogenetic, but instead are markers of prior neuronal cell destruction.

Infections involving the base of the brain, such as meningococcal,³⁹² *Streptococcus pneumoniae*,³⁹³ cryptococcal, listeria,³⁹⁴ toxoplasmosis meningitis,³⁹⁵ congenital cytomegalovirus infection,³⁹⁶ congenital syphilis,³⁹⁷ and nonspecific inflammatory disease of the brain³⁹⁸ can cause central diabetes insipidus. The disease is often transient, suggesting that it is caused by inflammation rather than destruction of vasopressin-containing neurons.

Brain Death. Central diabetes insipidus can appear in the setting of hypoxic brain death.³⁹⁹ Although its presence has been suggested as a marker for brain death in children,⁴⁰⁰ in some studies, only a minority of patients with brain death manifest the disorder,⁴⁰¹ and up to 15% of patients with cerebral insults and diabetes insipidus ultimately recover brain function.⁴⁰² Polyuria in the setting of brain death can be accompanied by high concentrations of plasma vasopressin,⁴⁰³ suggesting that some cases mistaken for diabetes insipidus are actually caused by other causes, such as cerebral salt wasting with polyuria, as discussed subsequently.

Increased Metabolism of Vasopressin. The metabolic clearance rate of vasopressin increases 4-fold during pregnancy because of the elaboration of a vasopressinase by the placenta.⁶⁰ If the mother cannot respond with a concomitant increase in vasopressin action because of preexisting subclinical central or nephrogenic diabetes insipidus,^{59,61} overt, transient disease will appear, usually early in the third trimester (although occasionally earlier⁴⁰⁴), and resolve within 1 week of delivery.^{64,405} Even without prior defects vasopressin function, an extreme elevation in vasopressinase concentrations in primigravidas with either preeclampsia, liver dysfunction, or multiple gestation,^{62,63,66,406–408} may result in development of the syndrome. The central diabetes insipidus responds to dDAVP, which cannot be metabolized by vasopressinase, and has no oxytocic or hypertensive activity, because it is specific for AVPR2.

Drugs. The most common agent associated with inhibition of vasopressin release and impaired urine concentrating ability is ethanol.⁴⁰⁹ Because inhibition of vasopressin release by ethanol can be overcome in the setting of concurrent hypovolemia, clinically important diabetes insipidus caused by ethanol ingestion is uncommon.⁴¹⁰ Phenytoin, opiate antagonists, ketamine, halothane, and alpha-adrenergic agents have also been associated with impaired vasopressin release.^{411–413}

Children With Primary Enuresis. Although normal children have a nocturnal rise in plasma vasopressin, associated with an increase in urine osmolality, and a decrease in urine volume, those with primary enuresis have a blunted or absent rise in vasopressin, and excrete a higher urine volume of lower tonicity.^{414,415} This has suggested that enuretic children have a primary deficiency in vasopressin secretion, although the same outcome could be caused solely by excessive water intake in these children. The use of the V2 agonist dDAVP is highly effective in abolishing bed wetting episodes, although relapse is high once therapy is stopped.^{416–418} Fluid intake must be limited while a child is exposed to the antidiuretic action of dDAVP to guard against water intoxication. It is therefore best that the medication (only available in tablet in the United States) be taken at bedtime, with no further drinking until the morning, after the antidiuretic effect has waned. Nasal spray dDAVP is no longer approved for use in enuretic children because of this safety concern, whereas dDAVP tablets are FDA approved. The efficacy of dDAVP compared with enuretic alarms is similar, as is their relapse rate.⁴¹⁹ Because of safety concerns, enuretic alarms may be preferable.

Treatment of Central Diabetes Insipidus

Fluid Therapy. Patients with otherwise untreated diabetes insipidus crave cold fluids, especially water. With complete central diabetes insipidus, maximum urine concentrating ability is approximately 100 mOsm/kg. Because 5 L of urine would be required to excrete an average daily solute load of 500 mOsm/m², fluid intake must match this to maintain normal plasma tonicity. With an intact thirst mechanism and free access to oral fluids, a person with complete diabetes insipidus can maintain plasma osmolality and sodium in the high normal range, although at great inconvenience. Furthermore, long-standing intake of these volumes of fluid in children can lead to hydrourerter,⁴²⁰ and even hyperfluorosis in communities that provide fluoridated water.⁴²¹ With fluid management alone or with the use of medications other than vasopressin or its analogues, these children can develop nonobstructive hydrourerteronephrosis, bladder wall thickening and trabeculation, overflow incontinence and impaired renal function requiring a drainage procedure.⁴²² These complications are more likely to occur in children with nephrogenic, as opposed to central, diabetes insipidus because treatment with vasopressin analogs is used most of the time in children with central diabetes mellitus.

There are two situations in which central diabetes insipidus may be treated solely with high levels of fluid intake, without vasopressin. Vasopressin therapy coupled with excessive fluid intake (usually greater than 1 L/m²/day as discussed subsequently) can result in unwanted hyponatremia. Because neonates and young infants receive all of their nutrition in liquid form, the obligatory high oral fluid requirements for this age (3 L/m²/day), combined with vasopressin treatment are likely to lead to this dangerous complication.²⁷⁵ In infants, oral tablet and intranasal liquid desmopressin are not only difficult to administer accurately, but also their use is associated with significant fluctuations in the serum sodium levels. Such neonates may be better managed with fluid therapy alone. A reduced solute load diet will aid in this regard. Human milk is best for this purpose (75 mOsm/kg H₂O), whereas cow's milk is worst (230 mOsm/kg H₂O). For example, in an infant with diabetes insipidus with a fixed urine osmolality of 100 mOsm/kg H₂O, 300 mL of urine per day is required to excrete the amount of solute consumed in human milk, whereas 900 mL of urine per day is required to excrete the higher amount of solute consumed in cow's milk. The Similac PM 60/40 formula has a renal solute load of 92 mOsm/kg H₂O. In addition, supplementation free water may be needed, depending on the severity of

the diabetes insipidus. Options, such as 20 to 30 mL of supplemental free water for every 120 to 160 mL of formula, or dilution of the formula with free water have been used. Although children managed with such a regimen may be chronically thirsty, parents may have difficulty keeping up with the voluminous fluid intake and urine output, and poor growth may occur if adequate calories are not provided along with water,¹⁸⁸ these problems are more easily addressed than is life-threatening hyponatremia. Alternatively, thiazide (chlorothiazide, 5–10 mg/kg/dose), twice or thrice daily, and/or amiloride diuretics may be added to facilitate renal proximal tubular sodium and water reabsorption⁴²³ and thereby decrease oral fluid requirements. This therapy may be accompanied by a mild degree of dehydration. More recently, parenteral desmopressin (0.02–0.08 mcg/dose given once or twice daily) has been administered subcutaneously in infants with good results, although this is not approved by the FDA.⁴²⁴ The successful use of subcutaneous desmopressin in conjunction with a sliding scale fluid regimen has been reported to treat an infant with central diabetes insipidus and an absent thirst mechanism. The desmopressin dose, which was titrated on the basis of plasma sodium levels monitored at home, ranged between 0.01 mcg and 0.024 mcg per dose, given twice daily.⁴²⁵ Parenteral desmopressin was originally formulated at a concentration of 4 mcg/mL, to be used at a dose of 0.3 mcg/kg/dose to treat bleeding diatheses, such as hemophilia A and von Willebrand disease type 1. Thus care must be taken if it is used at 1/40 to one-fourth of this dose to treat infants with diabetes insipidus. Buccal administration of a diluted intranasal formulation of dDAVP (10 mcg/mL; 1–5 mcg twice daily) in infants with central diabetes insipidus, whose mean age was 4.5 months, resulted in normalization and stabilization of sodium levels within days of starting the treatment.⁴²⁶ Neonates with central diabetes insipidus have been successfully treated with orally administered diluted formulation of intranasal dDAVP (10 mcg/mL) at doses ranging from 2 to 5 mcg twice daily. There was no need to restrict their feed volume, while on this treatment regimen.⁴²⁷

In the acute postoperative management of central diabetes insipidus occurring after neurosurgery in children, vasopressin therapy may be successfully used,^{428–430} but extreme caution must be exerted with its use. While under the full antidiuretic effect of vasopressin, a patient will have a urine osmolality of approximately 1000 mOsm/kg and become hyponatremic if she or he receives an excessive amount of fluids, depending on the solute load and nonrenal water losses. With a solute excretion of 500 mOsm/m²/day, normal renal function, and nonrenal fluid losses of 500 mL/m²/day, fluid intake of greater than 1 L/m²/day (two-thirds of the normal maintenance fluid requirement) will result in hyponatremia. In addition, vasopressin therapy will mask the emergence of the SIAD phase of the triple phase neurohypophyseal response to neurosurgical injury (as has been discussed).

Because of the concerns associated with perioperative vasopressin administration, two different approaches to managing central diabetes insipidus in the surgical patient have been used. The first approach may be particularly useful to manage acute postoperative diabetes insipidus in young children. It uses fluids alone and avoids the use of vasopressin.⁴³¹ This method consists of matching input and output hourly using between 1 and 3 L/m²/day (40–120 mL/m²/h). If IV therapy is used, a basal 40 mL/m²/h should be given as 5% dextrose (D5) in one-fourth normal saline (normal saline = 0.9% sodium chloride) and the remainder, depending on the urine output, as 5% dextrose in water. Potassium chloride (40 mEq/L) may be added if oral intake is to be delayed for several days. No additional fluid should be administered for hourly urine volumes under 40 mL/m²/h. For hourly urine volumes

above 40 mL/m²/h, the additional volume should be replaced with 5% dextrose up to a total maximum of 120 mL/m²/h. For example, in a child with a surface area of 1 m² (approximately 30 kg), the basal infusion rate would be 40 mL/h of 5% dextrose in one-fourth normal saline. For an hourly urine output of 60 mL, an additional 20 mL/h 5% dextrose would be given, for a total infusion rate of 60 mL/h. For urine outputs above 120 mL/h, the total infusion rate would be 120 mL/h. In the presence of diabetes insipidus, this will result in a serum sodium in the 150 mEq/L range and a mildly volume contracted state, which will allow one to assess both thirst sensation, as well as the return of normal vasopressin function or the emergence of SIAD. Patients may become mildly hyperglycemic with this regimen, particularly if they are also receiving postoperative glucocorticoids. However, because it does not use vasopressin, this fluid management protocol prevents any chance of hyponatremia.

Vasopressin and Vasopressin Analogs. Evidence suggests that perioperative use of IV vasopressin in children with central diabetes insipidus may be the treatment modality of choice in most situations, resulting in excursions of serum sodium of smaller magnitude and few adverse sequelae.⁴³⁰ Although IV therapy with synthetic aqueous vasopressin (Pitressin) had been shown to be useful in the management of central diabetes insipidus of acute onset,^{428,429} concern existed as to the safety of its administration in the complex, rapidly changing course of the child recovering from hypothalamic/pituitary surgery. If continuous vasopressin is administered, fluid intake must be limited to 1 L/m²/day or two-thirds maintenance fluid administration (assuming normal solute intake and nonrenal water losses as described). The potency of synthetic vasopressin is still measured using a bioassay and is expressed in bioactive units, with one milliunit (mU) equivalent to approximately 2.5 ng of vasopressin. For IV vasopressin therapy, 1.5 mU/kg/h results in a blood vasopressin concentration of approximately 10 pg/mL,⁴³² twice that needed for full antidiuretic activity.⁴³³ Vasopressin's effect is maximal within 2 hours of the start of infusion,⁴³³ and one must beware of it sticking to IV bottles and tubing. Occasionally, following hypothalamic (but not transphenoidal) surgery, higher initial concentrations of vasopressin are required to treat acute diabetes insipidus, which may be attributable to the release of a substance related to vasopressin from the damaged hypothalamo-neurohypophyseal system, which acts as an antagonist to normal vasopressin activity.⁴³⁴ Much higher rates of vasopressin infusion, resulting in plasma concentrations above 1000 pg/mL, should be avoided, as they may cause cutaneous necrosis,⁴³⁵ rhabdomyolysis,^{435,436} and cardiac rhythm disturbances.⁴³⁷

In light of the considerations described in the previous paragraph, an effective and safe algorithm for management of perioperative central diabetes insipidus with IV infusion of vasopressin has been used with encouraging results.⁴³⁰ This algorithm starts with the child receiving an IV infusion of normal saline at two-thirds maintenance or 1 L/m²/day. A tentative diagnosis of intraoperative or postoperative central diabetes insipidus is made by documenting a serum sodium of greater than 145 mEq/L, along with urine output of greater than 4 mL/kg/h. Additional confirmatory evidence includes plasma osmolality above 300 mOsm/kg H₂O and relatively hypotonic urine. When documentation of parameters consistent with central diabetes insipidus is obtained, an IV infusion of aqueous vasopressin begins at 0.5 mU/kg/h, with no change in IV fluid administration. The dose of vasopressin is titrated upward in 0.5 mU/kg/h increments to establish a urine output rate of less than 2 mL/kg/h at approximately 10-minute intervals. The vasopressin and IV fluid administration then remain stable at these rates, with additional normal saline, or equivalent volume expanding solutions, given only to replace ongoing

blood loss or to maintain hemodynamic stability. Postoperatively, this management paradigm requires intensive care unit monitoring, with frequent assessment of electrolytes (hourly initially), urine output and osmolality/specific gravity, and vital signs. This management scheme can also be followed for patients with established central diabetes insipidus requiring general surgery and prolonged restriction of oral intake. In this situation, the usual dose of chronic, long-acting vasopressin is withheld or reduced immediately before surgery, depending upon the timing of surgery in relation to the usual administration times. In preparation for surgery, normal saline is infused at two-thirds maintenance ($1 \text{ L/m}^2/\text{day}$). When measures consistent with emergence of central diabetes insipidus caused by termination of efficacy of the presurgical dose are obtained, the IV vasopressin is initiated and titrated as described earlier.

Patients treated with vasopressin for postneurosurgical diabetes insipidus should be switched from IV to oral fluid intake at the earliest opportunity, because thirst sensation, if intact, will help regulate blood osmolality, as discussed. With the concomitant absence of vasopressin secretion and thirst, the clinician must perform administration fluids and an antidiuretic agent. This must be done with utmost care, for the therapeutic window for fluid administration is narrow when the patient cannot modulate their own antidiuretic activity.⁵⁰ Either the patient can be put into a persistent antidiuretic state, with dDAVP or vasopressin, and fluid strictly limited to $1 \text{ L/m}^2/\text{day}$, or the patient can be given intermittent dDAVP with clear urinary "breakthrough" between doses, and a fixed amount of fluid empirically determined to result in normal blood electrolyte concentrations. IV dDAVP (desmopressin) should not be used in the acute management of postoperative central diabetes insipidus, for it offers no advantage over vasopressin, and its long half-life (8–12 hours) compared with that of vasopressin (5–10 minutes) is a distinct disadvantage, as it may increase the chance of causing water intoxication.¹⁷¹ In fact, the use of IV dDAVP, 0.3 mcg/kg , to shorten the bleeding time in a variety of bleeding disorders (as has been discussed), has been associated with water intoxication,²⁷⁶ particularly in young children who have high obligate oral fluid needs.^{438–440}

A special problem arises when a patient with established central diabetes insipidus must receive a high volume of fluid for therapeutic reasons, for example, accompanying cancer chemotherapy.⁴⁴¹ Such patients can be managed by discontinuing antidiuretic therapy and increasing fluid intake to 3 to $5 \text{ L/m}^2/\text{day}$ (rendering the patient moderately hypernatremic). This would be similar to what would occur in a patient with intact vasopressin secretion, in whom overhydration to this extent would suppress endogenous vasopressin secretion. However, although $5 \text{ L/m}^2/\text{day}$ is typically adequate to maintain serum sodium concentration in the range of 150 mEq/L in children with central diabetes insipidus, this rate may not be adequate in the setting of chemotherapy administration when solute excretion increases because of cell death and release of cellular contents. By using a low dose of IV vasopressin ($0.08\text{--}0.1 \text{ mU/kg/h}$, approximately one-eighth the full antidiuretic dose, titrated upward as needed), a partial antidiuretic effect allows the administration of higher amounts of fluid without causing hyponatremia.⁴⁴² Whereas management of diabetes insipidus, with fluids alone, may be used for chemotherapy with ifosfamide (which is associated with nephrotoxicity and hemorrhagic cystitis), recent data suggest that excretion of a hypotonic urine, as would occur in patients with diabetes insipidus management with fluids alone, increases the risk of developing nephrotoxicity during therapy with platinum-based antineoplastic agents.⁴⁴³ By allowing administration of 0.45% saline at rates of approximately $3 \text{ L/m}^2/\text{day}$, the low-dose vasopressin infusion yields a urine osmolality higher than

that achievable with fluids alone,⁴⁴² and may have the additional benefit of conferring renal protection.

In the outpatient setting, treatment of central diabetes insipidus in older children should begin with oral (see later) or intranasal dDAVP ($10 \text{ mcg}/0.1 \text{ mL}$, 0.025 mL (2.5 mcg) given by rhinal tube at bedtime and the dose increased to the lowest amount that gives an antidiuretic effect. If the dose is effective, but has too short a duration, it should be increased further, or a second, morning dose should be added. Patients should escape from the antidiuretic effect for at least 1 hour before the next dose, to ensure that any excessive water will be excreted. Otherwise, water intoxication may occur. dDAVP is also available as a nasal spray in the same concentration, with each spray delivering 10 mcg (0.1 mL). This is the standard preparation that was used for treatment of primary enuresis before this indication was removed. Oral dDAVP tablets and dissolvable wafers are now in widespread use and have largely replaced intranasal therapy.⁴⁴⁴ Although, when given orally, dDAVP is at least 20-fold less potent than when given via the intranasal route, oral dDAVP in doses of 25 to 300 mcg every 8 to 12 hours is reported to be highly effective and safe in children.^{445–447} Lysine vasopressin (Diapid) nasal spray (50 units/mL) may be used if a duration less than that of dDAVP is desired. One spray delivers 2 units (0.04 mL), with a duration of action between 2 and 8 hours.

As noted previously, cortisol deficiency may cause decreased free water clearance by stimulating a nitric oxide-mediated pathway, which results in the insertion of AQP2 channels into the apical membranes of collecting duct cells, in a vasopressin-independent fashion.^{198,199} Conversely, it is possible that excessive amounts of cortisol, caused by endogenous release during stress, or to treatment with exogenous drug, may inhibit the insertion of water channels. This may explain why patients, with central diabetes insipidus treated with desmopressin, become "resistant," and require an increased dosage, during times of stress or treatment with glucocorticoids.⁴⁴⁸

In addition to polyuria and polydipsia, decreased bone mineral density has been reported in patients with central diabetes insipidus.⁴⁴⁹ The decreased bone density was not corrected by vasopressin analog treatment alone, suggesting that institution of bisphosphonate or other therapies designed to prevent bone loss may be of long-term benefit in the treatment of diabetes insipidus.

Adipsic Hypernatremia

A subset of patients with central diabetes insipidus also have disorders of thirst mechanism. Lesions that affect the sensory circumventricular organs of the hypothalamus, including the organum vasculosum of the lamina terminalis, subfornical organ, and the area postrema, can result in either absent thirst or an elevated osmotic threshold for thirst perception. These areas lie outside the blood-brain barrier and constantly measure osmolality and sodium levels. Patients with diabetes insipidus and an intact thirst mechanism rarely have a significant hypernatremia because the thirst mechanism ensures that their water intake matches their excessive urinary water losses. However, patients with diabetes insipidus and adipsia can have severe hypernatremia and complications, such as rhabdomyolysis, acute renal failure, and venous thrombosis. Etiologies for adipsic hypernatremia include congenital malformations, such as holoprosencephaly and septooptic dysplasia sequence; vascular lesions, such as anterior communicating artery aneurysm; neoplasms, such as craniopharyngiomas and suprasellar germinomas; granulomatous conditions, such as histiocytosis and sarcoidosis; and miscellaneous conditions, such as arachnoidal cysts and hydrocephalus. Recently, there has been a case series reported of adipsic hypernatremia, without any abnormality on MRI of the hypothalamus and the pituitary gland. The affected children had associated hyperprolactinemia,

childhood obesity, and impaired growth hormone secretion. The presence of antibodies targeting the subfornical organ in these patients strongly suggests an autoimmune etiology for their adipsic hypernatremia.^{450,451} The treatment of adipsic hypernatremia involves giving a fixed daily dose of an dDAVP with controlled daily fluid intake and strict monitoring of fluid balance, body weight, and plasma sodium levels. Successful treatment of an infant with diabetes insipidus and absent thirst has been reported using a sliding scale fluid regimen and subcutaneous dDAVP, guided by the frequent home monitoring of plasma sodium levels.⁴²⁵

Nephrogenic Diabetes Insipidus

Causes of Nephrogenic Diabetes Insipidus. Nephrogenic (vasopressin-resistant) diabetes insipidus can be caused by genetic or acquired causes. Genetic causes are less common but more severe than acquired forms of the disease, although genetic etiologies are more common in children than in adults.

Genetic Causes

Congenital, X-Linked Diabetes Insipidus: V2 Receptor Mutations. Congenital, X-linked nephrogenic diabetes insipidus is caused by inactivating mutations of the vasopressin V2 receptor.¹⁷³ Approximately 250 mutations, mostly missense, have been reported to be associated with nephrogenic diabetes insipidus.³²⁴ Because of its mode of transmission, it is a disease of males, although rarely females may be affected, presumably caused by extreme lyonization during X chromosome inactivation.^{452,453} In keeping with a germline, as opposed to somatic mutation in the V2 receptor, these patients are deficient in all systemic V2 receptor-mediated actions,^{454,455} and have intact V1-receptor-mediated responses.^{456,457} As expected, the V2 receptor defect is proximal to the activation of renal adenylate cyclase.^{458,459} Unlike the function of other G protein-coupled seven transmembrane receptors, such as the parathyroid hormone and thyroid-stimulating hormone receptors, that of the V2 receptor is unaffected in patients with pseudohypoparathyroidism, who have inactivating mutations in the alpha subunit of G_s.⁴⁶⁰

Because of vasopressin resistance in congenital nephrogenic diabetes insipidus, the kidney elaborates large volumes of hypotonic urine, with osmolality ranging between 50 and 100 mOsm/kg. Manifestations of the disease are usually present within the first several weeks of life,^{461,462} but may only become apparent after weaning from the breast. The predominant symptoms are polyuria and polydipsia. Thirst may be more difficult to satisfy than in central diabetes insipidus. Many infants initially present with fever, vomiting, and dehydration, often leading to an evaluation for infection. Growth failure in the untreated child may be secondary to the ingestion of large amounts of water, which the child may prefer over milk and other higher caloric substances.⁴⁶³ Mental retardation of variable severity may result from repeated episodes of dehydration.⁴⁶⁴ Intracerebral calcification of the frontal lobes and basal ganglia is not uncommon in children with X-linked nephrogenic diabetes insipidus.^{465–468} Because this appears early and is not seen in children with central diabetes insipidus of equivalent severity, cerebral calcification is probably unrelated to the level of dehydration or therapeutic intervention. It is possible that elevated vasopressin concentrations, acting via intact V1 or V3 receptors, contribute to some of the unique manifestations of X-linked nephrogenic diabetes insipidus, such as cerebral calcification, intense thirst, vomiting, and growth failure. Older children may present with enuresis or nocturia. They may learn to reduce food intake (and therefore solute load) to decrease polyuria, which may contribute to growth failure. After long-standing ingestion and excretion of

large volumes of water, patients may develop nonobstructive hydronephrosis, hydroureter, and megabladder.⁴²⁰

Although one founder (arriving in North America from Scotland in 1761 on the ship *Hopewell*) was initially postulated to be the ancestor of most North American subjects with congenital, X-linked nephrogenic diabetes insipidus,⁴⁶⁹ hundreds of independent mutations in the V2 receptor have been found, with some appearing to have arisen independently more than once^{470–486} (Fig. 12.16). These are mostly single base mutations that either result in amino acid substitutions, translational frameshifts, or termination of peptide synthesis, and are distributed fairly evenly throughout the receptor protein. Mutations may affect either vasopressin binding, cyclic AMP generation, or possibly transcriptional regulation.^{487–491} Patients with different mutations will likely be found to exhibit phenotypic heterogeneity, including in severity of disease and response to treatment. Genetic heterogeneity may underlie the variable response of patients with X-linked diabetes insipidus to dDAVP treatment. In a family with a known mutation, prenatal or early postnatal DNA screening can unambiguously identify affected males, allowing the institution of appropriate therapy.⁴⁹²

Congenital, Autosomal Nephrogenic Diabetes Insipidus: AQP2 Mutations. After the initial description of X-linked nephrogenic diabetes insipidus,⁴⁹³ several patients were reported with similar clinical findings except for autosomal recessive transmission of the disease,⁴⁹⁴ or normal V2 receptor function outside of the kidney.⁴⁹⁵ With the cloning of the complementary DNA for the renal water channel, AQP2, many patients with autosomal recessive nephrogenic diabetes insipidus have been reported who have a total of 57 mutations different in this gene.^{324,488} Most are missense mutations, although four are nonsense or frameshift mutations.¹⁷² They are scattered throughout the molecule, including within four of the five transmembrane domains, two of three extracellular domains, and two of four intracellular domains (see Fig. 12.10). Recently, an autosomal dominant mode of inheritance for nephrogenic diabetes insipidus has been described, associated with mutations in AQP2. One of these dominant mutations results in mixed tetramers of the wild type and mutant alleles being retained in the Golgi apparatus.⁴⁹⁶ AQP2 mutations impair the ability of the luminal membrane to undergo an increase in water permeability, following signaling through the V2 receptor. They could include patients previously described who had a normal rise in urinary cyclic AMP in response to vasopressin, without a concomitant increase in urine osmolality.⁴⁵⁸ AQP2 protein is excreted in the urine in both soluble and membrane-bound forms. AQP2 excretion is low in untreated central and nephrogenic diabetes insipidus, but following dDAVP administration, increases markedly in the former, but not latter, disease.¹⁰⁶ For this reason, its measurement in urine has been suggested as an aid in the differential diagnosis of diabetes insipidus.¹⁰⁶

Acquired Causes

Acquired causes of nephrogenic diabetes insipidus are more common and less severe than genetic causes. Nephrogenic diabetes insipidus may be caused by drugs, such as lithium and demeclocycline, both of which are thought to interfere with vasopressin-stimulated cyclic AMP generation or action. Approximately 50% of patients receiving lithium have impaired urinary concentrating ability, although only 10% to 20% of them develop symptomatic nephrogenic diabetes insipidus, which is almost always accompanied by a reduction in the glomerular filtration rate.^{497,498} The risk increases with duration of therapy. Lithium impairs the ability of vasopressin to stimulate adenylate cyclase,⁴⁹⁹ resulting in a 90% fall in AQP2 messenger RNA expression in renal collecting duct,⁵⁰⁰

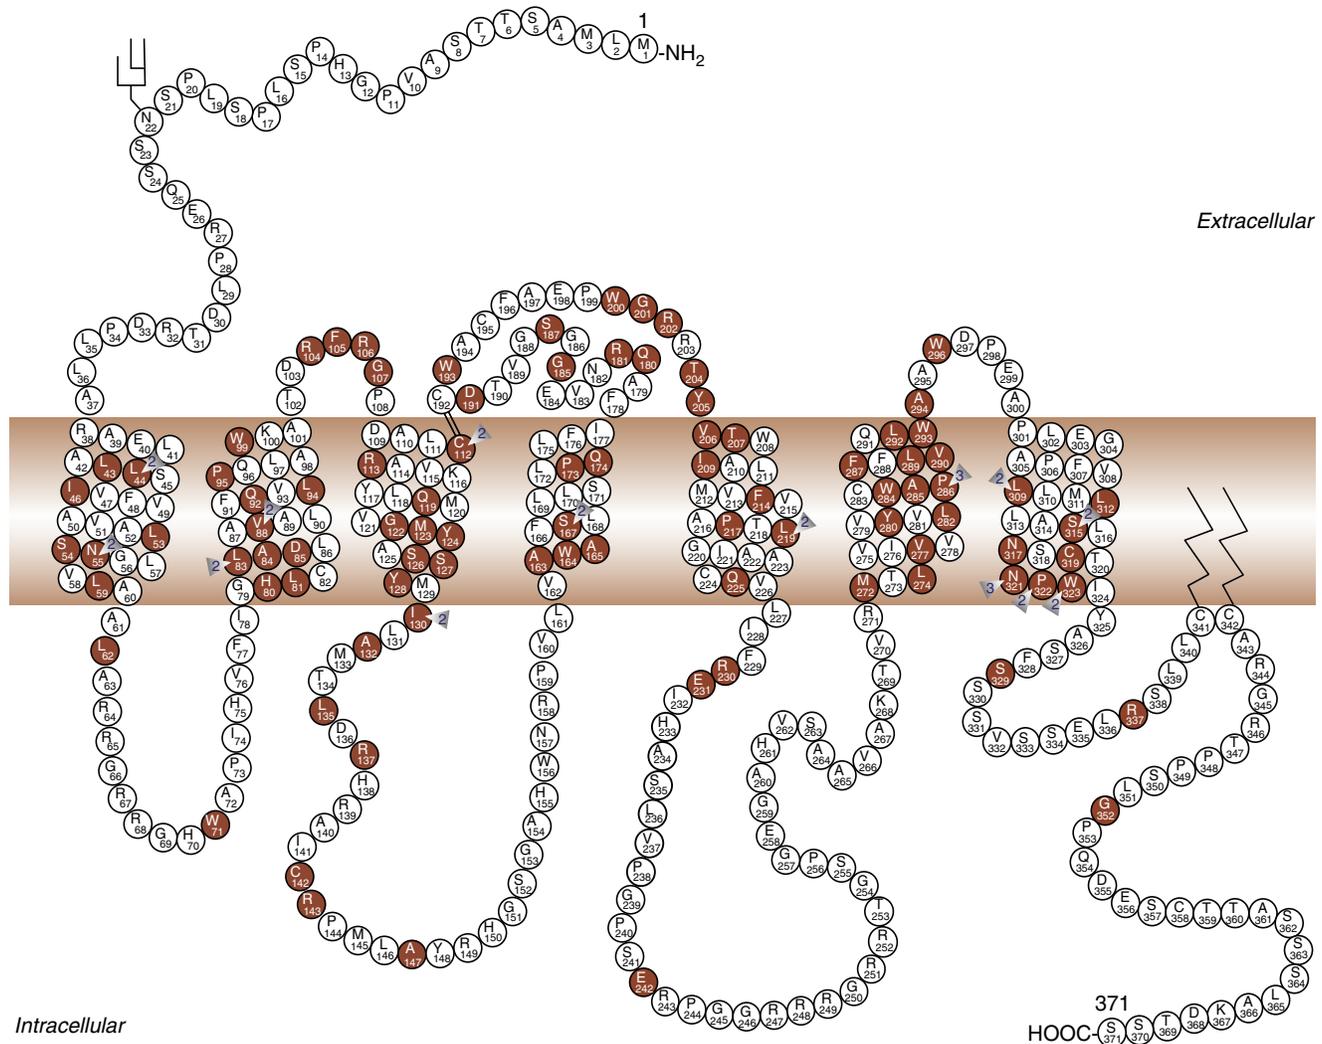

Fig. 12.16 Predicted structure of the V2 vasopressin receptor (AVPR2) and mutations, which cause X-linked nephrogenic diabetes insipidus. Depicted are predicted membrane topology, with the extracellular domain at the top of the figure and amino acids in the one-letter code. Shaded amino acids depict mutations, with numbers indicating more than one mutation at that position. (From Bichet, D.G., Bockenhauer, D. (2016). Genetic forms of nephrogenic diabetes insipidus (NDI): vasopressin receptor defect (X-linked) and aquaporin defect (autosomal recessive and dominant). *Best Pract Res Clin Endocrinol Metabol*, 30, 263–276. With permission.)

which may be the basis for its causing nephrogenic diabetes insipidus.

Demeclocycline treatment causes nephrogenic diabetes insipidus by inhibiting transepithelial water transport.⁵⁰¹ For this reason, it is useful in the treatment of dilutional hyponatremia associated with inappropriate secretion of vasopressin, as discussed previously. Other agents that cause nephrogenic diabetes insipidus include hypercalcemia, hyperkalemia, and therapy with foscarnet (used in treatment of cytomegalovirus infection in immunosuppressed patients),^{502,503} clozapine,⁵⁰³ amphotericin,⁵⁰⁴ methicillin,⁵⁰⁵ or rifampin.⁵⁰⁶ Whether any of these agents cause nephrogenic diabetes insipidus by interfering with the expression or insertion into apical collecting duct membranes of AQP2 water channels is not yet known. Ureteral obstruction,⁵⁰⁷ chronic renal failure, polycystic kidney disease, medullary cystic disease, Sjogren syndrome,⁵⁰⁸ and sickle cell disease can also impair renal concentrating ability.⁵⁰⁹ Osmotic diuresis caused by glycosuria in diabetes mellitus, or to sodium excretion with diuretic therapy, will interfere with renal water conservation. Primary polydipsia can result in secondary nephrogenic diabetes insipidus because the chronic excretion of a dilute urine lowers the osmolality of the

hypertonic renal interstitium, thus decreasing renal concentrating ability. Finally, decreased protein or sodium intake also can lead to diminished tonicity of the renal medullary interstitium and nephrogenic diabetes insipidus.

Treatment of Nephrogenic Diabetes Insipidus. The treatment of acquired nephrogenic diabetes insipidus focuses on elimination, if possible, of the underlying disorder, such as offending drugs, hypercalcemia, hypokalemia, or ureteral obstruction. Congenital nephrogenic diabetes insipidus is often difficult to treat. The main goals should be to ensure the intake of adequate calories for growth and to avoid severe dehydration. Foods with the highest ratio of caloric content to osmotic load should be ingested, to maximize growth and minimize the urine volume required to excrete urine solute. However, even with the early institution of therapy, growth and mental retardation are not uncommon.⁵¹⁰

Thiazide diuretics, in combination with amiloride or indomethacin, are the most useful pharmacologic agents in the treatment of nephrogenic diabetes insipidus.⁵¹¹ Thiazides work both by enhancing sodium excretion at the expense of water, as well as by causing a fall in glomerular filtration rate, which

results in proximal tubular sodium and water reabsorption.^{423,512} Indomethacin, 2 mg/kg/day, further enhances proximal tubular sodium and water reabsorption,^{423,513,514} although this effect is not mediated by inhibition of cyclooxygenase.⁵¹⁵ The combination of thiazide and amiloride diuretics is the most commonly used regimen for the treatment of congenital, X-linked nephrogenic diabetes insipidus, because amiloride counteracts thiazide-induced hypokalemia,⁴⁶¹ avoids the nephrotoxicity associated with indomethacin therapy, and is well tolerated, even in infants.⁵¹⁶ In addition, amiloride decreases the uptake of lithium by renal epithelial cells, and for this additional reason has been proposed in combination with thiazide as treatment for lithium-induced nephrogenic diabetes insipidus.⁵¹⁷ High-dose dDAVP therapy, in combination with indomethacin, has been reported to be helpful in treating some subjects with nephrogenic diabetes insipidus.⁵¹⁸ This treatment may prove to be useful in patients with genetic defects in the V2 receptor, which reduce the binding affinity for vasopressin.

A therapy that has thus far only been used in mice and not yet available for humans, in which abnormal stop codons are bypassed,⁵¹⁹ may prove useful to treat patients with nonsense mutations in AVPR2 and AQP2.

CONCLUDING REMARKS

Precise regulation of water balance is necessary for the proper function of multiple cellular pathways. Vasopressin released from the posterior pituitary, stimulated by both hyperosmolar and nonosmotic factors, acts via the kidney V2 vasopressin receptor to stimulate both an increase in AQP2 expression and its insertion into collecting duct luminal membrane, thereby enhancing renal water reabsorption to minimize subsequent water loss. Thirst controls the second major physiologic response to hyperosmolality and results in increased water intake to make up for past water loss. The renin-angiotensin-aldosterone and ANP systems also make important contributions to water and volume regulation by modulation of sodium intake and output.

The proper diagnosis of disorders caused by deficient and excessive action of vasopressin requires a thorough understanding of the physiologic regulation of this hormone. Recent advances in molecular medicine have revealed mutations in the vasopressin gene, and the V2 receptor or AQP2 genes, responsible for familial central and nephrogenic diabetes insipidus, respectively. Molecular methods allow the diagnosis of these disorders in the prenatal or early postnatal periods. Nevertheless, the most frequent cause of central diabetes insipidus remains a destructive lesion of the central nervous system caused by tumor or neurosurgical insult, and pharmacologic toxicity remains the most common cause of nephrogenic diabetes insipidus.

Hyponatremia is a common occurrence in childhood, but is rarely caused by a primary increase in vasopressin secretion or increase in intrinsic activity of the V2 receptor (SIAD). It is more commonly caused by hypovolemia (either primary or secondary to decreased effective vascular volume), salt loss, excessive ingestion of hypotonic fluids, or cortisol deficiency. Hyponatremia resulting from increased vasopressin action is most commonly caused by excessive vasopressin administration during the treatment of central diabetes insipidus or coagulopathies.

In infants, central diabetes insipidus is best treated with fluid therapy, which avoids the administration of vasopressin or its V2 receptor analog, dDAVP, whereas in older children, dDAVP is the drug of choice. Nephrogenic diabetes insipidus remains a therapeutic challenge. Hyponatremia caused by SIAD is best managed by restricting water intake, whereas salt and water replacement are indicated when hyponatremia is caused

by hypovolemia or excessive secretion of ANP, as occurs in cerebral salt wasting. Hyponatremia causing central nervous system dysfunction is a medical emergency. Blood sodium must be raised promptly, but at a rate not greater than 0.5 mEq/L/h to avoid the occurrence of central pontine myelinolysis.

INTRODUCTION

Thyroid disease can present with overt symptoms, insidiously, or with isolated thyromegaly. Thyroid disease in children can encompass isolated biochemical abnormalities that have little or no physiological consequence, or with overt clinical symptoms. Clinically, hypothyroidism occurs more commonly than hyperthyroidism. Thyroid nodules and masses occur much less commonly than functional disorders but can portend the presence of thyroid cancer. [Box 13.1](#) provides a classification of thyroid disorders in children. This chapter focuses on the most common conditions that affect the thyroid gland of children and adolescents.

Thyroid Hormones and Their Action

Few hormones exert as profound and essential role in human physiology as thyroid hormones. The major hormones released by the thyroid gland include tetraiodothyronine, or thyroxine (T₄), and triiodothyronine (T₃).¹ The production of these hormones involves several discrete biochemical steps that are shown in [Fig. 13.1](#). Of these hormones, T₃ plays the pivotal role in affecting physiology, being the molecule that principally

binds to the thyroid hormone receptor (TRs).¹ The thyroid hormone nuclear receptor belongs to the steroid hormone–retinoic acid receptor superfamily and is a regulator of deoxyribonucleic acid (DNA) transcription.

Two genes encode the TR; one on chromosome 17 designated alpha (*TRa*) and one on chromosome 3 designated beta (*TRb*). The TRs can exist as monomers or homodimers, and they can dimerize with other members of the family of nuclear receptors.¹ After T₃ binding to the TR, gene transcription is regulated in many tissues.

T₄ is the predominant hormone released from thyroid follicular cells. After release, it circulates in protein-bound and free states at a ratio of about 1000 to 1. Thyroid hormone-binding proteins in the blood include thyroxine-binding globulin (TBG), prealbumin or transthyretin, and albumin.² TBG is the predominant carrier protein for T₄; TBG and albumin also carry T₃. In the euthyroid study, the circulating concentration of free T₄ (FT₄) and free T₃ are about 0.03% and 0.30%, respectively, of total hormone concentrations.

It is important to recognize that circulating levels of thyroid hormones and carrier proteins change with age ([Tables 13.1](#) and [13.2](#)). Absolute mean free T₄ and free T₃ concentrations

BOX 13.1 Thyroid Disorders in Childhood and Adolescence**AUTOIMMUNE THYROID DISEASE**

- Hashimoto thyroiditis, juvenile acquired hypothyroidism
- Stimulating antibody, Graves disease
- Blocking antibody, hypothyroidism

INFECTIOUS THYROIDITIS

- Suppurative thyroiditis
- Subacute thyroiditis

BINDING PROTEIN ABNORMALITIES

- Complete TBG deficiency
- Partial TBG deficiency
- TBG excess
- Transthyretin variants

TSH RECEPTOR MUTATIONS

- Loss-of-function hypothyroidism
- Gain-of-function hyperthyroidism

THYROID HORMONE RESISTANCE SYNDROMES

- Thyroid hormone beta receptor (TR β) mutations
- Peripheral tissue resistance syndrome

- Pituitary resistance syndrome
- Thyroid hormone membrane transport defects

IODINE DEFICIENCY SYNDROMES

- Goiter
- Mental impairment
- Cretinism

DIFFUSE NONTOXIC GOITER

- Nonthyroidal illness
- Thyroid neoplasia
- Adenoma
- Nonfunctional
- Functional
- Papillary-follicular carcinoma
- Medullary carcinoma
- MEN2A, 2B, Ret mutations
- Sporadic
- Undifferentiated
- Metastatic

MEN, Multiple endocrine neoplasia; TBG, thyroxine-binding globulin; TSH, thyroid-stimulating hormone.

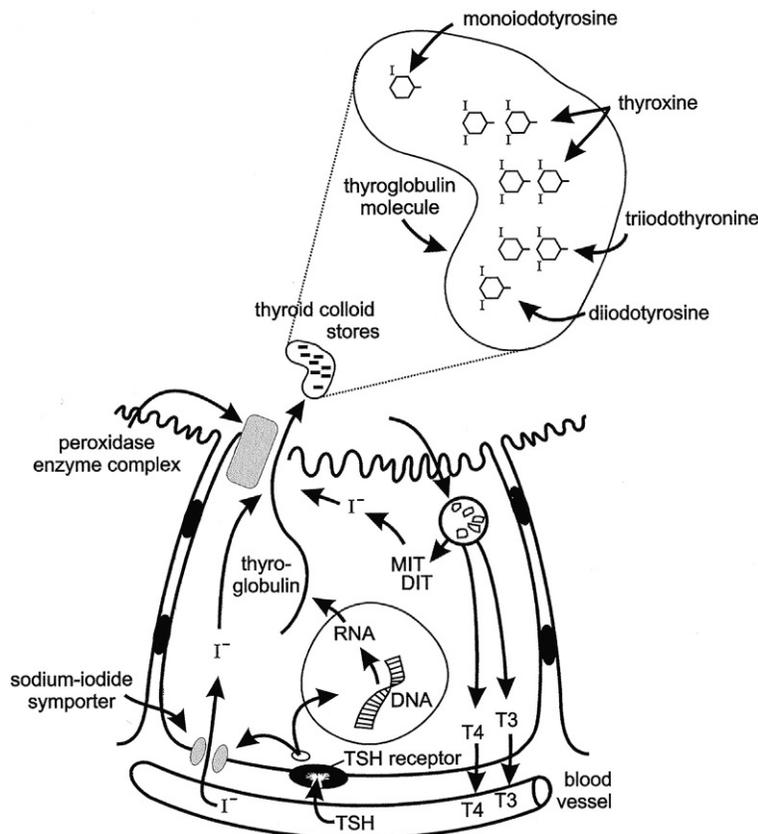

Fig. 13.1 Illustration of thyroid hormone synthesis and secretion. Thyroid-stimulating hormone (TSH) regulates the process via the G protein–linked plasma membrane TSH receptor. TSH binding stimulates thyroglobulin synthesis and sodium-iodide symporter (iodide transporter) uptake of circulating iodide. Iodide diffuses in the cytosol to the apical membrane and is transported to the apical lumen by Pendrin, an anion-bicarbonate family exchanger, making iodide available to the enzyme organification complex (Pendrin; thyroid peroxidase, TPO, THOX). The tyrosine residues of thyroglobulin are iodinated at the apical cell membrane and are catalyzed by thyroid peroxidase, the organification enzyme. The resulting monoiodotyrosine (MIT) and diiodotyrosine (DIT) residues couple to form the iodothyronines thyroxine (T₄) and triiodothyronine (T₃) within the stored thyroglobulin molecule. TSH stimulates micropinocytosis of colloid droplets and progressive thyroglobulin proteolysis within the resulting phagolysosomes. T₄ and T₃ are secreted into the circulation. The uncoupled MIT and DIT are deiodinated by iodotyrosine deiodinase to release iodide, which is largely recycled within the follicular cell. are about 10 and 4 pg/mL, respectively, and differ according to age. In adolescents and adults, the plasma concentrations of the several binding proteins are 1 to 3 mg/dL for TBG, 20 to 30 mg/dL for thyroxine-binding prealbumin, and 2 to 5 g/dL for albumin.² TBG concentrations are greater in children than in adults, and they decline to adult levels during adolescence.² Because the thyroid hormone-binding proteins are produced in the liver, they are acute phase reactants, with concentrations increasing during acute illness, they also increase in response to estrogen exposure.

Conversion of T4 to T3 involves the deiodination of T4 (Fig. 13.2). Monodeiodination of the beta or outer ring by monodeiodinase (MD) type II produces T3. Monodeiodination of the alpha or inner ring produces reverse T3 (rT3), which is inactive metabolically. Under normal circumstances, T3 and rT3 are produced at similar rates. About 70% to 90% of circulating T3 is derived from peripheral conversion of T4, and 10% to 30% of circulating T3 is from the thyroid gland. Reflecting

the age-related changes in the hormones that regulate T4 stability, the clearance of T4 generally decreases from infancy to adulthood (Table 13.3).

Regulation of Thyroid Function

The production of T4 and T3 within the thyroid gland is regulated by the thyroid-stimulating hormone ([TSH]; also called *thyrotropin*), which is released from the anterior pituitary gland (Fig. 13.3).³ TSH receptors are present on thyroid follicular cells and are G protein-coupled receptors with a large extracellular amino terminus.³ Mutations of the TSH receptor can result in constitutive activation of the receptor with severe hyperthyroidism, whereas inactivating mutations result in TSH unresponsiveness and hence hypothyroidism.

TSH receptor activation stimulates adenylate cyclase accumulation within follicular cells, which in turn causes accumulation of cyclic adenosine monophosphate (cAMP). Increased cellular concentrations of cAMP promote iodide trapping, iodotyrosine synthesis, thyroglobulin (TG) synthesis, and hormone release.

TSH release is regulated by the hypothalamic hormone thyrotropin-releasing hormone (TRH) (see Fig. 13.3). This peptide hormone is produced in medial neurons of the paraventricular nucleus of the hypothalamus and is released into the portal circulation of the pituitary gland. Several different neurotransmitters have been observed to influence TRH release.

In addition to normal regulation of TSH receptor activity by TSH, thyroid function can be adversely affected by antibodies that can either stimulate or block TSH action. TSH receptor-stimulating immunoglobulin antibodies (TSIs), or thyroid receptor antibodies (TRAbs), are present in the circulation of individuals with Graves disease (GD) and activate TSH receptors. Conversely, TSH receptor-blocking immunoglobulins (TBIs) antagonize TSH action and can lead to hypothyroidism.

CLINICAL AND BIOCHEMICAL ASSESSMENT OF THYROID STATUS

Clinical Evaluation of the Thyroid

Thyroid disease can present with overt symptoms, insidiously, or with isolated thyromegaly. Thus evaluation of the thyroid gland should be included in the routine examination of children. The thyroid gland can be visualized by having the patient

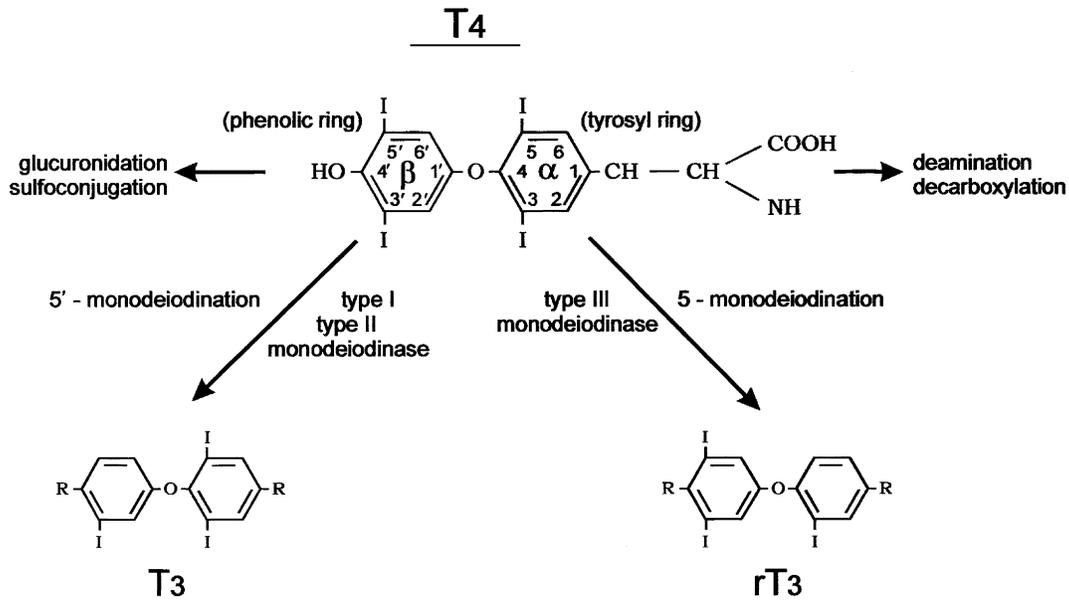

Fig. 13.2 The metabolism of thyroxine (tetraiodothyronine). The major metabolic pathway is progressive monodeiodination mediated by the three iodothyronine monodeiodinase enzymes type I, type II, and type III. Outer (phenolic) ring 5' monodeiodination produces active 3,5,3' triiodothyronine. Inner (tyrosyl) ring 5' monodeiodination produces inactive reverse 3,3,5' triiodothyronine. Type I deiodinase is also capable of inner-ring monodeiodination. The alanine side chain of the tyrosyl ring is also subject to degradative reactions, including deamination and decarboxylation. Sulfoconjugation and glucuronide conjugation reactions at the 4' phenolic ring site occur largely in liver tissue. (From Fisher and Greuters [2008] Thyroid disorders in childhood and adolescence. In: *Pediatric Endocrinology*, M. Sperling, ed. 3rd ed., Saunders, Philadelphia, pp. 227–253).

look to the ceiling and swallow.⁴ As the thyroid moves, the margins of the gland are viewed to estimate size and symmetry. The thyroid should be palpated to assess size, consistency, and symmetry. This can be performed with the clinician standing behind the patient and palpating the neck with the fingertips. The texture of the thyroid can be assessed to determine if it is smooth or irregular and if nodules are present, which may feel firm or soft. If any asymmetry or abnormal thyroid fullness is noted, ultrasonographic evaluation is recommended because pathological thyroid nodules may feel like normal tissue.

To assess gland size, one may estimate the size of each thyroid lobe relative to that of a teaspoon (5 g) or a tablespoon (15 g).⁴ In general, until the end of puberty, gland size (in grams) approximates the patient's age in years times 0.5 to 0.7.⁵ Thus

each thyroid lobe of a 10-year-old child is approximately one-half of a teaspoon for a total gland size of 5 to 7 g.⁵ For teens and adults, each lobe of the thyroid may reach one teaspoon in size for an approximate total gland size of about 10 g.⁵

In newborns and young infants, the thyroid can be examined by placing the infant supine on the parent's lap, with the head toward the parent's knees. The head can then be gently lowered backward to expose the neck, which facilitates thyroid palpation. If the examiner can palpate each ring of the trachea from the sternal notch to above the larynx, then the absence of pretracheal thyroid tissue is suggested, which is observed. Such an absence occurs in cases of failure of thyroid formation or migration. Failure to detect pretracheal thyroid tissue in older children warrants visual examination of the base of the tongue for ectopic thyroid tissue.

When a sublingual thyroid gland is discovered late in childhood or in adolescence, the tissue should be palpated with a gloved finger, during regular office visits, because nodules and malignancies may develop in ectopic thyroid glands.⁶ In contrast, when an ectopic thyroid is detected in infancy and replacement therapy is started, the residual thyroid tissue becomes atrophic and does not present long-term problems.

Biochemical Evaluation of Thyroid Function

Approximately 97% of the thyroid hormone released from the thyroid gland is T4.⁷ After its release, less than 1% of T4 remains free. The rest of the thyroid hormone circulates bound to the proteins thyroglobulin (TGB; 70%), prealbumin (transthyretin; 10%), and albumin (15% to 20%).⁷ T3 is also released from the thyroid and is generated peripherally. Although T4 constitutes the bulk of circulating thyroid hormone, T3 has far greater affinity for nuclear TRs and exerts most of the potent cellular effects of thyroid hormone action.^{8,9}

Thyroid function can be assessed by measurement of total T4 and total T3 levels, along with indices that reflect thyroid hormone-binding proteins (T3 or T4 resin uptake).⁷ The levels

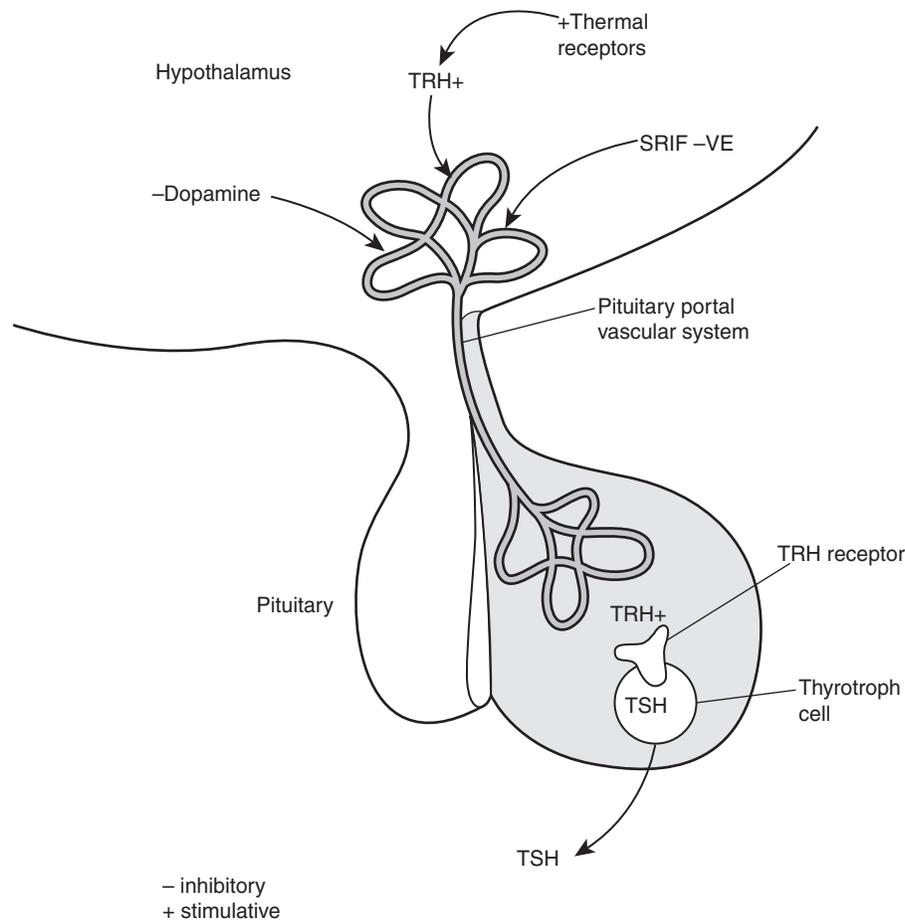

Fig. 13.3 The hypothalamic-pituitary thyroid-stimulating (TSH) axis. Thyrotropin-releasing hormone (TRH) secreted into the pituitary portal vascular system stimulates TSH synthesis and secretion from the pituitary thyrotroph cell. TRH secretion is modulated by central and peripheral thermal sensors. Dopamine or somatostatin (SRIF) can inhibit TSH release. (From Fisher and Greuters [2008] *Thyroid disorders in childhood and adolescence*. In: *Pediatric Endocrinology*, M. Sperling, ed. 3rd ed., Saunders, Philadelphia, pp. 227–253).

of estimated free (unbound) T₄ (FT₄) are measured to assess thyroid hormone status, without the confounding influences of carrier proteins.

Several conditions are seen in which thyroid hormone levels are abnormal, yet the individual is euthyroid. Because of their confusing nature, these conditions may result in the patient being erroneously diagnosed or treated for hypothyroidism or hyperthyroidism.

When FT₄ values are normal, yet total T₄ values are high, familial dysalbuminemic hyperthyroxinemia needs to be considered.^{10,11} This autosomal dominant disorder is most commonly seen in Hispanic individuals and can be diagnosed by thyroid hormone-binding protein electrophoresis. If FT₄ values are normal but total T₄ values are low, the possibility of TBG deficiency must be entertained. TBG deficiency is an X-linked disorder that may be associated with color blindness.¹² In these and other conditions affecting thyroid hormone binding, treatment is not needed and the patient should be educated about the condition to avoid treatment by unsuspecting practitioners.

T₄ is much more abundant in the circulation and T₃ is the more metabolically active thyroid hormone. T₃ is produced peripherally from T₄ and is also secreted by the thyroid. A metabolically inactive form of T₃, reverse T₃, is also produced, and its level is elevated in conditions, such as euthyroid sick syndrome, or nonthyroidal illness syndrome (see Fig. 13.2).^{13,14}

It is important to consider that estimated FT₄ values may not be accurate in infants because of the fact that circulating

levels of TBG are elevated,^{15–17} confounding biochemical assessment in this age group. FT₄ levels determined by equilibrium dialysis assay, though, are accurate.^{15,16}

Ultrasensitive thyrotropin or TSH assays have been developed, and assessment of TSH has greatly improved the evaluation of thyroid status.¹⁸ TSH levels help to distinguish many thyroid disorders that present with either low or high T₄ levels in most cases. TSH values within the normal range for the assay are indicative of a euthyroid state if the hypothalamic-pituitary axis is intact. Elevations of TSH generally indicate primary thyroid dysfunction; suppressed TSH values indicate hyperthyroidism. When both FT₄ and TSH levels are elevated, TSH-producing pituitary adenomas and thyroid hormone resistance need to be considered.

Hyperthyroidism is distinguished from subclinical hyperthyroidism, a condition in which levels of T₄, FT₄, and T₃ are normal, but TSH levels are suppressed in the absence of thyroid overt disease.¹⁹ The causes of subclinical hyperthyroidism are similar to those of overt hyperthyroidism. Thus it is important to reevaluate individuals with isolated suppression of TSH levels every 3 to 6 months, until the clinical situation declares itself.¹⁹

Critical in the interpretation of TSH levels in children is recognition that the normative range differs from that of adults (see Box 13.1), which is defined by an upper limit values of about 4 μU/mL or less.^{20–23} In comprehensive studies of this issue, the upper limit of TSH values in healthy children and

adolescents without thyroid disease is about 7 $\mu\text{U/mL}$.^{24–26} The application of adult reference range to children thus results in the erroneous diagnosis of subclinical hypothyroidism and results in the unnecessary referral of children for subspecialty care by primary care providers.

HYPOTHYROIDISM

Disorders of the thyroid lead to hypothyroidism much more commonly than to hyperthyroidism. Hypothyroidism may be present at birth, acquired during childhood or adolescence, present with or without symptoms, or present gradually or acutely.^{4,14,27–29}

It is commonly believed by the public and many practitioners that hypothyroidism is associated with and is a cause of obesity, yet there is little support for the notion that the hypothyroid state contributes to obesity.^{30,31} It is also important to note that TSH levels are slightly higher in obese individuals than nonobese individuals.^{32–35} With weight loss, TSH levels normalize in these children.^{32–34,36} Thus slight elevations in TSH in obese individuals are physiological and do not warrant therapy.

Hypothyroidism may be elusive, with symptoms elicited only in retrospect. In the extreme, hypothyroidism can be associated with cold intolerance, bradycardia, carotenemia, coarse and brittle hair, dry skin, pallor, and myxedema. These symptoms may not be distressing, which allows prolonged hypothyroidism to escape detection.

The most common causes of hypothyroidism in children are autoimmune processes resulting in Hashimoto thyroiditis.^{37,38} Autoimmune thyroiditis also leads to juvenile acquired hypothyroidism that can present with growth failure when chronically present.³⁹ Hypothyroidism in children can be caused by iodine exposure or hypothalamic pituitary dysfunction. Other causes of hypothyroidism include exogenous goitrogens, cystinosis, acute thyroiditis, and thyroid irradiation during cancer treatment. Hypothyroidism in the newborn is a serious health concern and is detected by newborn screening programs.

Hashimoto or Autoimmune Thyroiditis

Autoimmune thyroiditis with thyroid enlargement is one of the most common presentations of childhood thyroid disease.^{38,40} It is associated with antibodies against thyroglobulin and thyroperoxidase and is characterized by lymphocytic infiltration of the thyroid gland, which results in thyromegaly.^{38,40} Depending on the nature of the antithyroid antibodies, Hashimoto disease may be associated with a euthyroid state, hypothyroidism, or transient hyperthyroidism.^{38,40}

Hashimoto thyroiditis may rarely occur in very young infants,⁴¹ and typically presents in adolescents, affecting females more than males.³⁸ The thyroid gland is usually diffusely enlarged and may have an irregular, cobblestone feel. Asymmetric thyroid enlargement, mimicking a thyroid nodule, may be noted. The presence of antithyroid antibodies and the absence of nodules on ultrasonography can distinguish inflammation from other pathologic processes.

Importantly, the presence of antithyroid antibodies does not portend the development of complete or partial thyroid failure that will warrant therapy. In the healthy adult population, up to 5% of individuals had circulating antithyroid antibodies that are present.⁴² Less than 10% of these individuals will develop hypothyroidism, with those having elevated antithyroperoxidase (anti-TPO) antibodies being much more at risk than those having anti-TG antibodies.⁴²

In children, the incidence of antithyroid antibodies at a population level is not generally known. Of those children with antithyroid antibodies, about 20% are reported to develop

hypothyroidism needing therapy.^{43,44} These children often have very high antithyroid antibody titers. Thus if a child is found to have low levels of antithyroid antibodies, it is reasonable to assess thyroid indices every 6 to 12 months and initiate therapy when the TSH rises above the upper limit of normal for children. However, if high titers are present at presentation, it is reasonable to initiate therapy at that point.

Untreated in some children, Hashimoto thyroiditis can result in progressive thyromegaly and hypothyroidism.^{38,43} Treatment with levothyroxine prevents hypothyroidism and the TSH elevations that stimulate gland enlargement. When T4 levels are modestly depressed ($>5 \mu\text{dL}$) or normal, treatment can be initiated with 1 to 2 mcg/kg/day of levothyroxine. If profound hypothyroidism is present, pseudotumor cerebri may develop when children are treated with conventional doses.⁴⁵ Thus treatment is often initiated with one-third to one-half of the usual dose of levothyroxine. After 2 to 4 weeks, the patient can be advanced to conventional doses. However, children with profound hypothyroidism can develop pseudotumor cerebri, even if treatment is initiated with low doses of levothyroxine.^{46–48}

Interestingly, it has been recently reported that severe hypothyroidism in children with TSH elevations $>500 \mu\text{U/mL}$, experience complete resolution of the hypothyroid state.⁴⁹ Based on the experience of others, this happenstance is very uncommon.

Although it has been reported that there are some differences in the oral bioavailability of different levothyroxine preparations,^{50–52} from a practical vantage, these differences are small.^{51–53} Thus the routine use of less expensive generic compounds versus more expensive brand-name products is justified.

The timing of levothyroxine ingestion has been the subject of study. Taking the medication at bedtime is associated with higher T4 levels and lower TSH levels over the course of the day.^{54,55} This is believed to be related to better gastrointestinal absorption in the evening than day.^{54,55}

The suggestion has also been made that hypothyroidism in adolescents can be treated with a single dose given weekly.⁵⁶ This approach is not recommended, however, because thyroid hormone levels are high, shortly after the dose is administered, and are low by the week's end.⁵⁶ Treatment of congenital hypothyroidism with weekly doses of levothyroxine also can result in mental retardation.⁵⁷ It is also recognized that excessive soy intake can interfere with the absorption of levothyroxine.^{58–60}

Of note, other potential therapies that may theoretically alter the autoimmune process have been tested. No proven benefit has been observed in patients who have taken selenium.⁶¹

Hashitoxicosis

Uncommonly, patients may present with Hashitoxicosis, in which immunologic destruction of thyroid tissue results in the release of preformed thyroid hormone, which leads to elevated T4 levels.⁶² In contrast to GD, hyperthyroidism is transient, eye findings are absent, radionuclide uptake is low, and elevated levels of thyroid-stimulating immunoglobulins are not present.⁶²

Hashimoto thyroiditis may be associated with other autoimmune diseases, including diabetes mellitus, adrenal insufficiency, vitiligo, and hypoparathyroidism.⁶³ Autoimmune thyroiditis is also seen in patients with inflammatory bowel disease and juvenile arthritis.^{63,64} Annual surveillance of thyroid gland size and TSH levels should thus be considered for children with other autoimmune problems, and clinicians should be vigilant for signs of hyperthyroidism or hypothyroidism. Conversely, children with autoimmune thyroiditis should be observed for signs of diabetes mellitus and Addison disease.

The incidence of celiac disease in the setting of Hashimoto thyroiditis is about 1%.⁶⁵ If patients manifest abdominal discomfort, weight loss, or gastrointestinal symptoms, Celiac disease screening should be performed, but it does not need to be done routinely in children with thyroid disease. We have found a 1% incidence of autoimmune liver disease in children with autoimmune thyroid disease. Because such liver disease can be occult, we annually assess circulating transaminase levels, and if levels are elevated, evaluation of possible liver disease is initiated.

Several groups of children are at risk for autoimmune thyroiditis. Because girls with Turner syndrome are predisposed to autoimmune thyroiditis,⁶⁶ TSH levels should be assessed annually. Turner syndrome should also be considered in girls with hypothyroidism, especially if the child is prepubertal at presentations.^{67,68} Children with Down syndrome also warrant annual screening for hypothyroidism.^{69,70}

Subclinical Hypothyroidism

Subclinical hypothyroidism refers to a condition in which circulating T4 and T3 levels are normal, but TSH levels are elevated.^{31,71} As noted earlier, many children are erroneously diagnosed with this condition when TSH levels are found to be elevated relative to adult reference range values.²⁵ However, if proper pediatric-based TSH levels are applied, the vast majority of children so diagnosed will not have hypothyroidism. Thus some experts have questioned if subclinical hypothyroidism is a real entity in children.^{31,71}

Studies of children with mild TSH elevations (5–10 $\mu\text{U/mL}$) reveal that only a small fraction will progress to TSH elevations over 10 $\mu\text{U/mL}$.^{31,71} Data also show that treatment of children with TSH levels 5 to 10 $\mu\text{U/mL}$ does not exhibit somatic or other benefits when treated with levothyroxine.^{31,71} Thus treatment of children with TSH levels lower than 10 $\mu\text{U/mL}$ is not needed. For children with TSH levels over 10 $\mu\text{U/mL}$, treatment with low doses of levothyroxine is indicated.

Juvenile Acquired Hypothyroidism

When autoimmune thyroiditis occurs during childhood, it is referred to as juvenile acquired hypothyroidism. In children, severe hypothyroidism can be well tolerated. Thus prolonged hypothyroidism may not be detected until growth failure occurs.^{39,72}

Because untreated infantile hypothyroidism is associated with mental retardation, the assumption is often made that juvenile hypothyroidism is associated with learning problems and poor academic performance. This notion is not correct, as children with juvenile hypothyroidism can be successful academically and do not manifest overt learning problems related to the hypothyroid state, nor cognitive impairment.

Children with severe hypothyroidism may manifest cold intolerance, decreased frequency of bowel movements, and decreased physical activity.^{39,72} Bradycardia, facial puffiness, delayed reflexes, and carotenemia may be present. In comparison with Hashimoto thyroiditis, the thyroid gland is either small or only modestly enlarged.^{39,72} Antithyroid antibodies are usually present.^{39,72} These patients are generally not obese, and body mass index values are similar before and after treatment.^{30,73} The development of slipped capital femoral epiphyses may antedate the detection of hypothyroidism.⁷⁴

Some children with juvenile hypothyroidism may present with signs of puberty without pubic hair.^{75–77} Boys may present with testicular enlargement and girls may present with menarche, with or without breast development.⁷⁸ With treatment of the hypothyroid state, these characteristics may regress.^{75–77} Available evidence suggests that the hypothyroid state leads

to increased gonadotropin secretion, which triggers gonadal activity.^{75,78} In some children, puberty may develop within a year or two of treatment onset, which may limit catch-up growth.³⁹

Juvenile hypothyroidism may not be recognized until a sizable statural deficit is present, and the lost height is usually not completely recovered.³⁹ Children with juvenile hypothyroidism who present with growth failure manifest very low T4 values that are often less than 2 mcg/dL, and profoundly elevated TSH levels that are higher than 250 $\mu\text{U/mL}$.³⁹ Hypercholesterolemia and anemia may be present.³⁹

The magnitude of the height deficit is proportional to the duration of hypothyroidism, which can be estimated as the difference between the chronologic and bone ages.³⁹ When the individual is treated with conventional doses of levothyroxine, accelerated skeletal maturation is observed, with the skeletal age advancing disproportionately faster than gains in height.³⁹ Thus predicted heights fall, and generic growth potential is not achieved.

Because of the poor outcomes of patients with hypothyroidism, we have treated these patients with low doses of levothyroxine (0.25–0.5 mcg/kg/day; e.g., 50 mcg for a 10-year-old). Interestingly, we find that, with low-dose levothyroxine therapy, T4 values normalize (6–7 mcg/dL) within 2 months, and TSH levels normalize or remain only modestly elevated. When serial bone age determinations have been made, we have not observed the disproportionate advancement of skeletal age seen with conventional therapy. However, we do not know if this approach leads to more favorable height outcomes.⁷⁹ Some have also suggested that treating these children with gonadotropin-releasing hormone analogs will lead to improved long-term growth.^{80–84} Yet, we have found that catch-up growth slows markedly in some hypothyroid children receiving gonadotropin-releasing hormone analog therapy and predicted adult heights fall and others have not observed added benefit.⁸⁵ Because the loss in adult height is proportional to the duration of hypothyroidism,³⁹ early detection of this disorder is the best intervention for preventing statural deficits.

Iodine-Induced Hypothyroidism

Iodine is a trace element that is essential for thyroid hormone formation (see Fig. 13.1). Recommended dietary iodine intake is approximately 8 pg/kg, or 100 to 150 pg/day, for adolescents and adults.^{86,87} Although modest iodine intake is essential for thyroid function, high-level iodine exposure results in an acute block in the release of preformed thyroid hormone and impaired thyroid hormone synthesis, a phenomenon referred to as the Wolff-Chaikoff effect.⁸⁸ When iodine-induced hypothyroidism is suspected, it can be diagnosed by the detection of high iodine levels in urine samples.⁸⁹

In children, iodine can be absorbed through the skin, and iodine-induced hypothyroidism has been observed after cutaneous iodine or betadine use.^{89–91} We have also observed iodine-induced suppression of thyroid hormone production in children with central intravenous lines, when regular cleansing of the insertion site with iodine was included in central line care. Neonatal hypothyroidism has also been associated with maternal povidone iodine exposure at the time of delivery.⁹⁰

In preterm infants, iodine-induced hypothyroidism warrants special attention, because the suggestion has been made that cutaneous iodine exposure is a major cause of hypothyroidism in premature infants.⁹² Fortunately, studies show that iodine-induced hypothyroidism is uncommon in the United States.⁹³

Significant iodine exposure also occurs from amiodarone, an antiarrhythmic drug that contains 37% iodine.⁹⁴

Hypothyroidism occurs in 10% of individuals treated with this compound.^{95,96} Amiodarone can also reach the fetus by transplacental passage and induce fetal hypothyroidism.⁹⁴

In addition to iodine excess, iodine deficiency also leads to hypothyroidism. Estimates are that more than 1 billion people worldwide are at risk for iodine deficiency.⁹⁷ Clinically, iodine deficiency is associated with goiter, hypothyroidism,⁹⁷ and endemic cretinism.⁹⁸

In the United States, geographic areas of iodine deficiency exist.^{99,100} With the prevalent use of iodized salt, however, the incidence of iodine deficiency has been markedly reduced, and hypothyroidism and goiter caused by iodine deficiency are rare.^{99,100} Of note, the iodine intake in the United States has declined over the past decade, an issue that may have future clinical implications.^{99,100} In Australia, reduction in iodine intake has been recently observed, with potential implications for pregnant and lactating women.¹⁰¹ The exclusive use of deiodized salt, which includes sea salt, is thus not recommended.

Hypothalamic-Pituitary Dysfunction

Central hypothyroidism should be considered in children with a history of head trauma, brain tumors, meningitis, central nervous system irradiation, or congenital nervous system malformations. Central hypothyroidism has also been associated with the use of retinoid X receptor-selective ligands in the treatment of lymphomas.¹⁰²

In contrast to primary hypothyroidism, the diagnosis of hypothyroidism, secondary to hypothalamic-pituitary dysfunction, may be difficult to establish. Often, circulating levels of T4 are in the low-normal range, and TSH levels may be low, normal, or elevated.^{103,104} FT4 values, however, are usually low.

Whereas congenital central hypothyroidism will be diagnosed in states that perform T4 screening of newborns, neonatal screening programs that rely on TSH determinations will not detect this condition. Central hypothyroidism should therefore be suspected in infants with cholestasis, poor growth, hypoglycemia, structural nervous system problems, or pituitary insufficiency.¹⁰⁵ When neonatal T4 values are interpreted, care should also be taken to use infant thyroid hormone values for comparison, because infantile T4 levels are higher than those seen in adults (see Tables 13.1 and 13.2).¹⁰⁶

Importantly, up to 30% of children who will develop central hypothyroidism may have normal T4 and TSH levels at birth.¹⁰⁷ Thus all children with evidence of hypopituitarism should be regularly monitored for the onset of central hypothyroidism.

When central hypothyroidism is suspected, the TRH test helps distinguish pituitary (secondary) and hypothalamic (tertiary) hypothyroidism.^{104,106,108} Central nervous system imaging should also be performed to look for congenital malformations or hypothalamic-pituitary lesions. Care should be taken to search for other pituitary hormone deficiencies, especially abnormalities of the hypothalamic-pituitary adrenal and growth hormone axes.

Treatment consists of replacement therapy with levothyroxine. Interestingly, some children with central hypothyroidism require doses lower than those used to treat primary hypothyroidism.¹⁰⁹ Because TSH values are not helpful in guiding treatment, measurement of FT4 levels is recommended.¹⁰⁹ One recommendation is to use a dose 1.6 mcg/kg body weight. This dose was found to be associated with improved markers commonly associated with central hypothyroidism and suggests that levothyroxine dosage, based on body weight, and aiming for a FT4 level in the upper reference range, is superior to titration of levothyroxine dose, aiming at middle normal FT4 concentrations in these patients.¹¹⁰

It is important to consider that children with central hypothyroidism may also have other endocrine deficiencies. These

individuals have been shown to be at increased risk for sudden death.¹¹¹

Giant Hemangiomas

Hypothyroidism has been associated with giant hemangiomas.¹¹² In some infantile hemangiomas, the endothelium of these vascular structures produces type 3 iodothyronine deiodinase, which degrades circulating T4 (see Fig. 13.2). Treatment of hypothyroidism (consumptive) in this setting requires high doses of levothyroxine.¹¹²

Hypothyroidism in Cancer Survivors

It is well recognized that children who are cancer survivors, who have had head and neck irradiation, are at increased risk for differentiated thyroid cancer.^{113,114} More common, though, is the development of mild hypothyroidism.^{115–117} Up to 30% of children who have had head and neck irradiation will develop primary hypothyroidism.¹¹⁷ Thus annual TSH screening is suggested. In addition, ultrasound studies are recommended, beginning 5 years after radiation exposure. Practitioners who argue that palpation alone is sufficient for the follow-up of individuals who have had head and neck irradiation need to recognize that ultrasonography will detect thyroid nodules well before palpation.^{114,118}

THYROID HORMONE RESISTANCE

Thyroid hormones exert their effects by binding to specific nuclear receptors to regulate cellular gene expression.¹¹⁹ When the TR is mutated, impaired tissue responsiveness results, leading to thyroid enlargement, elevated levels of T4 and T3, tachycardia, and behavioral problems.^{120–123} Unlike GD, TSH levels are normal or slightly elevated.

The most common forms of thyroid hormone resistance are caused by mutations of the TR beta gene.^{121–123} More than 100 mutations have been identified that result in impaired affinity for T3.¹²¹ Mutant TRs also block the function of normal TRs.¹²¹ Thus thyroid hormone resistance is a dominant-negative mutation, and inheritance is autosomal dominant.¹²² Detection of thyroid hormone resistance in the index case may therefore lead to diagnosis of the condition in other family members. In up to 50% of children with thyroid hormone resistance, the mutations are spontaneous.

Most individuals with resistance to thyroid hormone have generalized thyroid hormone resistance.¹²¹ These individuals are eumetabolic and asymptomatic, with TSH levels in the normal range.

In contrast, some individuals have isolated pituitary thyroid hormone resistance. These individuals have symptoms of hyperthyroidism, because they are sensitive to the effects of increased thyroid hormone levels.¹²⁴ Resistance to thyroid hormone can also be associated with central nervous system problems. Approximately 50% of individuals with resistance to thyroid hormone have attention deficit hyperactivity disorder, and a minority have mental retardation.¹²⁵

Because individuals compensate for thyroid hormone resistance by secreting more thyroid hormone, treatment is generally not necessary.^{121,126} However, patients with thyroid hormone resistance may be improperly diagnosed as having GD and undergo ablation of the thyroid. In this situation, replacement therapy with large doses of exogenous thyroid hormone is needed. With the earlier recognition of resistance to thyroid hormone because of newborn screening, the issue of whether children with resistance to thyroid hormone should be treated prenatally or during infancy has been raised.^{121,126} Treatment is generally reserved for infants who show elevated TSH levels, growth failure, seizures, and developmental delay.^{121,126}

In some cases, TSH secretion may be profound, leading to massive thyromegaly, which may adversely impact upper airway function.^{127,128} These cases are generally associated with severe loss of function mutations. Treatment with high doses of T3 every other day has been shown to be somewhat effective in this setting.^{127,128} In other cases,^{127,128} thyroidectomy is needed to prevent airway compromise.

HYPERTHYROIDISM

Hyperthyroidism has profound influences on the fetus, neonate, growing child, and adolescent, including physical and behavioral effects.^{28,29,129–132} In children, thyrotoxicosis is often present for extended periods before recognition, contributing to significant health problems. A number of conditions result in hyperthyroidism in childhood (see Table 13.1), yet GD is the most common cause,^{131,132} and thus will be the major focus of this chapter with treatment approaches stratified (Fig. 13.4).

Other causes of hyperthyroidism in children include autonomously functioning thyroid nodules, Hashitoxicosis, neonatal thyrotoxicosis, and infections of the thyroid. Hyperthyroidism also results from thyroid hormone ingestion, McCune–Albright syndrome, struma ovarii, and TSH-producing pituitary adenomas. Epidemic hyperthyroidism has also been seen when thyroid tissue has been inadvertently included in meat products.¹³³ Several conditions can masquerade as hyperthyroidism, including thyroid hormone resistance and thyroid hormone-binding protein disorders, yet are best left untreated.

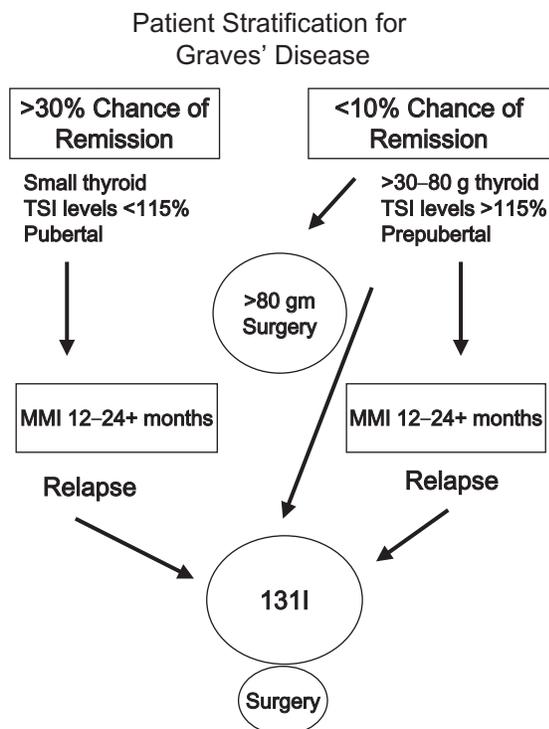

Fig. 13.4 Graves disease therapy in children: stratification by clinical characteristics. Patients can be grouped into those with a better or worse chance of remission based on age, TSI levels, and thyroid size. For very large glands (>80 g), surgery is the treatment of choice. Patients can be treated with antithyroid drugs for 12 to 24 months and the drug withdrawn to see if remission is achieved. If there is no remission, either surgery or radioactive iodine can be administered. Alternatively, the patient can be restarted on antithyroid medication. Only methimazole or carbimazole should be used.

Clinical Evaluation of the Hyperthyroid State

Pediatric thyroid disease can present with overt symptoms, silently, or with isolated thyromegaly.^{28,29,129–132} When hyperthyroidism is suspected during childhood, the practitioner should look for somatic signs (see Table 13.2). One of the universal features of hyperthyroidism is tachycardia.^{28,29} In the absence of such, it is unlikely that hyperthyroidism is present. Other clinical features can include a prominent stare and proptosis, although eye findings occur less commonly in children and adults.^{132,134} It is the common perception that children presenting with hyperthyroidism present thin with weight loss, yet this is often not the situation.¹³⁵

Graves Disease

GD is the most common cause of hyperthyroidism in children and affects 1 in 10,000 children.⁵ Interestingly, the incidence of GD in children may be increasing.¹³⁶ An autoimmune disorder, GD is caused by thyroid gland stimulation by TRAbs or TSI, and involves genetic factors.⁵

Hyperthyroidism can exert profound adverse effects on children, including excessive physical activity, tremor, tachycardia, flushing, palpitations, weight loss, accelerated linear growth, reduced bone mineralization, and poor school performance.⁶ In comparison with adults,^{7,8} eye disease occurs in the minority of pediatric patients with GD, and when it occurs, is usually mild.⁹

Over the past several years, additional outcome data have become available^{137–141} to complement older studies looking at spontaneous remission rates of children with GD.^{7,10–13,18,20–23} Collectively, these studies show that the majority of pediatric patients with GD will not undergo spontaneous remission, even after many years of antithyroid drug (ATD) therapy (see Table 13.3). Thus most pediatric patients will require either radioactive iodine (RAI,¹³¹I) or surgery.

Antithyroid Drug Therapy

ATDs act by inhibiting oxidation and organic binding of thyroid iodide to impair thyroid hormone production and include methimazole (MMI) and propylthiouracil (PTU).²⁹ MMI is 10- to 20-fold more potent than PTU and has a longer half-life.¹²⁹ Importantly, these medications do not cure the hyperthyroid state, rather they palliate the condition, until spontaneous remission occurs or definitive therapy is rendered.

Each of these medications is associated with adverse events that must be considered when prescribed. Before the initiation of drug therapy, a back-up plan that takes into account the patient's age and treatment risks must be developed at therapy onset in the event that a toxic reaction occurs. Failure to initially consider alternative treatments can result in a crisis when adverse effects occur.

Because it takes 1 or 2 months until biochemical hyperthyroidism resolves on drug therapy,¹³⁰ treatment with beta-blockers (propranolol, atenolol, or metoprolol), can be used to control GD symptoms. Focusing on symptom control with beta-blockers also alleviates the false perceived need for initial high-dose ATD therapy. Because atenolol does not cross the blood barrier as much as propranolol, patients will not feel as tired on this medication and thus is preferred.¹⁴² For individuals who have reactive airway disease,¹⁴³ the cardiac selective beta-blocker metoprolol may be used.

In 2008 Rivkees brought to public attention a number of serious complications associated with PTU therapy in children.^{40,130,133} PTU-induced liver injury occurs in up to 1 in 2000 children, occurs rapidly, and is often irreversible.^{144,145} Serial monitoring of transaminase levels in a child on PTU is not viewed as useful in reducing the hepatotoxicity risk.¹⁴⁶ Thus the only way to reduce the risks of PTU-related hepatotoxicity is to avoid the use of this medication.

PTU, though, may be needed in special circumstances.¹⁴⁷ These conditions include situations when neither prompt ¹³¹I or surgical treatment are options in a patient who has had a toxic reaction to MMI and ATD medication is necessary. In this setting, PTU use should be short term.²⁵

If PTU is prescribed, patients and guardians must be informed of the risk of liver failure and to be alert for signs and symptoms of liver abnormalities, including pruritus, jaundice, anorexia, light colored stools, dark urine, and abdominal pain. If these symptoms develop, the patient should immediately stop the medication, a physician contacted, and laboratory tests obtained to evaluate hepatic function and transaminase levels.²⁵

MMI is now the drug choice for hyperthyroidism. The MMI doses described in published reports range from 0.1 to 1.0 mg/kg/day.^{148–153} However, one does not need to use high doses at treatment onset, as MMI side effects are in part dose related.¹⁴⁵ The response to ATDs influencing circulating thyroid hormone levels is not instantaneous, and several months are needed for thyroid hormone levels to normalize.^{154,155} Thyroid function tests should be obtained monthly after therapy onset. After T4 levels become normal, in most cases the MMI dose can be cut by half to maintain euthyroidism.¹⁴⁵ Although MMI is often prescribed in divided doses over the day, once-a-day dosing is sufficient,¹⁵⁴ and is associated with better compliance than multiple daily doses.^{155–157}

MMI is available in 5, 10, and 20 mg tablets. When used in children, the following doses that are fractions of tablets can be used: infants, 1.25 mg/day; 1 to 5 years, 2.5 to 5.0 mg/day; 5 to 10 years, 5 to 10 mg/day; and 10 to 18 years, 10 to 20 mg/day. Because the hyperthyroid state can be associated with low white cell counts, and patients will be treated with a medication that can depress neutrophil levels, one should obtain a complete blood count at therapy onset.¹⁴⁵

MMI therapy is not without risks. Minor side effects may affect up to 20% of children, and major side effects may occur in 1% of children.^{158,159} The most common minor adverse side effects related to MMI are hives, arthralgia, and neutropenia.^{138,160} Children may also develop major side effects, including agranulocytosis, Stevens-Johnson syndrome, and vasculitis.¹³⁸ MMI adverse events most commonly occur within 6 months of therapy onset.^{159,161} Yet, children may develop adverse events more than 12 months after treatment onset.

Agranulocytosis is a potential serious ATD adverse event and occurs in 0.3% of adults taking PTU or MMI.^{138,160} The agranulocytosis risk is dose dependent and is rare.^{137,162} If an individual receiving MMI feels ill, becomes febrile, or develops pharyngitis, MMI should be stopped immediately, a practitioner contacted, and a complete blood cell count obtained.

Note that in the MMI-only era that we are now in, reports of MMI-associated agranulocytosis have recently been published.¹⁶³ Similar to the monitoring of adverse events associated with PTU, it is important that adverse events related to MMI be monitored and brought to the attention of the US Food and Drug Administration by practitioners via the MedWatch program (<https://www.fda.gov/Safety/MedWatch/>).

Antithyroid Drug Therapy Duration and Prediction of Remission

Based on considerable evidence,^{132,134,146,164–168} prolonged ATD therapy will not result in an increased chance of remission for most children, whereas in a minority of children it may. As such, with the initial evaluation of a child with GD, practitioners should attempt to stratify children into two groups: children with a 30% to 40% chance of remission with prolonged ATD therapy, and children with a slim chance of spontaneous remission.

Data shows that one can distinguish patients with a greater likelihood of remission from those with a much lower chance, following prolonged ATD therapy. The chance of remission after years of ATDs will be low if the thyroid gland is large (>2 times normal size for age), the child is young (<12 years), not Caucasian, serum TRAB/TSI levels are elevated, or the patient presents with profound hyperthyroidism at presentation ($FT_4 > 4$ ng/dL).^{113,169,170}

Prospective studies in adults show that if remission does not occur after 12 to 18 months of ATD therapy, it is unlikely remission will occur with prolonged therapy.¹⁶⁷ In the pediatric population, published data show that when ATDs are used for 1 to 2 years, remission rates are 15% to 30%, and possibly up to 40% in some children.^{113,146,151,166,167,170–172} Please note that remission is defined as being either euthyroid or hypothyroid for 1 year or more after cessation of therapy.

In adults, assessment of TRAB or TSI levels is useful in determining disease course and remission likelihood.^{169,173} This issue has been less studied in children. Consistent with the notion that GD will remit in only a small proportion of children, TRAB levels normalize after 24 months in only 18% of pediatric patients on ATDs.¹⁶⁹ TRAB levels thus persist longer in children than in adults.¹⁷⁴ There are no data showing normalization of TRAB levels in pediatric patients on ATDs for longer.

For children with unfavorable risk factors for spontaneous remission at treatment onset, it is reasonable to treat children for up to 2 years with MMI and see if spontaneous remission occurs. At that point, if there is no remission, it is appropriate to move on to definitive therapy if desired by the family. Alternatively, treatment for longer periods can be considered, as long as side effects to medication do not occur. This approach may be especially useful if the child is considered too young for surgery or RAI. For the child with favorable risk factors for remission, if spontaneous remission has not occurred after the 2 years of ATDs, continuation of antithyroid medication for prolonged periods is also acceptable, yet one needs to be attentive to adverse effects.

Strategies for the Child With an Adverse Event to Methimazole

With MMI being the drug of choice for treatment, and the risk of hepatotoxicity being present with the use of PTU, practitioners may face a clinical dilemma of what to do when a patient taking MMI develops an adverse reaction. There are few published reports addressing this issue in children.

For children who develop allergic symptomatology, antihistamine medications may be attempted.¹⁷⁵ However, this approach is generally not effective.

If an individual develops neutropenia, agranulocytosis, or hepatotoxicity, the antithyroid medication must be discontinued immediately. Because the hyperthyroid state will resume quickly, and it is best not to treat patients with RAI or surgery, while profoundly hyperthyroid, therapy to control the hyperthyroid state, until definitive therapy must be initiated within days. If a patient will be treated with RAI, beta blockade should be initiated and treatment rendered within the week the ATD is stopped to prevent recurrence of profound hyperthyroidism. This approach requires a coordinated effort with nuclear medicine experts, as soon as the decision is made to discontinue the ATD.

If the individual is viewed as being too hyperthyroid for treatment with RAI, practitioners may consider the short-term use of PTU to control the hyperthyroid state, until the patient is viewed as stable enough for treatment with RAI. Because PTU may also be associated with agranulocytosis,^{176–178} if PTU is used, white blood counts need to be very closely followed.

If the plan is surgical intervention, iodine drops may be started immediately after MMI is discontinued and continued

for at least 2 weeks. This period will allow the hyperthyroid state to resolve and allow adequate time for surgical planning.

Radioactive Iodine Therapy

The goal for ^{131}I therapy for GD is to induce hypothyroidism. There are several important caveats related to the use of RAI in children. RAI should not be given to cause euthyroidism in children, as this results in partially irradiated residual thyroid tissue that may be associated with a higher risk of thyroid neoplasm than the normal population.^{179,180}

It has been suggested that dosages delivering 30,000 to 40,000 centigray (cGy) (rad) to the thyroid are necessary to ablate the thyroid gland.^{181,182} But, dosages delivering 10,000 to 20,000 cGy to the thyroid are more often used and result in partial or complete destruction of the thyroid.^{181–183} Typically, administered thyroid doses of 150 $\mu\text{Ci/g}$ (5.5 mega-Becquerel [MBq]/g) generate radiation doses of 12,000 cGy to the thyroid.¹⁸⁰

Dosing is based on the Quimby-Marinelli equation: Dose ($\beta + \gamma$ radiation; in Gy) = $90 \times [\text{oral } ^{131}\text{I} \text{ dose (microcurie } [\mu\text{Ci}]) \times \text{oral 24-hour uptake (\%)/g} \times 100\%]$. For example, if the desired dosage is 300 $\mu\text{Ci/g}$, and the thyroid is 30 g with an uptake of 75% (0.75), the desired administered dosage will be 12 mCi. (Dosage in mCi = $300 \mu\text{Ci/g} \times 30 \text{ g}/0.75 \text{ uptake} = 12,000 \mu\text{Ci}$ or 12 mCi).

Some centers give a fixed administered dosage of 10 or 15 mCi ^{131}I to all children,¹⁸¹ rather than individually calculated administered activation. There are no studies comparing outcomes of fixed doses versus calculated doses in children. In adults, the two different approaches lead to similar outcomes;^{180,182} however, in children, a potential advantage of calculated versus fixed dosing, is that it is possible to use lower dosages of ^{131}I if the administered dose is calculated.

When children are to be treated with ^{131}I , ATDs should be stopped 3 to 5 days before treatment.¹⁸¹ Patients are placed on beta-blockers until T4 and/or FT4 levels normalize posttherapy. Whereas some clinicians restart ATDs after treatment with ^{131}I , this is rarely required in children.^{181–184} Thyroid hormone levels begin to decrease about 7 days after radioiodine therapy in children. Continued ATD use can make it difficult to assess if posttreatment hypothyroidism is the result of ^{131}I or the ATD.

Side effects of ^{131}I therapy are unusual. Less than 10% of children will complain of mild tenderness over the thyroid in the first week after ^{131}I therapy.^{184,185} This problem can be treated with either acetaminophen or nonsteroidal antiinflammatory agents for 24 to 48 hours.¹⁸⁶

There are rare reports of children with severe hyperthyroidism developing thyroid storm after ^{131}I .^{186,187} In general, these children were severely hyperthyroid when ^{131}I was rendered. Thus if T4 levels are over 20 mcg/dL or FT4 levels are greater than 5 ng/dL, children should be treated with MMI until T4 and/or free T4 levels normalize, before proceeding with ^{131}I therapy.^{183,188} Importantly, most children with GD have been hyperthyroid for months before diagnosis; there is no need to rush to ^{131}I therapy.

It usually takes 6 to 12 weeks after ^{131}I treatment for the patient to become biochemically euthyroid or hypothyroid. Until then, symptoms of hyperthyroidism can be controlled using beta-blockers.^{186,189,190} The use of potassium iodide or Lugol solution, 1 week after ^{131}I , will also quickly attenuate biochemical hyperthyroidism, without adversely affecting the outcome of radioiodine therapy.¹⁸⁵

Several studies have reported the details of ^{131}I therapy for childhood GD.^{191–194} Children as young as 1 years old have been treated with ^{131}I with excellent results.^{194,195} But, treatment of such young children is not common, nor is now recommended. ^{131}I dosages in children and teenagers have ranged

from 100 to 400 $\mu\text{Ci/g}$ of thyroid tissue.¹⁹⁶ Similar to that found in adults,^{197–199} responses to ^{131}I therapy are related to gland size and dose. Some 25% to 40% of children treated with 50 to 100 μCi of ^{131}I per gram of thyroid tissue are hyperthyroid several years after therapy.²⁰⁰ In children treated with 150 to 200 μCi of ^{131}I per gram of thyroid, hyperthyroidism remains in 5% to 20%, and 60% to 90% become hypothyroid.^{201–203}

The development of progression of ophthalmopathy following ^{131}I in adults has been reported.^{204–206} However, children rarely develop severe ophthalmopathy and proptosis is mild.^{146,207} Studies show that eye disease worsens in only a small percentage of children with GD, irrespective of therapy type.^{208,209}

In adults, it has been shown that progression of ophthalmopathy can be prevented by treatment with prednisone for 3 months following ^{131}I therapy.^{206,207} Adjunctive prednisone therapy is not routinely recommended for the majority of children, as most do not have significant eye disease. The prolonged administration of prednisone is also associated with growth failure, weight gain, and immune suppression. Nevertheless, prednisone (0.5 mg/kg \times 4–6 weeks) may be useful for the child who has moderate or severe eye disease and will be treated with ^{131}I .

Risks of Radioactive Iodine in Children Treated for Graves Disease

There is no evidence showing adverse effects to offspring of children treated with ^{131}I . Birth defects are not higher in offspring born to individuals treated with ^{131}I for hyperthyroidism during childhood or adolescence.¹⁴⁶ In addition, the rates of birth defects are not higher in children treated with 80 to 700 mCi of ^{131}I for thyroid cancer, which are dosages that are much higher than those used for GD.²¹⁰

The thyroid gland is unique in its developmental sensitivity to malignancy after low-level radiation exposure.^{113,169,170,174} There is an increased risk of thyroid cancer in individuals less than 20 years of age at the time of low-level thyroid irradiation.^{113,170,174} In contrast, individuals who are older than 20 years of age do not exhibit an increased risk of thyroid cancer when exposed to low-level thyroid irradiation.^{113,169,170,174}

The risk of thyroid neoplasms in children is greatest with exposure to low-level external radiation (0.1–25 Gy; \sim 0.09–30 $\mu\text{Ci/g}$),^{113,169,170,173,174} and not with the higher dosages used to treat GD. At present, we are not aware of any cases of thyroid cancer that developed in pediatric patients treated with more than 150 μCi of ^{131}I per gram of thyroid tissue for childhood GD that can be attributed to ^{131}I therapy.

Important in considering RAI use in children, is the potential influences of ^{131}I therapy on other cancers, as ^{131}I therapy results in low-level, whole-body radiation exposure. Several studies in adults have examined potential risks of ^{131}I therapy for GD on cancers. These studies have not revealed increased mortality or increased rates of cancer following ^{131}I for GD.^{211–217}

In comparison with studies in adults, few studies have focused on outcomes of ^{131}I therapy for childhood GD. The most extensive study of pediatric patients involved 36-year outcomes of patients who were less than 20 years old when treated with ^{131}I therapy for GD.¹⁶⁴ There was no evidence for increase cancer risk in this population. Yet, this sample size was modest.

The total-body radiation dose after ^{131}I varies with age, and the same absolute dose of ^{131}I will result in more radiation exposure in a young child than in an adolescent or adult.^{218,219} Currently, we do not have dosimetry data on ^{131}I use in pediatric patients with GD to assess total-body exposure in pediatric patients. Based on phantom modeling, it is estimated that at 0, 1, 5, 10, 15 years, and adulthood, respective total-body

radiation doses will be 11.1, 4.6, 2.4, 1.45, 0.90, and 0.85 Roentgen equivalent man (rem) (0.01 Sievert [Sv]) per millicurie of ^{131}I administered.^{218,219} Based on the Biologic Effects of Ionizing Radiation Committee V (BEIR VII) analysis of low-level, acute exposure to radiation,²²⁰ theoretical lifetime attributable risk of cancer mortality and all cancer incidence can be projected. Based on these theoretical calculations, we feel that it is prudent to avoid RAI therapy in children under 5 years of age and to avoid more than 10 mCi in patients less than 10 years old.

Thyroidectomy and Risks

Surgery is an effective form of therapy for GD if an expert surgeon can perform it, and in some situations it is preferable to RAI. When surgery is performed, near-total or total thyroidectomy is indicated, as subtotal thyroidectomy is associated with a higher relapse rate.²²¹ Hypothyroidism is nearly universal in children and adults who undergo total thyroidectomy.^{221–224} In comparison, after subtotal thyroidectomy, hyperthyroidism recurs in 10% to 15% of patients.^{221–223}

Surgery is preferred in children younger than 5 years when definitive therapy is needed and can be performed by a skilled thyroid surgeon. In individuals who have large thyroid glands (>80 g), the response to ^{131}I is poor,^{225,226} and surgery is recommended for these patients.

In preparation for surgery, the patient should be rendered euthyroid. Typically, this is done by continuing MMI until T4 levels normalize. A week before surgery, iodine drops are started (1–3 drops, three times per day), which inhibits thyroid hormone production and causes the gland to become firm and less vascular.²²⁷

Postoperatively, younger pediatric patients are at a higher risk for transient hypoparathyroidism than adolescents or adults.²²⁸ To mitigate postoperative hypocalcemia, we treat children with 0.5 mcg of calcitriol, twice a day, for 3 days before surgery. Postoperatively, the calcitriol is weaned over 15 days (0.5 mcg twice a day \times 5 days; 0.5 mcg every day \times 5 days; 0.5 mcg every other day \times 5 days).²²⁹ Using this approach, only 5% of patients require postoperative calcium infusions versus 40% of patients without preoperative treatment.²²⁹

Acute complications that follow thyroidectomy include hemorrhage, hypocalcemia, and recurrent laryngeal nerve paresis.^{228,230–233} In children, rates from 0 to 6 years were 22%; from 7 to 12 years, 11%; and from 13 to 17 years, 11%.²²⁸ These rates are higher than those observed in adults.

Complication rates are related to the expertise of the surgeon.²²⁹ Considering these data, if local pediatric thyroid surgery expertise is unavailable, referral of a child with GD to a high-volume, thyroid surgery center with pediatric experience should be considered.^{234,235} Very low complication rates for children undergoing the thyroidectomies for GD have been reported with this type of multidisciplinary model.^{229,234}

Following our model,²²⁹ there is the recent trend in the development of pediatric thyroid centers across the United States. These centers often have experts in pediatric thyroid surgery.

Somatic Complications of Graves Disease

In addition to focusing on the thyroid-related aspects of GD, somatic considerations are important as well. Individuals with GD have an increased basal metabolic rate and increased caloric needs. This may result in altered dietary patterns, resulting in increased caloric intake. After correction of the hyperthyroid state, it is recognized that body mass index will increase, which can be dramatic in some individuals.^{135,236} As such, anticipatory guidance and monitoring of body weight after implementation of antithyroid therapy is important.

GD is also associated with increased bone turnover, which can lead to osteopenia in affected individuals.^{237,238} GD has thus been associated with an increased fracture risk.

Thyrotoxicosis can trigger thyrotoxic periodic paralysis,²³⁹ which is a life-threatening condition associated with profound hypokalemia. This condition is most frequently observed in Asian men and is associated with hypokalemia, which affects the lower extremities and is secondary to thyrotoxicosis. The condition results from an intracellular shift of potassium induced by the thyroid hormone sensitization of Na^+/K^+ -adenosine triphosphatase and is associated with mutations of the inwardly rectifying potassium channel Kir2.6.^{239–241}

Another potential concern related to the resolution of GD is the development of acute myopathy.²⁴² This has been sporadically reported in children following correction of the hyperthyroid state, resulting in large increases in circulating muscle enzymes as hyperthyroid state transitions to hypothyroidism.²⁴² Following treatment, individuals presenting with muscle cramps should be evaluated for this possibility through the monitoring of creatine phosphokinase levels.

Autoimmune thyroiditis may be associated with other autoimmune diseases, including diabetes mellitus, adrenal insufficiency, vitiligo, and hypoparathyroidism.²⁴³ Autoimmune thyroiditis is also seen in patients with inflammatory bowel disease and juvenile arthritis.^{63,64} Annual surveillance of thyroid gland size and TSH levels should thus be considered for children with other autoimmune problems, and clinicians should be vigilant for signs of hyperthyroidism or hypothyroidism. Conversely, children with autoimmune thyroiditis should be observed for signs of diabetes mellitus and Addison disease.

The incidence of celiac disease in the setting of autoimmune thyroiditis is about 1%.⁶⁵ If patients manifest abdominal discomfort, weight loss, or gastrointestinal symptoms, Celiac disease screening should be performed, but it does not need to be done routinely in children with thyroid disease. We have found a 1% incidence of autoimmune liver disease in children with autoimmune thyroid disease. Because such liver disease can be occult, we annually assess circulating transaminase levels, and if levels are elevated, evaluation of possible liver disease is initiated.

Several groups of children are at risk for autoimmune thyroiditis and GD. Because girls with Turner syndrome are predisposed to autoimmune thyroiditis,⁶⁶ TSH levels should be assessed annually. Turner syndrome should also be considered in girls with hypothyroidism, especially if the child is prepubertal at presentation.^{67,68} Children with Down syndrome also warrant annual screening for thyroid dysfunction.^{69,70}

NEONATAL THYROTOXICOSIS

Thyrotoxicosis in the neonate is a severe and life-threatening condition that can be associated with lasting neurologic problems.^{186,244,245} Neonatal thyrotoxicosis most commonly occurs in the setting of active or past maternal GD. If a mother has GD, the chance is 1 in 80 that TRAbs will be transferred to the fetus, resulting in intrauterine or neonatal hyperthyroidism.¹⁸⁴ Rarely neonatal thyrotoxicosis will persist, like the GD disease seen in older children.¹⁸⁶ In other rare cases, persistent neonatal thyrotoxicosis is caused by activation of the TSH receptor.^{246,247}

The fetal thyroid gland is responsive to maternal TRAbs, which, if present at elevated levels, may result in hyperthyroidism.^{180–182,207} Fetal hyperthyroidism manifests during the second half of gestation, as transfer of TRAbs from the mother to the fetus increases with progression of pregnancy.^{180–182}

The risk of fetal hyperthyroidism and neonatal GD is proportional to the magnitude of elevation of TRAb levels.^{180–182,245} Fetal hyperthyroidism is generally associated with levels of

TRABs more than 2- to 4-fold greater than the upper limit of normal for assay.^{180–182} Because the fetus is at risk for hyperthyroidism when there is active or past maternal GD, fetal growth and heart rate should be regularly assessed from mid-pregnancy onward.^{180–182} Excessive fetal heart rate (>160 beats per minute after 20 weeks) and the presence of a fetal goiter suggest hyperthyroidism in the fetus. In addition, accelerated maturation of the femoral ossification center is seen with fetal hyperthyroidism.¹⁸¹

If a mother with GD is taking antithyroid medications during pregnancy, fetal thyroid hormone synthesis will be inhibited, which will prevent the development of intrauterine hyperthyroidism.¹⁸³ However, the infant may be born with a goiter and hypothyroidism.¹⁶⁵ At birth, circulating levels of T4 may be low and TSH levels elevated. In most cases, the effects of ATDs wane, and thyroid function normalizes within a week.¹⁸⁴ If significant transplacental passage of TRABs has occurred, however, thyrotoxicosis will develop.^{184,185}

If a mother with a history of GD is not taking ATDs during pregnancy, the fetus may develop intrauterine hyperthyroidism.¹⁸⁶ If the condition is not recognized, it may result in profound intrauterine thyrotoxicosis and growth retardation.¹⁸⁶ Such infants have prematurely fused cranial sutures, advanced skeletal age, long-term learning problems, and mental retardation.^{186,188} If fetal hyperthyroidism is recognized prenatally by the presence of fetal tachycardia (heart rate >160 beats per minute after 22 weeks), treatment of the mother with ATDs will reduce intrauterine thyrotoxicosis.^{183,189,190}

Treatment of thyrotoxic infants consists of administration of MMI (1.25 mg per day) and beta-blockers (propranolol 1 mg per kg per day). Lugol solution or saturated potassium iodide may be given (1–2 drops every 8 hours) for 7 to 10 days to more rapidly control biochemical hyperthyroidism. After approximately 2 weeks of ATD therapy, thyroid hormone levels will decline. When thyroid hormone levels fall below normal, supplementary levothyroxine (37.5 mcg/day for full-term infants) is added to prevent hypothyroidism. As TRABs are cleared from the infant's circulation, spontaneous recovery begins within 3 months and is usually complete by 6 months.^{185,186} Thus the infant can be weaned from treatment after 3 months. Monitoring of the infant's TRAB levels is also a useful predictor of when antithyroid medication can be tapered.^{191,192}

OTHER CAUSES OF HYPERTHYROIDISM

Activating Mutations of the Thyroid-Stimulating Hormone Receptor

Several mutations of the TSH receptor have been reported that resulted in ligand-independent receptor activation and hyperthyroidism.^{248,249} Affected individuals present with hyperthyroidism in the neonatal period with potential serious adverse effects on the child including advanced skeletal maturation and craniosynostosis, impaired growth, and neurologic impairment.^{248,249} This diagnosis should be considered in the young child presenting with hyperthyroidism and bone age advancement, in the absence of TSI elevation. The hyperthyroid state may be controlled with ATDs, yet, either RAI if surgery is needed. Because hyperthyroidism in the neonatal and early childhood can be associated with abnormal growth and maturation and neurologic abnormalities, it is essential that the hyperthyroid state be exquisitely controlled in young children.

McCune–Albright Syndrome

McCune–Albright syndrome is an inherited disorder characterized by spontaneous activation of the G protein alpha

subunit.^{250–252} Because the TSH receptor is G protein-coupled, somatic rotations of the G protein alpha subunit within the thyroid gland may result in hyperthyroidism. Children with McCune–Albright syndrome may be recognized with a distinctive pattern of café au lait spots with a ragged border, and/or history of polyostotic or monostotic fibrous dysplasia. Because there is clonal activation in the thyroid gland, which results in areas of increased thyroid proliferation and activity, and other regions that will not be affected, similar to the treatment of isolated hyperfunctioning thyroid nodules, definitive treatment by surgery is recommended.

Thyroid-Stimulating Hormone Producing Adenomas

Thyrotropinomas are rare in adults and exceedingly rare in children.²⁵³ Such tumors are typically macroadenomas presenting with the signs of hyperthyroidism and occasional central nervous system symptoms that may include visual field loss and headaches. Such individuals will have elevated levels of circulating thyroid hormones, but without a suppressed TSH.

Transsphenoidal surgery is the preferred treatment and adjunctive radiotherapy may be needed. In adults, successful treatment with octreotide has been reported.²⁵³ It is important to distinguish this condition from isolated central thyroid hormone resistance, which can present with similar biochemical features. Distinguishing features include the presence of a pituitary mass with TSH-producing tumors, the lack of response to TRH stimulation, and elevated levels of the α -glycoprotein subunit, in pituitary adenomas.²⁵³

Infectious Bacterial Thyroiditis

Occasionally, a child presents with hyperthyroidism, tenderness over the thyroid gland, and fever caused by bacterial infection of the thyroid, a condition called acute thyroiditis.¹⁹³ Acute thyroiditis can be associated with the presence of a fistula connecting the piriform sinus on the left side of the pharynx to the thyroid.¹⁹³ Fevers can be high, and erythrocyte sedimentation rates and white counts elevated. Ultrasonography may reveal a local abscess. In contrast to GD, uptake of technetium 99-pertechnetate or radioiodine is reduced when thyroid scanning is performed.

The offending bacteria include *Haemophilus influenzae* and group A streptococci.¹⁹³ Thus treatment with an antibiotic resistant to disruption by β -lactamase is recommended. In severe cases, hospitalization and intravenous antibiotic administration is indicated, because lymphatic drainage into the mediastinal region may occur. Surgical drainage is needed if a localized abscess develops and the response to antibiotics is poor.¹⁹³

Because the infectious process results in destruction of thyroid tissue, release of preformed thyroid hormone and hyperthyroidism may occur during infection. The hyperthyroid state is usually transient, and treatment with ATDs is not indicated.¹⁹³ If the patient becomes symptomatic, beta-blockers may be used.

After the child has recovered, pharyngography is indicated to test for a patent piriform sinus tract. Occasionally, the tract may close as the result of the infection. If the tract persists, however, and acute thyroiditis recurs, resection is needed.

Subacute Thyroiditis

Viral infections of the thyroid may occur and result in subacute thyroiditis.¹⁹⁴ In comparison with acute thyroiditis, subacute thyroiditis may be less severe.^{194,195} Fever, thyroid tenderness, and hyperthyroidism may be present and may last for several weeks.¹⁹⁶ Because clinically distinguishing between bacterial

and viral thyroid infections is difficult, antibiotic treatment is indicated when infectious thyroiditis is suspected.

Hyperfunctioning Nodules

Warm or hot nodules lead to excessive production of thyroid hormone and can be associated with clinical and biochemical hyperthyroidism.¹⁹⁷ Interestingly, activating mutations of the TSH receptor and G_s have been discovered in hyperfunctioning nodules.^{198,199} Although hyperfunctioning nodules may be ablated with radioiodine, surgical excision of hyperfunctioning nodules is recommended in children and adolescents, because radiation-exposed normal thyroid tissue will remain after the hyperfunctioning nodule is ablated. Although the risk of malignancy in hyperfunctioning nodules is low, thyroid cancers have been described in warm nodules.^{200,201}

Toxic Multinodular Goiters

Multinodular goiters are uncommon in children, but patients with this condition can develop thyrotoxicosis, which is usually related to the time the goiter has been present and goiter size. In this setting, hyperthyroidism develops when a single nodule in the thyroid becomes overly active, and functions autonomously.^{202,203} Some 46% of patients may have T3 thyrotoxicosis, and nodules are 3 cm or more in diameter.^{202,203}

In adults, ^{131}I is routinely used in the treatment of isolated toxic adenomas and toxic multinodular goiters.^{202,203} The use of radioiodine to treat these conditions in children is uncommon, and few follow-up data are available. Although strong justification exists for the use of radioiodine in the treatment of childhood GD, especially when appropriate doses are used, we recommend that radioiodine be avoided in children with toxic adenomas or multinodular goiters. When a toxic nodule is present, either as an isolated nodule or in the setting of a multinodular goiter, thyroid function is suppressed in the nontoxic regions. When radioiodine is given, uptake will be limited to the autonomously functioning tissue, and if large doses are administered, the remaining thyroid tissue will receive external irradiation. Because the risk of thyroid cancer following external radiation is very low after 20 years of age,^{254,255} the use of radioiodine for toxic nodule ablation in adults is not associated with increased thyroid cancer risks. In the child or adolescent treated with ^{131}I for toxic nodules, however, low-level irradiation to the remaining thyroid tissue will occur with an increased thyroid cancer risk.

Amiodarone

Amiodarone is a class III antiarrhythmic medication that is associated with both hyper- and hypothyroidism caused by amiodarone's high iodine content and direct toxic effect on the thyroid.^{95,96,256,257} Two types of amiodarone-induced thyrotoxicosis (AIT) have been described. In type I AIT, excess iodine results in enhanced thyroid hormone production.^{95,96,256,257} Type II AIT, is more common than type I and is a destructive thyroiditis that results in direct toxic effect of amiodarone on thyroid follicular epithelial cells in excess release of T4 and T3, without increased hormone synthesis. The treatment of this condition involves glucocorticoids.^{95,96,256,257}

Excessive Iodine Intake

Iodine is a micronutrient and typical intake is 150 mg/day for adults.⁸⁷ In general, excessive iodine intake does not result in thyroid disease. However, in some individuals with iodine deficiency who are predisposed to getting GD, excess iodine can trigger hyperthyroidism, a condition referred to as the *Jod-Basedow effect*.⁸⁷

THYROID NODULES AND THYROID CANCER

Background

Thyroid nodules in children and adolescents are less common when compared with adults; however, the risk of malignancy for a nodule diagnosed in a pediatric patient is approximately twofold higher.^{258,259} Over the past 2 decades, there has been a 2% to 4% per year increase in the number of patients diagnosed with thyroid nodules and differentiated thyroid cancer (DTC), with the largest increase noted in females between 15 and 19 years of age, where thyroid cancer accounts for 8% of all cancers.^{260,261} Similar to adults, over 85% of pediatric thyroid cancers are papillary thyroid cancer (PTC), with the remainder divided between follicular thyroid carcinoma (FTC) and medullary thyroid cancer (MTC), the latter most commonly associated with multiple endocrine neoplasia type 2 (MEN2).²⁶⁰

Thyroid nodules may be detected by physical examination or by incidental discovery during unrelated head and neck radiologic imaging. When a thyroid nodule is detected, serum TSH and a thyroid and neck ultrasound (US) should be obtained to determine the best plan for management.²⁶² If the TSH is suppressed, a radionuclide scan may be performed to identify a hyperfunctioning nodule, a lesion associated with a lower risk for malignancy.²⁶³ Serum calcitonin levels are not routinely assessed; however, calcitonin immunohistochemistry or a calcitonin washout from the fine needle aspiration (FNA) needle should be considered based on a family history of MEN2, physical examination concerns for MEN2B, or cytologic findings consistent with MTC.^{264,265}

Evaluation of a Thyroid Nodule

US is the most efficient and accurate method for determining if a thyroid nodule may be surveilled or should undergo further evaluation with FNA. US characteristics of nodules that should be assessed, included in the radiology report, and used to stratify nodules for FNA per the Thyroid Imaging and Reporting Data System (TI-RADS) include composition (cystic, spongiform, mixed or solid), echogenicity, (anechoic, hyperechoic, isoechoic, or hypoechoic), shape on transverse imaging (taller than wide or wider than tall), margin (smooth, ill-defined, lobulated, or with extrathyroidal extension), and echogenic foci (none, comet-tail, macrocalcifications, rim calcifications, or punctate calcifications) (Fig. 13.5).²⁶⁶ Cystic or mixed composition, with a greater than 75% cystic component, is the single, most reliable feature associated with a lower risk of malignancy.^{258,267} Features associated with a higher risk of malignancy include solid composition, hypoechogenicity, taller than wide shape on transverse imaging, lobulated or irregular margin, and punctate echogenic foci.²⁶⁸ US assessment of the lateral neck must be performed on all patients found to have an indeterminate or suspicious thyroid nodule to determine if there is lymphadenopathy concerning thyroid cancer metastasis. US features that are most predictive of an abnormal lymph node include rounded shape, punctate echogenic foci, and the presence of peripheral vascularity.²⁶⁹ Size is generally not a predictive feature for malignancy, and lymph nodes in the upper neck (level II) are typically larger than lymph nodes in the lower (levels III and IV) or posterior (level V) regions of the neck (see Fig. 13.6).

For many nodules, the US appearance alone cannot reliably distinguish between a benign and a malignant lesion.²⁷⁰ Thus FNA is indicated for children with indeterminate or suspicious thyroid nodules in an effort to determine if surgery is warranted, as well as to plan for the extent of surgery.²⁶² FNA is the most accurate means to evaluate if a thyroid nodule is malignant. Reports of FNAs performed in children describe

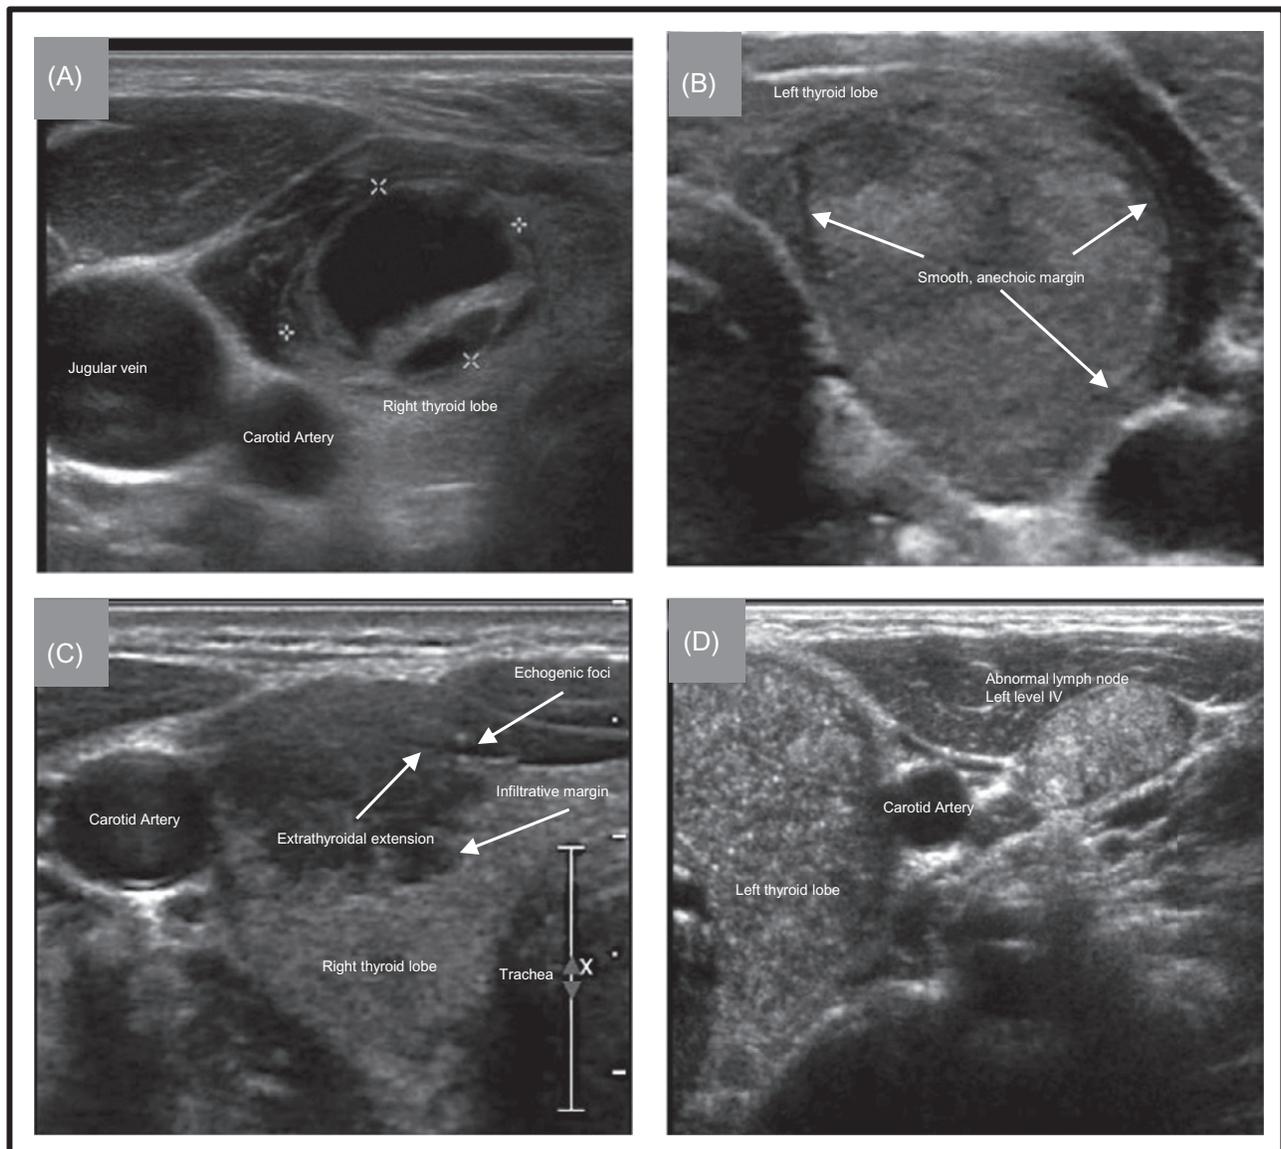

Fig. 13.5 Representative images of thyroid nodules depicting different features used in the Thyroid Imaging Reporting and Data System (TI-RADS). (A) Complex, mixed solid-cystic nodule (>80% cystic), solid portion is isoechoic with smooth margins, no echogenic foci, with small solid not taller than wide, smooth margins, and no echogenic foci (TI-RADS 2). (B) Solid, iso- (larger, posterior portion) and slightly hypoechoic (smaller, anterior area) nodule, not taller than wide, with smooth margins, and no echogenic foci (TI-RADS 3). (C) Solid, very hypoechoic, not taller than wide, lobulated, invasive margins with evidence of extrathyroidal extension (arrows), and several echogenic foci (TI-RADS 5). (D) Solid, hypoechoic, diffusely invasive lesion with too numerous to count echogenic foci (TI-RADS 5). An abnormal lymph node is noted in lateral neck with similar ultrasound features to the primary tumor.

similar specificity and sensitivity as adults, with a metaanalysis reporting sensitivity and specificity of 94% and 81%, respectively, and accuracy, positive, and negative predictive values of 84%, 55%, and 98%, respectively, assuming a 20% risk of malignancy.²⁷¹ Difficulty arises when the FNA cytology is “indeterminate,” as malignancy can be present up to 40% of nodules characterized by The Bethesda System for Reporting Thyroid Cytopathology (TBSRTC).^{272,273} The addition of oncogene testing may be of value with the presence of a known thyroid oncogene driver mutation associated with an increased risk of malignancy (see “Molecular Landscape” later).²⁷⁴ Alternative options for nodules with an indeterminate category III TBSRTC classification (“follicular lesion of undetermined significance” or “atypia of undetermined significance”) are to perform a diagnostic lobectomy or to consider repeat FNA within 3 to 6 months. For patients with a nodule having

indeterminate TBSRTC category IV classification (“follicular neoplasm” or “suspicious of a follicular neoplasm”), a diagnostic lobectomy should be performed (see Fig. 13.6). In adults, recent recommendations suggest that FNA be performed only when nodule diameter is or exceeds 1.5 cm.^{275,276} There are no data to stratify FNA based on size in pediatric patients. Clinical judgment based on predisposing risks of malignancy and US appearance of the nodule, and cervical lymph nodes should be considered before performing FNA on a nodule smaller than 1 cm in size.

Differentiated Thyroid Cancer

Over the last 2 decades, there has been an increasing number of children and adults diagnosed with thyroid cancer.²⁶¹ Within pediatrics, the greatest increase in the incidence of diagnosis

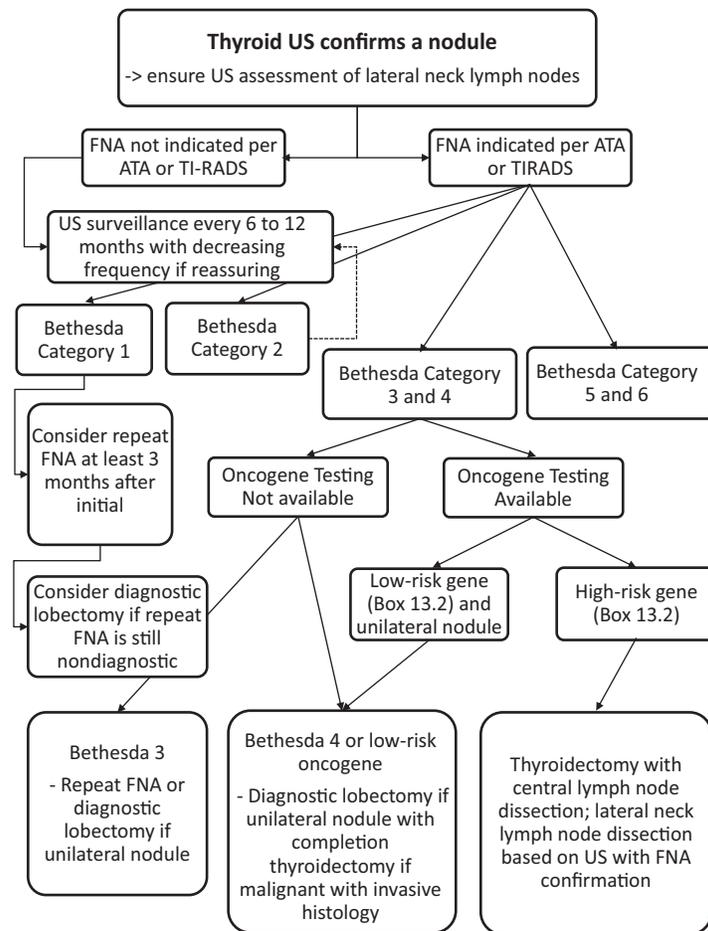

Fig. 13.6 Algorithm for the initial evaluation and management of sporadic thyroid nodules in children and adolescents. For patients with a thyroid nodule associated with autoimmune thyroid disease, postradiation exposure, or with a thyroid cancer predisposition syndrome, thyroidectomy may be preferable over lobectomy. ATA, American Thyroid Association; FNA, fine-needle aspiration; TI-RADS, Thyroid Imaging, Reporting and Data System; US, ultrasound.

is in adolescent girls and, similar to adults, the majority of tumors are PTC.^{260,261} In the most recent update from the National Cancer Institute Surveillance Epidemiology and End Results (SEER) database, PTC accounted for 58.8%, follicular-variant of PTC 23%, FTC 10.1%, and MTC 8.1%, with the predominance of MTC diagnosed in patients younger than 10 years of age associated with MEN2.²⁶⁰

Compared with adults, children with DTC present with more extensive disease at the time of diagnosis. Cervical neck lymph node involvement at diagnosis is seen in 50% to 90% of children,²⁷⁷ compared with 20% to 50% of adults.²⁷⁸ The prevalence of distant metastases, most commonly lung, is 6% to 8% in children versus 2% to 3% in adults, with an increased risk of 10% to 20% for pediatric patients with lateral neck (levels II, III, and IV) lymph node metastasis.^{262,279–281} Multifocal disease is more common in children than adults and is seen in about 40% of childhood PTC cases.²⁶² There are several reports that PTC in children less than 10 years of age at the time of diagnosis have an increased rate of regional and distant metastasis, a higher risk for recurrence, and increased disease-specific mortality when compared with adolescents and adults.^{282–284} However, other investigators report that DTC has similar clinical behavior when comparing younger children to adolescents.²⁸⁵

Fortunately, even in the presence of metastatic disease, long-term follow-up data show 30-year survival rates of 90% to 99% for children with DTC (see Fig. 13.2).^{261,286–290} Even with distant metastases, mortality rates are more favorable in children than adults,²⁹¹ and pulmonary metastases can remain stable over years to decades of time.^{292,293} The favorable prognosis reflects the fact that most young patients have well-differentiated tumors that maintain expression of the sodium-iodine symporter and an indolent pattern of growth.

Etiology of Differentiated Thyroid Cancer

For the majority of children, a specific risk factor for the development of DTC cannot be identified. However, several factors increase the risk of developing DTC. Exposure to low-level head and neck irradiation has been recognized for more than 6 decades as predisposing to thyroid nodules and DTC.^{294,295} Low-level radiation doses to the thyroid of less than 30 Gy (3000 cGy or rad) increase the risk for developing cancer, with the risk being higher at progressively younger ages.^{169,173,174} Above 20 years of age, the risk of thyroid cancer following low-level irradiation is either very low or undetectable.^{169,174} The latency period between the time of radiation

exposure and DTC onset in children is typically 10 to 20 years; however, thyroid cancer may develop within 5 to 10 years in patients exposed to radiation at a young age (<5–10 years of age).^{169,174,295,296} Ingestion of ionizing radiation also increases the risk for developing thyroid disease, including DTC. This may occur during medical treatment of radiosensitive tumors, such as neuroblastoma where ¹³¹I-labeled metaiodobenzylguanidine (MIBG) is commonly one of several agents used for therapy,²⁹⁷ or via accidental ingestion, as occurred after the 1981 Chernobyl nuclear accident.^{297–299} Recent guidelines suggest that either physical examination or US may be used to surveil patients at risk for developing radiation-induced thyroid cancer, with US having greater sensitivity for detection of earlier disease.^{300,301}

Thyroid cancer in children can also be observed in families, associated with an increased risk for developing DTC as a single tumor type or as one of several tumors associated with a tumor-predisposition syndrome. Familial nonmedullary differentiated thyroid cancer (FNMTc) is an inherited predisposition to developing DTC without an increased risk for developing other tumor types. Under the most strict criteria, FNMTc is diagnosed when three or more individuals in the family have DTC³⁰²; however, even in families with two or more first-degree relatives with DTC, there is a 8- to 10-fold increased risk of developing either PTC or FTC.³⁰³ Similar to sporadic DTC, 85% of FNMTc is comprised of patients with PTC. The transmission pattern is most consistent with an autosomal dominant mode of inheritance; however, to date, a single germline locus has not been identified.^{303,304} When FNMTc is present, it is recommended that thyroid ultrasonography be performed every year or 2, beginning at 8 years as part of tumor surveillance. DTC in children with FNMTc has been identified as early as 8 years of age and FNMTc displays “genetic anticipation,” with the age of cancer occurrence generally younger in the second and subsequent generations.^{304–307}

There are several familial tumor predisposition syndromes that have DTC as one of several different tumors that may develop in an affected person over their lifetime. These syndromes mostly follow an autosomal dominant pattern of inheritance, where there is a 50% risk of transmission of the germline mutation to offspring; however, de novo mutations may also occur in a child and be the index case for the family. Phosphatase and tensin homolog (PTEN) hamartoma tumor syndrome, previously known as Cowden syndrome, is caused by mutation in the *PTEN* gene and is associated with macrocephaly, hamartomas of mucosal surfaces (oral), gastrointestinal polyps, breast cancer (women only), endometrial cancer, colorectal cancer, renal cell carcinoma, and DTC.³⁰⁸ There is enrichment in the incidence of FTC in patients with PTEN hamartoma tumor syndrome (PHTS); however, patients may have nodules with mixed histological diagnosis and PTC is still more common than FTC.³⁰⁸ Thyroid nodules are ultimately diagnosed in more than 75%, with approximately 35% developing DTC as early as 8 years of age.^{308,309} Familial adenomatous polyposis, or Gardner syndrome, is caused by mutations of the adenomatous polyposis coli (*APC*) gene and is associated with hypertrophy of the retinal pigment epithelium (CHRPE), a propensity to develop hundreds to thousands of intestinal polyps with malignant transformation to small bowel and colorectal carcinoma, hepatoblastoma, dental and cutaneous abnormalities, and a 10% to 15% risk of developing DTC.³¹⁰ DICER1 syndrome is caused by a mutation in the *DICER1* gene and is associated with an increased risk of developing pleuropulmonary blastoma (birth to 5-years of age), Sertoli-Leydig cell tumors, cystic nephroma, botryoid embryonal rhabdomyosarcoma, several additional rare-tumors of the eye and nose, as well as multinodular goiter, and DTC.³¹¹ Carney complex is

one of the lentiginosis syndromes caused by mutations in the *PRKAR1A* gene.³¹² Carney complex is associated with an increased risk of developing nerve sheath tumors (schwannomas), myxomas, primary pigmented nodular adrenocortical disease (hypercortisolism), pituitary tumors (growth hormone secreting), and large-cell calcifying Sertoli-cell tumors of the testes, with about 50% developing thyroid nodules and less than 5% developing DTC.^{313,314} Updated reviews for familial tumor predisposition syndromes can be found at the National Institute of Health GeneReviews® website (<https://www.ncbi.nlm.nih.gov/books/NBK1116/>).

Molecular Landscape

Alterations in the oncogenes (mutations and fusions) that drive tumorigenesis in DTC and MTC are similar between pediatric and adult patients.²⁷⁴ However, because of the observed differences in clinical behavior of these tumors, most importantly, maintenance of cellular differentiation, there are likely differences in gene expression, as well as downstream signaling pathways between pediatric and adult DTC. The consequences of these differences are reflected by lower disease specific mortality for pediatric patients with regional and distant metastasis when compared with adults with similar disease burden.^{262,275}

In DTC, thyroid tumorigenesis and progression are associated with somatic point mutations in the *BRAF* and *RAS* genes, as well as fusions involving the rearranged during transfection (*RET*), *TRK*, and *ALK* tyrosine kinases with resultant constitutive activation of the mitogen-activated protein kinase (MAPK) and phosphoinositide 3-kinase (PI3K) signaling pathways.²⁷⁴ These oncogene mutations are most commonly mutually exclusive events and there is a predictable relationship between oncogenic genotype and histopathologic phenotype, with the fusion oncogenes (*RET*, *TRK*, and *ALK*) and *BRAF* mutations almost exclusively found in PTC. *RAS* is commonly associated with FTC; however, it may be found across the spectrum of thyroid tumors, from benign follicular adenomas to follicular variant PTC, FTC, and poorly differentiated thyroid carcinoma.²⁷⁴ In addition to the potential utility of oncogene testing in the diagnosis of thyroid nodules with indeterminate cytology (TBSRTC category III and IV), the presence of *RET/PTC* and *TRK*-fusion genes may be helpful in predicting PTC with increased metastatic potential, although there are no data to suggest that these alterations are associated with increased disease-specific mortality.²⁷⁴

Surgical Management

Confirmation of an accurate and complete preoperative evaluation of pediatric patients with thyroid nodules and thyroid cancer is the first step in deciding on surgical options and optimizing the surgical plan.³¹⁵ Cervical US using a high-frequency linear transducer (12.0 MHz) should be performed to examine the thyroid, as well as the central (levels VI and VII) and lateral (levels II, III, IV and V) levels of the neck. More than 70% of children with PTC will have metastatic cervical lymph node disease that follows a consistent pattern of metastasis based on the lymphatic drainage of the thyroid.^{262,316} Lowering the transducer frequency to 8 to 10 MHz allows for improved imaging of deeper fields of view, including the paratracheal region and tracheoesophageal groove. In addition, lower frequencies may also help improve imaging for patients with excess soft tissue.³¹⁷ FNA of at least one suspicious lymph node per cervical level before surgery should be performed to determine the extent of lymph node dissection. For patients with extensive, lymph node involvement or signs/symptoms of vocal cord

paresis/paralysis (hoarseness, cough), dysphagia, or respiratory symptoms (stridor, dyspnea, hemoptysis), cross-sectional imaging of the neck and upper mediastinum with computed tomography (CT) or magnetic resonance imaging (MRI) may provide supplemental information, including the location of suspicious lymph nodes in areas where US has a lower sensitivity for detection (parapharyngeal, retropharyngeal, subclavicular, or upper mediastinum regions), as well as assessment of the aerodigestive tract.³¹⁷ There is no contraindication for using iodinated contrast for CT imaging of the neck or mediastinum before surgery as the majority of patients will achieve an adequate, low-urine iodine level (defined as a spot urine iodine/creatinine <66.2 µg/gCr) 1 month after exposure to iodinated contrast on a 1- to 2-week low-iodine diet.^{317,318}

The goal of surgery is to maintain the low disease-specific mortality in pediatric patients with DTC, while reducing potential complications from therapy.^{228,319} Access to a high-volume thyroid surgeon, defined as a surgeon completing >25 total thyroidectomies annually, is associated with a lower rate of complications.^{228,262,319–322} Although the exact number of surgeries performed annually may not reflect the quality of the surgeon, it increases the likelihood that the surgeon understands the disease process in children and adolescents in an effort to balance complete resection, while minimizing the risk of incomplete surgical resection, permanent hypoparathyroidism, and recurrent laryngeal nerve damage.

For the majority of patients with PTC, a total thyroidectomy, with prophylactic central compartment lymph node dissection, is recommended secondary to the increased incidence of bilateral/multifocal disease in pediatric PTC,³²³ the high incidence of regional lymph node metastasis, and the increased risk for recurrence and subsequent second surgery when less than a near-total thyroidectomy or total thyroidectomy is performed.^{285,324–326} Routine prophylactic lateral neck dissection is not recommended. Lateral neck dissection should be based on preoperative imaging with confirmation of metastasis by preoperative FNA.²⁶² Any patient who is undergoing a lateral neck dissection should also undergo a therapeutic, ipsilateral central neck lymph node dissection based on lymphatic drainage anatomy. Lymph node dissections should be compartment-based lymph node dissection rather than individual lymph node dissection ('berry picking'), in an effort to achieve surgical remission.²⁶²

Similar to adults, a portion of pediatric patients with DTC will have noninvasive disease that is limited to the thyroid where lobectomy may be adequate to achieve surgical remission. On preoperative USS, nodules that are isoechoic to hyperechoic with round to oval shape, smooth margins, and no echogenic foci, are more likely to be associated with noninvasive behavior.³²⁷ Thus even in pediatrics, lobectomy may be considered for patients with an isolated, unilateral thyroid nodule, with noninvasive features on US to avoid lifelong thyroid hormone replacement therapy. On review of the anatomic pathology, lobectomy with surveillance may be considered adequate, even for a select group of patients with follicular variant PTC and FTC, based on the absence of histological evidence of multifocality, lymphovascular invasion, and extrathyroidal extension, features that are associated with an increased risk of regional metastasis.^{328–332} Risk factors where lobectomy would be contraindicated include a history of exposure to ionizing radiation, a personal history of a thyroid tumor predisposition syndrome, or a history of autoimmune thyroiditis where there is an increased risk of developing additional nodules and DTC in the remaining lobe if lobectomy were performed. For patients with unifocal papillary microcarcinoma (<1 cm), and no evidence of lymph node metastasis on preoperative imaging, lobectomy with surveillance may also be adequate; however, there are no data to predict the risk of persistent or recurrent disease.

BOX 13.2 Somatic Driver Mutations in Pediatric Thyroid Nodules and Differentiated Thyroid Cancer With Risk of Invasive Behavior and Potential Application in Stratifying Surgical Management

Somatic Driver Mutation	Increased Risk of Invasive Behavior	Considerations for Surgical Care
BRAF V600E	Yes – N1a common	Total thyroidectomy with strong consideration for prophylactic central neck lymph node dissection; lateral neck dissection based on US and FNA
RET-PTC fusion	Yes – N1b common	
NTRK-fusion	Yes – limited data	
ALK-fusion	Yes – limited data	
BRAF-fusion		
RAS	Lower risk for invasive disease	Consider lobectomy if unilateral disease in a patient without thyroid cancer predisposition syndrome and reassuring US features (smooth margins/encapsulated and no abnormal lymph nodes)
PTEN	Rare cases of	
DICER1	DICER1 associated	
APC	with poorly differentiated thyroid cancer	
PAX8-PPARgamma		
TSHR	Commonly associated with benign lesions	Surveillance or definitive treatment if associated with suppressed TSH
THADA		
GNAS		
AKT1	Unknown	No specific recommendation
CTNNB1		
EIF1AX		
TERT		
Others		

FNA, Fine needle aspiration; TSH, thyroid-stimulating hormone; US, ultrasound.

All patients undergoing lobectomy for DTC need to be compliant with surveillance and be counseled for the potential need for additional surgery if persistent or recurrent disease is found.^{333,334} Knowledge of the somatic driver mutation driver may be helpful in guiding the surgical approach; however, additional studies are needed to confirm the utility to this approach to stratification of care (Box 13.2).²⁷⁴

Unlike PTC, FTC is often unifocal and does not have a propensity toward lymph node invasion, but may exhibit early hematogenous metastasis. As the diagnosis of FTC is based on evidence of anatomic invasion, not on nuclear or cytoplasmic alterations, the majority of patients ultimately diagnosed with FTC will have indeterminate cytology on FNA and undergo a lobectomy for their initial surgery. Similar to PTC, completion thyroidectomy should be considered for patients with underlying thyroid disease, bilateral nodules, or a known diagnosis of a thyroid tumor predisposition syndrome. In contrast to PTC, there is no advantage in performing a prophylactic central neck lymph node dissection for patients with FTC, as regional lymph node metastasis is uncommon. Minimally invasive FTC is defined as FTC with microscopic or no capsular invasion and/or limited vascular invasion, defined as less than 4 vessels

in or adjacent to the tumor capsule. Widely invasive FTC is defined as FTC with widespread capsular invasion, widespread vascular invasion, or extension into surrounding thyroid tissue. Invasion of 4 or more vessels is associated with more aggressive disease, an increased risk of distant metastases, and a poorer prognosis. A completion thyroidectomy should be performed for patients diagnosed with widely invasive FTC so that patients can be assessed for evidence of distant metastasis on postoperative RAI whole-body scan.²⁶²

Surgical complication rates from pediatric thyroidectomy range from 0% to 32% for permanent hypoparathyroidism and 0% to 40% for recurrent laryngeal nerve injury,^{277,333} with higher complication rates in children aged 0 to 6 years (22%) when compared with older children (15% for 7–12 years and 11% for 13–17 years).²²⁸ Patients treated in low-volume hospitals and by low-volume surgeons (≤ 30 thyroidectomies/year) are more likely to undergo care that is discordant to national practice guidelines, have an increased rate of complications (14.3% vs. 35.9%, odds ratio [OR], 0.16; 95% confidence interval [CI] 0.05–0.51; $P = .02$) and an increased rate of readmission within 30 days of surgery compared with high-volume centers.^{279,335} The use of intraoperative parathyroid hormone levels helps identify patients at risk of postoperative hypoparathyroidism affording an opportunity for early administration of calcium and calcitriol.³³⁶ Early identification of hypoparathyroidism, with subsequent initiation of calcitriol and calcium decreases the risk of symptomatic hypocalcemia, as well as shortens the duration of postoperative hospitalization.³³⁷ The perioperative calcium and phosphorus must be monitored to ensure stable values before discharge from the inpatient setting.^{338,339}

The risk of vocal fold paralysis from recurrent laryngeal nerve (RLN) injury ranges from 1% to 8.6%, with rates of bilateral nerve injury at the lower end of the range, a particular challenge, because of respiratory distress and potential need for tracheotomy.^{279,340} Flexible fiberoptic laryngoscopy³⁴¹ or transcutaneous laryngeal US^{342,343} should be performed before surgery for patients with a history of preoperative voice abnormalities, extensive cervical and/or upper mediastinal lymph node metastasis. Because of the significant morbidity associated with bilateral RLN paresis, ipsilateral RLN function should be assessed midway during total thyroidectomy, after completing the dissection of the first thyroid lobe. RLN function can be monitored either actively with neuromonitoring, or manually. If the RLN is intact but not responsive to stimulation, the surgeon should consider altering the surgical plan to avoid the risk of bilateral RLN injury.³⁴⁴ Thus although the use of active RLN monitoring may not decrease the rate of unilateral RLN injury, it is very effective at reducing the potential need for a surgical airway secondary to bilateral RLN injury.

Radioactive Iodine Therapy

RAI, ¹³¹I, also referred to as *radioiodine*, was observed to kill thyroid tumor cells more than 70 years ago.^{345,346} To this date, RAI remains the most effective and safe targeted therapeutic agent to destroy persistent DTC that is not amenable to surgical resection. There are several considerations that should be kept in mind when considering using RAI in pediatrics: (1) RAI benefit is clearly demonstrated in patients with metastasis, but not with disease limited to the thyroid, and remnant ablation is not associated with improved outcome; (2) different approaches have been used to select delivered therapeutic activity including empiric dosing, blood-based upper-limit dosimetry, and tumor dosimetry, without one approach showing clear efficacy over the others; (3) RAI efficacy is dependent on factors that include tumor biology and the radiation dose to the tumor; (4) relatively high cumulative activities of RAI

(>300 mCi; 11 GBq) may be associated with an increased risk of second primary malignancies (SPMs); and (5) patients may be considered RAI-refractory in the following situations: the foci never concentrate RAI, foci that previously concentrated RAI lose avidity, there is anatomic progression within 1-year of RAI therapy, or the cumulative RAI dose exceeds 600 mCi.²⁷⁵

There are similar considerations and concerns with using RAI in children and adolescents amplified by 3-fold increased use of RAI treatment in pediatric patients with DTC over the last four decades, the length of time that pediatric patients bear the burden of short-term RAI-induced complications, and the length of time over which long-term RAI-induced complications have time to develop. Short-term complications of RAI therapy in treating DTC include acute sialoadenitis, xerostomia, bone-marrow suppression, and pneumonitis. Long-term complications include xerostomia, dental caries, pulmonary fibrosis, gonadal toxicity, and development of SPM.²⁶² Initiation of sialogogues, 2 hours after administration of a therapeutic dose of RAI, with continuous use over the next 1 to 2 days (every 15–30 minutes, even overnight) can help reduce salivary gland exposure to RAI.^{347,348} In regard to the risk of RAI-induced SPM, the most recent retrospective review of the National Cancer Institute SEER cancer registry reported that approximately 1 in 227 RAI-treated patients will develop an SPM (a 0.125% increased risk over patients that did not receive RAI) with 1 in 588 developing an RAI-induced salivary gland cancer.³⁴⁹ Thus the overall risk of RAI-associated complications is very low and must be taken within the context of the benefit of RAI, where multiple studies have shown a reduced risk of recurrence associated with the administration of RAI to patients found to have regional and distant metastasis at the time of diagnosis.^{350–353}

In contrast with adults with thyroid cancer, there is no staging system for children and adolescents with PTC, secondary to the extremely low disease-specific mortality, even for patients with pulmonary metastasis.²⁶¹ However, the American Joint Committee on Cancer Tumor, Nodes, Metastases (TNM) classification system³⁵⁴ is used to describe the extent of disease and stratify an approach to further evaluation and management, based on the risk of persistent postsurgical disease.²⁶² The three groups from 2015 American Thyroid Association (ATA) Pediatric guidelines²⁶² are as follows, adjusted based on more recent data^{330–332}:

1. **ATA Pediatric Low-Risk:** Disease grossly confined to the thyroid with N0 (no lymph node metastasis) or NX (no lymph nodes assessed) disease or patients with incidental ≤ 5 metastatic lymph nodes in the central neck (N1a).
2. **ATA Pediatric Intermediate-Risk:** Presence of extrathyroidal extension or >6 metastatic lymph nodes (N1a) or lateral neck lymph node metastasis (N1b).
3. **ATA Pediatric High-Risk:** Presence of more than 10 metastatic lymph nodes or distant metastasis.

Irrespective of risk level, all patients undergo surveillance. For ATA Low-Risk patients, patients may be placed on TSH-suppressive (TSH <0.5 $\mu\text{U/L}$) levothyroxine therapy and initiate laboratory surveillance with 3- to 6-month interval TG and anti-TG levels and neck US on a 6- to 12-month interval rather than pursuing a stimulated TG level, with diagnostic whole-body scan (DxWBS) in the immediate postoperative time frame. The TSH-stimulated TG and DxWBS can be performed at a later time, if there is any concern over persistent or recurrent disease that cannot be located on nonradioisotope imaging.^{262,321,322} For intermediate- and high-risk patients, a TSH-stimulated TG and a ¹²³I DxWBS are recommended to assess for evidence of residual disease. Some 2 to 3 weeks before the DxWBS, liothyronine or levothyroxine is withheld with a goal of achieving a TSH above 30 $\mu\text{U/L}$. The ability to

achieve adequate TSH elevation using recombinant-human TSH (rhTSH) has been studied in children using the typical adult dose (0.9 mg given 24 hours apart); however, pediatric data on the efficacy of rhTSH on treatment outcomes are limited.^{355,356} During this time frame, patients are also placed on a low-iodine diet to optimize absorption of radioiodine. For children who received iodinated contrast agents, it is recommended to wait 1 to 2 months and to confirm iodine deficiency with a spot or 24-hour urine iodine level before administration of RAI.³¹⁸ For the DxWBS, either ¹³¹I or ¹²³I may be used, however, ¹²³I is favored secondary to superior imaging quality, decreased radiation exposure, and prevention of stunning (reduced ¹³¹I absorption of the therapeutic dose).³⁵⁷ The addition of single-photon emission computed tomography (SPECT) should be considered to confirm disease that is discovered in unexpected or unusual anatomic locations.³⁵⁸

For patients with minimal thyroid bed uptake on DxWBS after initial surgery, ¹³¹I therapy can be considered based on the TSH-stimulated TG level, on a case-by-case basis. A TSH-stimulated TG lower than 2 ng/mL has a 94.9% predictive value for being disease-free.³⁵⁹ If TSH-stimulated TG is 2 to 10 ng/mL, ¹³¹I therapy can be considered for patients with thyroid bed uptake and should be considered for DTC with invasive histology (diffuse sclerosing variant PTC and widely invasive follicular variant PTC), and for tumors found to have invasive features on anatomic pathology, including extra-thyroidal extension, extensive regional metastasis (>6 lymph node), or evidence of extranodal extension.^{262,330} If the TSH-stimulated TG is greater than 10 ng/mL, ¹³¹I therapy is indicated. Repeat surgery before administration of ¹³¹I should be pursued if there is evidence of “bulky,” macroscopic, persistent disease noted during the initial postoperative evaluation.²⁶²

Options for selection of the therapeutic ¹³¹I dose is either empiric or determined based on bone marrow dose limited dosimetry. Empiric dosing is given as a fraction (child’s weight in kilograms divided by 70 kg) of a typical adult dose used to treat similar disease extent or based on weight (1.0–1.5 mCi/kg).²⁶² Bone marrow dose-limited dosimetry is targeted to limit lung retention to less than 80 mCi at 48 hours and blood/bone marrow exposure to less than 200 cGy. Dosimetry should be considered in younger children (<10 years), those with diffuse pulmonary metastases, and those who may have reduced bone marrow reserve, including a history of radiation therapy for other malignancies.^{360,361} A posttreatment WBS (RxWBS) should be obtained 5 to 7 days after all ¹³¹I therapy as up to 15% of patients may have newly identified foci not seen on the DxWBS that may impact the subsequent surveillance and treatment plan.³⁶²

Levothyroxine Therapy

After completion of initial therapy for DTC, patients are placed on supraphysiologic doses of levothyroxine to suppress the TSH below the lower limit of detection, as it is well recognized that TSH suppression can reduce rates of recurrence.^{363,364} The optimal degree of TSH suppression is debated in low-risk patients, as it is not clear if complete suppression of TSH secretion confers benefit. In adults, the long-term impact of supraphysiologic doses of thyroid hormone on bone mineral density and cardiovascular risks is well recognized.^{365,366} In children, high levels of thyroid hormones can have effects on growth and profoundly impact on behavior and learning ability.³⁶⁷

The TSH goals proposed in the ATA pediatric guidelines recommend maintaining TSH levels in the low normal range

(0.5–1.0 µU/mL) for low-risk patients, between 0.1 to 0.5 µU/L for intermediate-risk patients, and less than 0.1 µU/L for high-risk patients.²⁶² Once a patient enters remission TSH, suppression may be relaxed into the low-risk range, between 0.5 to 1.0 µU/L.

Follow-Up

Follow-up care of the child with DTC involves the regular assessment of circulating thyroid hormone levels, measurement of TG and anti-TG, and radiological imaging. TG levels must be interpreted in relation to simultaneous TSH and every effort must be made to use the same laboratory and assay method to accurately determine the trend in the TG level.³⁶⁸ Laboratory assessment is typically obtained every 3 to 6 months, decreasing to 6 to 12 months for patients in remission, and then to once annually once linear growth has been completed.

A very pertinent issue is the criteria used to assess if a patient is disease free. With highly sensitive TG assays, one can aim for an undetectable TG level (<0.2 mcg/L) as indicative of a disease-free state. However, with these highly sensitive TG assays, there will be patients that have a minimally detectable TG or anti-TG that may not have any evidence of anatomic disease. For many of these patients, continued surveillance may be the best plan in an attempt to balance the risks and benefits of additional therapy.

Up to 25% of patients with DTC have detectable anti-TG levels that can interfere with TG assays. For these patients, the trend in TGAb should be followed as a marker of disease status.³⁶⁹ Many laboratories will reflexively run the TG by radioimmunoassay or liquid chromatography/tandem mass spectrometry, if TGAb is detected. For patients that did not receive postsurgical RAI therapy, the TSH-suppressed TG should decrease to less than 0.5 mcg/L 6 to 12 months after total thyroidectomy.³⁷⁰ If the TG remains mildly elevated, between 2 to 10 mcg/L, continued monitoring may be pursued depending on the trend in TG over time, as well as evidence of persistent or recurrent disease based on radiological imaging. Increasing or frankly elevated levels of TSH-suppressed TG (>10 mcg/L) warrant further evaluation to localize disease and to decide whether additional surgery and/or ¹³¹I therapy would be beneficial.²⁶² A TSH-stimulated TG can be obtained with a repeat DxWBS for patients being evaluated for additional therapy, as well as to confirm remission for patients with a history of invasive disease.

Neck US is the most effective and efficient radiologic tool to monitor for persistent or recurrent anatomic disease. The first US should be performed approximately 6 months after the initial surgery and then at 6- to 12-month intervals for ATA pediatric intermediate- and high-risk patients. Serial chest CT at 6- to 12-month intervals should be used to monitor patients with known pulmonary metastasis. A TSH-stimulated TG and a DxWBS may be obtained in ATA pediatric intermediate- and high-risk patients, previously treated with ¹³¹I, with known iodine-avid metastatic disease, if the TG level has plateaued or is increasing, and anatomic disease is not found on neck US or cross-sectional imaging (chest CT or MRI).²⁶² This is particularly important for patients with diffuse, micronodular pulmonary metastasis because up to 50% of the time the WBS will detect small 1- to 2-mm lesions that may be missed even with high-resolution CT scanning.²⁸³ The use of 18(F)-fluorodeoxyglucose-positron emission tomography (FDG-PET)/CT should be limited to patients with increasing TG levels suspected to have persistent anatomic disease that is non-RAI avid, based on previous RAI treatment and WBS imaging.³⁷¹

Treatment of Persistent or Recurrent Disease

Cervical lymph nodes are the most common location for residual and recurrent PTC.³⁷² The decision to treat or to observe identifiable cervical disease should be individualized according to the size, anatomic location, prior treatment history, the iodine avidity of cervical disease, and the presence of distant metastasis. For macroscopic cervical disease (≥ 1 cm in size) confirmed by FNA, surgery is preferable to ¹³¹I therapy.²⁶² For children with iodine-avid small volume cervical disease, therapeutic ¹³¹I therapy can be considered or the patient may be observed with continued TSH suppression, depending on the individual risk to benefit ratio, as well as the absence or presence of distant metastasis.³⁷³

The majority of children with pulmonary metastasis have micronodular disease demonstrating excellent iodine avidity. Thus in contrast to adults, children and adolescents with pulmonary metastasis have low disease-specific mortality.^{293,374} However, although many pediatric patients achieve remission from pulmonary disease,^{293,350,374} at least one-third of children will have stable, persistent disease that will not respond to repeat doses of ¹³¹I.²⁹³ Re-treatment of ¹³¹I iodine-avid pulmonary metastases should be considered in children who have demonstrated previous improvement but continue to have persistent disease based on a plateau or increasing trend in TG or TGA, as well as data from cross-sectional imaging.^{262,353} The timing of additional ¹³¹I should be at least 12 or more months from the previous treatment, with several studies demonstrating a continuous decline in serum TG levels for 18 to 24 months, or longer, following the previous RAI therapy.^{374,375}

Systemic Therapy for Children With Progressive Disease

RAI-refractory (RAIR) disease is more common in patients over 45 years of age; however, a small proportion of children and adolescents also develop progressive DTC that is refractory to ¹³¹I treatment. Over the last decade, there have been an increasing number of oral systemic therapies that have been incorporated into clinical practice. These agents target constitutively activated protein kinases in the MAPK and PI3K signaling pathways.³⁷⁶ Knowledge of the somatic oncogene driver mutation in the refractory tumor is critical in selection of the drug that is likely to have the greatest clinical effect. The multitargeted tyrosine kinase inhibitors (TKIs), including sorafenib, lenvatinib, and others, target the vascular endothelial growth factor receptors, as well as a combination of the epithelial growth factor receptors, fibroblast growth factor receptors, platelet-derived growth factor receptor, and RET. These agents have been shown to slow progression and to decrease tumor burden for many patients, including tumors with BRAF v600E, as well as in tumors with unknown oncogene status. Unfortunately, the effect is often transient and many patients experience side effects, including hypertension, diarrhea, anorexia with weight loss, and fatigue.³⁷⁷ The newer selective inhibitors have increased efficacy and less toxicity. Resensitization of tumors to RAI has been achieved for patients with tumors harboring either BRAF or RAS mutations after administration of selective BRAF, as well as MEK inhibitors.³⁷⁸ Equally effective selective inhibitors are also in clinical trial and practice, with several approved down to 12 years of age for patients with tumors harboring BRAF, RET, NTRK, ALK, or ROS1 fusion genes.³⁷⁷ Although these agents are providing clinical benefit, the majority are cytostatic, not cytotoxic. Tumors eventually develop resistance and there is limited knowledge on the best choice for a follow-on drug for salvage therapy if or when a tumor

becomes refractory to the initial agent. With the potential for significant side effects, pediatric patients that may benefit from therapy should be referred to centers that have experience with these drugs in the treatment of RAI thyroid cancer, so that the timing, selection, monitoring, and adjustment of therapy can be optimized, and the risk of adverse reactions minimized.^{262,377,379}

Medullary Thyroid Cancer

MTC is a neuroendocrine cancer that derives from the neural crest and originated parafollicular C-cells of the thyroid gland.²⁶⁵ Thus in contrast to PTC and FTC, follicular-cell-derived thyroid tumors, MTC cells are not responsive to TSH, do not express the sodium-iodine symporter, and do not produce TG. Rather, MTC secretes calcitonin and carcinoembryonic antigen (CEA), both of which serve as the tumor markers of MTC. In children, MTC is most commonly a monogenic disorder caused by a dominantly inherited or de novo gain-of-function mutation in the RET protooncogene, associated as one component of MEN2, either MEN2A or 2B, depending on the specific mutation.^{380,381} Sporadic MTC is not associated with a germline mutation; rather it develops secondary to somatic mutations in the RET protooncogene, RAS, or several others genes, including ALK fusions.³⁸²

There is a strong genotype and phenotype correlation in the RET protooncogene allowing for prediction of the rapidity with which an individual may develop MTC, as well as the risk and timing for development of the other MEN2-related characteristics and tumors, including pheochromocytoma and hyperparathyroidism.^{265,380,381,383} The ATA divides the most common RET mutations into three risk categories: (1) highest risk, (2) high risk, and (3) moderate risk, and bases the recommended age for initial screening, and the timing of prophylactic thyroidectomy to coincide with the goal of achieving surgical remission from disease.²⁶⁵ There are multiple codon mutations associated with MEN2A with the highest risk of developing MTC associated with mutations in C634 and A883F. The remaining mutations carry an increased risk of developing MTC, although for individual patients, the course from C-cell hyperplasia to MTC may be indolent with MTC not developing until the third, fourth, or later decades of life. In addition to MTC, in MEN2A there is a 10% to 50% risk of developing hyperparathyroidism and/or pheochromocytoma, defined by the individual codon mutation. Two additional features associated with MEN2A are cutaneous lichen amyloidosis, a pruritic, plaque-like rash typically on the upper back associated with mutations in C634 and V804M, and Hirschsprung disease, associated with mutations in C609, C611, C618, and C620.²⁶⁵

MEN2B is associated with a mutation at codon 918 in the RET protooncogene. Because mutations in codon 918 are more often de novo compared with other RET protooncogene codon mutations, recognition of the early clinical signs and symptoms is critically important to diagnose the syndrome before MTC metastasis, which typically occurs before 4 years of age.³⁸⁴ These signs and symptoms include alacrima (the inability or decreased ability, to make tears), constipation (associated with ganglioneuromatosis), and hypotonia (feeding difficulties with failure to thrive, club feet, hip dislocation). The more classically defining symptoms, including oral and lip mucosal neuromas and elongated Marfanoid facies, are not clinically evident until school age, around 5 years of age.^{384,385} Some 50% of patients will develop a pheochromocytoma; however, unlike patients with MEN2A, there does not appear to be an increased risk for developing hyperparathyroidism.²⁶⁵

Based on these observations, the ATA recommends the timing of total thyroidectomy as follows; within the first year of life for carriers of the highest risk mutation (codon 918), at or before age 5 years for those with a high risk mutation (codons 634 and 883), and for all other moderate risk mutations when the serum calcitonin level shows an increasing upward trend, a nodule is found on surveillance thyroid US, or if the parents do not wish to continue to embark on a long period of laboratory and radiological surveillance. For patients with MEN2B,²⁶⁵ if thyroidectomy is not completed by 4 years of age, there is reduced likelihood for surgical remission.³⁸⁶

For patients undergoing thyroidectomy, a central lymph node dissection is recommended in children whose basal calcitonin is greater than 40 pg/mL or with any evidence of lymph node metastasis.^{265,387} After initial surgery, levothyroxine medication is given to normalize, not suppress, the TSH. In contrast to the follicular cell in nonmedullary DTC, parafollicular C-cells do not accumulate iodine because they do not express the sodium-iodide symporter. Thus postoperative ¹³¹I therapy is not indicated following thyroidectomy for MTC.³⁸⁸ Calcitonin and CEA levels should be monitored as tumor markers every 6 to 12 months, with decreasing frequency once remission is confirmed. Neck US should be followed for patients with persistently detectable tumor markers or initial lymph node metastasis. If the tumor markers remain significantly elevated, or show rapid doubling time, additional imaging, such as chest CT, contrast-enhanced liver MRI or CT, bone scan, MRI of the axial skeleton, 18F-FDG PET/CT or gallium-68 dotatate PET/CT should be performed.^{265,389}

Patients with hereditary MTC should receive continued and life long follow-up, including genetic counseling, psychosocial support, and prospective screening of pheochromocytoma and primary hyperparathyroidism. Annual screening for pheochromocytoma with a urine or serum fractionated metanephrine panel is initiated at age 11 years for ATA highest risk patients⁹¹⁸ and at 16 years for ATA high and moderate risk patients, with the addition of annual screening for hyperparathyroidism for ATA high- and moderate-risk patients at the same time.²⁶⁵

Metastatic MTC is generally incurable, but may show an indolent clinical course with stable disease over decades. A rapid calcitonin doubling time and a disparate low calcitonin, associated with a high CEA level, is associated with aggressive behavior and poorer prognosis.^{265,390} For MTC patients with symptomatic or progressive metastatic disease, the treatment using multi-targeted TKI, or, the newer and more effective selective targeted therapies that inhibit *RET*, should be considered.^{376,391} Similar to the use of these drugs in patients with DTC, pediatric patients that may benefit from these oral chemotherapeutic agents should be referred to centers that have experience with these drugs in the treatment of progressive MTC, so that the timing, selection, monitoring, and adjustment of therapy can be optimized and the risk of adverse reactions minimized.^{262,377,392}

HISTORY, EMBRYOLOGY, AND ANATOMY

The adrenal cortex produces three principal categories of steroid hormones that regulate a wide variety of physiologic processes from fetal to adult life. Mineralocorticoids, principally aldosterone, regulate renal retention of sodium and thus profoundly influence electrolyte balance, intravascular volume, and blood pressure. Glucocorticoids, principally cortisol, are named for their carbohydrate-mobilizing activity, but they are ubiquitous physiologic regulators, influencing a wide variety of bodily functions. Adrenal androgens serve no known physiologic role but do mediate some secondary sexual characteristics in women (e.g., pubic and axillary hair), and their overproduction may result in virilism. Thus the adrenal cortex is of considerable interest because of the widespread effects of its secretions and because derivatives of these secreted steroids are widely used as pharmacologic agents. Disorders of the adrenal cortex, once thought to be rare, are being recognized with increasing

frequency. The severe congenital adrenal hyperplasias (CAHs) affect nearly 1 in 10,000 persons, and the very mild forms may affect as many as 1 in 100 in some populations. Cushing disease, once regarded as a true rarity in pediatrics, may affect as many children as adults. Primary aldosteronism is a common cause of hypertension, especially in adults.

History

The history of adrenal research has been reviewed recently.¹ The adrenal glands apparently were first described in 1563 by the Italian anatomist Bartolomeo Eustaccio, better known for his description of the eustacian tube of the ear. Medical interest in the adrenals as something other than an anatomic curiosity began in the mid-19th century with Addison's classical description of adrenal insufficiency and Brown-Sequard's experimental creation of similar disorders in animals subjected to adrenalectomy. The signs and symptoms of glucocorticoid

excess caused by adrenal tumors were well known by 1932, when Cushing described the pituitary tumors that cause what is now known as *Cushing disease*. Effects of adrenalectomy on salt and water metabolism were reported in 1927, Loeb showed that saline administration extended the life of Addisonian patients in 1933, and by the late 1930s, Selye had proposed the terms *glucocorticoid* and *mineralocorticoid* to distinguish the two broad categories of actions of adrenal extracts.

Numerous adrenal steroids were painstakingly isolated and their structures determined during the 1930s in the laboratories of Reichstein and Kendall. Many of these steroids were synthesized chemically, providing pure material for experimental purposes. In 1949 Kendall and Hench reported that glucocorticoids ameliorated the symptoms of rheumatoid arthritis, greatly stimulating interest in synthesizing new pharmacologically active analogues of naturally occurring steroids. Kendall, Reichstein, and Hench shared the 1950 Nobel Prize in Medicine. The structures of the various adrenal steroids suggested precursor/product relationships, leading in 1950 to the first treatment of CAH with cortisone by both Wilkins and Bartter. This opened a vigorous era of clinical investigation of the pathways of steroidogenesis in a variety of inherited adrenal and gonadal disorders. The association of cytochrome P450 with 21-hydroxylation was made in 1965, and some of the steroidogenic enzymes were then isolated in the 1970s, but it was not until the genes for most of these enzymes were cloned in the 1980s that it became clear which proteins participated in which steroidal transformations.² The identification of these genes (Table 14.1) then led to an understanding of the genetic lesions causing heritable disorders of steroidogenesis. At the same time, studies of steroid hormone action led to the discovery of steroid hormone receptors in the 1960s, but it was not until they were cloned in the 1980s that their biology has begun to be understood.³

Embryology

The cells of the adrenal cortex are of mesodermal origin, in contrast to cells of the adrenal medulla, which are derived from the neuroectoderm. In human embryos, adrenogonadal progenitor cells first appear at around the fourth week of gestation as a thickening of the coelomic epithelium (or intermediate mesoderm) between the urogenital ridge and dorsal mesentery⁴ (Fig. 14.1). These progenitor cells give rise to the steroidogenic cells of the gonads and to the adrenal cortex. The adrenal and gonadal cells then separate, with the adrenal cells migrating retroperitoneally to the cranial pole of the mesonephros and the gonadal cells migrating caudally. Between the seventh and eighth week of development, the adrenal primordium is invaded by sympathetic cells derived from the neural crest that give rise to the adrenal medulla. By the end of the eighth week, the rudimentary adrenal has become encapsulated and is clearly associated with the upper pole of the kidney, which at this time is much smaller than the adrenal.⁵

The fetal adrenal cortex consists of an outer “definitive” zone, the principal site of glucocorticoid and mineralocorticoid synthesis, and a much larger “fetal” zone that makes androgenic precursors (dehydroepiandrosterone [DHEA], dehydroepiandrosterone sulfate [DHEAS]) that the placenta converts to estriol. A putative “transitional” zone exists between these regions toward the end of fetal development, but its role is unclear. The fetal adrenal glands are huge in proportion to other structures, and continue to grow well into the third trimester (Fig. 14.2). At birth, the adrenals weigh 8 to 9 g, about the same size of adult adrenals, and represent approximately 0.4% of total body weight. Following birth, cells of the fetal zone undergo apoptosis, and the fetal adrenal zone rapidly involutes and has virtually disappeared by 6 to 12 months of

TABLE 14.1 Physical Characteristics of Human Genes Encoding Steroidogenic Enzymes

mRNA, Messenger ribonucleic acid.

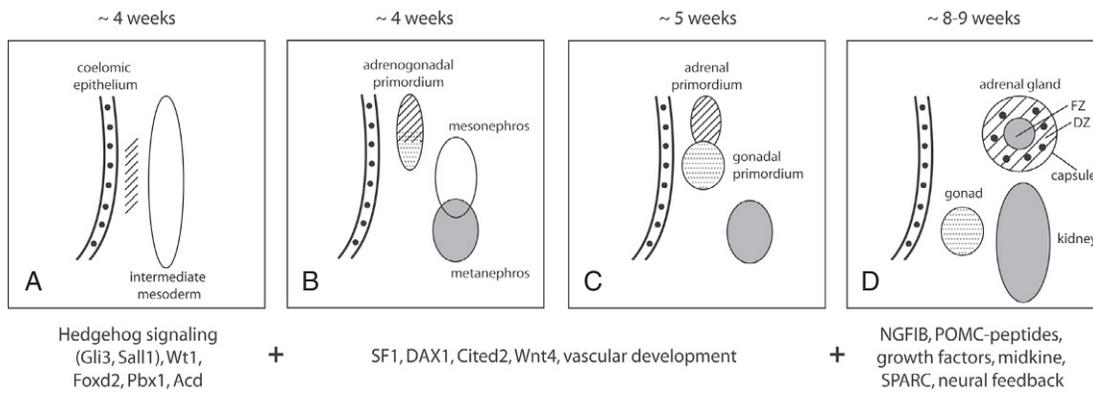

Fig. 14.1 Overview of human adrenal development. **A–C**, The adrenogonadal primordium develops at around 4 weeks, gestation, after which the adrenal primordium becomes a distinct structure that then migrates retroperitoneally to the cranial pole of the mesonephros. **D**, By 8 to 9 weeks' gestation, the adrenal gland is encapsulated, contains chromaffin cells (black) and has distinct fetal (FZ) and definitive zones (DZ). Some of the signaling molecules, transcription factors, and growth factors implicated in adrenal development are shown later, although the exact timing and interaction of many of these factors remains poorly understood at present. (Modified from Else, T., & Hammer, G. D. (2005). Genetic analysis of adrenal absence: agenesis and aplasia. *Trends Endocrinol Metab*, 16, 458–468. With permission.)

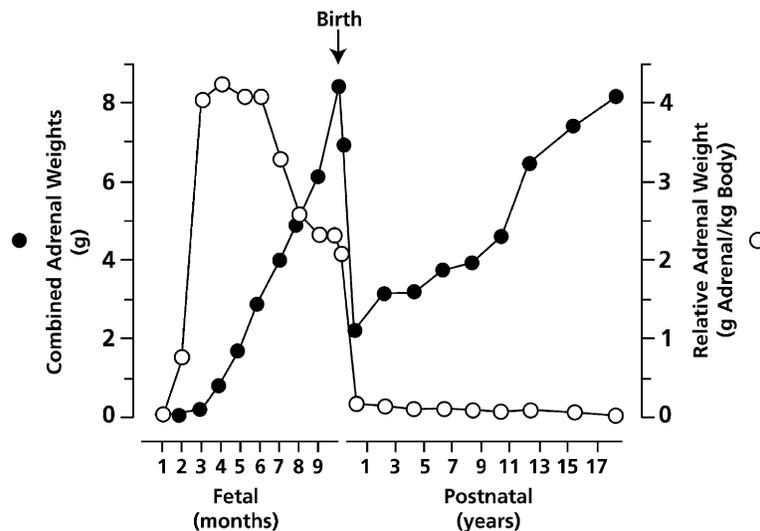

Fig. 14.2 Combined adrenal weight (filled circles) and relative adrenal weight (open circles) from the first trimester through to early adulthood. (From Mesiano, S., & Jaffe, R. B. (1997). Developmental and functional biology of the primate fetal adrenal cortex. *Endocr Rev*, 18, 378–403.)

postnatal life. Thereafter adrenal growth is comparatively slow, so that the adrenal glands represent only 0.01% of body weight in the adult.

The complex mechanisms regulating adrenal development are still relatively poorly understood. However, important insight into key factors has been obtained from studies of transgenic mice and from patients with disorders of adrenal development.⁶ For example, the early stages of adrenal differentiation and development involve a number of signaling pathways (hedgehog/GLI3, WNT3/WNT4/WNT11, midkine), transcription factors (SALL1, FOXD2, PBX1, WT1, SF1 [NR5A1], DAX1 [NR0B1]), coregulators (CITED2), matrix proteins (SPARC), and regulators of telomerase activity (ACD).⁷ Subsequent fetal adrenal growth is highly dependent on the trophic effects of adrenocorticotropic hormone (ACTH), its receptor (MC2R), and its downstream signaling pathways, as well as growth factor signaling pathways, such as insulin-like growth factor-2 (IGF-2), basic fibroblast growth factor (bFGF, now termed *FGF2*), and epidermal growth factor (EGF).

Anatomy

The adrenals, once termed *suprarenal glands*, derive their name from their anatomic location, sitting on top of the upper pole of each kidney. Unlike most other organs, the arteries and veins serving the adrenal do not run parallel. Arterial blood is provided by several small arteries arising from the renal and phrenic arteries, the aorta, and sometimes the ovarian and left spermatic arteries. The veins are more conventional, with the left adrenal vein draining into the left renal vein and the right adrenal vein draining directly into the vena cava. Arterial blood enters the sinusoidal circulation of the cortex and drains toward the medulla, so that medullary chromaffin cells are bathed in very high concentrations of steroid hormones. High concentrations of cortisol are required for expression of medullary phenylethanolamine-N-methyltransferase, which converts norepinephrine to epinephrine, linking the adrenal cortical and medullary responses to stress.⁸

The adrenal cortex consists of three histologically recognizable zones: the zona glomerulosa is immediately below the

capsule, the zona fasciculata is in the middle, and the zona reticularis lies next to the medulla. The glomerulosa, fasciculata, and reticularis, respectively, constitute about 15, 75, and 10% of the adrenal cortex of the older child and adult. These zones appear to be distinct functionally, as well as histologically, but considerable overlap exists, and immunocytochemical data show that the zones physically interdigitate. After birth, the large fetal zone begins to involute and disappears by about 3 to 6 months of age. The definitive zone simultaneously enlarges, but two of the adult zones, the glomerulosa and fasciculata, are not fully differentiated until about 3 years of age, and the reticularis may not be fully differentiated until about 15 years of age. The origin of the distinct adrenocortical zones and the mechanisms that regulate their proliferation are still poorly understood. One model suggests that a population of undifferentiated stem cells exists between the zona glomerulosa and zona fasciculata, which represents a pool of common precursor cells that can contribute to either the inner or outer zones. In contrast, the “centripetal migration” theory proposes that a subcapsular population of progenitor/stem cells first differentiates into cells of the zona glomerulosa, which then convert into zona fasciculata cells (and presumably later into zona reticularis cells), as they migrate centripetally toward the adrenal medulla, where they complete their life span and undergo apoptosis.⁹

STEROID HORMONE SYNTHESIS

Early Steps: Cholesterol Uptake, Storage, and Transport

Much is now known about steroid biosynthesis,¹⁰ and about the early steps in the intracellular cholesterol trafficking.^{11,12} The human adrenal can synthesize cholesterol *de novo* from acetate, but most of its supply of cholesterol comes from plasma low-density lipoproteins (LDLs) derived from dietary cholesterol. Rodent adrenals derive most of their cholesterol from high-density lipoproteins via a receptor termed *SR-B1*, but this pathway plays a minor role in human steroidogenesis. Adequate concentrations of LDL will suppress 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme in cholesterol synthesis. ACTH, which stimulates adrenal steroidogenesis, also stimulates the activity of HMG-CoA reductase, LDL receptors, and uptake of LDL cholesterol. LDL cholesterol esters are taken up by receptor-mediated endocytosis, then are stored directly or converted to free cholesterol and used for steroid hormone synthesis. Cholesterol can be esterified by acyl-CoA: cholesterol transferase (ACAT), stored in lipid droplets, and accessed by activation of hormone-sensitive lipase (HSL) and by the so-called NPC proteins, which derive their name from their causative role in Niemann-Pick type C disease. ACTH stimulates HSL and inhibits ACAT, thus increasing the availability of free cholesterol for steroid hormone synthesis.

Steroidogenic Enzymes

Cytochrome P450

Most steroidogenic enzymes are cytochrome P450 enzymes.¹⁰ “Cytochrome P450” designates a group of oxidative enzymes, all of which have about 500 amino acids and contain a single heme group. “P450” means “pigment 450” because all absorb light at 450 nm in their reduced states. Human beings have 57 genes for P450 enzymes; seven human P450s are targeted to mitochondria and 50 are targeted to the endoplasmic reticulum, especially in the liver, where they metabolize countless toxins, drugs, xenobiotics, and environmental pollutants.¹³ Each P450 enzyme, including the steroidogenic P450s, can metabolize multiple substrates, catalyzing a broad array of oxidations.

Five P450s are involved in adrenal steroidogenesis (Fig. 14.3). Mitochondrial P450_{sc} (CYP11A1) is the cholesterol

side-chain cleavage enzyme catalyzing the series of reactions formerly termed *20,22 desmolase*. The two mitochondrial isozymes of P450c11, P450c11 β (CYP11B1) and P450c11AS (CYP11B2), catalyze 11 β -hydroxylase, 18-hydroxylase, and 18-methyl oxidase activities. P450c17 (CYP17A1), found in the endoplasmic reticulum, catalyzes both 17 α -hydroxylase and 17,20 lyase activities, and P450c21 (CYP21A2) catalyzes the 21-hydroxylation of both glucocorticoids and mineralocorticoids. In the gonads and elsewhere P450aro (CYP19A1) in the endoplasmic reticulum catalyzes aromatization of androgens to estrogens.

Hydroxysteroid Dehydrogenases

The hydroxysteroid dehydrogenases (HSDs) have molecular masses of about 35 to 45 kDa, do not have heme groups, and require nicotinamide adenine dinucleotide (NAD⁺) or nicotinamide adenine dinucleotide phosphate (NADP⁺) as cofactors.^{14,15} Whereas most steroidogenic reactions mediated by P450 enzymes are catalyzed by a single form of P450, each of the reactions mediated by HSDs can be catalyzed by at least two isozymes. The HSDs include the 3 α - and 3 β -hydroxysteroid dehydrogenases, two 11 β -hydroxysteroid dehydrogenases, and a series of 17 β -hydroxysteroid dehydrogenases; the 5 α -reductases are unrelated to this family. Based on their structures, the HSDs fall into two groups: the short-chain dehydrogenase/reductase (SDR) family, structurally characterized by a “Rossmann fold,” and the aldo-keto reductase (AKR) family, characterized by a triosephosphate isomerase barrel motif.^{16,17} The SDR enzymes include 11 β -HSDs 1 and 2, and 17 β -HSDs 1, 2, 3, and 4; the AKR enzymes include 17 β -HSD5, which is important in extraglandular activation of androgenic precursors, and the 3 α -hydroxysteroid dehydrogenases that participate in the so-called *backdoor pathway* of fetal androgen synthesis (see later). Based on their activities, it is physiologically more useful to classify them as dehydrogenases or reductases. The dehydrogenases use NAD⁺ as their cofactor to oxidize hydroxysteroids to ketosteroids, and the reductases mainly use NADPH to reduce ketosteroids to hydroxysteroids. Although these enzymes are typically bidirectional *in vitro*, they tend to function in only one direction in intact cells, with the direction determined by the cofactor(s) available.^{16,17}

P450_{sc}

Conversion of cholesterol to pregnenolone in mitochondria is the first, rate-limiting and hormonally regulated step in the synthesis of all steroid hormones.^{10,11} This involves cholesterol 20 α -hydroxylation, 22-hydroxylation, and scission of its side chain to yield pregnenolone and isocaproic acid. Because 20-hydroxycholesterol, 22-hydroxycholesterol, and 20,22-hydroxycholesterol could be isolated from adrenals in significant quantities, it was previously thought that three separate enzymes were involved. However, a single protein, termed P450_{sc} (‘sc’ refers to the side-chain cleavage of cholesterol) encoded by the *CYP11A1* gene on chromosome 15 catalyzes all the steps between cholesterol and pregnenolone. Deletion of the mouse or rabbit *cyp11a1* gene eliminates all steroidogenesis, indicating that all steroidogenesis is initiated by this one enzyme.

Transport of Electrons to P450_{sc}: Ferredoxin Reductase and Ferredoxin

Mitochondrial P450 enzymes (P450_{sc}, P450c11 β , P450c11AS, and the vitamin D 1 α - and 24-hydroxylases) are terminal oxidases in an electron transport system.¹⁸ NADPH donates electrons to ferredoxin reductase (FDR, also termed *adrenodoxin reductase*), a flavoprotein that is loosely associated with the inner mitochondrial membrane. FDR transfers the electrons to ferredoxin (FDX, also termed *adrenodoxin*), a 14-kDa iron/sulfur protein, which then transfers the electrons to P450_{sc} (Fig. 14.4).

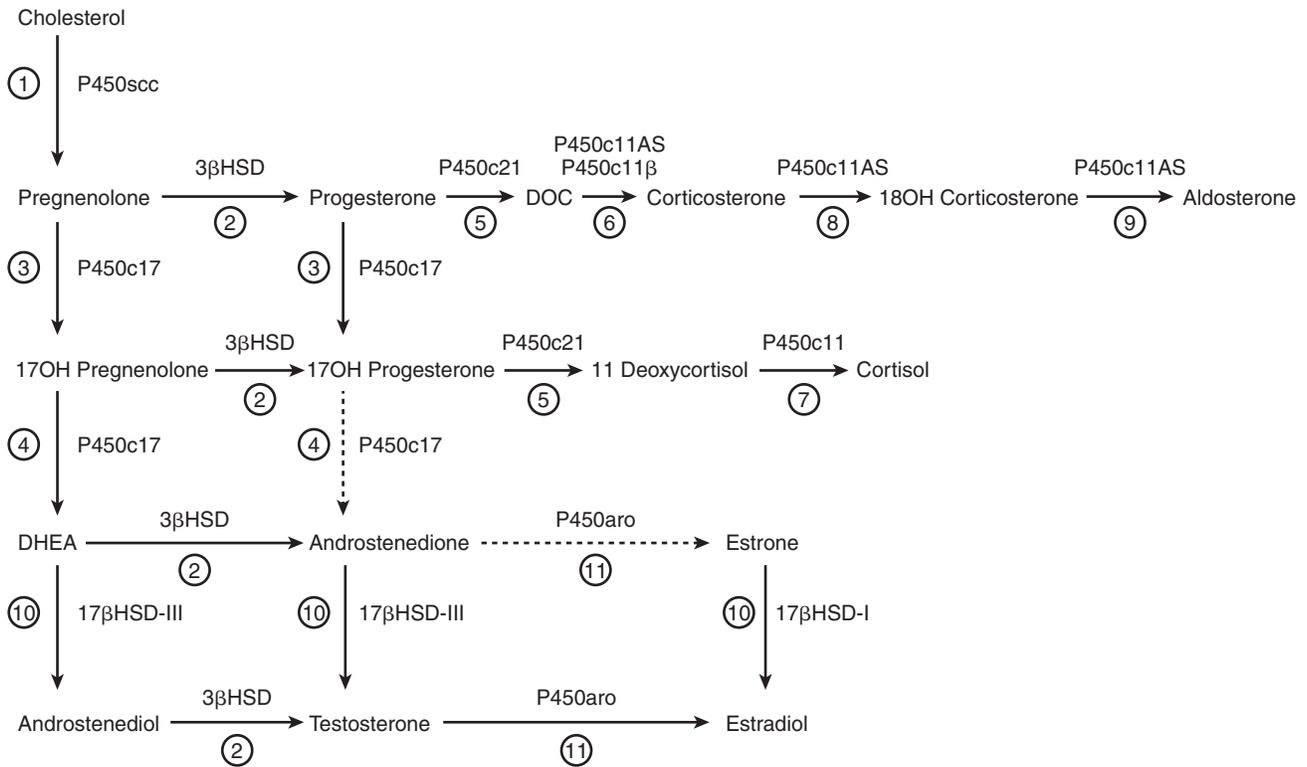

Fig. 14.3 Principal pathways of human adrenal steroid hormone synthesis. Other quantitatively and physiologically minor steroids are also produced. The names of the enzymes are shown by each reaction, and the traditional names of the enzymatic activities correspond to the circled numbers. Reaction 1: Mitochondrial cytochrome P450scc mediates 20 α -hydroxylation, 22-hydroxylation, and scission of the C20-22 carbon bond. Reaction 2: 3 β HSD mediates 3 β -hydroxysteroid dehydrogenase and isomerase activities, converting Δ^5 steroids to Δ^4 steroids. Reaction 3: P450c17 catalyzes the 17 α -hydroxylation of pregnenolone to 17OH-pregnenolone and of progesterone to 17OH-progesterone. Reaction 4: The 17,20 lyase activity of P450c17 converts 17OH-pregnenolone to dehydroepiandrosterone (DHEA); only insignificant amounts of 17OH-progesterone are converted to Δ^4 androstenedione by human P450c17, although this reaction occurs in other species. Reaction 5: P450c21 catalyzes the 21-hydroxylation of progesterone to deoxycorticosterone (DOC) and of 17OH-progesterone to 11-deoxycortisol. Reaction 6: DOC is converted to corticosterone by the 11-hydroxylase activity of P450c11AS in the zona glomerulosa and by P450c11 β in the zona fasciculata. Reaction 7: 11-Deoxycortisol undergoes 11 β -hydroxylation by P450c11 β to produce cortisol in the zona fasciculata. Reactions 8 and 9: The 18-hydroxylase and 18-methyl oxidase activities of P450c11AS convert corticosterone to 18OH-corticosterone and aldosterone, respectively, in the zona glomerulosa. Reactions 10 and 11 are found principally in the testes and ovaries. Reaction 10: 17 β HSD-III converts DHEA to androstenedione and androstenedione to testosterone, whereas 17 β HSD-I converts estrone to estradiol. Reaction 11: Testosterone may be converted to estradiol and androstenedione may be converted to estrone by P450aro.

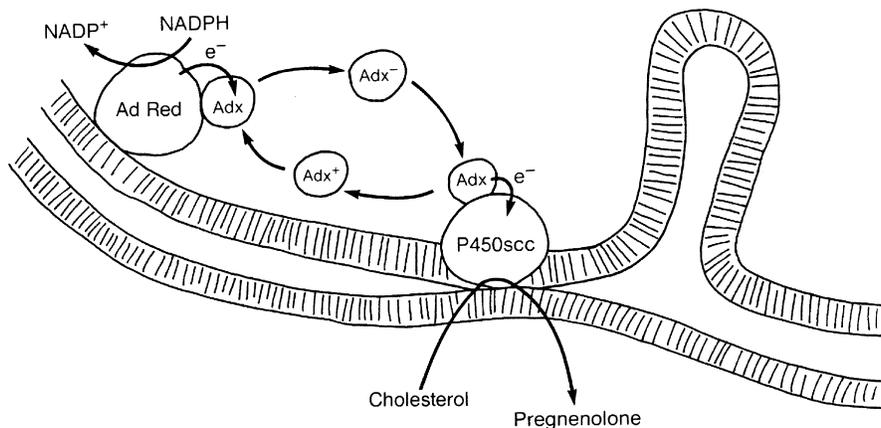

Fig. 14.4 Electron transport to mitochondrial forms of cytochrome P450. Adrenodoxin reductase (AdRed), a flavoprotein loosely bound to the inner mitochondrial membrane, accepts electrons (e^-) from nicotinamide adenine dinucleotide phosphate hydrogen (NADPH), converting it to NADP $^+$. These electrons are passed to adrenodoxin (Adx), an iron-sulfur protein in solution in the mitochondrial matrix that functions as a freely diffusible electron shuttle mechanism. Electrons from charged adrenodoxin (Adx $^-$) are accepted by any available cytochrome P450, such as P450c11, or P450scc shown here. The uncharged adrenodoxin (Adx $^+$) may then be again bound to adrenodoxin reductase to receive another pair of electrons. For P450scc, three pairs of electrons must be transported to the P450 to convert cholesterol to pregnenolone. The flow of cholesterol into the mitochondria is facilitated by steroidogenic acute regulatory protein, which is not shown in this diagram. (©W.L. Miller.)

FDX forms a 1:1 complex with FDXR, dissociates, then reforms an analogous 1:1 complex with the P450, thus functioning as a diffusible electron shuttle mechanism. FDXR and FDX are widely expressed in human tissues, but FDXR expression is two orders of magnitude higher in steroidogenic tissues.¹⁹ The primary ribonucleic acid (RNA) transcript from the *FDXR* gene is alternatively spliced yielding two messenger RNA (mRNA) species that encode proteins differing by six amino acids,²⁰ but only the shorter protein is active in steroidogenesis.²¹ FDXR is also essential in the formation of the iron/sulfur centers used by many enzymes. There are two human FDX isozymes encoded by genes on different chromosomes: FDX1 interacts with mitochondrial P450 enzymes; FDX2 is used for synthesis of iron-sulfur clusters, but not for steroidogenesis.^{22,23} FDX1 is ubiquitously expressed but is especially abundant in adrenal cortex. Human mutations in FDX have not been described, but several FDXR mutations that partially impair formation of iron/sulfur centers are associated with neuropathic hearing loss.^{24–26}

Mitochondrial Cholesterol Uptake: the Steroidogenic Acute Regulatory Protein, StAR

ACTH regulates steroidogenic capacity (chronic regulation) by inducing the transcription of genes for steroidogenic enzymes, but acute regulation, where steroids are released within minutes of a stimulus, is at the level of cholesterol access to P450scc.^{27,28} Treating either steroidogenic cells or intact rats with inhibitors of protein synthesis (e.g., cycloheximide) eliminated the acute steroidogenic response, suggesting that a short-lived protein triggers the response. A long search led to the identification and cloning of the steroidogenic acute regulatory protein, StAR.^{27–29} The central role of StAR in steroidogenesis was proven by finding that mutations of StAR caused congenital lipid adrenal hyperplasia.^{30,31} Thus StAR is the acute trigger that is required for the rapid flux of cholesterol from the outer to the inner mitochondrial membrane that is needed for the acute response of aldosterone to angiotensin II, of cortisol to ACTH, and of sex steroids to a luteinizing hormone (LH) pulse.

Some adrenal steroidogenesis is independent of StAR; this StAR-independent steroidogenesis is about 14% of the StAR-induced rate.^{30,31} The placenta uses P450scc to initiate steroidogenesis but does not express StAR. The mechanism of StAR-independent steroidogenesis is unclear; it may occur without a triggering protein, or some other protein may exert StAR-like activity to promote cholesterol flux, but without StAR's rapid kinetics.¹² The mechanism of StAR's action is unclear, but it is established that StAR acts on the outer mitochondrial membrane (OMM), does not need to enter the mitochondria to be active, and undergoes conformational changes on the OMM that are required for StAR's activity.^{28,32} Some studies suggest that StAR functions as a component of a molecular machine that consists of StAR, TSPO (the translocator protein formerly known as the peripheral benzodiazepine receptor), and other proteins on the OMM,³³ although studies with TSPO-knockout mice question its role.²⁹ The precise fashion in which cholesterol is loaded into the OMM and moves from the OMM to P450scc with the assistance of StAR remains unclear, and remains under active investigation.³⁴

3 β -Hydroxysteroid Dehydrogenase/ $\Delta^5 \rightarrow \Delta^4$ Isomerase

Once pregnenolone is produced from cholesterol, it may undergo 17 α -hydroxylation by P450c17 to yield 17-hydroxypregnenolone (17-Preg), or it may be converted to progesterone. Two 42-kDa isozymes of 3 β -hydroxysteroid dehydrogenase (3 β HSD), encoded by the *HSD3B1* and

HSD3B2 genes,³⁵ can catalyze both conversion of the hydroxyl group to a keto group on carbon 3 and the isomerization of the double bond from the B ring (Δ^5 steroids) to the A ring (Δ^4 steroids).¹⁰ These isozymes share 93.5% amino acid sequence identity and are enzymatically very similar: both can convert pregnenolone to progesterone, 17-Preg to 17 α -hydroxypregnenolone (17OHP), DHEA to androstenedione, and androstenediol to testosterone. However, 3 β HSD2, the isozyme expressed in the adrenals and gonads, has a high Michaelis-Menten constant (Km) of about 5.5 μ M,²⁰⁵ about 10 times higher than 3 β HSD1 expressed in placenta, brain, and "extraglandular" tissues.²⁰⁶ The low Km of extraglandular 3 β HSD1 permits it to act on the low concentrations of some steroids found in the circulation. Ultrastructural data show that 3 β HSD can be found in the mitochondria, endoplasmic reticulum, and cytoplasm.³⁶ It is not clear if this subcellular distribution differs in various types of steroidogenic cells, but this could be a novel point regulating the direction of steroidogenesis.³⁴

P450c17

P450c17 (CYP17A1) catalyzes both 17 α -hydroxylase and 17,20-lyase activities. The 17 α -hydroxylase activity of P450c17 can convert pregnenolone to 17-Preg and progesterone to 17OHP. The 17,20-lyase activity of P450c17 can convert 17-Preg to DHEA, but very little 17OHP is converted to androstenedione because human P450c17 catalyzes this reaction at only around 2% to 3% of the rate for conversion of 17-Preg to DHEA.³⁷ P450c17 is the key branch point in steroid hormone synthesis: in its absence, as in the adrenal zona glomerulosa, 17 α -hydroxylase and 17,20-lyase activities are absent, so that pregnenolone is converted to mineralocorticoids; in the presence of its 17 α -hydroxylase activity in the zona fasciculata, only the 17 α -hydroxylase activity is present so that pregnenolone is sequentially converted to cortisol; in the zona reticularis where both activities are present, pregnenolone is sequentially converted to sex steroids (see Fig. 14.3).¹⁰

17 α -Hydroxylase and 17,20 lyase were once thought to be separate enzymes. The adrenals of prepubertal children synthesize ample cortisol but virtually no DHEA (i.e., have 17 α -hydroxylase activity but not 17,20 lyase activity) until adrenarche initiates production of adrenal androgens (i.e., turns on 17,20 lyase activity). Furthermore, patients had been described lacking 17,20 lyase activity but retaining normal 17 α -hydroxylase activity.³⁸ However, both 17 α -hydroxylase and 17,20 lyase activities reside in the same active site, and cells transfected with a vector expressing P450c17 acquire both 17 α -hydroxylase and 17,20 lyase activities. P450c17 is encoded by the *CYP17A1* gene on chromosome 10q24.3, and is structurally related to the *CYP21A2* gene for P450c21 (21-hydroxylase). Thus the distinction between 17 α -hydroxylase and 17,20 lyase is functional and not genetic or structural. Human P450c17 catalyzes 17 α -hydroxylation of pregnenolone and progesterone equally well, but its 17,20 lyase activity uses 17-Preg almost exclusively, and not 17OHP,³⁷ consistent with the large amounts of DHEA secreted by both the fetal and adult adrenal. The principal factor regulating the 17,20 lyase reaction is electron transport from NADPH via P450 oxidoreductase (POR).³⁸

Electron Transport to P450c17: P450 Oxidoreductase and Cytochrome b₅

POR, a membrane-bound flavoprotein that is unrelated to mitochondrial ferredoxin reductase, receives electrons from NADPH and transfers them to the 50 microsomal forms of cytochrome P450, including P450c17, P450c21, and P450aro.¹⁸ For the 17,20 lyase reaction of P450c17, electron

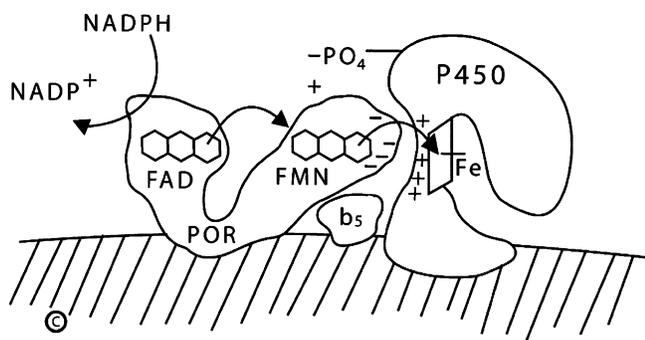

Fig. 14.5 Electron transport to microsomal forms of cytochrome P450. Nicotinamide adenine dinucleotide phosphate hydrogen (NADPH) interacts with P450 oxidoreductase (POR), bound to the endoplasmic reticulum, and gives up a pair of electrons (e^-), which are received by the flavin adenine dinucleotide (FAD) moiety. Electron receipt elicits a conformational change, permitting the isoalloxazine rings of the FAD and flavin mononucleotide (FMN) moieties to come close together, so that the electrons pass from the FAD to the FMN. Following another conformational change that returns the protein to its original orientation, the FMN domain of POR interacts with the redox-partner binding site of the P450. Electrons from the FMN domain of POR reach the heme group to mediate catalysis. The interaction of POR and the P450 is coordinated by negatively charged acidic residues on the surface of the FMN domain of POR, and positively charged basic residues in the concave redox-partner binding site of the P450. The active site containing the steroid lies on the iron side of heme ring (Fe) opposite from the redox-partner binding site. In the case of human P450c17, this interaction is facilitated by the allosteric action of cytochrome b_5 , and by the serine phosphorylation of P450c17. (©W.L. Miller)

transfer is facilitated by the action of cytochrome b_5 , acting as an allosteric factor rather than as an alternate electron donor;³⁷ 17,20 lyase activity is also increased by the serine/threonine phosphorylation of P450c17 by p38 α , a cyclic adenosine monophosphate (cAMP)-dependent protein kinase³⁹ (Fig. 14.5). Thus the availability of electrons determines whether P450c17 performs only 17 α -hydroxylation, or also performs 17,20 bond scission: increasing the ratio of POR or cytochrome b_5 to P450c17 increases the ratio of 17,20 lyase activity to 17 α -hydroxylase activity. Thus the regulation of 17,20 lyase activity, and consequently of DHEA production, depends on factors that facilitate the flow of electrons to P450c17: high concentrations of POR, the presence of cytochrome b_5 , and serine phosphorylation of P450c17.³⁸

P450c21

After the synthesis of progesterone and 17OHP, these steroids are 21-hydroxylated to yield deoxycorticosterone (DOC) and 11-deoxycortisol, respectively¹⁰ (see Fig. 14.3). The nature of the 21-hydroxylating step is of great interest because disordered 21-hydroxylation causes more than 90% of all cases of CAH. The clinical findings in CAH are complex and potentially devastating. Decreased cortisol and aldosterone synthesis often lead to sodium loss, potassium retention, acidosis, and hypotension, which will lead to cardiovascular collapse and death, usually within a month after birth if not treated appropriately. Decreased adrenal steroidogenesis in utero leads to overproduction of adrenal androgens via several pathways (see later), resulting in severe prenatal virilization of female fetuses.⁴⁰ Adrenal 21-hydroxylation is catalyzed by P450c21 found in smooth endoplasmic reticulum, using POR to receive electrons from NADPH. Duplicated *CYP21A1P* and *CYP21A2* genes lie on chromosome 6p21, but only the human *CYP21A2* gene encodes P450c21.¹⁰ As this gene lies in the middle of the major

histocompatibility locus, disorders of adrenal 21-hydroxylation are closely linked to specific human leukocyte antigen (HLA) types. Extraadrenal 21-hydroxylase activity is found in many adult and fetal tissues, especially in the liver, but is catalyzed by other enzymes, notably CYP2C19 and CYP3A4, which are principally involved in drug metabolism. CYP2C19 and CYP3A4 can 21-hydroxylate progesterone but not 17OHP, and hence may contribute to the synthesis of mineralocorticoids but not glucocorticoids.⁴¹

P450c11 β and P450c11AS

The closely related P450c11 β and P450c11AS enzymes catalyze the final steps in the synthesis of glucocorticoids and mineralocorticoids.^{10,42} These two isozymes have 93% amino acid sequence identity and are encoded by tandemly duplicated genes on chromosome 8q21-22. Like P450scc, the two forms of P450c11 are found on the inner mitochondrial membrane, and use ferredoxin and ferredoxin reductase to receive electrons from NADPH. By far the more abundant of the two isozymes is P450c11 β (encoded by *CYP11B1*), which is the classic 11 β -hydroxylase that converts 11-deoxycortisol to cortisol and 11-deoxycorticosterone to corticosterone. The less abundant isozyme, P450c11AS (encoded by *CYP11B2*), is found only in the zona glomerulosa, where it has 11 β -hydroxylase, 18-hydroxylase, and 18-methyl oxidase (aldosterone synthase) activities; thus P450c11AS is able to catalyze all the reactions needed to convert DOC to aldosterone. *CYP11B1* is induced by ACTH via cAMP and is suppressed by glucocorticoids; *CYP11B2* is induced by angiotensin II and K^+ . Patients with mutations in *CYP11B1* have classic 11 β -hydroxylase deficiency but can still produce aldosterone, whereas patients with mutations in *CYP11B2* have rare forms of aldosterone deficiency (so-called *corticosterone methyl oxidase deficiency*), while retaining the ability to produce cortisol.^{10,42}

17 β -Hydroxysteroid Dehydrogenase

Androstenedione is converted to testosterone, DHEA is converted to androstenediol, and estrone is converted to estradiol by the 17 β -hydroxysteroid dehydrogenases (17 β HSD; HSD17B), sometimes also termed 17-oxidoreductases or 17-ketosteroid reductases. The terminologies for these enzymes vary, depending on the direction of the reaction being considered. The literature about the 17 β HSDs can be confusing because (1) there are several different 17 β HSDs; (2) some are preferential oxidases, whereas others are preferential reductases; (3) they differ in their substrate preference and sites of expression; (4) the nomenclature is inconsistent; and (5) some proteins termed 17 β HSD actually have very little 17 β HSD activity, and are principally involved in other reactions.¹⁰

Type 1 17 β HSD (17 β HSD1, encoded by *HSD17B1*), is a 34-kDa reductive, estrogenic SDR enzyme expressed in ovarian granulosa cells (where it produces estradiol) and placenta (where it produces estriol).^{10,15,43-47} 17 β HSD1 uses NADPH as its cofactor, acts as a dimer, and only accepts steroid substrates with an aromatic A ring, so that its activity is confined to activating estrogens. No genetic deficiency syndrome for 17 β HSD1 has been described.

17 β HSD2 is a microsomal oxidase that uses NAD^+ to inactivate estradiol to estrone and testosterone to Δ^4 androstenedione. 17 β HSD2 is found in the placenta, liver, small intestine, prostate, secretory endometrium, and ovary. Whereas 17 β HSD1 is found in placental syncytiotrophoblast cells, 17 β HSD2 is expressed in endothelial cells of placental intravillous vessels, consistent with its apparent role in defending the fetal circulation from transplacental passage of maternal estradiol or testosterone.^{10,15,43-46} No deficiency state for 17 β HSD2 has been reported.

Microsomal 17 β HSD3 is the principal androgenic form of 17 β HSD, apparently expressed only in the testis. This enzyme is disordered in the classic syndrome of male pseudohermaphroditism that is often termed *17-ketosteroid reductase deficiency*.^{10,15,43,45,46}

An enzyme termed 17 β HSD4 was initially identified as an NAD⁺-dependent oxidase with activities similar to 17 β HSD2, but this peroxisomal protein is primarily an enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase.¹⁰ Deficiency of 17 β HSD4 causes a form of Zellweger syndrome, in which bile acid biosynthesis is disturbed but steroidogenesis is not.

17 β HSD5, originally cloned as a 3 α -hydroxysteroid dehydrogenase, is an AKR enzyme (whereas 17 β HSD types 1-4 are SDR enzymes) termed AKR1C3 that catalyzes the reduction of Δ^4 androstenedione to testosterone.^{10,48} The 17 β HSD activity of 17 β HSD5 is quite labile in vitro, and this enzyme catalyzes different activities under different conditions.⁴⁸ The adrenal zona reticularis expresses this enzyme at low levels, accounting for the small amount of testosterone produced by the adrenal.⁴⁹

17 β HSD6, encoded by the *HSD17B6* gene on chromosome 12q13.3, is also known as RoDH for its homology to retinol dehydrogenases.⁵⁰ 17 β HSD6 is expressed at low but detectable levels in the fetal testes, where it appears to catalyze oxidative 3 α HSD activities in the so-called "backdoor pathway" to dihydrotestosterone (DHT) synthesis.⁵¹

Steroid Sulfotransferase and Sulfatase

Steroid sulfates may be synthesized directly from cholesterol sulfate or may be formed by sulfation of steroids by cytosolic sulfotransferase (SULT) enzymes.^{52,53} SULTs use 3'-phosphoadenine-5'-phosphosulfate (PAPS) as sulfate donor, synthesized from adenosine triphosphate (ATP) and sulfate by two isozymes of PAPS synthase: PAPSS1, which is ubiquitously expressed, and PAPSS2, principally expressed in cartilage, adrenal, and liver.⁵⁴ At least 44 distinct isoforms of these enzymes have been identified belonging to five families of *SULT* genes; many of these genes yield alternately spliced products accounting for the large number of enzymes. The SULT enzymes that sulfonate steroids include SULT1E (estrogens), SULT2A1 (non-aromatic steroids), and SULT2B1 (sterols). SULT2A1 is the principal sulfotransferase expressed in the adrenal, where it sulfates the 3 β hydroxyl group of Δ^5 steroids (pregnenolone, 17OH-pregnenolone, DHEA, androsterone) but not cholesterol.⁵⁵ SULT2B1a will also sulfonate pregnenolone but not cholesterol, whereas cholesterol is the principal substrate for SULT2B1b in the skin, liver, and elsewhere. It is not clear whether most steroid sulfates are simply inactivated forms of steroid or if they serve specific hormonal roles. Knockout of the mouse *sult1e1* gene is associated with elevated estrogen levels, increased placental expression of tissue factor, and increased platelet activation, leading to placental thrombi and fetal loss that could be ameliorated by anticoagulant therapy. Mutations ablating the function of human SULT enzymes have not been described, but PAPSS2 mutations deplete adrenal PAPS, increasing production of unconjugated DHEA.⁵⁶ African Americans have a high rate of polymorphisms in SULT2A1, apparently influencing plasma ratios of DHEA:DHEAS, which may correlate with risk of prostatic and other cancers.

Steroid sulfates may also be hydrolyzed to the native steroid by steroid sulfatase. Deletions in the steroid sulfatase gene on chromosome Xp22.3 cause X-linked ichthyosis. The fact that males have a single copy of this gene probably accounts for males having higher DHEAS levels than females of the same age. In the fetal adrenal and placenta, diminished or absent sulfatase deficiency reduces the pool of free DHEA available for

placental conversion to estrogen, resulting in low concentrations of estriol in the maternal blood and urine. The accumulation of steroid sulfates in the stratum corneum of the skin causes the ichthyosis.

Aromatase: P450aro

Estrogens are produced by the aromatization of androgens, including adrenal androgens, by a complex series of reactions catalyzed by aromatase, P450aro.^{57,58} This microsomal cytochrome P450 is encoded by a single gene (*CYP19A1*) on chromosome 15q21.1 that uses several different promoter sequences, transcriptional start sites, and alternatively chosen first exons to encode identical P450aro in different tissues under different hormonal regulation. Aromatase expression in the extraglandular tissues, especially adipose tissue, can convert adrenal androgens to estrogens. Aromatase in the epiphyses of growing bone converts testosterone to estradiol; the tall stature, delayed epiphyseal maturation and osteopenia of males with aromatase deficiency, and their rapid reversal with estrogen replacement indicate that estrogen, not androgen, is responsible for epiphyseal maturation in males.

Rare patients with aromatase deficiency illustrate that placental aromatase activity and consequent fetoplacental estrogen synthesis are not needed for normal fetal development.⁵⁸ However, in the absence of placental aromatase activity, fetal adrenal androgens and androgen precursors pass into the maternal circulation, causing maternal virilization.⁵⁹ Furthermore, placental aromatase converts maternal androgens to estrogens, protecting the fetus from potential virilization (as in pregnant women with undertreated 21-hydroxylase deficiency [21OHD]).⁶⁰ Children with aromatase deficiency grow normally and continue to grow after puberty, because only estrogens, not androgens, mediate epiphyseal fusion. Treating aromatase-deficient patients with estrogens will fuse their epiphyses and arrest growth.⁶¹ These observations underlie the use of aromatase inhibitors for inhibiting accelerated bone maturation.

5 α -Reductases

Testosterone is converted to the more potent androgen, DHT, by 5 α -reductase, an enzyme found in testosterone's target tissues. There are two hydrophobic, 30-kDa isozymes of 5 α -reductase that share 50% identity. The type I enzyme, found in the scalp and other peripheral tissues, is encoded by the *SRD5A1* gene on chromosome 5; the type II enzyme, the predominant form found in male reproductive tissues, is encoded by the structurally related *SRD5A2* gene on chromosome 2p23.^{62,63} The syndrome of 5 α -reductase deficiency, a disorder of male sexual differentiation, is caused by a wide variety of mutations in the *SRD5A2* gene.⁶⁴ In the fetus, the *SRD5A1* gene is expressed in the testis,⁵¹ then is expressed briefly in the skin of the newborn, and then remains unexpressed until its activity and protein are again found after puberty. The *SRD5A2* gene is expressed in fetal genital skin, in the normal prostate, and in prostatic hyperplasia and adenocarcinoma. Thus the type I enzyme may be responsible for the pubertal virilization seen in patients with classic 5 α -reductase deficiency, and the type II enzyme may be involved in male pattern baldness.^{62,64}

11 β -Hydroxysteroid Dehydrogenases

Although certain steroids are typically categorized as glucocorticoids or mineralocorticoids, the "mineralocorticoid" (glucocorticoid type II) receptor has equal affinity for both aldosterone and cortisol.⁶⁵ Nevertheless, cortisol does not act as a mineralocorticoid in vivo, even though cortisol concentrations can exceed aldosterone concentrations by 100- to

1000-fold, because mineralocorticoid responsive tissues (such as the kidney) convert cortisol to cortisone, a metabolically inactive steroid.^{66,67} The interconversion of cortisol and cortisone is mediated by two membrane-bound isozymes of 11 β -hydroxysteroid dehydrogenase (11 β HSD; HSD11B), each of which can catalyze both oxidase and reductase activity, depending on the cofactor available (NADP⁺ or NADPH).^{68–74} The ratio of NADP⁺ to NADPH is regulated by hexose-6-phosphate dehydrogenase (H6PDH).⁷⁵

The type 1 enzyme (HSD11B1; 11 β HSD1) is expressed mainly in glucocorticoid-responsive tissues, such as the liver, fat, testis, and lung. HSD11B1 can catalyze both the oxidation of cortisol to cortisone using NADP⁺ as its cofactor (Km 1–2 μ M), or the reduction of cortisone to cortisol using NADPH as its cofactor (Km 0.1–0.3 μ M); the reaction catalyzed depends on which cofactor is available, but the enzyme can only function with high (micromolar) concentrations of steroid. HSD11B1 is located on the luminal side of the endoplasmic reticulum, and hence is not in contact with the cytoplasm, permitting HSD11B1 to receive NADPH provided by H6PDH.^{70,76} This links HSD11B1 to the pentose monophosphate shunt, providing a direct paracrine link between local glucocorticoid production and energy storage as fat.^{70,71} Prednisone and cortisone are inactive 11-ketosteroids that must be reduced to their active 11 β -hydroxy derivatives by HSD11B1, mainly in the liver. By activating cortisone, HSD11B1 amplifies glucocorticoid action in the tissues in which it is expressed, especially in liver and fat, potentially contributing to obesity, insulin resistance, metabolic syndrome, and possibly nonalcoholic fatty liver disease; consequently, studies of HSD11B1 inhibitors are of substantial pharmaceutical interest.^{73,74}

HSD11B2 (11 β HSD2) catalyzes the oxidation of cortisol to cortisone using NADH, and can function with low (nanomolar) steroid concentrations (Km 10–100 nM). HSD11B2 is expressed in mineralocorticoid-responsive tissues, such as the distal nephron and thus serves to “defend” the mineralocorticoid receptor (MR) by inactivating cortisol to cortisone, so that only “true” mineralocorticoids, such as aldosterone or deoxycorticosterone, can exert a mineralocorticoid effect; thus HSD11B2 prevents cortisol from overwhelming renal MRs. Placental HSD11B2 also inactivates maternal cortisol to cortisone (and prednisolone to prednisone), and the placenta has abundant NADP⁺ favoring the oxidative action of HSD11B1, so that in the placenta both enzymes protect the

fetus from high maternal concentrations of cortisol, but not from maternally administered beta-methasone or dexamethasone, which are not substrates for HSD11B enzymes. Thus the HSD11B isozymes determine whether a steroid “crosses the placenta.”

3 α -Hydroxysteroid Dehydrogenases

The 3 α -hydroxysteroid dehydrogenases (3 α HSDs) are not familiar to most endocrinologists, but are clinically important because of the recent discovery of the “backdoor pathway” of steroidogenesis.⁷⁷ This remarkable pathway (Fig. 14.6), first discovered as the mechanism by which the male marsupial fetal testis makes androgens,^{77,78} plays a central role in human male sexual differentiation.⁵¹ In this pathway, 17OHP is converted to DHT without going through DHEA, androstenedione, or testosterone, and hence provides a mechanism for 17OHP to contribute to the virilization of female fetuses with 21OHD.^{40,79,80} The reductive 3 α HSDs are AKR enzymes and the oxidative 3 α HSDs are SDR enzymes. There are four reductive 3 α HSDs, termed AKR1C4-1.¹⁵ These enzymes are structurally very similar, are encoded by a cluster of very similar genes on chromosome 10p14-15, and catalyze a wide array of steroidal conversions (notably 17-ketosteroid reduction and 20 α -reduction) and other reactions.¹⁰ AKR1C3, also known as 17 β HSD5, converts androstenedione to testosterone in the adrenal.

The backdoor pathway is characterized by both reductive and oxidative 3 α HSD activities; the reductive activity can apparently be catalyzed by either AKR1C2 or AKR1C4.⁵¹ The oxidative 3 α HSDs are SDRs that are similar to the retinol dehydrogenase or cis-retinol/androgen dehydrogenase (RoDH/CRAD) subfamily.⁸¹ The most active member of these is RoDH, also called 17 β HSD6, which probably catalyzes the final step in the backdoor pathway. In the brain, 3 α HSDs reduce 5 α -dihydroprogesterone to allopregnanolone, which is an allosteric activator of the gamma-aminobutyric acid (GABA)_A receptors.⁸² Further studies of the role of the backdoor pathway will be central to pediatric endocrinology.

Fetal Adrenal Steroidogenesis

Embryonic adrenocortical steroidogenesis begins around 7 weeks after fertilization. Steroidogenic enzymes are immunocytochemically identifiable, principally in the fetal zone, at 50 to 52 days

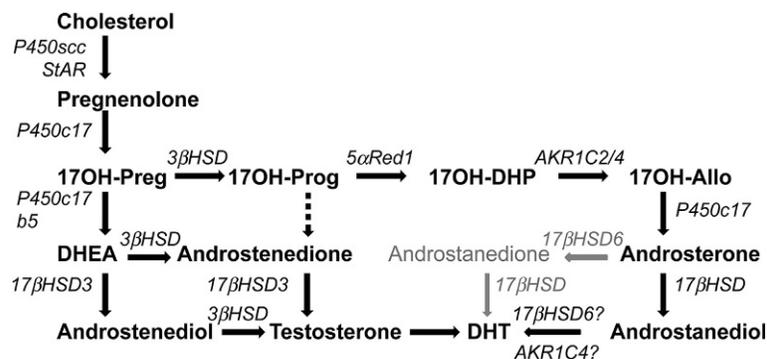

Fig. 14.6 Pathways to androgens in congenital adrenal hyperplasia (CAH). In the absence of P450_{c21} activity, the adrenal can produce androgens by three pathways. First, the pathway from cholesterol to dehydroepiandrosterone (DHEA) remains intact in 21-hydroxylase deficiency, and increased production of DHEA will lead to some DHEA being converted to androstenedione and thence to testosterone. Second, although minimal amounts of 17 α -hydroxyprogesterone (17OHP) are converted to androstenedione in the normal adrenal, the huge amounts of 17OHP produced in CAH permit some 17OHP to be converted to androstenedione and then to testosterone. Third, the so-called “backdoor pathway” depends on the 5 α and 3 α reduction of 17OHP to 17OH-allopregnenolone. This steroid is readily converted to androstenediol, which can then be oxidized to dihydrotestosterone (DHT) by a 3 α -hydroxysteroid dehydrogenase (HSD) enzyme, AKR1C2. Mass spectrometric examinations of human urinary steroids indicate this pathway is a major contributor in CAH.

postconception, and by 8 weeks postconception, the adrenal contains cortisol and responds to ACTH in primary culture systems.⁸³ This cortisol synthesis is regulated by pituitary ACTH and involves transient expression of adrenal 3 β HSD2: following the ninth week postconception, expression of 3 β HSD2 and synthesis of cortisol wane, and 3 β HSD2 is barely detectable at 10 to 11 weeks and absent at 14 weeks. At the same time, the fetal adrenal also produces 17 β HSD5,⁸³ which can convert androstenedione to testosterone. Thus the fetal adrenal makes cortisol at the same time during gestation that fetal testicular testosterone is virilizing the genitalia of the normal male fetus. This fetal adrenal cortisol apparently suppresses ACTH, which otherwise would drive adrenal androgen synthesis and virilization of 46,XX fetuses.

Fetuses affected with genetic lesions in adrenal steroidogenesis can produce sufficient adrenal androgen to virilize a female fetus to a nearly male appearance, and this masculinization of the genitalia is complete by about the 12th week of gestation. The definitive zone of the fetal adrenal produces steroid hormones according to the pathways in Fig. 14.3. In contrast, the large fetal zone of the adrenal is relatively deficient in 3 β HSD2 activity after 12 weeks.^{83,84} Robust 17,20 lyase activity and low 3 β HSD activity in the fetal adrenal account for the abundant production of DHEA and its sulfate, DHEAS, which are then converted to estrogens by the placenta (Fig. 14.7).⁸⁵ The fetal adrenal also has considerable sulfotransferase activity but little steroid sulfatase activity, also favoring conversion of DHEA to DHEAS. The resulting DHEAS is not a substrate for adrenal 3 β HSD2, and is secreted, 16 α -hydroxylated in

the fetal liver, and then acted on by placental 3 β HSD1, 17 β HSD1, and P450aro to produce estriol; steroids that escape 16 α -hydroxylation in the fetal liver yield estrone and estradiol. Placental estrogens inhibit adrenal 3 β HSD activity, providing a feedback system to promote production of DHEAS. Fetal adrenal steroids account for 50% of the estrone and estradiol and 90% of the estriol in the maternal circulation.

Although the fetoplacental unit produces huge amounts of DHEA, DHEAS, and estriol (and other steroids), they do not appear to serve an essential role.⁸⁵ Successful pregnancy requires placental synthesis of progesterone, which suppresses uterine contractility and prevents spontaneous abortion; however, fetuses with genetic disorders of adrenal and gonadal steroidogenesis develop normally, reach term gestation, and undergo normal parturition and delivery. Mineralocorticoid production is only required postnatally, estrogens are not required, and androgens are only needed for male sexual differentiation. It appears that human fetal glucocorticoids are needed at about 8 to 12 weeks,⁸³ but it is not clear that they are needed thereafter; if they are, the small amount of maternal cortisol that escapes placental inactivation suffices. A single newborn has been described with profound glucocorticoid resistance who was homozygous for a frameshift mutation at codon 772 in the glucocorticoid-binding domain of the glucocorticoid receptor (GR).⁸⁶ Although the infant had severe hypoglycemia and hypertension postnatally, pulmonary and other aspects of fetal development were normal, suggesting that glucocorticoid action is not required for normal human fetal development.

The regulation of steroidogenesis and growth of the fetal adrenal are not fully understood, but both are related to ACTH. ACTH effectively stimulates steroidogenesis by fetal adrenal cells in vitro, and excess ACTH is clearly involved in the adrenal growth and overproduction of androgens in fetuses affected with CAH. Experimental prenatal treatment of such fetuses by administering pharmacologic doses of dexamethasone to the mother at 6 to 10 weeks' gestation can significantly reduce fetal adrenal androgen production and thus reduce the virilization of female fetuses, indicating that the hypothalamic-pituitary-adrenal (HPA) axis functions very early in fetal life.⁴⁰ In contrast, anencephalic fetuses lacking pituitary ACTH have adrenals that contain a fairly normal complement of steroidogenic enzymes and retain their capacity for steroidogenesis. Thus fetal adrenal steroidogenesis may be regulated by both ACTH-dependent and ACTH-independent mechanisms.

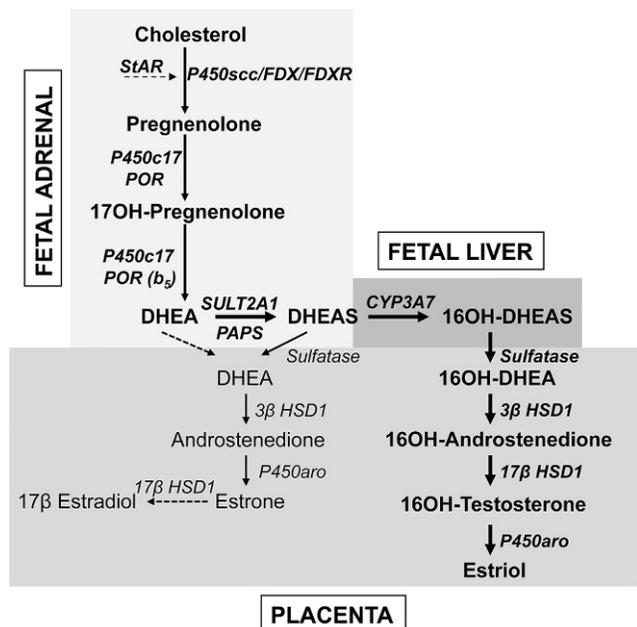

Fig. 14.7 Steroid synthesis by the fetoplacental system. The fetal adrenal has minimal 3 β -hydroxysteroid dehydrogenase (3 β HSD) activity, hence the pathway from cholesterol to dehydroepiandrosterone (DHEA) predominates. Most DHEA is converted to DHEAS by the sulfotransferase SULT2A1 and is then 16 α -hydroxylated by CYP3A7 in the fetal liver. The 16 α -hydroxy DHEAS reaches the placenta, where the sequential action of steroid sulfatase, 3 β HSD1, 17 β HSD1 and aromatase (P450aro) yield estriol, the principal steroidal product of the placenta. Small amounts of DHEA reach the placenta without being 16 α -hydroxylated, where it can be converted to estrone by 3 β HSD1 and P450aro; small amounts of estrone may also be converted to estradiol. About 80% of placental estrogen is estriol, 15% is estrone, and only 5% is estradiol.

REGULATION OF STEROIDOGENESIS

The Hypothalamic-Pituitary-Adrenal Axis

Hypothalamus: Corticotropin-Releasing Factor and Arginine Vasopressin

The principal steroidal product of the human adrenal is cortisol, which is mainly secreted in response to ACTH (corticotropin) produced in the pituitary; secretion of ACTH is stimulated primarily by corticotropin-releasing factor (CRF) from the hypothalamus. The history of the discovery of the components of the HPA axis and their interrelationships has been reviewed recently.⁸⁷ Hypothalamic CRF is a 41-amino acid peptide synthesized mainly by neurons in the paraventricular nucleus. These same hypothalamic neurons also produce the decapeptide arginine vasopressin (AVP, also known as antidiuretic hormone or ADH).⁸⁸ Both CRF and AVP are proteolytically derived from larger precursors, with the AVP precursor containing the sequence for neurophysin, which is the AVP-binding protein.

CRF and AVP travel through axons to the median eminence, which releases them into the pituitary portal circulation, although most AVP axons terminate in the posterior pituitary. AVP is cosecreted with CRF in response to stress, and both CRF and AVP stimulate the synthesis and release of ACTH, but they appear to do so by different mechanisms. CRF binds to a G protein-coupled receptor on the membranes of pituitary corticotropes and activates adenylyl cyclase, increasing cAMP, which activates the protein kinase A (PKA) signaling pathway. PKA triggers ACTH secretion by concerted regulation of cellular potassium and calcium fluxes, and enhances proopiomelanocortin (POMC) gene transcription. AVP binds to its G protein-coupled receptor and activates phospholipase C, which leads to the release of intracellular Ca^{++} and to the activation of protein kinase C (PKC). AVP seems to amplify the effects of CRF on ACTH secretion without affecting synthesis. However, CRF is the more important physiologic stimulator of ACTH release, although maximal doses of AVP can elicit a maximal ACTH response. When given together, CRF and AVP act synergistically, as would be expected from their independent mechanisms of action.

Pituitary: Adrenocorticotrophic Hormone and Proopiomelanocortin

Pituitary ACTH is a 39-amino acid peptide derived from POMC, a 241-amino acid protein.⁸⁹ POMC undergoes a series of proteolytic cleavages, yielding several biologically active peptides (Fig. 14.8). The N-terminal glycopeptide (POMC 1-75) can stimulate steroidogenesis and may function as an adrenal mitogen. POMC 112-150 is ACTH 1-39, POMC 112-126 and POMC 191-207 constitute α - and β -MSH (melanocyte stimulating hormone), respectively, and POMC 210-241 is β -endorphin. POMC is also produced in small amounts by the brain, testis, liver, kidney, and placenta, but this extrapituitary POMC does not contribute significantly to circulating ACTH. Malignant tumors will commonly produce "ectopic ACTH" in adults and rarely in children; this ACTH derives from ectopic biosynthesis of the same POMC precursor. Only the first 20 to 24 amino acids of ACTH are needed for its full biologic activity, and synthetic ACTH 1-24 is widely used in diagnostic tests of adrenal function. However, these shorter forms of ACTH have a shorter half-life than does native ACTH 1-39. POMC gene transcription is stimulated by CRF and inhibited by glucocorticoids.⁸⁹

Actions of Adrenocorticotrophic Hormone

ACTH stimulates the G protein-coupled melanocortin 2 receptor (MCR2), which is located almost exclusively in the adrenal cortex. Activation of MCR2 triggers the production of cAMP, activating PKA that catalyzes the phosphorylation of many proteins involved in steroidogenesis, thereby modifying their activity. ACTH elicits both acute and long-term effects. ACTH stimulates the biosynthesis of LDL receptors and the uptake of LDL, which provides most of the cholesterol used for steroidogenesis, and stimulates transcription of the gene for HMG-CoA reductase, the rate-limiting step in cholesterol biosynthesis, but adrenal biosynthesis of cholesterol is quantitatively much less important than the uptake of LDL cholesterol.¹¹ Cholesterol is stored in steroidogenic tissues as cholesterol esters in lipid droplets. ACTH stimulates the activity of cholesterol esterase, while inhibiting cholesterol ester synthetase, thus increasing the intracellular pool of free cholesterol, the substrate for P450_{scc}. Finally, ACTH facilitates transport of cholesterol into mitochondria, by stimulating the synthesis and phosphorylation of StAR, thus increasing the flow of free cholesterol into the mitochondria.¹¹ All of these actions are mediated by cAMP and occur within minutes, constituting the "acute" effect of ACTH on steroidogenesis.²⁸ The adrenal contains relatively modest amounts of steroid hormones; thus release of preformed cortisol does not contribute significantly to the acute response to ACTH; acute responses occur by the rapid provision of large supplies of cholesterol to mitochondrial P450_{scc}.^{11,28}

The long-term "chronic" effects of ACTH are mediated directly at the level of the steroidogenic enzymes. ACTH via cAMP stimulates the accumulation of the steroidogenic enzymes and their mRNAs by stimulating the transcription of their genes.^{2,10} ACTH also increases adrenal blood flow, increasing the influx of oxygen and metabolic fuel and the delivery of newly secreted hormones to the circulation.⁹⁰ Thus ACTH increases both the uptake of the cholesterol substrate and its conversion to steroidal products. The stimulation of this steroidogenesis occurs at each step in the pathway, and not only at the rate-limiting step, P450_{scc}.

The role of ACTH and other peptides derived from POMC, in stimulating growth of the adult adrenal, is supported by the observations that lack of pituitary POMC causes severe adrenal hypoplasia, and chronic ACTH excess causes adrenal hyperplasia. In the fetal adrenal, ACTH stimulates the local production

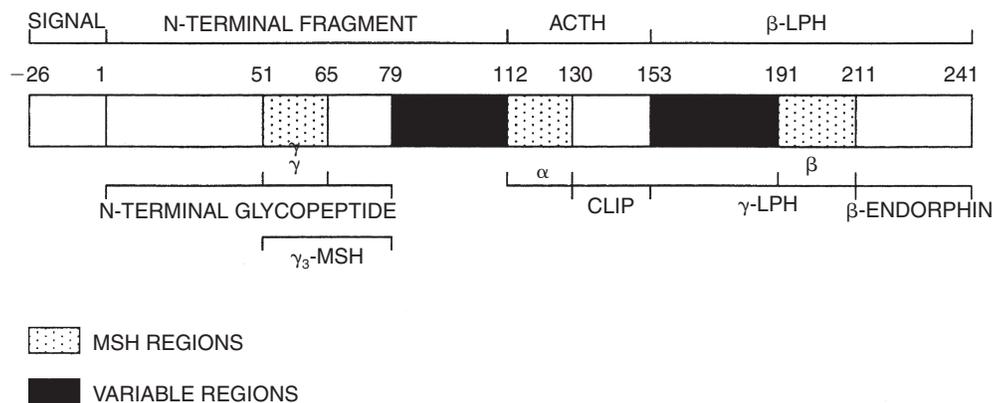

Fig. 14.8 Structure of human preproopiomelanocortin (POMC). The numbers refer to amino acid positions, with No. 1 assigned to the first amino acid of POMC after the 26-amino acid signal peptide. The α -, β -, and γ -MSH regions, which characterize the three "constant" regions, are indicated by diagonal lines; the "variable" regions are solid. The amino acid numbers shown refer to the N-terminal amino acid of each cleavage site; because these amino acids are removed, the numbers do not correspond exactly with the amino acid numbers of the peptides as used in the text. ACTH, Adrenocorticotrophic hormone; CLIP, corticotropin-like intermediate lobe peptide; LPH, lipotropic hormone; MSH, melanocyte-stimulating hormone.

of IGF-2, FGF2, and EGF. These, and possibly other factors work together to mediate ACTH-induced growth of the fetal adrenal.⁵

Diurnal Rhythms of Adrenocorticotrophic Hormone and Cortisol

Plasma concentrations of ACTH and cortisol tend to be high in the morning and low in the evening. Peak ACTH levels are usually seen at 4 to 6 AM and peak cortisol levels follow at about 8 AM. Both ACTH and cortisol are released episodically in pulses every 30 to 120 minutes throughout the day, but the frequency and amplitude of these is much greater in the morning. The basis of this diurnal rhythm is complex and poorly understood. The hypothalamic content of CRF itself shows a diurnal rhythm with peak content at about 4 AM. At least four factors appear to play a role in the rhythm of ACTH and cortisol: intrinsic rhythmicity of synthesis and secretion of CRF by the hypothalamus; light/dark cycles; feeding cycles; and inherent rhythmicity in the adrenal, possibly mediated by adrenal innervation. These factors are clearly interdependent and related. Dietary rhythms may play as large a role as light/dark cycles. Animal experiments show that altering the time of feeding can overcome the ACTH/cortisol periodicity established by a light/dark cycle. In normal human subjects, cortisol is released before lunch and supper, but not at these times in persons eating continuously during the day. Thus glucocorticoids, which increase blood sugar, appear to be released at times of fasting and are inhibited by feeding.

As all parents know, infants do not have a diurnal rhythm of sleep or feeding. Infants acquire such behavioral rhythms in response to their environment long before they acquire a rhythm of ACTH and cortisol. The diurnal rhythms of ACTH and cortisol begin to be established at 6 to 12 months and often are not well established until after 3 years of age. Once the rhythm is well established in the older child or adult, it is changed only with difficulty. When people move to different parts of the world, their ACTH/cortisol rhythms generally take 15 to 20 days to adjust appropriately. Reentrainment of the circadian clock following jet lag requires approximately 1 to 2 hours/day, more for eastward and less for westward travel.⁹¹

Physical stress (such as major surgery, severe trauma, blood loss, high fever, or serious illness) can increase the secretion of both ACTH and cortisol, but minor surgery and minor illnesses (such as upper respiratory infections) have little effect on ACTH and cortisol secretion.⁹²⁻⁹⁶ Infection, fever, and pyrogens can stimulate the release of cytokines, such as interleukin (IL)-1 and IL-6, which stimulate secretion of corticotropin-releasing hormone (CRH), and also stimulate IL-2 and tumor necrosis factor (TNF), which stimulate release of ACTH, providing further stimulus to cortisol secretion during inflammation⁹⁷; furthermore, IL-6 can directly stimulate adrenal synthesis and release of cortisol.⁹⁸ Conversely, glucocorticoids inhibit cytokine production in the immune system, providing a negative feedback loop. Most psychoactive drugs, such as anticonvulsants, neurotransmitters, and antidepressants, do not affect the diurnal rhythm of ACTH and cortisol, although cyproheptadine (a serotonin antagonist) can suppress ACTH release.

Adrenal: Glucocorticoid Feedback

The HPA axis is a classic example of an endocrine feedback system. ACTH increases production of cortisol, and cortisol decreases production of ACTH. Cortisol and other glucocorticoids exert feedback inhibition of both CRF and ACTH (and AVP), principally through the GR. Like the acute and chronic phases of the action of ACTH on the adrenal, there are acute and chronic phases of the feedback inhibition of ACTH (and

presumably CRF). The acute phase, which occurs within minutes, inhibits release of ACTH (and CRF) from secretory granules. With prolonged exposure, glucocorticoids inhibit ACTH synthesis by directly inhibiting the transcription of the gene for POMC (and AVP), which can result in secondary adrenal insufficiency. Some evidence also suggests that glucocorticoids can directly inhibit steroidogenesis at the level of the adrenal fasciculata cell itself, but this appears to be a physiologically minor component of the regulation of cortisol secretion.

Mineralocorticoid Secretion: The Renin-Angiotensin System

Renin is a serine protease enzyme synthesized primarily by the juxtaglomerular cells of the kidney, but it is also produced in a variety of other tissues, including the glomerulosa cells of the adrenal cortex. The role of adrenally produced renin is not well established; it appears to maintain basal levels of P450c11AS, but it is not known if angiotensin II is involved in this action. Renin is synthesized as a precursor of 406 amino acids that is cleaved to prorenin (386 amino acids) and finally to the 340-amino acid protein found in plasma.⁹⁹ Decreased blood pressure, upright posture, sodium depletion, vasodilatory drugs, kallikrein, opiates, and β -adrenergic stimulation all promote release of renin. Renin enzymatically attacks angiotensinogen, the renin substrate, in the circulation. Angiotensinogen is a highly glycosylated protein, and therefore has a highly variable molecular weight from 50,000 to 100,000 daltons. Renin proteolytically releases the amino-terminal 10 amino acids of angiotensinogen, referred to as *angiotensin I*. This decapeptide is biologically inactive until converting enzyme, an enzyme found primarily in the lungs and blood vessels, cleaves off its two carboxy-terminal amino acids, to produce an octapeptide, termed *angiotensin II*. Angiotensin II binds to specific membrane receptors located in the zona glomerulosa of the adrenal cortex to stimulate aldosterone production. Angiotensin-converting enzyme can be inhibited by captopril and related agents; alternatively angiotensin II receptors may be blocked by pharmacologic agents, such as candesartan for the diagnosis and treatment of (hyperreninemic) hypertension.

Angiotensin II has two principal actions, both of which increase blood pressure. It directly stimulates arteriolar vasoconstriction within a few seconds and it stimulates synthesis and secretion of aldosterone within minutes. Increased plasma potassium is a highly potent, direct stimulator of aldosterone synthesis and release. Aldosterone, secreted by the glomerulosa cells of the adrenal cortex, has the greatest mineralocorticoid activity of all naturally occurring steroids. Aldosterone causes renal potassium excretion and sodium retention, with a consequent increase in intravascular volume and blood pressure. Expansion of the blood volume provides the negative feedback signal for regulation of renin and aldosterone secretion. Angiotensin II binds to AT₁, its G protein-coupled receptor (G_q) to stimulate production of phosphatidylinositol, mobilize intracellular and extracellular Ca⁺⁺, and activate signaling via PKC and the calcium-calmodulin system.¹⁰⁰ These intracellular second messengers stimulate transcription of the *CYP11A1* gene for P450c11 independently of the actions of ACTH and cAMP. Increases in plasma potassium directly regulate aldosterone production by depolarizing zona glomerulosa cells, which leads to an influx of Ca⁺⁺ through voltage-dependent calcium channels. Thus angiotensin II and increased concentrations of potassium converge on the same intracellular second messenger pathway to regulate aldosterone synthesis and secretion. Although the renin-angiotensin system is clearly the major regulator of mineralocorticoid secretion, ACTH (and possibly

other POMC-derived peptides) can also promote secretion of aldosterone. Ammonium ion, hyponatremia, dopamine antagonists, and some other agents can also stimulate secretion of aldosterone, and atrial natriuretic factor is a potent physiologic inhibitor of aldosterone secretion.

The trophic roles of angiotensin II and hyperkalemia are supported by animal studies showing a dynamic expansion of the zona glomerulosa in response to chronic volume depletion, MR blockade, a low-sodium diet, and/or a high-potassium diet. In contrast, chronic volume expansion, as occurs with a high-sodium diet and/or hypokalemia, inhibits growth of the zona glomerulosa.¹⁰¹

Adrenal Androgen Secretion and the Regulation of Adrenarche

DHEA, DHEAS, and androstenedione, which are almost exclusively secreted by the adrenal zona reticularis, are generally referred to as adrenal androgens because they can be peripherally converted to testosterone. However, these steroids have little if any capacity to bind to and activate androgen receptors, hence they are only androgen precursors, and not true androgens. The fetal adrenal secretes large amounts of DHEA and DHEAS, and these steroids are abundant in the newborn, but their concentrations fall rapidly as the fetal zone of the adrenal involutes following birth. After the first year of life, the adrenals of young children secrete very small amounts of DHEA, DHEAS, and androstenedione until the onset of adrenarche, usually around age 7 to 8 years, preceding the onset of puberty by about 2 years. Adrenarche is independent of puberty, the gonads, or gonadotropins, and the mechanism by which the onset of adrenarche is triggered remains unknown. The secretion of DHEA and DHEAS continues to increase during and after puberty and reach maximal values in young adulthood, following which there is a slow, gradual decrease in the secretion of these steroids in the elderly ("adrenopause") (Fig. 14.9).¹⁰² Men have higher serum concentrations of DHEAS than women,¹⁰² probably because men have a single copy of the X-linked steroid sulfatase gene.¹⁰³ Throughout much of adult life, adrenal secretion of DHEAS exceeds that of cortisol; in adult women, adrenal secretion of androgen precursors and androgens is equal to their secretion from the ovary. Despite the huge increases in the adrenal secretion of DHEA and DHEAS during adrenarche, circulating concentrations of ACTH and cortisol do not change with age. Thus ACTH plays a permissive role in adrenarche but does not trigger it. Searches for hypothetical polypeptide hormones that might specifically stimulate the zona reticularis have been unsuccessful. Adrenarche is a unique phenomenon confined to few

higher primates, such as chimpanzees or orangutans, but the significance of adrenarche remains unknown.

Recent studies of adrenarche have focused on the roles of 3 β HSD and P450c17. The abundance of 3 β HSD in the zona reticularis appears to decrease with the onset of adrenarche, and the adrenal expression of cytochrome b₅, which fosters the 17,20 lyase activity of P450c17,^{37,38} is almost exclusively confined to the zona reticularis; these factors strongly favor the production of DHEA.¹⁰⁴ The phosphorylation of P450c17, apparently by p38 α ,³⁹ also increases 17,20 lyase activity, but its potential role in adrenarche remains unexplored. Premature and exaggerated adrenarche may be associated with insulin resistance and/or being overweight, and girls with premature exaggerated adrenarche appear to be at much higher risk of developing the polycystic ovary syndrome as adults (characterized by hyperandrogenism, fewer ovulatory cycles, insulin resistance, and hypertriglyceridemia). Recent evidence suggests that infants born small for gestational age may be at increased risk for this syndrome. Thus studies of physiology, biochemistry, and clinical correlates of adrenarche suggest premature adrenarche may be an early sign of a metabolic disorder. The suggestion that replacing the DHEA may improve memory and a sense of well-being in the elderly and in adrenal insufficiency remains controversial.¹⁰⁵

Whereas it has long been thought that DHEA, DHEAS, and androstenedione are "adrenal androgens," recent work has shown that the principal adrenal androgens are 11-oxygenated (Oxo) steroids, mainly 11-keto-testosterone (11-KT).^{106,107} In addition to being expressed in the zona fasciculata, P450c11 β , the classic 11-hydroxylase that converts 11-deoxycortisol to cortisol, is expressed in the zona reticularis, where it converts androstenedione and testosterone to 11OH-androstenedione and 11OH-testosterone, respectively. These 11-Oxo steroids can be converted into the nonaromatizable 11-keto androstenedione and 11-KT by HSD11B2 (Fig. 14.10). 11-KT may also be 5 α -reduced to 11-keto dihydrotestosterone (11-KDHT); 11-KT and 11-KDHT are androgens that bind and activate the androgen receptor with affinities similar to those of testosterone and DHT;^{108–111} these androgens are found at similar levels in men and woman,¹⁰⁹ are higher in the adrenal vein than in peripheral veins,¹¹² and are elevated in CAH and polycystic ovary syndrome. Thus 11-KT appears to be the dominant circulating bioactive androgen during both normal and premature adrenarche,¹¹³ as well as in classic CAH.^{112,114} These 11-Oxo steroids correlate with adrenal size and may be useful biomarkers for adrenal rest tumors in CAH patients.¹¹⁵

PLASMA STEROIDS AND THEIR DISPOSAL Structure and Nomenclature

All steroid hormones are derivatives of pregnenolone (Fig. 14.11). Pregnenolone and its derivatives that contain 21 carbon atoms are often termed C21 steroids. Each carbon atom is numbered, indicating the location at which the various steroidogenic reactions occur (e.g., 21-hydroxylation, 11-hydroxylation). The 17,20 lyase activity of P450c17 cleaves the bond between carbon atoms 17 and 20, yielding C19 steroids, which include all the androgens; P450aro converts C19 androgens to C18 estrogens. With the exception of estrogens, all steroid hormones have a single unsaturated carbon-carbon double bond. Steroids having this double bond between carbon atoms 4 and 5, including all the principal biologically active steroids, are termed Δ^4 steroids; their precursors having a double bond between carbon atoms 5 and 6 are termed Δ^5 steroids. The two isozymes of 3 β HSD convert Δ^5 to Δ^4 steroids.

There is a logically systematic, unambiguous chemical terminology to describe accurately the structure of all the steroid

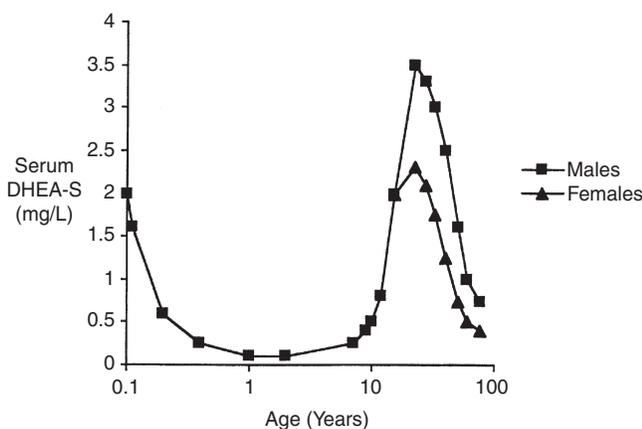

Fig. 14.9 Concentrations of dehydroepiandrosterone sulfate as a function of age. Note that the x-axis is on a log scale.

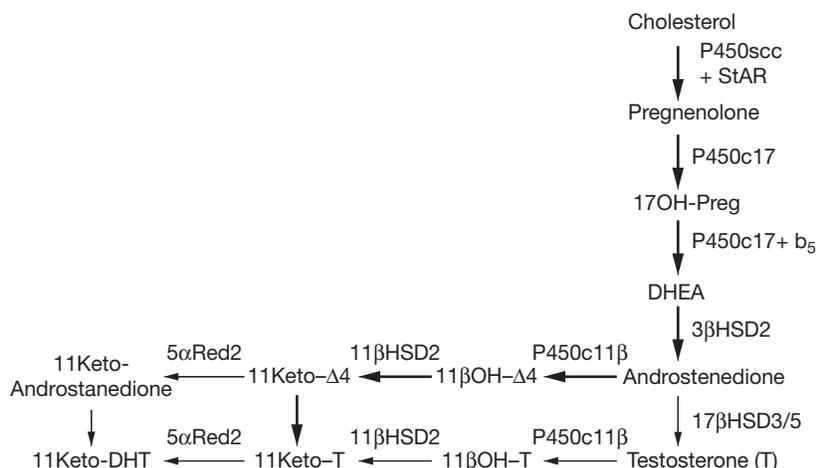

Fig. 14.10 Adrenal androgen synthesis. The traditional view of adrenal androgen synthesis is cholesterol→pregnenolone→17OH-pregnenolone (17OH-Preg)→DHEA→androstenedione, as shown on the right. However, rather than being androgens, dehydroepiandrosterone (DHEA), DHEA sulfate (S), and androstenedione have virtually no capacity to bind to and transactivate the androgen receptor, and hence are simply C19 (19-carbon) precursors of androgens. Small amounts of androstenedione may be converted to testosterone by adrenal 17 β -hydroxysteroid dehydrogenase 5 (17 β HSD5) (AKR1C3), but the principal androgenic steroid secreted by the adrenal is 11-keto-testosterone (11Keto-T). Both androstenedione and testosterone may be 11-hydroxylated by P450c11 β to yield 11OH-androstenedione (11OH- Δ 4 and 11OH-testosterone (11OH-T), respectively. These steroids can be oxidized by 11 β HSD (the same enzyme that oxidizes of cortisol to cortisone) to 11-keto-androstenedione (11Keto- Δ 4) and 11-keto-testosterone (11Keto-T), respectively. Although 11Keto-T is the principal androgen in the adrenal vein, it may be 5 α -reduced by 5 α -reductase type 2 in peripheral tissues and possibly also by 5 α -reductase type 1 in the adrenal itself, to 5 α -dihydrotestosterone, respectively. The quantitatively predominant pathway is androstenedione→11OH- Δ 4→11Keto- Δ 4→11-Keto-T, as indicated by the bold arrows. (© W.L. Miller)

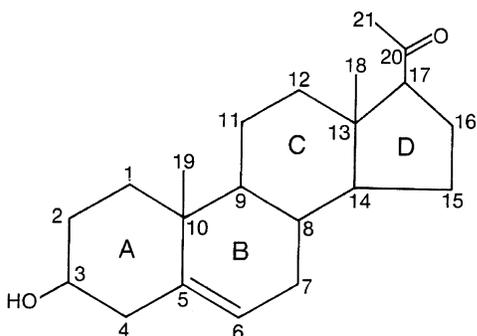

Fig. 14.11 Structure of pregnenolone. The carbon atoms are indicated by numbers and the rings are designated by letters according to standard convention. Pregnenolone is derived from cholesterol, which has a 6-carbon side chain attached to carbon #21. Pregnenolone is a “ Δ^5 compound,” having a double bond between carbons #5 and 6; the action of 3 β -hydroxysteroid dehydrogenase/isomerase moves this double bond from the B ring to carbons #4 and 5 in the A ring, forming Δ^4 compounds. All of the major biologically active steroid hormones are Δ^4 compounds.

hormones and all their conceivable derivatives. However, this terminology is unbelievably cumbersome (e.g., cortisol is 11 β ,17 α ,21-trihydroxy-pregn-4-ene-3,20-dione, and dexamethasone is 9 α -fluoro-11 β ,17 α ,21-trihydroxypregna-1,4-diene-3,20-dione). Therefore we use only the standard “trivial names.” Before the structures of the steroid hormones were determined in the 1930s, Reichstein, Kendall, and others identified them as spots on paper chromatograms and designated them A, B, C, and so on. Unfortunately, some persist in using this outmoded terminology more than 80 years later, so that corticosterone is sometimes termed compound B, cortisol compound F, and 11-deoxycortisol compound S. This archaic terminology obfuscates the precursor-product relationships of the steroids, confuses students, and should not be used.

Circulating Steroids

Although over 50 different steroids have been isolated from adrenocortical tissue, the main pathways of adrenal steroidogenesis include only a dozen or so steroids, of which only a few are secreted in sizable quantities. The adult secretory rates for DHEA and cortisol are each about 20 mg/24 hours and the secretion of corticosterone, a weak glucocorticoid, is about 2 mg/24 hours. Although glucocorticoids, such as cortisol, and mineralocorticoids, such as aldosterone, are both needed for life and hence are of physiologic importance, diagrams, such as Fig. 14.3, fail to indicate that these steroids are not secreted in molar equivalents. The adult secretion rate of aldosterone is only about 0.1 mg/24 hours. This 100- to 1000-fold molar difference in the secretory rates of cortisol and aldosterone must be borne in mind when considering the effects of steroid-binding proteins in plasma and when conceptualizing the physiologic manifestations of incomplete defects in steroidogenesis.

Most circulating steroids are bound to plasma proteins, including corticosteroid-binding globulin (CBG), albumin, and α_1 acid glycoprotein.^{116,117} CBG has a very high affinity for cortisol but a relatively low binding capacity albumin has a low affinity and high capacity and α_1 acid glycoprotein is intermediate for both variables. The result is that about 90% of circulating cortisol is bound to CBG and a little more is bound to other proteins. Interestingly, absence of CBG does not cause a detectable physiologic disorder. Therefore these plasma proteins are thought to act as a nonessential reservoir for steroids that facilitates broad and even distribution of cortisol throughout the body. Most synthetic glucocorticoids used in therapy do not bind significantly to CBG and bind poorly to albumin, partially accounting for their increased potencies, which are also associated with increased receptor-binding affinities. Aldosterone is not bound well by any plasma protein; hence changes in plasma protein concentration do not affect plasma aldosterone concentrations, but greatly influence plasma cortisol concentrations. Estradiol and testosterone bind

strongly to a different plasma protein termed sex steroid-binding globulin and also bind weakly to albumin.

Because steroids are hormones, it is often thought that the concentration of “free” (i.e., unbound) circulating steroids determines biologic activity. However, the target tissues for many steroid hormones contain enzymes that modify those steroids. Thus many actions of testosterone are actually caused by DHT produced by local 5α -reductase. Similarly, cortisol will have differential actions on various tissues because of the presence or absence of the two isozymes of 11β HSD, which can inactivate cortisol to cortisone or reactivate cortisone back to cortisol. Analogous peripheral metabolism occurs via “extraglandular” 21 -hydroxylase, $P450_{aro}$, 3β HSD, and 17β HSD. Thus circulating steroids are both classic hormones and precursors to locally acting autocrine or paracrine factors.

Steroid Catabolism

Only about 1% of circulating plasma cortisol and aldosterone are excreted unchanged in the urine; the remainder is metabolized by the liver. Technologies, such as labeled tracers and mass spectroscopy, have enhanced our understanding of adrenal physiology and have advanced clinical care. Understanding the processes and pathways of steroid metabolism can facilitate more rapid and precise diagnoses and avoid unwanted side effects from drugs. Liquid chromatography-mass spectrometry (LC-MS/MS) can now specifically and simultaneously identify and quantify major and minor metabolites. The major enzymes that metabolize steroids are summarized later.

Major Enzymes That Metabolize Steroids

The liver is the primary site of glucocorticoid metabolism. Cortisol is reduced, oxidized, or hydroxylated and then conjugated with sulfate or glucuronic acid, rendering it water soluble, and is excreted in the urine. 3α -Hydroxysteroid dehydrogenase (e.g., AKR1C2 and AKR1C4) is the major enzyme group that reduces cortisol at the 3-keto group, and 5α - or 5β -reductases (SRD5A1 and AKR1D1, respectively) reduce the 4-5 double bond in the A ring. The tetrahydrocortisols and tetrahydrocortisones that result from these reactions can be reduced by 20 -hydroxysteroid dehydrogenases, producing cortols and cortolones. Depending on cofactor availability, 11β -hydroxysteroid dehydrogenase type 1 (HSD11B1) can have either dehydrogenase (inactivation) or reductase (activation) activities, but in the liver, this enzyme usually functions as a reductase to activate cortisone to cortisol.^{68,118} Cortisol, and the metabolites generated in the reactions described earlier, are oxidized. This process removes the C20-C21 side chain, resulting in C19 steroids with a 17-ketone group, but the enzyme that drives this reaction has not yet been identified. CYP3A4 can 6β -hydroxylate cortisol; when cortisol levels are normal, the rate of this reaction is very low.¹¹⁹ However, when cortisol levels are elevated, the rate of the reaction increases, which can make the measurement of urinary 6β -hydroxycortisol a useful adjunct test for excess glucocorticoids. Finally, uridine diphosphoglucuronosyl transferases can conjugate glucuronic acid or sulfate to C19 and C21 metabolites, increasing their water solubility and facilitating their urinary excretion.¹²⁰

Similarly to cortisol, aldosterone is reduced and conjugated in the liver. $4,3$ -Ketosteroid-reductase (which also has 5β -hydroxysteroid reductase activity) and a 3α -hydroxysteroid dehydrogenase are the major enzymes that result in the conversion of aldosterone to 3α , 5β -tetrahydroaldosterone.¹²¹ Tetrahydroaldosterones are conjugated to glucuronic acid at the 3-keto position (which increases water solubility) and is the major metabolite of aldosterone that is excreted in the urine.

DHEA is the adrenal steroid produced in greatest quantity. DHEA is converted to androstenedione and 5α -reduced to androsterone, which is then converted to etiocholanolone by 5β -reductase. Finally, 17β -hydroxysteroid dehydrogenases reduce etiocholanolones into -diol derivatives, which can be conjugated and excreted in the urine. However, fecal excretion of DHEA and its metabolites is higher than other steroids. The sulfate ester of DHEA (DHEAS), on the other hand, can be directly excreted in the urine. Although these pathways can seem somewhat esoteric, as illustrated later, these pathways can be perturbed by common therapies and conditions, hence they need to be considered in clinical diagnostic and treatment plans.

Examples of Drugs That Alter Steroid Metabolism

Thyroid Hormone accelerates cortisol metabolism by inducing hepatic 5α - and 5β -reductase activity and inhibiting CYP3A enzymes.¹²² The converse process occurs in patients with hypothyroidism. In both situations, serum cortisol levels are usually normal because the HPA axis remains intact. However, in cases of hypopituitarism, it is prudent to replace cortisol before initiating thyroid hormone replacement, to avoid an acute adrenal crisis because of accelerated cortisol clearance.

Spirolactone increases serum aldosterone levels, in part by inhibition of 18 -glucuronidation of aldosterone.

Troglitazone induces CYP3A4 activity, disrupting cortisol metabolism.¹²³ Although neither rosiglitazone nor pioglitazone appear to affect CYP3A4,¹²⁴ thiazolidinedione drugs generally inhibit steroidogenic $P450_{c17}$ and HSD3B2.^{125,126}

Drugs That Alter P450 Enzymes. The results of a randomized control trial supported reports that consuming *Hypericum perforatum* (St. John’s Wort, a common herbal remedy) decreased efficacy of estradiol-based oral contraception. St. John’s Wort induces CYP3A4, CYP2C19, and CYP2C9, accelerating the metabolism of the oral contraceptives, decreasing their effectiveness.^{127,128} In contrast, the antifungal drug ketoconazole acts principally by inhibiting CYP51 (lanosterol demethylase), but it also inhibits several steroidogenic P450 enzymes and has been used as adjunctive therapy in prostate cancer¹²⁹ and Cushing syndrome.¹³⁰

Examples of Disorders That Alter Steroid Metabolism

Stress: Surprisingly, elevations in ACTH levels are usually a transient processes, even when stress is prolonged. The persistently elevated cortisol levels during chronic stress are caused by stimulating cytokines and diminished clearance of cortisol through enzymatic inactivation by 5α - and 5β -reductases and by HSD11B2.¹³¹

Cushing Syndrome: It is thought that when glucocorticoid levels remain persistently elevated, the oxidation and reduction pathways that metabolize them become saturated and CYP3A4 is induced. This results in increased levels of 6β -hydroxylation (and concomitantly lower levels of cortols, cortolones, tetrahydrocortisone, and 5α -tetrahydrocortisol) excreted, which can be confirmed by analysis of the urine.¹¹⁹ Elevations in the levels of glucocorticoids also stimulate hepatic HSD11B2 activity.

Obesity: Obese individuals have elevated levels of cortisol metabolites in their urine, even when normalized for body surface area.¹³² It is important to distinguish this process from Cushing syndrome. In obese patients, serum cortisol levels are normal as the higher excretion rate is matched by higher production rates.

Insulin Resistance: Individuals with insulin resistance, including those with hyperinsulinemia, have increased levels of hepatic SRD5A1 activity, increasing urinary excretion of 5α -reduced metabolites of cortisol.¹³³

Renal Disease: Although metabolism of cortisol is usually normal in patients with renal disease, clearance of glucuronides can be reduced, causing accumulation of the inactive conjugated compounds in the circulation.¹³⁴ This process could potentially be used to monitor disease but is not thought to contribute to pathology.

Heart Failure: Patients with severe congestive heart failure and impaired perfusion of the liver also have impaired aldosterone metabolism, resulting in lower levels of urinary tetrahydroaldosterone glucuronide.¹³⁵

CLINICAL AND LABORATORY EVALUATION OF ADRENAL FUNCTION

Clinical Evaluation

Astute clinical evaluation can generally reveal the presence of primary adrenal deficiency or hypersecretion before performing laboratory tests. Thomas Addison described adrenal insufficiency in 1849, long before immunoassays became available. Virtually all patients with chronic adrenal insufficiency will have weakness, fatigue, anorexia, weight loss, hypotension, and hyperpigmentation. Patients with acute adrenal insufficiency may have hypotension, shock, weakness, apathy, confusion, anorexia, nausea, vomiting, dehydration, abdominal or flank pain, hyperthermia, and/or hypoglycemia. Deficient adrenal androgen secretion will compromise the acquisition of virilizing secondary sexual characteristics (pubic and axillary hair, acne, axillary odor) in female adolescents. Early signs of glucocorticoid excess include increased appetite, weight gain, mood changes, and growth arrest without a concomitant delay in bone age. Chronic glucocorticoid excess in children results in typical Cushingoid facies and muscle wasting, but the “buffalo hump” and centripetal distribution of body fat that are characteristic of adult Cushing disease are seen only in long-standing undiagnosed disease in children. Mineralocorticoid excess is mainly characterized by hypertension, but patients receiving very low sodium diets (e.g., the newborn) will not be hypertensive, as mineralocorticoids increase blood pressure primarily by retaining sodium and thus increasing intravascular volume. Moderate hypersecretion of adrenal androgens is characterized by mild signs of virilization, whereas substantial hypersecretion of adrenal androgens is characterized by accelerated growth, with a disproportionate increase in bone age, increased muscle mass, acne, hirsutism, and deepening of the voice. A key feature of any physical examination of a virilized male is careful examination and measurement of the testes. Bilaterally enlarged testes suggest true (central) precocious puberty; unilateral testicular enlargement suggests testicular tumor; prepubertal testes in a virilized male indicate an extratesticular source of androgen, such as the adrenal.

Imaging studies are of limited utility in adrenocortical disease. Computed tomography (CT) will only rarely detect pituitary tumors hypersecreting ACTH, and magnetic resonance imaging (MRI) will detect less than half of these, even with gadolinium enhancement. The small size, odd shape, and location near other structures also compromise the use of imaging techniques for the adrenals. CT is currently the first choice of imaging the adrenal gland; while entailing radiation exposure, it has the advantage of higher resolution compared with MRI. Patients with Cushing disease or CAH will have modestly enlarged adrenals, but such enlargement is not detectable by imaging techniques with any useful degree of certainty. Imaging studies may be of assistance in diagnosing gross enlargement of the adrenals in congenital lipoid adrenal hyperplasia, their hypoplasia in adrenal hypoplasia congenita, or in the hereditary ACTH unresponsiveness syndromes, and with many malignant tumors; however, many adrenal

adenomas are too small (<2 mm) to be detected. Thus imaging studies may establish the presence of pituitary or adrenal tumors, but they can never establish their absence. Complementary functional tests, with radiopharmaceuticals targeted to the adrenal cortex and medulla, may enhance the diagnostic utility of imaging studies and are used in combination with scintigraphy, positron emission tomography (PET), and single-photon emission computed tomography (SPECT).

Catheter-directed hormonal sampling is rarely performed in children. Petrosal sinus sampling may be of use in suspected Cushing disease, when imaging studies fail to reveal the pituitary ACTH-secreting tumor. Adrenal vein sampling may distinguish unilateral from bilateral hypersecretory adrenal adenomas (e.g., hyperaldosteronism, Conn syndrome), but these are usually seen in adults.

Laboratory Evaluation

The diagnostic evaluation of adrenal function is essentially chemical. The nonspecificity of many of the clinical signs described earlier and the disappointing results with imaging studies remind us that any proper evaluation of HPA function must rely on a series of carefully performed physiologic maneuvers associated with hormonal assays. The development of highly specific, exquisitely sensitive assays that can be done on small volumes of blood now permit the direct examination of virtually every hormone involved in adrenal metabolism. In addition, steroid profiling and analysis of serum and urine samples, using chromatographic, mass-spectrometric methods, with which conventional and novel steroid metabolites may be detected simultaneously from a single sample, has developed into a powerful tool to identify characteristic steroidal signatures of complex disorders.

Measurement of Steroids

Measurement Techniques. Steroids are typically measured by immunoassays (IAs) or mass spectrometry (MS) methods. IAs are the traditional technique used in most routine laboratories: they are easy, fast, cheap, and widely available. IAs are limited by their specificity, which is limited by (1) a size mismatch between small steroid molecules and the binding fragment of the immunoglobulin, (2) cross-reactivity of antisera to related steroids, and (3) the quality of the antisera themselves. Furthermore, matrix effects caused by cross-reacting nonsteroidal molecules, other lipophilic compounds, or binding proteins in unprocessed samples may also affect specificity of IAs. This effect may be ameliorated by sample purification by liquid or solid phase extraction, chromatography, or precipitation. However, direct IAs on automated high-throughput instruments have pushed IAs to their limits.¹³⁶ Although the reliability of IAs has been questioned recently, especially for measuring sex steroids,^{136,137} validated IAs performed properly remain a valuable tool for clinical steroid measurements.^{136,138,139}

MS may be the most versatile and precise method for the qualitative and quantitative measurement of steroids.¹³⁹ Chromatographic methods (gas or liquid) serve as separation techniques, and the mass spectrometer serves as the detector; together, these methods achieve the highest analytical specificity and selectivity. In contrast to IAs, where one test measures a single steroid, a single run in an MS-based assay provides a steroid profile of multiple steroids. Depending on the specific methods applied, instruments may be run in a nondiscriminatory, untargeted scanning mode, which is typically used for research studies. In contrast, in clinical applications, the instruments record preselected ions corresponding to specific steroid analytes. Quantitative analysis of steroids requires

internal standards labeled with stable isotopes; these are now commercially available for most steroids of interest, including the newly identified steroid metabolites derived from the “backdoor” and 11-Oxo pathways. In general, gas chromatography followed by mass spectrometry (GC-MS) is the ideal method for separating steroids and is widely used in research laboratories for characterizing steroid metabolites in new or complex disorders of steroidogenesis. However, GC-MS/MS requires sample derivatization, it is complex and time-consuming, and is not suitable for high-throughput analysis of clinical samples. In contrast, LC-MS/MS is easier, faster, and can analyze sulfated and glucuronidated steroids. Thus LC-MS/MS is used as a high-throughput method for steroid analysis and has now become the method of choice. However, all MS-based methods require knowledge of complex analytics and biochemistry and hence are only established in specialized laboratories. Interpreting a steroid profile of a serum or urine sample is not trivial. Concentrations or excretion rates of multiple metabolites are compared with reference values and/or precursor:product ratios calculated as surrogates of enzyme activities.¹⁴⁰ Diagnosis of complex steroid disorders requires pattern recognition from quantitative datasets of multiple steroids. This may be facilitated by unbiased mathematical approaches (“machine learning”) and has been used for some steroid disorders.¹⁴¹

Plasma/Serum Concentrations of Cortisol and Other Steroids. Plasma cortisol may be measured by IAs, such as radioimmunoassay (RIA), immunoradiometric assay (IRMA), and electrochemiluminescence assay (ECLIA), the latter being the preferred method in automated high-throughput laboratories. Alternatively, cortisol can also be determined by LC-MS/MS in a standardized setting. It is essential to know what method one’s laboratory is using and precisely what this method is measuring. All immunoassays have some degree of cross-reactivity with other steroids. Most cortisol IAs will detect both cortisol and cortisone; in contrast, these are readily distinguished by mass spectrometric techniques. The newborn’s plasma contains mainly cortisone rather than cortisol, hence comparison of newborn data obtained by high-performance liquid chromatography (HPLC) or LC-MS/MS to published standards obtained by IAs may incorrectly suggest adrenal insufficiency. Tables 14.2 and 14.3 summarize the normal plasma concentrations for a variety of steroids measured by LC-MS/MS (<https://www.endocrinesciences.com/>). With the notable exception of DHEAS, most adrenal steroids exhibit a diurnal variation, based on the diurnal rhythm of ACTH. Because the stress of illness or hospitalization can increase adrenal steroid secretion and because diurnal rhythms may not be well established in children under 3 years of age, it is best to obtain two or more samples for the measurement of any steroid.

Data exist for the concentrations of a large number of steroid hormones throughout normal infancy, childhood, and adolescence (see Tables 14.2 and 14.3). Not all endocrine laboratories perform all of these assays, and, depending on the assay procedures used, various laboratories may have different “normal” values. Most central hospital and commercial laboratories are designed primarily to serve adult, rather than pediatric, patients. Thus it is important to know whether the available assays will be sufficiently sensitive with small volumes of blood to be useful in measuring pediatric values. This is especially true for the measurement of sex steroids (and gonadotropins), which can exhibit pathological elevations in children and still remain below the limit of detection of most “adult” assays. Efforts to achieve standardization of analytical methods and normative values are active topics in the field.^{138,139}

Urinary Steroid Excretion. Measurement of the 24-hour urinary excretion of steroid metabolites, one of the oldest procedures for assessing adrenal function, has recently been revived by novel analytical mass spectrometric methods. Examination of total 24-hour urinary steroid excretion eliminates the diurnal fluctuations in serum steroid concentrations, and the variations attributable to episodic bursts of ACTH and transient stress (such as a visit to the clinic or difficult venipuncture). Collection of a complete 24-hour urine sample can be difficult in the infant or small child, hence urine should also be assayed for creatinine to monitor the completeness of the collection. Because of the diurnal and episodic nature of steroid secretion, one should never infer the 24-hour excretory rate from partial collections. This is important when assessing the absolute excretion rate of a single steroid, such as free cortisol. In contrast, a spot urine (preferably the first morning void, which is most concentrated and has been produced under peak ACTH stimulation), in which multiple excreted steroids are quantified in relation to creatinine, may suffice for qualitative pattern diagnostic of a specific steroid disorder.

Contemporary procedures for urinary steroid analysis use chromatography for separating steroids, followed by an MS detection method, usually GC-MS/MS, permitting very sensitive and specific assays of urinary steroids. However, each steroid is metabolized to multiple forms before being excreted in urine, and this metabolism can vary with age and sex in pediatric populations, so that the analyses are complex and require specialized expertise that is not yet widely available.^{139,140} Urinary free cortisol (UFC) measurements are highly reliable for diagnosing Cushing syndrome in adults. Excretion of UFC and of total cortisol metabolites is closely correlated with age, body surface area, and adiposity, but are typically $11 \pm 5 \mu\text{g}/\text{m}^2/\text{day}$.^{142,143} Values vary substantially among different reference laboratories, reflecting variations in assay technologies, thus it is essential to use a laboratory with good data for normal children. It remains important to measure urinary creatinine to monitor the completeness of the collection.

Plasma Renin

Renin may be assayed by its enzymatic activity or by direct measurements of its concentration. Plasma renin activity (PRA) is simply an assay of the amount of angiotensin I generated per milliliter of serum, per hour at 37° C. In normal serum, the concentration of both renin and angiotensinogen (the renin substrate) are limiting. Another test, which is technically more challenging, directly measures plasma renin content (PRC) by immunoassay.

PRA is sensitive to dietary sodium intake, posture, diuretic therapy, activity, and sex steroids. Because PRA values can vary widely, it is best to measure PRA twice, once in the morning, after overnight supine posture, and then again after maintenance of upright posture for 4 hours. A simultaneous 24-hour urine for total sodium excretion is generally needed to interpret PRA results. Decreased dietary and urinary sodium, decreased intravascular volume, diuretics, and estrogens will increase PRA. Sodium loading, hyperaldosteronemia, and increased intravascular volume decrease PRA.

Renin measurements are used in the evaluation of hypertension and in the management of CAH. Assessment of the renin-angiotensin system is essential in children with simple virilizing (SV) CAH who lack clinical evidence of urinary salt loss (hyponatremia, hyperkalemia, acidosis, hypotension, shock), but who may nevertheless have increased PRA, especially when dietary sodium is restricted. This is a clinical sign that this form of 21OHD is simply a milder form of the more common salt-wasting form. Treatment of SV CAH with sufficient

(From LabCorp (Laboratory Corporation of America)/Endocrine Sciences, Calabasas Hills, California 2019.)

mineralocorticoid, to suppress PRA into the normal range, will reduce the child's requirement for glucocorticoids, thus maximizing final adult height and reducing exposure to excess glucocorticoids. Children with CAH need to have their mineralocorticoid replacement therapy monitored routinely by measuring PRA.⁴⁰ Measurement of angiotensin II is also possible in some research laboratories, but most antibodies to angiotensin II strongly cross-react with angiotensin I. Thus PRA remains the usual way of evaluating the renin-angiotensin-aldosterone system.

Plasma Adrenocorticotrophic Hormone and other Proopiomelanocortin Peptides

Accurate immunoassay of plasma ACTH is available in most centers, but its measurement remains more difficult and variable than the assays for most other pituitary hormones. Handling of the samples must be done with care; samples must be drawn into a plastic syringe containing heparin or ethylenediamine tetraacetic acid (EDTA) and quickly transported in plastic tubes on ice, as ACTH adheres to glass and is quickly inactivated. Thus elevated plasma ACTH concentrations can be highly informative, but most assays cannot detect low or low-normal values, and such values can be spurious if the samples are handled badly. In adults and older children who have well-established diurnal rhythms of ACTH, normal 8 AM values rarely exceed 50 pg/mL, whereas 8 PM values are usually undetectable. Patients with Cushing disease often have normal morning values, but the diagnosis can be suggested by consistently elevated afternoon and evening values; patients with the ectopic ACTH syndrome can have values up to 1000 pg/mL.

Secretory Rates

The secretory rates of cortisol and aldosterone (or other steroids) can be measured by administering a small dose of tritiated cortisol or aldosterone and measuring the specific activity of one or more known metabolites in a 24-hour urine collection. This procedure permitted measurement of certain steroids, such as aldosterone, before specific immunoassays were available. These procedures have also provided much information about the normal rate of production of various steroids. Based on this procedure, most authorities have agreed that children and adults secrete about 6 to 9 mg of cortisol per square meter of body surface area per day.^{144,145}

Dexamethasone Suppression Test

Administration of dexamethasone, a potent synthetic glucocorticoid, will suppress secretion of pituitary ACTH and adrenal cortisol; the dexamethasone suppression test is useful for distinguishing whether glucocorticoid excess is caused primarily by pituitary disease or adrenal disease. As dexamethasone also suppresses adrenal androgen secretion, this test is useful for distinguishing between adrenal and gonadal sources of sex steroids. A complete formal dexamethasone suppression test requires the measurement of basal values and those obtained in response to both low- and high-dose dexamethasone. This is described in the section on the evaluation of Cushing syndrome. Variations of this test are commonly used, notably the single dose 1.0-mg in adults or 0.3 mg/m² in children. This is a useful outpatient screening procedure for distinguishing Cushing syndrome from exogenous obesity. It can be useful for the same purpose in adolescents and older children, but is otherwise of limited utility in pediatrics. An overnight high-dose dexamethasone suppression test is probably more reliable than the standard 2-day, high-dose test in

differentiating adults with Cushing disease from those with the ectopic ACTH syndrome. However, the utility of this test in pediatric patients has not been established.

Stimulation Tests

Direct stimulation of the adrenal with ACTH is a rapid, safe, easy way to evaluate adrenocortical function. The original ACTH test consisted of a 4- to 6-hour infusion of 0.5 units/kg of ACTH(1-39). This will maximally stimulate adrenal cortisol secretion, and thus effectively distinguishes primary adrenal insufficiency (Addison disease), in which the adrenal is incapable of responding, from secondary adrenal insufficiency caused by hypopituitarism. In secondary adrenal insufficiency, some steroidogenic capacity is present, therefore some cortisol is produced in response to the ACTH; thus cortisol secretion is less than normal but greater than the negligible values seen in primary adrenal insufficiency. The 4- to 6-hour intravenous ACTH test has been replaced by the 60-minute test, wherein a single bolus of ACTH(1-24) is administered intravenously and cortisol and possibly other steroids are measured at 0 and 60 minutes. Normal responses to a 60-minute test are shown in Table 14.4.¹⁴⁶ Synthetic ACTH(1-24) (cosyntropin) is preferred, as it has a more rapid action and shorter half-life than ACTH(1-39). The usual dose is 15 µg/kg in children up to 2 years of age, and 0.25 mg for children older than 2 years and adults. All of these doses are pharmacologic. A very-low-dose (1 µg) test may be useful in assessing adrenal recovery from glucocorticoid suppression. Newer data show that maximal steroidal responses can be achieved after only 30 minutes, but the best available standards are for a 60-minute test. One of the widest uses of intravenous ACTH tests in pediatrics is in diagnosing CAH. Stimulating the adrenal with ACTH increases steroidogenesis, resulting in accumulation of steroids proximal to the disordered enzyme. For example, inspection of Fig. 14.3 shows that impaired activity of P450c21 (21-hydroxylase) should lead to the accumulation of progesterone and 17OHP. However, progesterone does not accumulate in appreciable quantities, because it is converted to 17OHP. In routine practice, measuring the response of 17OHP to a 60-minute challenge, with intravenous ACTH, is the single most powerful and reliable means of diagnosing 21OHD; genetic testing can provide a useful confirmation.⁴⁰ Comparing the patient's basal and ACTH-stimulated values of 17OHP against those from large numbers of well-studied patients usually permits the discrimination of normal persons, heterozygotes, patients with nonclassic CAH, and patients with classic CAH, although there inevitably is some overlap between groups (Fig. 14.12).⁴⁰ Measurement of testosterone or Δ⁴ androstenedione in response to ACTH can distinguish normal persons from patients with classic CAH, but heterozygotes and patients with cryptic CAH have values overlapping both normal and classic CAH.

Longer ACTH tests of up to 3 days have also been used to evaluate adrenal function. It is important to remember that ACTH has both acute and chronic effects. Thus short tests measure only the acute effects of ACTH, that is, the maximal stimulation of preexisting steroidogenic machinery. In contrast, a 3-day test will examine the more chronic effects of ACTH to stimulate increased capacity for steroidogenesis by increasing the synthesis of steroidogenic machinery. Few situations exist where a 3-day intramuscular ACTH test is indicated, although it is occasionally useful in diagnosing the rare syndromes of hereditary unresponsiveness to ACTH.¹⁴⁶

Insulin-induced hypoglycemia is an effective but potentially risky test, and hence is rarely used. Insulin (0.1 U/kg/IV) is administered and blood is obtained at 0, 30, 45, and 60 minutes. The insulin-induced hypoglycemia will stimulate the release of "counterregulatory" hormones that have actions

to increase plasma glucose concentrations: ACTH and cortisol, growth hormone, epinephrine, and glucagon. Because of the inherent risk of convulsions as a result of hypoglycemia, an experienced physician must be in attendance (not merely “available”) throughout the entire course of the test. Blood glucose must fall to half of the initial value or to 45 mg/dL to achieve an adequate test, and it is wise to terminate the test after this level is reached. Most patients will experience hunger, irritability, diaphoresis, and tachycardia; when these are followed by drowsiness or sleep, blood sugar levels are likely below acceptable limits. If this occurs, a blood sample should be obtained and 2 mL/kg of 20% to 25% glucose given intravenously, to a maximum of 100 mL.

Metyrapone Test

Metyrapone blocks the action of P450c11 β and, to a much lesser extent, P450sc. It is thus a chemical means of inducing a transient deficiency of 11-hydroxylase activity, which results in decreased cortisol secretion and subsequently increased ACTH secretion. Metyrapone testing is done to assess the capacity of the pituitary to produce ACTH in response to a physiologic stimulus. This test is useful in evaluating the hypothalamic-pituitary axis in the presence of central nervous system lesions, after neurosurgery, or long-term suppression by glucocorticoid therapy.¹⁴⁷ Patients with a previous history of hypothalamic, pituitary, or adrenal disease, or those who have been withdrawn from glucocorticoid therapy should be reevaluated with a metyrapone test. A normal response indicates recovery of the HPA axis and predicts that the patient will respond normally to the stress of surgery.

Metyrapone is generally given orally as 300 mg/m² every 4 hours for a total of six doses (24 hours). Unlike many other drugs, it is appropriate to continue to increase the dose in older or overweight patients, but the total dose should not exceed 3.0 g. Blood should be obtained for cortisol, 11-deoxycortisol, and ACTH, before and after the test. In a normal response to metyrapone, cortisol decreases, ACTH increases, and 11-deoxycortisol (the substrate for P450c11 β) increases greatly, to about 5 μ g/dL. Adults and older children can be tested with the administration of a single oral dose of 30 mg/kg at midnight, given with food to reduce the gastrointestinal irritation. Blood samples are drawn at 8 AM the mornings before and after administering the drug.

GENETIC LESIONS IN STEROIDOGENESIS

Autosomal recessive genetic disorders disrupt each of the steps shown in Fig. 14.3; most of these diminish cortisol synthesis. In response to hypocortisolemia, the pituitary produces increased amounts of POMC and ACTH, which promotes increased steroidogenesis; ACTH and POMC amino-terminal peptides also stimulate adrenal hypertrophy and hyperplasia. Thus the term “congenital adrenal hyperplasia” refers to a group of diseases traditionally grouped together on the basis of the most prominent finding at autopsy.

In theory, the CAHs are easy to understand: a genetic lesion in a steroidogenic enzyme interferes with normal steroidogenesis. The signs and symptoms of the disease derive from deficiency of the steroidal end product and the effects of accumulated steroidal precursors, proximal to the blocked step. Thus reference to the pathways in Fig. 14.3 and a knowledge of the biologic effects of each steroid should permit one to deduce the manifestations of the disease.

In practice, the CAHs can be clinically and scientifically confusing. Each steroidogenic enzyme has multiple activities and many extraadrenal tissues, especially the liver, express other enzymes with steroidogenic activity, hence the complete elimination of an adrenal enzyme may not result in the complete elimination of its steroidal products from the circulation. Furthermore, there are “partial deficiencies” in each enzyme, where some enzymatic activity remains, typically causing milder “nonclassic” disease with later onset. The key clinical, laboratory, and therapeutic features of each form of CAH are summarized in Table 14.5.

Disorders in Cholesterol Synthesis and Trafficking

In addition to the enzymatic steps shown in Fig. 14.3, upstream disorders in cholesterol synthesis and intracellular trafficking can impair steroidogenesis. The early fetus needs to synthesize its own cholesterol, with less being supplied transplacentally, hence disorders of cholesterol biosynthesis cause well-defined congenital malformation syndromes: Smith-Lemli-Opitz syndrome (SLOS, 7-dehydrocholesterol reductase deficiency), lathosterolosis (lathosterol Δ 5-desaturase deficiency), desmosterolosis (sterol Δ 24-reductase deficiency), CHILD syndrome (C-4 demethylation complex disorders), and Conradi-Hunermann syndrome (X-linked sterol isomerase deficiency).¹⁴⁸ Consequent impaired fetal steroidogenesis may result in 46,XY disorder of sex development (DSD), but adrenal insufficiency is not reported.¹²

Wolman Disease and Cholesteryl Ester Storage Disease

Most cellular cholesterol derives from the uptake of circulating lipoproteins that contain cholesterol esters; these esters are cleaved to free cholesterol by lysosomal acid lipase (cholesterol esterase), encoded by the *LIPA* gene on chromosome 10q23.31.¹¹ Mutations of *LIPA* cause Wolman disease (WD, primary xanthomatosis) and its milder variant, cholesteryl ester storage disease (CESD).^{149–154} In WD, cholesteryl esters and triglycerides accumulate in the liver, spleen, lymph nodes, and other tissues. In the adrenal, there is insufficient free cholesterol available for steroidogenesis, causing adrenal insufficiency. The disease is less severe than lipoid CAH with respect to steroidogenesis, and patients may survive for several months after birth. However, the disease affects all cells, not just steroidogenic cells, as all cells must store and use cholesterol; hence, the disorder is relentless and fatal. Vomiting, steatorrhea, failure to thrive, hepatosplenomegaly, jaundice, and anemia, are the usual presenting findings sometimes beginning in the first week of life, leading to

TABLE 14.5 Clinical and Laboratory Findings in the Congenital Adrenal Hyperplasias

developmental delay, and malabsorptive malnutrition. Characteristic bilateral subcapsular adrenal calcification that outlines the adrenals may be seen on pre- or postnatal ultrasound scan.^{155,156} The diagnosis is established by bone marrow aspiration, yielding foam cells containing large lysosomal vacuoles, engorged with cholesterol esters, and is confirmed by finding absent cholesterol esterase activity in fibroblasts, leukocytes, bone marrow cells, or cultured amniocytes (for prenatal diagnosis). Treatment by bone marrow transplantation appears to ameliorate the course of the disease in about half of cases, but the mechanism of this effect is unclear.^{157,158}; enzyme replacement therapy may ameliorate disease progression.¹⁵⁹ Supportive treatments include corticosteroid replacement, vitamin, and mineral supplementation. One survey found WD in around 3% of pediatric adrenal insufficiency.¹⁶⁰

CESD is a milder, later-onset form of WD caused by *LIPA* mutations that retain partial activity.^{152,161} CESD typically presents in later childhood and adolescence with hypercholesterolemia, atherosclerosis, and hepatosplenomegaly (hepatic infiltration with macrophages containing cholesteryl

esters);¹⁵⁴ hepatic fibrosis may lead to esophageal varices.¹⁶¹ There may be early onset with severe cirrhosis or later onset with more slowly progressive hepatic disease. Some patients reach adulthood.

Niemann-Pick Type C Disease

The endosomal processing of cholesterol esters requires the action of NPC1 and NPC2, two proteins named for NPC disease.¹⁶² NPC is a rare neurological disorder of cholesterol trafficking characterized by accumulated cholesterol and glycosphingolipids in endosomes, leading to progressive neurodegeneration, robust glial infiltration, and death.¹⁶³ NPC typically presents at 2 to 4 years, with mild intellectual impairment, speech loss, supranuclear vertical gaze palsy, ataxia, dystonia, dementia, seizures, and extrapyramidal deficits.¹⁶⁴ An infantile, rapidly progressive form presents with severe hepatic dysfunction, psychomotor delay, supranuclear vertical gaze palsy, ataxia, spasticity, and dementia; the hepatosplenomegaly and childhood cirrhosis can be lethal. However, despite

the seemingly central role of the NPC proteins in intracellular cholesterol trafficking, adrenal insufficiency is not reported in NPC. Thus although there is good evidence for disordered steroidogenesis in the NPC brain,¹⁶⁵ the adrenal appears to escape, suggesting it may use other pathways for intracellular cholesterol trafficking.¹²

Congenital Lipoid Adrenal Hyperplasia

Classic lipoid CAH, the most severe genetic disorder of steroidogenesis, typically presents in infancy with low or absent concentrations of all steroids, high basal ACTH and plasma renin, absent steroidal responses to long-term treatment with high doses of ACTH or human chorionic gonadotropin (hCG), and grossly enlarged adrenals laden with cholesterol and cholesterol esters; these findings indicate a lesion in the conversion of cholesterol to pregnenolone.¹⁶⁶ It was initially thought that the lesion was in an enzyme, and before the role of P450_{scc} was understood, lipoid CAH was misnamed “20,22-desmolase deficiency.” However, the gene for P450_{scc} is normal in these patients, as are the mRNAs for adrenodoxin reductase and adrenodoxin;¹⁶⁷ rare disorders in P450_{scc} are clinically indistinguishable from lipoid CAH (see later). Furthermore, placental steroidogenesis persists in lipoid CAH, permitting normal term gestation. These findings suggested that the lesion may be caused by a factor involved in cholesterol transport into mitochondria. A long search led to the discovery of StAR,²⁹ and its causal role in lipoid CAH established StAR’s essential function.^{30,31} StAR facilitates the influx of cholesterol from the OMM to the inner mitochondrial membrane, where it may be converted to pregnenolone by P450_{scc}. P450_{scc} is the slowest steroidogenic enzyme, but the true rate-limiting step in steroidogenesis is import of cholesterol into mitochondria, facilitated by StAR.

Lipoid CAH is the StAR gene knockout experiment of nature, revealing the complex physiology of the StAR protein.¹⁶⁶ StAR

promotes steroidogenesis by increasing the movement of cholesterol into mitochondria, but in the absence of StAR, steroidogenic cells make steroids at about 14% of the StAR-induced level.^{10,11,31,32} The discovery of StAR-independent steroidogenesis led to the two-hit model of lipoid CAH^{31,166} (Fig. 14.13). The first hit is the loss of StAR itself, leading to a loss of most, but not all steroidogenesis, and compensatory increases in ACTH and LH. These hormones increase cellular cAMP, which increases biosynthesis of LDL receptors, their consequent uptake of LDL cholesterol, and de novo synthesis of cholesterol. In the absence of StAR, this increased intracellular cholesterol accumulates as in a storage disease, causing the second hit, which is the mitochondrial and cellular damage caused by the accumulated cholesterol, cholesterol esters, and their auto-oxidation products.^{10,11,31}

The two-hit model explains the unusual clinical findings in lipoid CAH. In the fetal testis, which normally makes large amounts of testosterone in fetal life, the Leydig cells are destroyed early in gestation, eliminating testosterone biosynthesis, hence an affected 46,XY fetus does not undergo normal virilization, and is born with female external genitalia and a blind vaginal pouch. However, Wolffian duct derivatives are well developed,¹⁶⁸ indicating the presence of some testosterone synthesis early in fetal life, as predicted by the two-hit model. The undamaged Sertoli cells produce Müllerian inhibitory hormone, so that the phenotypically female 46,XY fetus has no cervix, uterus, or fallopian tubes. The steroidogenically active fetal zone of the adrenal is similarly affected, eliminating most DHEA biosynthesis and hence eliminating the fetoplacental production of estriol, so that mid-gestation maternal and fetal estriol levels are very low.¹⁶⁹ The definitive zone of the fetal adrenal, which differentiates into the zona glomerulosa and fasciculata, normally produces very little aldosterone, and as fetal salt and water metabolism are maintained by the placenta, stimulation of the glomerulosa by angiotensin II generally does not begin until birth. Consistent with this, many

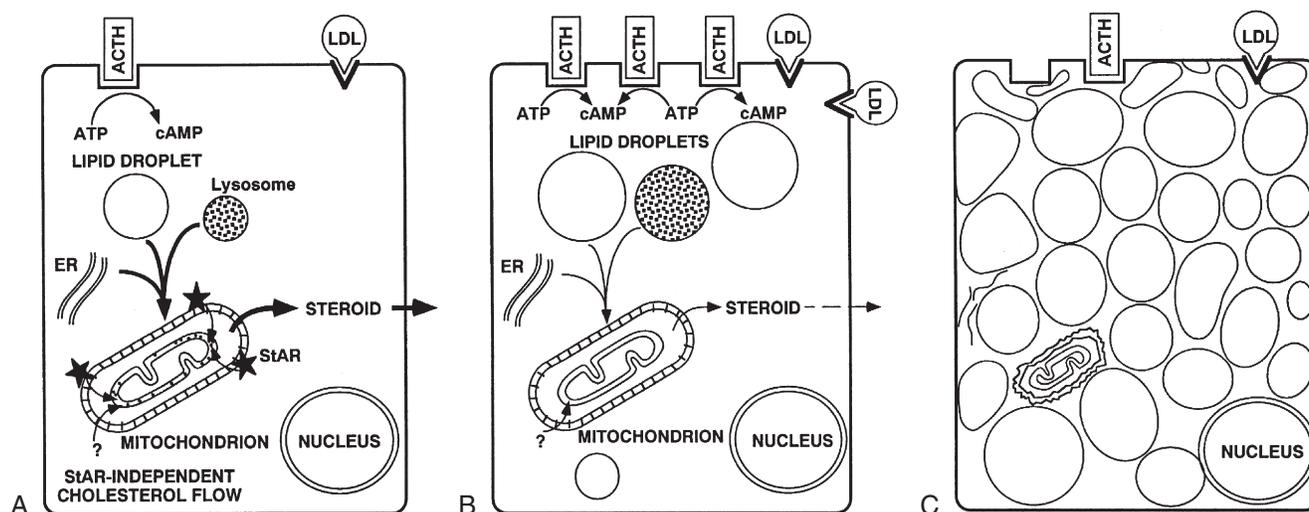

Fig. 14.13 Two-hit model of lipoid congenital adrenal hyperplasia (CAH). **A**, In a normal adrenal cell, cholesterol is primarily derived from low-density lipoprotein (LDL) by receptor-mediated endocytosis and is processed in lysosomes before entering the cellular pool, but cholesterol can also be synthesized de novo from acetyl CoA. Cholesterol from both sources is stored as cholesterol esters in lipid droplets. Cholesterol reaches the mitochondria by poorly defined processes, then travels from the outer to inner mitochondrial membrane by both steroidogenic acute regulatory protein (StAR)-dependent and StAR-independent mechanisms. **B**, In early lipoid CAH, the absence of StAR reduces cholesterol flow and steroidogenesis, but some steroidogenesis persists via the StAR-independent pathway. The decreased secretion of cortisol leads to increased adrenocorticotropic hormone, which stimulates further cholesterol uptake and synthesis; this cholesterol accumulates in lipid droplets. **C**, Accumulating lipid droplets damage the cell, both through physical disruption of cytoarchitecture and by the chemical action of autooxidation products, eventually destroying all steroidogenic capacity. In the ovary, follicular cells remain unstimulated and undamaged until they are recruited at the beginning of each cycle. They can then produce small amounts of estradiol, as in panel B, leading to feminization and anovulatory cycles in affected females.

newborns with lipid CAH do not have a salt-wasting crisis until after several weeks of life, when chronic stimulation then leads to cellular damage.^{31,170}

The two-hit model also explains the spontaneous feminization of affected 46,XX females who are treated in infancy and reach adolescence.^{10,11,31,171,172} The fetal ovary makes little or no steroids and contains no steroidogenic enzymes after the first trimester; consequently, the ovary remains largely undamaged until it is stimulated by gonadotropins at the time of puberty, when it then produces some estrogen by StAR-independent steroidogenesis. Continued stimulation results in cholesterol accumulation and cellular damage, so that biosynthesis of progesterone in the latter part of the cycle is impaired. Because gonadotropin stimulation only recruits individual follicles and does not promote steroidogenesis in the whole ovary, most follicles remain undamaged and available for future cycles. Cyclicity is determined by the hypothalamic-pituitary axis, and remains normal. With each new cycle, a new follicle is recruited and more estradiol is produced by StAR-independent steroidogenesis. Although net ovarian steroidogenesis is impaired, enough estrogen is produced to induce breast development, general feminization, monthly estrogen withdrawal, and cyclic vaginal bleeding.^{31,171} However, progesterone synthesis in the latter half of the cycle is disturbed by the accumulating cholesterol esters so that the cycles are anovulatory and ovarian cysts may develop. Measurements of estradiol, progesterone, and gonadotropins throughout the cycle in affected adult females with lipid CAH confirm this model,¹⁷² as do experiments with StAR-knockout mice.^{173,174} Thus examination of patients with lipid CAH has elucidated the physiology of the StAR protein in each steroidogenic tissue.

Studies in over 100 patients with lipid CAH have identified over 40 StAR mutations.^{10–12} Lipoid CAH is the second-most common form of CAH in Japan and Korea, where the mutation Q258X predominates,^{31,175,176} with a carrier frequency of about 1 in 300, so that one in every 250,000 to 300,000 newborns in these countries is affected.^{177,178} Lipoid CAH is also common in Arab populations, with R182L found among Palestinians,³¹ R188C in eastern Saudi Arabia,¹⁷⁰ and R182H and c.201-202delCT among other Arab populations;^{179,180} in Switzerland, L260P is a recurrent mutation.¹⁸¹

The typical clinical presentation in lipid CAH is an infant with normal-appearing female genitalia who experiences failure to thrive and salt loss in the first weeks of life.^{31,175,176,182}

Other clinical presentations include apparent sudden infant death syndrome (SIDS)¹⁸³ and late initial presentation of salt loss at about 1 year of age.¹⁷⁰ Nonclassic lipid CAH caused by mutations that retain about 20% to 25% of normal StAR activity was found in 46,XY children with normal-appearing male external genitalia children, who experience symptomatic adrenal insufficiency at several years of age.¹⁸⁴ Adults with nonclassic lipid CAH are recognized with increasing frequency and have often been mistaken for having “familial glucocorticoid deficiency,” a blanket term referring to disorders of ACTH action; many of these patients have mildly compromised mineralocorticoid secretion, with normal serum electrolytes and elevated plasma renin, and some may have mild hypergonadotropic hypogonadism.^{185–187} Most of these patients carry the same R188C mutation first described in children.¹⁸⁴ Thus the spectrum of clinical presentation of congenital lipid adrenal hyperplasia is substantially broader than initially appreciated.

Treatment of lipid CAH is straightforward if the diagnosis is made. Physiologic replacement with glucocorticoids, mineralocorticoids, and salt, in the newborn period, will permit survival to adulthood. Glucocorticoid doses are as in Addison disease and are less than in the virilizing adrenal hyperplasias because it is not necessary to oversuppress excess adrenal androgen production, so that growth in these patients should

be normal. Mineralocorticoid doses are not increased with age or size, as children become progressively more sensitive to mineralocorticoids with age; salt supplementation is weaned after about 1 year. Severely affected 46,XY newborns have normal female external genitalia and may be advised to undergo orchiectomy later in life and be raised as females, with sex hormone replacement therapy, started at age of puberty. Affected 46,XX females typically have spontaneous pubertal feminization, but anovulatory cycles and early secondary amenorrhea, then also requiring sex hormone replacement therapy. Pregnancy has been induced in two reports.^{188,189}

Disorders Resembling Lipoid Congenital Adrenal Hyperplasia: P450scc Deficiency and Steroidogenic Factor 1 Deficiency

Mutations in other genes can produce a clinical phenotype that is essentially indistinguishable from that caused by StAR mutations, but these disorders should not be called lipid CAH. Beginning in 2001, several patients were described with mutations in P450scc.¹⁹⁰ Their clinical and hormonal findings are indistinguishable from those with StAR mutations, so that gene sequencing is the only definitive way to distinguish these disorders¹⁹¹; however, to date no patient with a P450scc mutation has had the adrenal hyperplasia typically seen in lipid CAH.^{182,190–193} It would seem logical that elimination of all P450scc activity would be incompatible with term gestation, as the placenta, a fetal tissue, must produce progesterone in the second half of pregnancy to suppress maternal uterine contractions, thus preventing miscarriage. However, about 40 such cases were reported through 2018, many from southeastern Turkey.^{12,194,195} Fetuses with P450scc mutations probably reach term gestation when there is protracted maintenance of the maternal corpus luteum of pregnancy, which normally involutes in the second trimester, but this has not been investigated directly. Nonclassic P450scc deficiency that is clinically and hormonally indistinguishable from nonclassic lipid CAH has been reported in patients with P450scc mutations that retain 10% to 20% of wild-type activity.^{196,197}

More than 50 patients have also been described carrying mutations in the gene for steroidogenic factor 1 (SF1), a transcription factor required for adrenal and gonadal, but not for placental, expression of genes for the steroidogenic enzymes.^{198,199} There is broad phenotypic variability in SF1-deficient patients; some are 46,XY with a female phenotype and adrenal failure, thus resembling lipid CAH, but in most cases the gonadal phenotype predominates and there is little if any impairment of adrenal steroidogenesis. SF1 mutations may be found in about 10% of 46,XY patients who have disordered sexual development. The Leydig cells may have lipid accumulation and progressive degeneration, similar to the findings in lipid CAH.¹⁹⁹

3 β -Hydroxysteroid Dehydrogenase Deficiency

3 β HSD deficiency is a rare, potentially fatal cause of glucocorticoid, mineralocorticoid, and sex steroid deficiency.¹⁸² There are two functional human genes for 3 β HSD: the type 1 gene (*HSD3B1*) is expressed in the placenta and peripheral tissues, and the type 2 gene (*HSD3B2*) is expressed in the adrenals and gonads.¹⁰ All mutations causing 3 β HSD deficiency are found in the type 2 gene^{200,201}; mutations have never been found in 3 β HSD1, presumably because this would prevent placental biosynthesis of progesterone, resulting in a spontaneous first-trimester abortion. 3 β HSD deficiency causes DSD in both sexes: genetic females have clitoromegaly and mild virilization because the fetal adrenal overproduces large amounts of

DHEA, a small portion of which is converted to testosterone by 3β HSD1; genetic males synthesize some androgens by peripheral conversion of adrenal and testicular DHEA, but the concentrations are insufficient for complete male genital development.²⁰²

One would expect that infants with 3β HSD2 deficiency would have low concentrations of 17OHP, yet some newborns with 3β HSD deficiency have very high concentrations of serum 17OHP, approaching those seen in patients with classic 21OHD,²⁰³ and registering a positive newborn screen for 21OHD.²⁰⁴ Whereas 3β HSD2 has a high Km of around 5.5 μ M,²⁰⁵ the Km of 3β HSD1 is only around 0.2 μ M,²⁰⁶ permitting hepatic 3β HSD1 to act on the high circulating concentrations of 17-Preg in patients with 3β HSD2 deficiency, producing 17OHP. This 17OHP is not effectively picked up by the adrenal for subsequent conversion to cortisol because the circulating concentrations are below the Km of P450c17 (\sim 0.8 μ M 17OHP, or \sim 40,000 ng/dL).³⁷ The ratio of the Δ^5 to the Δ^4 compounds remains high, consistent with the adrenal and gonadal deficiency of 3β HSD.²⁰³ Thus the principal diagnostic test in 3β HSD deficiency is intravenous administration of ACTH, with measurement of the three Δ^5 compounds (Preg, 17-Preg, DHEA), and the corresponding Δ^4 compounds (progesterone, 17OHP, androstenedione). Unlike the case of 21OHD, where heterozygotes can be diagnosed by the response of 17OHP to ACTH, steroidal responses to ACTH cannot be used to identify carriers of 3β HSD deficiency.²⁰⁷

Mild or "partial" defects of adrenal 3β HSD activity have been reported on the basis of ratios of Δ^5 steroids to Δ^4 steroids, following an ACTH test that exceed 2 or 3 standard deviations (SD) above the mean; these patients are typically young girls with premature adrenarche, or young women with a history of premature adrenarche and complaints of hirsutism, virilism, and oligomenorrhea. However, these patients do not have 3β HSD deficiency as their *HSD3B2* genes are normal.²⁰⁸ Patients with mild 3β HSD2 mutations have ratios of Δ^5 to Δ^4 steroids that exceed 8 SD above the mean.^{209,210} Thus ratios of Δ^5 to Δ^4 steroids are not reliable and cannot be used to diagnose 3β HSD deficiency; the diagnosis requires an ACTH test with a rise in Δ^5 steroids (typically a rise in 17-Preg to $>$ 3000 ng/dL).²⁰⁹ The basis of the mildly elevated ratios of Δ^5 to Δ^4 steroids, in these hirsute individuals with normal *HSD3B* genes, remains unknown.³⁴ In adult women, the hirsutism can be ameliorated and regular menses can be restored by suppressing ACTH with 0.25 mg of dexamethasone given orally each day, but such treatment is contraindicated in girls who have not yet reached their final adult height.

17 α -Hydroxylase/17,20-Lyase Deficiency

P450c17 catalyzes both 17 α -hydroxylase and 17,20-lyase activities.¹⁰ 17-hydroxylase deficiency is well understood clinically and genetically,^{211,212} and is common in Brazil and China.¹⁸² Deficient 17 α -hydroxylase activity results in decreased cortisol synthesis, overproduction of ACTH, and stimulation of the steps proximal to P450c17. These patients may have mild symptoms of glucocorticoid deficiency, but this is not life-threatening, as the cortisol deficiency is compensated by overproduction of corticosterone, which has glucocorticoid activity. This is similar to the situation in rodents, whose adrenals lack P450c17 and consequently produce corticosterone as their glucocorticoid. Affected patients also typically overproduce DOC in the zona fasciculata, which causes sodium retention, hypertension, and hypokalemia, and also suppresses plasma renin activity and aldosterone secretion from the zona glomerulosa, although the suppression of aldosterone is rather variable.^{211,212} When P450c17 deficiency is treated with

glucocorticoids, DOC secretion is suppressed and plasma renin activity and aldosterone concentrations rise to normal.

The absence of 17 α -hydroxylase and 17,20-lyase activities in complete P450c17 deficiency prevents the synthesis of adrenal and gonadal sex steroids. As a result, affected females are phenotypically normal, but fail to undergo adrenarche and puberty, and genetic males have absent or incomplete development of the external genitalia (male pseudohermaphroditism; 46,XY DSD). The classic presentation is that of a teenage female with sexual infantilism and hypertension. The diagnosis is made by finding low or absent 17-hydroxylated C21 and C19 plasma steroids, which respond poorly to stimulation with ACTH, and elevated DOC, corticosterone, and 18OH-corticosterone, which are hyperresponsive to ACTH and suppressible with glucocorticoids. Physiologic glucocorticoid replacement therapy will suppress the mineralocorticoid hypertension; sex steroid replacement concordant with the sex of rearing is instituted in adolescence.

More than 100 distinct mutations have been found in the *CYP17A1* gene on chromosome 10q24.3, causing 17 α -hydroxylase deficiency.^{211,212} Four mutations appear recurrently: a duplication of four nucleotides causing a frameshift is found among descendants of Dutch Frieslanders,²¹³ 7-489 is common in Asia^{214,215}; a frameshift mutation common in Northern China and Korea,²¹⁵⁻²¹⁷; and the common W406R and R362C mutations, found among Brazilians of Spanish and Portuguese ancestry, respectively.²¹⁸ Most reported P450c17 mutations ablate all activity, whereas some others partially affect both activities, usually about equally.

17,20 Lyase Deficiency: P450c17, Cytochrome b5 and Other Factors

Early reports of selective 17,20-lyase deficiency initially led to the incorrect conclusion that 17 α -hydroxylase and 17,20-lyase are separate enzymes. Isolated 17,20 lyase deficiency can result from mutations in several genes, but all are involved with electron transfer to P450c17 from POR.³⁸ The first genetically proven cases of isolated 17,20 lyase deficiency were two patients with genital ambiguity, normal excretion of 17OHCS (17-hydroxycorticosteroids), and markedly reduced production of C19 steroids.²¹⁹ These patients were homozygous for the P450c17 mutations R347H or R358Q; both mutations changed the distribution of surface charges in the redox-partner binding site of P450c17, and enzymatic and cell biologic experiments showed that the loss in lyase activity was caused by impaired electron transfer.^{219,220} Just as altering the charge distribution in the redox-partner binding site of P450c17 from positive to negative with the R347H or R358Q mutants caused isolated 17,20 lyase activity, so changing the electrostatic change from negative to positive with the G539R mutant in the electron-donating domain of POR was also found in patients with isolated 17,20 lyase deficiency.²²¹ Thus mutations in either the redox-partner binding site of P450c17 or in the electron-donating domain of POR can cause isolated 17,20 lyase deficiency, showing that isolated 17,20 lyase deficiency is a disorder of electron transport to P450c17.³⁸

In addition to rare, specific mutations in P450c17 and POR, mutations in cytochrome b5, a small hemoprotein that stimulates 17,20 lyase activity about 10-fold,³⁷ will also cause 17,20 lyase deficiency. Adrenal expression of b5 is specific to the zona reticularis and coincides with the onset of adrenarche.^{103,104,222} The first report of b5 deficiency was in a male with DSD and methemoglobinemia who was not evaluated hormonally.²²³ Methemoglobinemia is an expected consequence of b5 deficiency because the reduction of methemoglobin is the

principal physiologic role of b5, and the usual cause of methemoglobinemia is deficiency of cytochrome b5 reductase. Elevated concentrations of methemoglobin, without clinical methemoglobinemia, may be more common.^{224,225} 17,20-Lyase activity can also be augmented by the serine/threonine phosphorylation of P450c17,^{226,227} catalyzed by p38 α (MAPK14),³⁹ but disruption of this system has not (yet) been reported to cause clinical 17,20 lyase deficiency. Interestingly, the first patients reported to have 17,20 lyase deficiency were subsequently found to have mutations in AKR1C2 and AKR1C4, two enzymes that catalyze 3 α -reduction in the backdoor pathway of androgen synthesis.⁵¹ This pathway participates in the virilization seen in 21OHD,⁷⁹ but has no role in 17,20 lyase activity. These multiple genetic causes illustrate that 17,20 lyase deficiency is a syndrome rather than a specific disease.³⁸

P450 Oxidoreductase Deficiency

POR deficiency is a recently recognized form of CAH.^{228,229} POR is the 2-flavin protein that transfers electrons from NADPH to all 50 microsomal forms of cytochrome P450, including P450c17, P450c21, and P450aro, as well as the drug-metabolizing P450 enzymes of the liver (see Fig. 14.5).¹³ Because POR participates in many functions, its mutation might be expected to yield a very severe phenotype, and POR-deficient mice die during fetal development, but many patients with POR deficiency have been reported since 2004. A wide array of POR mutations has been described, affecting various P450 enzymes to differing degrees, apparently explaining the great variability in the clinical and hormonal findings in POR deficiency.^{228–233} The serum and urinary steroids indicate defects in P450c17, with defects in P450c21 and P450aro being more variable; the clinical findings vary from severely affected infants with ambiguous genitalia, cortisol deficiency, and the Antley-Bixler skeletal malformation syndrome (ABS) to mildly affected women who appear to have a form of polycystic ovary syndrome, or mildly affected men, with gonadal insufficiency.^{228–233} ABS is characterized by craniosynostosis, brachycephaly, radioulnar or radiohumeral synostosis, bowed femora, arachnodactyly, midface hypoplasia, proptosis, and choanal stenosis. When ABS is seen in association with abnormal steroids and ambiguous genitalia in either sex, the cause is an autosomal recessive mutation in POR^{228,229}; in contrast, when ABS is seen without a lesion in steroidogenesis or genital development, the cause is an autosomal dominant, gain-of-function mutation in FGF receptor 2.²²⁹ Thus the term “Antley-Bixler syndrome” should be reserved for the phenotypic description of the skeletal malformations, and should not be equated with POR deficiency, which may or may not be associated with ABS.^{228,229} The ABS skeletal phenotype probably results from diminished activity of CYP26B1, the POR-dependent microsomal enzyme that degrades retinoic acid.²³⁴ Studies of two families with CYP26B1 mutations, and recreating such mutations in transgenic mice and zebrafish provides powerful evidence that retinoic acid must be degraded locally at embryonic sites that normally form skeletal joints and sutures; interference with this activity in POR deficiency appears to be the principal mechanism accounting for the skeletal phenotype.²³⁴ Other mechanisms, including defective signaling by *hedgehog* proteins secondary to a POR-associated defect in cholesterol synthesis, may also play a role.²³¹

In some POR-deficient patients, the impairment of P450c21 activity may generate levels of 17OHP detected by newborn screening for 21OHD.^{228,235} Patients with POR deficiency typically have normal electrolytes and mineralocorticoid function, nearly normal levels of cortisol that respond poorly to stimulation with ACTH, high concentrations of 17OHP that respond variably to ACTH, and low levels of C19 precursors to sex

steroids.^{228–233} A notable feature of POR deficiency is that there is genital ambiguity in both sexes; females may be virilized and males may be underdeveloped, although there is considerable variation among individuals. Because the 17,20 lyase activity of P450c17 is especially sensitive to perturbations in electron transport,^{18,38,219} defects in fetal testicular steroidogenesis leading to incompletely developed external genitalia in 46,XY males is the predicted outcome. In contrast, the partial virilization seen in 46,XX genetic females appears to be the result of two causes. First, placental aromatase (P450aro) requires POR. Pregnant women carrying a fetus with the POR mutation R457H (but not POR A287P) may experience virilization during pregnancy,^{228–230} similar to that experienced by women carrying a fetus with P450aro deficiency.⁵⁸ The fetus normally disposes of large amounts of adrenal C19 steroids by excreting them through the placenta, which aromatizes them to the maternal estrogens of pregnancy (see Fig. 14.7). A defect in this placental aromatase activity, either from mutation of POR or P450aro itself, will permit large amounts of fetal C19 steroids to enter and virilize the mother. This is evidenced by the low estriol values seen in women carrying a fetus with certain POR mutations. Second, analysis of urinary steroids from patients with POR deficiency indicates that the alternative backdoor pathway of androgen production (see Fig. 14.6) also contributes to the prenatal virilization of affected females.^{230,232,233}

Because POR is required by the hepatic drug-metabolizing cytochrome P450 enzymes, it is logical to expect impaired drug metabolism in POR-deficient patients. Although transgenic mice with liver-specific POR defects metabolize drugs poorly and accumulate hepatic lipids, similar problems have not yet been described in patients with POR deficiency. Numerous studies of drug-metabolizing enzymes in vitro show major impairment by POR mutations^{236,237}; however, only one study has found such an effect in a POR-deficient patient.²³⁸ Much remains to be learned about POR deficiency.

The incidence of POR deficiency varies among ethnic groups. Two mutations are especially common: A287P, the predominant mutation in patients of European ancestry,^{228,232} and R457H, the predominant mutation in patients of Japanese ancestry.^{229, 230} The clinical phenotype in females with POR deficiency depends on their POR mutation. POR A287P disrupts activity of P450c17 but not P450c21,²³⁹ and R457H disrupts P450aro activity but A287P does not.²⁴⁰ Defective placental P450aro activity may permit fetal androgen precursors to virilize the mother, hence a woman carrying a fetus with POR R457H (but not A287P) may become virilized during pregnancy; such pregnancies are characterized by low maternal estriol levels.^{228–230,240} The polymorphic variant A503V, which mildly affects many P450 activities,²³⁶ is found in around 28% of POR alleles, varying from around 19% in African Americans to around 37% in Chinese Americans.²⁴¹

Treatment of POR deficiency requires multidisciplinary management of craniosynostosis, orthopedic problems, and DSD, including sex hormone replacement therapy, starting at pubertal age in both sexes. Some patients may benefit from low-dose glucocorticoid replacement therapy, especially during severe illness; this should be determined individually by assessing the response of cortisol to ACTH.

21-Hydroxylase Deficiency

21OHD, caused by mutations in the CYP21A2 gene encoding adrenal P450c21, is one of the most common inborn errors of metabolism, and accounts for over 90% of all patients with CAH. Because of improved diagnosis and treatment in infancy, patients with severe 21OHD now routinely reach adulthood, so that the management of 21OHD concerns physicians dealing with all age groups.^{40,80,242,243}

Pathophysiology

In severe 21OHD, there is an inability to convert progesterone to DOC, resulting in aldosterone deficiency that causes severe hyponatremia, hyperkalemia, and acidosis. The associated hypotension, shock, and cardiovascular collapse may result in death in an untreated newborn. As the control of fluids and electrolytes in the fetus are maintained by the placenta and the mother's kidneys, this salt-losing crisis develops only after birth, usually during the second week of life. The inability to convert 17OHP to 11-deoxycortisol results in cortisol deficiency, which impairs postnatal carbohydrate metabolism and exacerbates cardiovascular collapse, because a permissive action of cortisol is required for full pressor action of catecholamines. High concentrations of cortisol in the adrenocortical capillary effluent that bathes the medulla are needed for the transcription of medullary phenylethanolamine N-methyltransferase, which converts norepinephrine to epinephrine, hence children with 21OHD have low epinephrine concentrations, which may exacerbate the hypoglycemia associated with cortisol deficiency.²⁴⁴

Although a role for cortisol in fetal physiology is not well established,^{83,85,86} cortisol deficiency is manifested prenatally. Low fetal cortisol stimulates ACTH secretion, which stimulates adrenal hyperplasia and transcription of the genes for all the steroidogenic enzymes, especially for P450_{sc}, the rate-limiting enzyme in steroidogenesis. This increased transcription increases enzyme production and activity, with consequent accumulation of non-21-hydroxylated steroids. There are four pathways by which these steroids are diverted to androgens (see Fig. 14.6). First, 17-Preg may be converted to DHEA by the 17,20 lyase activity of P450_{c17}; if not inactivated by sulfation to DHEAS, DHEA may be converted to androstenedione by 3 β HSD2. Androstenedione may then be converted to testosterone in the fetal adrenal or in target tissues by 17 β HSD5 (see Fig. 14.3). Second, although 17OHP is not normally an effective substrate for the 17,20 lyase activity of P450_{c17}, the very high levels of 17OHP characteristic of 21OHD will "force" some conversion to androstenedione by mass action. Third, as described in Section III (Adrenal Androgen Secretion and the Regulation of Adrenarche), androstenedione may be converted to 11-keto-testosterone, the principal adrenal androgen, in the zona reticularis. Fourth, in the alternative or backdoor pathway to DHT, 17OHP is 5 α - and 3 α -reduced to 17OH-allopregnenolone, which is readily converted by P450_{c17} to androsterone and thence by 17 β HSD to androstenediol and an oxidative 3 α HSD to DHT, so that this most

potent androgen is produced without DHEA, androstenedione, or testosterone as intermediates.⁷⁷ Recent work has established that this pathway exists in the human fetus⁵¹ and that it contributes substantially to the production of androgens in children with 21OHD.^{79,245} Also as described earlier (see Fetal Adrenal Steroidogenesis), the fetal adrenal transiently expresses 3 β HSD2 at about 7 to 12 weeks, permitting cortisol synthesis, which in turn suppresses ACTH and hence suppressing fetal adrenal production of DHEA and other C-19 steroids.⁸³ Thus fetal adrenal androgen synthesis is normally suppressed during the time when the external genitalia may become virilized. In 21OHD, this transient production of cortisol is not possible, further driving the androgenization of female fetuses.

Early in gestation, the fetal testes produce testosterone by the conventional androgenic pathway and DHT by the backdoor pathway, both of which are needed to differentiate the pluripotent embryonic precursor structures into male external genitalia.⁵¹ In the male fetus with 21OHD, the additional androgens produced in the adrenals have no phenotypic effect. In contrast, the fetal ovaries normally produce minimal sex steroids or other factors needed for differentiation of the female external genitalia. The androgens inappropriately produced by the adrenals of the 21OHD female fetus cause varying degrees of external genital virilization, which can range from mild clitoromegaly, with or without posterior fusion of the labioscrotal folds, to complete labioscrotal fusion that includes a urethra traversing the enlarged clitoris (Fig. 14.14). These infants have normal ovaries, fallopian tubes, and a uterus, but have "ambiguous" external genitalia or may be sufficiently virilized so that they appear to be male, resulting in errors of sex assignment at birth. 21OHD is the most common form of 46, XX DSD.

The diagnosis of 21OHD is suggested by DSD in females, a salt-losing episode in either sex, or rapid growth and virilization in males or females in infancy. Plasma 17OHP is markedly elevated (>2000 ng/dL or 60 nmol/L, and often exceeding 40,000 ng/dL or 1200 nmol/L after 24 h of age, in an otherwise healthy full-term infant), and hyperresponsive to stimulation with ACTH (see Fig. 14.12). The clinician must also measure 11-deoxycortisol, DHEA, and androstenedione, both to distinguish among the forms of CAH and because adrenal and testicular tumors can also produce 17OHP. ACTH will also induce a substantial rise in serum 21-deoxycortisol in all forms of 21OHD, but not in normals, providing a useful test when this steroid can be measured. High newborn 17OHP values that rise further after ACTH can also be seen in 3 β HSD2 deficiency (because of the activity of hepatic 3 β HSD1) and in

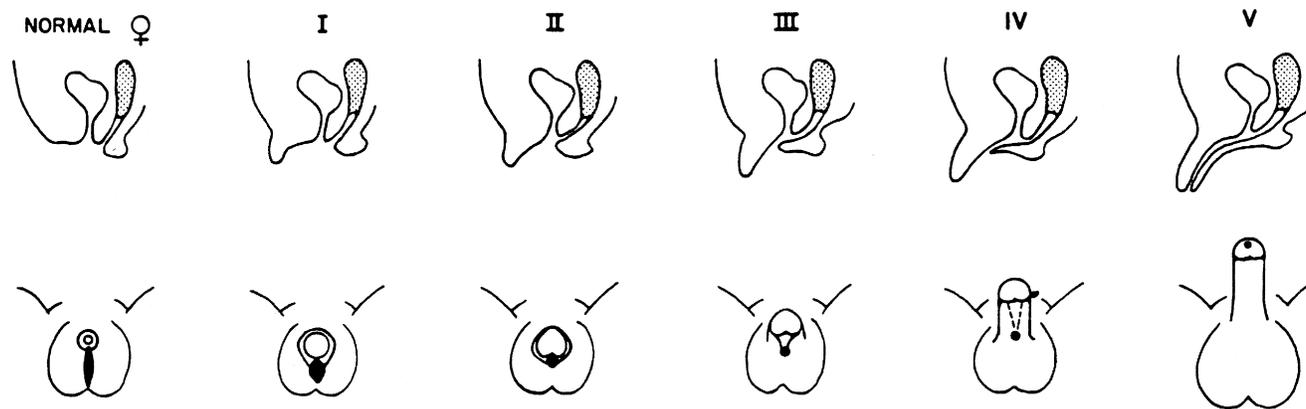

Fig. 14.14 Virilization of the external genitalia. A continuous spectrum is shown from normal female to normal male in both sagittal section (above) and perineal views (below), using the staging system of Prader. Disorders of external genitalia can occur either by the virilization of a normal female, as in congenital adrenal hyperplasia, or because of an error in testosterone synthesis in the male. In females with congenital adrenal hyperplasia caused by 21-hydroxylase deficiency, the degree of virilization correlates poorly with the presence or absence of clinical signs of salt loss.

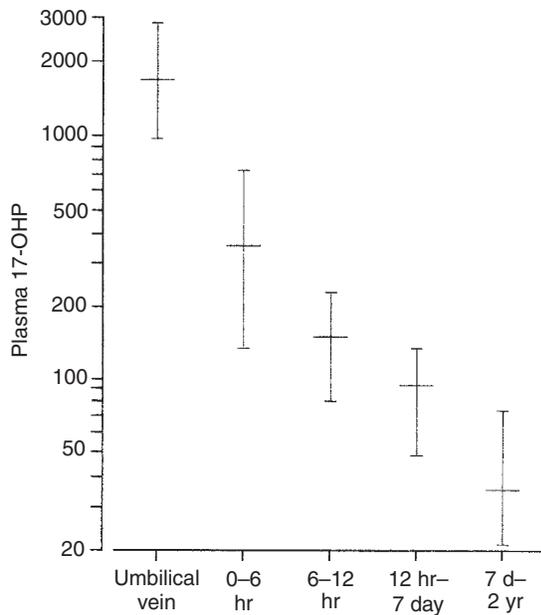

Fig. 14.15 Means and ranges of 17 α -Hydroxyprogesterone in normal newborns (data are in ng/100 mL). Note that values can be very high and quite variable for the first 24 hours of life.

P450c11 β deficiency (because of end-product inhibition of P450c21).²⁰³ 17OHP is normally high in cord blood, but falls to normal newborn levels after about 24 h (Fig. 14.15), so that assessment of 17OHP levels should not be made in the first day of life. Premature infants and term infants under severe stress (e.g., with cardiac or pulmonary disease) may have persistently elevated 17OHP concentrations with normal 21-hydroxylase. Newborn screening programs for CAH, based on 17OHP measurements, are used throughout the industrialized world. The technologies used and “cut-off” values used vary in different healthcare systems. When testing is done on full-term infants more than 24 hours after birth, the screening is reliable.⁴⁰ Endocrinologists and neonatologists must become familiar with local assays and the values found in the extremely premature, which may be read as false positives for CAH requiring repeat testing. Also negative neonatal screening does not exclude milder 21OHD causing nonclassic 21OHD beyond the newborn period.

Clinical Forms of 21-Hydroxylase Deficiency

There is a broad spectrum of clinical manifestations of 21OHD, depending on the particular gene mutation. These different forms of 21OHD are not different diseases, as there is a continuous spectrum of manifestations, ranging from the severe “salt-wasting” form to clinically inapparent forms that may be normal variants. Thus the typical disease forms discussed later are mainly a clinical convenience.⁴⁰

Salt-wasting 21-hydroxylase deficiency. Salt-wasting (SW) 21OHD is caused by a nearly complete lack of P450c21 activity, effectively eliminating both glucocorticoid and mineralocorticoid synthesis. Females with SW 21OHD are frequently diagnosed at birth because of their DSD. After appropriate resuscitation of the cardiovascular collapse, acidosis, and electrolyte disorders, the mineralocorticoids and glucocorticoids can be replaced orally and the DSD may be corrected with plastic surgical procedures. The steroidal replacement management is difficult because of the rapidly changing needs of a growing infant or child (see section on “Treatment”). Drug doses must

be adjusted frequently, and there is individual variability in what constitutes “physiologic” replacement. As an underdose of glucocorticoids can be life-threatening, especially during illness, most pediatricians have tended to “err on the safe side,” so that these children often receive inappropriately large doses of glucocorticoids. It is not possible to compensate for the growth lost during the first 2 years of life, when growth is fastest, so these children typically end up shorter than predicted from their genetic potential. Adult females may have sexual dysfunction, marry with a low frequency, are more reluctant to form intimate relationships, and have decreased fertility. Prenatal androgens appear to affect behavior, but not sexual identity.⁴⁰ Males with SW 21OHD are generally undiagnosed at birth and come to medical attention through the neonatal screening or during the salt-losing crisis that follows at day 5 to 15 of life; untreated infants typically die. Adult males appear to have less steady heterosexual relationships and decreased fertility, especially with insufficient treatment, which promotes the occurrence of testicular adrenal rest tumors. The most common CYP21A2 mutations causing around 50% of SW 21OHD are large gene deletions, large gene conversions, and a C to G substitution 13 bases from the splice acceptor site in intron 2.^{246,247}

Simple virilizing 21-hydroxylase deficiency. Virilized females who have elevated concentrations of 17OHP, but who do not suffer a salt-losing crisis, have long been recognized as having the SV form of 21OHD. Unless detected by newborn screening, males with SV 21OHD may escape diagnosis until age 3 to 7 years, when they come to medical attention because of early development of pubic, axillary and facial hair, acne, and phallic growth. These signs may be mistaken for premature puberty, but the testes remain of prepubertal size because there is no gonadotropic stimulation, whereas boys with true central precocious puberty have pubertal-sized testes (≥ 4 mL). These children grow rapidly and are tall for age when diagnosed, but their epiphyseal maturation (bone age) advances disproportionately rapidly, so that ultimate adult height is compromised. Untreated or poorly treated children with 21OHD may fail to undergo normal puberty, and boys may have small testes and azoospermia because of the feedback of the adrenally produced testosterone on pituitary gonadotropins. When treatment is begun at several years of age, suppression of adrenal testosterone secretion may remove tonic inhibition of the hypothalamus, occasionally resulting in true central precocious puberty, requiring treatment with a gonadotropin-releasing hormone (GnRH) agonist. High concentrations of ACTH may stimulate the enlargement of testicular adrenal rest tumors (TARTs). Because of the high (~25%) incidence of TARTs,²⁴⁸ the testes of postpubertal males with 21OHD should be examined every 1 to 2 years by ultrasound.⁴⁰ Because the adrenal normally produces 100 to 1000 times as much cortisol as aldosterone, mild defects (amino acid replacement mutations) in P450c21 are less likely to affect mineralocorticoid secretion than cortisol secretion. This is reflected physiologically by the increased plasma renin activity seen in patients with SV 21OHD, after moderate salt restriction. The most common mutation causing SV 21OHD is I172N,^{249,250} which retains about 5% of normal activity.²⁵¹

Nonclassic 21-hydroxylase deficiency. Very mild, nonclassic (NC) forms of 21OHD may be evidenced by mild to moderate hirsutism, virilism, acne, menstrual irregularities, and decreased fertility in adult women (sometimes called “late-onset” 21OHD), or there may be no phenotypic manifestations other than an increased response of plasma 17OHP to an intravenous ACTH test (so-called “cryptic” 21OHD).⁴⁰ These individuals may also have hormonal

evidence of a mild impairment in mineralocorticoid secretion, evidenced by an unusually greater rise in PRA when dietary sodium is restricted. *CYP21A2* genotype analyses identified a heterozygous carrier rate of 15% (95% confidence interval [CI], 10.4–20.7) among 200 Ashkenazi Jews and a carrier rate of 9.5% (95% CI, 5.8–14.4) among 200 non-Jewish Caucasians; this difference was not significant ($P = .13$), yielding an overall frequency of about 1 in 200.²⁵² The most common *CYP21A2* mutation causing NC 21OHD is V281L,^{253,254} which retains around 20% of normal activity.^{255,256}

There is some inconsistency in classifying patients with 21OHD because the three “forms” are not separate diseases but represent typical pictures in a continuous spectrum of disease, caused by a spectrum of genetic lesions. Because some mutant *CYP21A2* alleles are common in the general population, most patients are compound heterozygotes, carrying a different mutation on the allele inherited from each parent. Finally, factors other than the specific mutations found in *CYP21A2* will influence the clinical phenotype, including the presence of extraadrenal 21-hydroxylases and variations in androgen metabolism and sensitivity. Thus discordances between genotype and phenotype are to be expected.

Incidence of 21-Hydroxylase Deficiency

Perinatal screening for elevated serum 17OHP has shown that the incidence of classic SW and SV 21OHD is about 1 in 14,000,

yielding a heterozygous carrier rate of 1 in 60. Screening of 1.9 million newborns in Texas yielded an overall incidence of 1 in 16,000, including incidences of 1 in 15,600 Caucasians, 1 in 14,500 Hispanics (mostly Mexican-Americans of indigenous American ancestry), and 1 in 42,300 African-Americans.²⁵⁷ Because about 20% of the African-American gene pool is of European origin, the calculated incidence in individuals of wholly sub-Saharan African ancestry is about 1 in 250,000; the basis for this apparent ethnic difference is unknown.³⁴ NC 21OHD is much more common, with the highest incidence among Mediterranean peoples.^{10,40,258} The high incidence of NC 21OHD, its nonlethality, and its negligible impact on fertility suggest it is a polymorphic variant and not a disease in the classic sense. Nevertheless, patients with NC 21OHD may seek help for complaints of virilism, menstrual disorders, and fertility.²⁵⁸

Genetics of 21-Hydroxylase Deficiency

The *CYP21* Genes. The functional *CYP21A2* gene and the nearby nonfunctional *CYP21A1P* pseudogene consist of 10 exons, are ~3.4kb long, are duplicated in tandem with the *C4A* and *C4B* genes encoding the fourth component of serum complement, and lie in the class III region of the human major histocompatibility complex (MHC)^{10,242,243} (Fig. 14.16). *CYP21A1P* is transcribed, but the resultant RNAs do not encode protein.^{259,260} The MHC locus on chromosome 6p21 is characterized by a very high rate of genetic recombination; this high

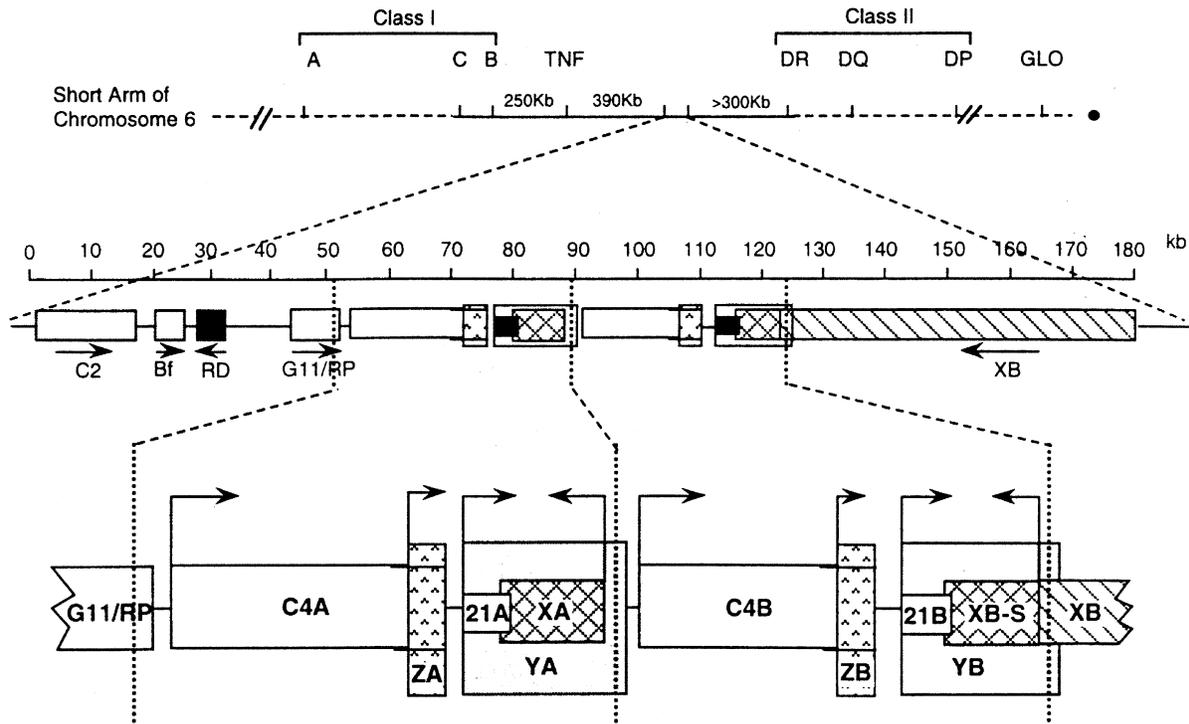

Fig. 14.16 Genetic map of the human leukocyte antigen (HLA) locus containing the genes for P450c21. The top line shows the p21.1 region of chromosome 6, with the telomere to the left and the centromere to the right. Most *HLA* genes are found in the class I and class II regions; the class III region containing the P450c21 genes lies between these two. The second line shows the scale (in kilobases) for the diagram immediately subsequent, showing (from left to right) the genes for complement factor C2, properdin factor Bf, and the RD and *G11/RP* *STK19* genes of unknown function; arrows indicate transcriptional orientation. The bottom line shows the 21-hydroxylase locus on an expanded scale, including the *C4A* and *C4B* genes for the fourth component of complement, the inactive *CYP21A1P* gene (21A) and the active *CYP21A2* gene (21B) that encodes P450c21. XA, YA, and YB are adrenal-specific transcripts that lack open reading frames. The *XB* gene encodes the extracellular matrix protein Tenascin-X; *XB-S* encodes a truncated adrenal-specific form of the Tenascin-X protein whose function is unknown. ZA and ZB are adrenal-specific transcripts that arise within the *C4* genes and have open reading frames, but it is not known if they are translated into protein; however, the promoter elements of these transcripts are essential components of the *CYP21A* and *CYP21B* promoters. The arrows indicate transcriptional orientation. The vertical dotted lines designate the boundaries of the genetic duplication event that led to the presence of A and B regions.

rate of intergenic exchange of DNA results in the *CYP21A2* and *CYP21A1P* genes differing in only 87 or 88 bases. The *cyp21* genes of mice and cattle are similarly duplicated in the MHC loci, but the gene duplication borders differ, and some mammals have only single *cyp21* genes, indicating that the gene duplication postdates mammalian speciation.^{242,261}

Human Leukocyte Antigen Linkage. Because the *CYP21* genes lie in the MHC locus, HLA typing had been used for prenatal diagnosis and to identify heterozygous family members, but this approach has now been replaced by direct genetic analysis. Statistical associations (linkage disequilibrium) are well established between 21OHD and certain specific HLA types.^{10,242,243} SW 21OHD is associated with HLA-B60 and HLA-40 in some populations, and HLA Bw47 is strongly associated with SW 21OHD. HLA-Bw51 is associated with SV 21OHD in some populations, and about 40% of haplotypes for NC 21OHD carry HLA-B14. HLA-B14 is often associated with a duplication of the *C4B* gene, but all HLA-B alleles can be found linked to 21OHD. HLA-identical individuals in a single family may have different clinical features of 21OHD, despite HLA identity, possibly representing extraadrenal 21-hydroxylation, de novo mutations, or multiple genetic crossover events.

Other Genes in the *CYP21* Locus. The *C4A* and *C4B* genes produce very similar isoforms of complement component C4; the *C4B* protein has greater hemolytic activity, despite greater than 99% sequence identity with *C4A*.^{10,242} The *C4A* gene is 22 kb long, but there are long (22 kb) and short (16 kb) forms of *C4B* caused by a variation in one intron. The 3' ends of the *C4* genes are only 2466bp upstream from the transcriptional start sites of the *CYP21* genes. Promoter sequences needed for the transcription of *CYP21A2* lie within intron 35 of *C4B*.²⁶² Several other genes also lie within about 100 kb of *CYP21A2*, including the genes for complement factor C2 and properdin factor Bf (see Fig. 14.16). Lying just 3' of the *Bf* gene, on the opposite strand of DNA from *CYP21A2*, is the *STK19* gene (formerly termed *G11*), which encodes a nuclear serine/threonine kinase.²⁶³

Tenascin-X and the congenital adrenal hyperplasia-X (CAH-X) syndrome. Tenascin-X (TNX), encoded by the *TNXB* gene, is an extracellular matrix protein whose actions are largely antiadhesive, but extend beyond cellular architecture.²⁶⁴⁻²⁶⁷ The *TNXA* and *TNXB* genes are duplicated with the *C4* and *CYP21* genes, and lie on the opposite strand of DNA from the *C4* and *CYP21* genes.^{264,266} The last exons of *TNXA* and *TNXB* lie within the 3' untranslated region of exon 10 in *CYP21A1P* and *CYP21A2*, respectively. *TNXA* was truncated during the duplication of the ancestral *C4-CYP21-TNX* genetic unit; it is transcribed in the adrenal, but has no known function.²⁶¹ The TNX protein encoded by *TNXB* is a large extracellular matrix protein that is expressed in most tissues, especially connective tissue.²⁶⁴ The *TNXB* gene spans about 65 kb and includes 43 exons encoding a 12-kb mRNA. *TNXB* also encodes a truncated 74-kDa form of TNX (XB-Short; XB-S), which is identical to the carboxy-terminal 673 amino acids of TNX, arises from an intergenic promoter, and is expressed uniquely in the adrenal.²⁶⁸ XB-S associates with mitotic motor kinesin Eg5, but its precise function remains unclear.²⁶⁹ Identification of a 21OHD patient with a "contiguous gene syndrome," comprising a deletion of both the *CYP21A2* and *TNXB* genes, demonstrated that TNX deficiency results in Ehlers-Danlos syndrome (EDS).²⁷⁰ Most forms of EDS are caused by autosomal dominant mutations in collagen genes; the recessive forms are caused by mutations in genes for collagen-modifying enzymes, including TNX, which is associated with and stabilizes collagen fibrils. Homozygous TNX deficiency causes a

severe, clinically distinct, recessive form of EDS, either with or without associated 21OHD;²⁷¹ haploinsufficiency of TNX causes the mild "hypermobility form" of EDS, manifesting with joint hypermobility, pain, multiple dislocations, and, less commonly, chronic arthralgia, hernias, and cardiac defects.²⁷² Up to 10% of patients with SW 21OHD have *CYP21A2* gene deletions on one allele that extend into the *TNXB* gene, so that they are also haploinsufficient for TNX and have a distinct form of 21OHD termed CAH-X.²⁷³

CYP21A2 Gene Lesions Causing 21-Hydroxylase Deficiency

21OHD can be caused by *CYP21A2* gene deletions, gene conversions, and apparent point mutations. The most common apparent point mutations are actually small gene conversion events,^{10,242} so that gene conversions account for about 85% of the lesions in 21OHD. Each person has two *CYP21A2* alleles, one contributed by each parent. Most patients with 21OHD are compound heterozygotes, having different lesions on their two alleles. Gene deletions and large conversions eliminate gene transcription; homozygosity for these cause salt-losing 21OHD. Some microconversions, such as those creating premature translational termination, also cause salt-losing 21OHD. Milder forms, such as SV and NC 21OHD, are associated with amino acid replacements in the P450c21 protein caused by gene microconversion events. Patients with these forms of 21OHD are usually compound heterozygotes bearing a severely disordered allele and a mildly disordered allele, so that the clinical manifestations are based on the nature of the mildly disordered allele. The *CYP21A2* and *CYP21A1P* genes differ by only 87 or 88 nucleotides. Two unusual and related features of the 21-hydroxylase locus complicate its analysis. First, the gene deletions in this locus are most unusual in that they extend 30 kb from one of several points in the middle of *CYP21A1P* to the precisely homologous point in *CYP21A2*. Second, gene conversions are extremely common.^{10,242}

Gene Conversions and Microconversions Causing Salt-Wasting 21-Hydroxylase Deficiency. If a segment of gene A replaces the corresponding segment of the related gene B, the structure of recipient gene B is said to be "converted" to that of donor gene A. The hallmark of gene conversion is that the number of closely related genes remains constant, while their diversity decreases. Two types of gene conversions commonly cause 21OHD: large gene conversions that can be mistaken for gene deletions, and small microconversions that resemble point mutations. The frequency of large gene conversions versus gene deletions was formerly controversial, principally because initial studies used relatively small groups of patients from single locations or ethnic groups. A compilation of multiple studies shows that about 19% of mutant alleles have gene deletions, 8% have large gene conversions, 67% have microconversions, and 6% had other lesions²⁴² (Fig. 14.17). Because of ascertainment bias, such numbers emphasize more severely affected patients. About 75% of mutated *CYP21A2* genes are grossly intact and appear to carry point mutations, but most apparent point mutations are also found in the *CYP21A1P* pseudogene, indicating that they result from small gene conversion events (Table 14.6). Three changes in the pseudogene (8-bp deletion, exon 3; T insertion, exon 7; Gly 318 Stop, exon 8) render its RNA product nonfunctional, because of an altered reading frame and/or premature stop codon; these have been found in *CYP21A2* alleles that cause SW 21OHD. Three closely clustered base changes in *CYP21A1P* alter the normal amino acid sequence Ile-Val-Glu-Met at codons 236 to 239 in exon 6 to Asn-Glu-Glu-Lys in a small number of genes causing SW 21OHD.

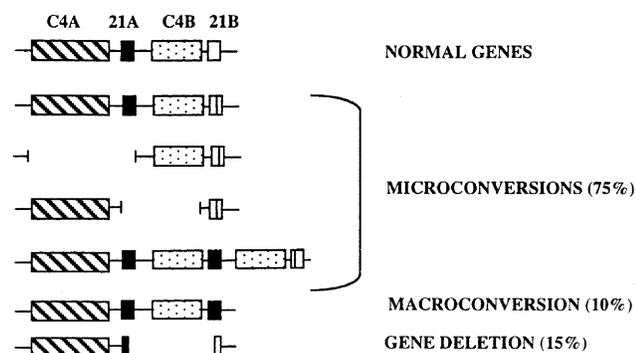

Fig. 14.17 Classes of genetic rearrangements causing 21-hydroxylase deficiency. Deletions or duplications of the *C4A* and *C4B* genes can occur with or without associated lesions in the *P450c21B* gene. Note that all “point mutations” in *P450c21B* are actually “microconversion.” Many authors combine the “gene deletion” and “macroconversion” groups because these are difficult to distinguish by Southern blotting, as both result in a loss of the *P450c21B* gene, but the genotypes are clearly distinct, as shown.

TABLE 14.6 Microconversions in the *CYP21A2* Gene That Cause 21-Hydroxylase Deficiency

Mutation	Location	Associated Phenotypes	Activity
Pro 30 → Leu	Exon 1	NC/SV	30%–60%
A → G	Intron 2	SV/SW	Minimal
8 bp deletion	Exon 3	SW	0
Ile 172 → Asn	Exon 4	SV	3%–7%
Ile 236 → Asp			
Val 237 → Glu	Exon 6	SW	0
Met 239 → Lys			
Val 281 → Leu	Exon 7	NC	18% ± 9%
Gly 292 → Ser	Exon 7	SW	
T insertion @ 306	Exon 7	SW	0
Gly 318 → Stop	Exon 8	SW	0
Arg 339 → His	Exon 8	NC	20%–50%
Arg 356 → Trp	Exon 8	SV/SW	2%
Pro 453 → Ser	Exon 10	NC	20%–50%
GG → C @ 484	Exon 10	SW	0

The most common lesion in classic 21OHD is an A → G change in the second intron, 13 bases upstream from its normal 3' splice acceptor site; this is a microconversion found in over 25% of severely affected 21OHD alleles. This intronic mutation causes abnormal splicing of the encoded RNA, which eliminates activity. However, a small portion of this mRNA may be spliced correctly in some patients so that the phenotypic presentation is variable; most such patients have SW 21OHD, but some have SV 21OHD. This intron 2 microconversion is often associated with the Ser/Thr polymorphism at codon 268, which does not alter enzymatic activity. The microconversion R356W, which is found in about 10% of severely affected alleles, may retain slight activity and has been found in both SW and SV 21OHD. A large number of rare mutations have been described in single individuals.

Mutations Causing Simple Virilizing and Nonclassic 21-Hydroxylase Deficiency. The microconversion I172N is the most common cause of SV 21OHD. When this residue is changed to Asn, Leu, Gln, or His and the resulting mutant *P450c21* protein is assayed in vitro, it retains around 3% to 7% of normal 21-hydroxylase activity. The intron 2 microconversion is occasionally seen in SV 21OHD. The microconversion P30L is generally associated with NC 21OHD, but is

found in some patients with SV 21OHD. The most common mutation causing NC 21OHD is V281L, a microconversion linked to HLA-B14 and HLA-DR1, but also found in patients with other HLA types. The microconversion P30L is found in about 15% to 20% of NC 21OHD alleles, and the mutations R339H and P453S have been associated with NC 21OHD; the P453S mutation is polymorphic in about 20% of *CYP21A1P* pseudogenes, and hence also represents a microconversion event.

Diagnosis of 21-Hydroxylase Deficiency

Prenatal Diagnosis. The diagnosis of 21OHD can be approached prenatally by measuring fetally produced steroids, such as 17OHP or Δ^4 -androstenedione in amniotic fluid, but these steroids may not be elevated above the broad range of normal in fetuses with SV or NC 21OHD. HLA typing of fetal amniocytes can be informative if there is previous linkage analysis of an affected index case and parents, but some HLA alleles are expressed weakly in cultured amniocytes, hence this procedure is rarely used. DNA sequencing is now widely used, but the complex genetics of the *CYP21* locus means this procedure is reliable only when the genetic lesion in a previously affected sibling or the parents is known.

Newborn Screening. Newborn screening programs throughout the industrialized world now incorporate measurements of 17OHP to detect 21OHD. By reducing the time to diagnosis, screening dramatically reduced mortality, morbidity from hyponatremia, length of hospitalization, learning disability, and errors of sex assignment.^{243,257,274} However, screening programs in different jurisdictions use different 17OHP assays, thresholds, and follow-up procedures, hence the physician must become familiar with local procedures. Current guidelines recommend a standardized 17OHP immunoassay from the dried blood samples used for other newborn screens.⁴⁰ Because 17OHP is elevated in premature and sick infants, and in healthy babies in the first 2 days, secondary screening by liquid chromatography followed by tandem mass spectrometry (LC-MS/MS) is recommended for all elevated results.⁴⁰ Initial screening results are improved when small babies are stratified for gestational age rather than birth weight.²⁷⁵ Because immunoassays can yield false positive results, if LC-MS/MS is not available, follow-up testing should be done with an intravenous ACTH test. About 40% of samples that are initially reported as positive will have normal 17OHP levels when measured by LC-MS/MS. Genotyping is not recommended for screening programs because of cost, high error rate, undetected mutations, and inability to distinguish mutations in *cis* versus *trans* without genotyping at least one parent.⁴⁰ Measuring additional steroids and their ratios may improve the specificity of screening by LC-MS/MS: the ratio of sum of 17OHP plus 21-deoxycortisol divided by the cortisol level identified all affected children with no false positives.²⁷⁶

Postnatal Diagnosis. When there is no newborn screening, genital ambiguity and/or a salt-losing crisis will generally alert pediatricians to most cases of severe 21OHD. Salt-losing crises generally occur in the second week of life, presenting with vomiting, diarrhea, dehydration, hyperkalemia, and hyponatremia. Occasionally, such infants are thought to have viral syndromes or gastrointestinal obstructions; such a failure to make the diagnosis can result in the infant's death. Boys with SV 21OHD may escape diagnosis until they are 3 to 7 years old, when they present with isosexual precocity, advanced bone age, and characteristically prepubertal testes. Teenage and adult females with NC 21OHD may consult an internist, obstetrician, or dermatologist for virilism, hirsutism, menstrual irregularity, infertility, or acne.

The key diagnostic maneuver is to measure 17OHP and other steroids in response to intravenous synthetic ACTH. The usual doses are 15 µg/kg in infants, 0.125 mg in children up to 2 years of age, and 0.25 mg in older children and adults. 17OHP and cortisol should be measured at 0 and 60 minutes. Individual patient responses must be compared with age- and sex-matched data from normal children. Normal responses are shown in Table 14.4 and Fig. 14.12. Both basal and stimulated levels of 17OHP are markedly elevated in patients with SW and SV 21OHD. Basal levels are usually greater than 2000 ng/dL and increase to more than 5000 to 10,000 ng/dL after ACTH. Patients with NC 21OHD typically have normal or minimally elevated basal levels, but have supranormal responses to ACTH stimulation, that is, 1500 to more than 10,000 ng/dL. The cortisol response to ACTH is absent or subnormal in patients with SW or SV 21OHD and is normal in patients with NC 21OHD. Basal plasma ACTH levels may be markedly elevated in severe forms and may be normal in patients with the milder forms who are not overtly adrenal insufficient.

Other ancillary tests are listed in Table 14.5. Urinary excretion of 17-ketosteroids is generally elevated, but this test is no longer in general use and is more useful for monitoring suppressive therapy than for initial diagnosis. When urinary steroids are measured, a complete 24-hour sample must be obtained, and a concomitant measurement of creatinine excretion is required to monitor the completeness of the collection. Less than 24-hour urine collections are not quantitatively accurate because of diurnal variations in steroid excretion. Urine steroid profiling with mass-spectrometric methods (usually GC/MS-MS) typically shows elevated metabolites of 17OHP: pregnanetriol, 17-OH-pregnanolone and pregnanetriolone.

Plasma renin, measured as renin activity or total content, and its response to salt restriction can be especially useful. Most patients with SV 21OHD have high plasma renin, which increases further on sodium restriction, confirming that these patients are partially mineralocorticoid deficient and can maintain a normal serum sodium only by hyperstimulation of the zona glomerulosa.

Treatment

The management of 21OHD remains difficult.⁴⁰ Overtreatment with glucocorticoids causes delayed growth, even when the degree of overtreatment is insufficient to produce signs of Cushing syndrome. Undertreatment results in continued overproduction of adrenal androgens, which hastens epiphyseal maturation and closure, again resulting in compromised growth and other manifestations of androgen excess.

Doses of glucocorticoids should be based on the expected normal cortisol secretory rate, which is about 6 to 8 mg/m² per day.^{145,277,278} However, effective suppression of ACTH and adrenal androgen production requires somewhat higher doses of about 10 to 15 mg/m² per day.⁴⁰ Newly diagnosed patients, especially newborns, require higher initial dosages to suppress their hyperactive CRH-ACTH-adrenal axis. The glucocorticoid used is important. Most tables of glucocorticoid dose equivalencies are based on their equivalence in antiinflammatory assays; however, growth-suppressant equivalences do not parallel antiinflammatory equivalencies: long-acting synthetic steroids, such as dexamethasone, have a disproportionately greater growth-suppressant effect and hence must be avoided in treating growing children and adolescents (Table 14.7). Most authorities favor the use of oral hydrocortisone in three divided daily doses in growing children. However, adults and older teenagers who already have fused their epiphyses may be managed with prednisone.⁴⁰

Mineralocorticoid therapy in 21OHD returns plasma volume to normal and eliminates the hypovolemic drive to ACTH secretion. Thus mineralocorticoid therapy often permits the use of lower doses of glucocorticoids in patients with SV 21OHD, optimizing growth in children and diminishing unwanted weight gain in adults. The only oral mineralocorticoid preparation generally available is fludrocortisone (9α-fluorocortisol). When the oral route is not available in severely ill patients, mineralocorticoid replacement is achieved with intravenous hydrocortisone plus sodium chloride. About 20 mg of hydrocortisone has a mineralocorticoid effect of about 0.1 mg of 9α-fluorocortisol (see Table 14.7). Mineralocorticoid dosing is not based on body mass or surface area: newborns are quite insensitive to mineralocorticoids as reflected by their high serum aldosterone concentrations (see Fig. 14.17), and often require larger doses than do adults (0.15–0.30 mg/day, depending on the sodium supplementation). In older children, the replacement dose of 9α-fluorocortisol is 0.05 to 0.15 mg daily. Mineralocorticoids are ineffective unless adequate sodium is presented to the renal tubules, hence additional salt supplementation, usually 1 to 2 g NaCl/day in the newborn, is typically needed. Some adult patients with SW 21OHD can discontinue mineralocorticoid replacement and salt supplementation; this probably reflects the increased mineralocorticoid sensitivity in adults, their free access to salty foods, and the induction of hepatic extraadrenal 21-hydroxylating enzymes.⁴¹

Long-term management requires careful clinical and laboratory monitoring. Growth should be monitored at 3- to 4-month

TABLE 14.7 Potency of Various Therapeutic Steroids (Set Relative to the Potency of Cortisol)

Steroid	Antiinflammatory Glucocorticoid Effect	Growth-Retarding Glucocorticoid Effect	Salt-Retaining Mineralocorticoid Effect	Plasma Half-Life (min)	Biologic Half-Life (h)
Cortisol (hydrocortisone)	1.0	1.0	1.0	80–120	8
Cortisone acetate (oral)	0.8	0.8	0.8	80–120	8

intervals in children; bone age should be assessed annually. Each visit should be accompanied by measurement of blood pressure, plasma renin and serum androstenedione, DHEA, DHEAS, and testosterone. Plasma 17OHP is generally measured but may be difficult to interpret because of its variation as a function of the timing of glucocorticoid doses, its diurnal variation, and its hyperresponsiveness to stress (e.g., clinic visits).

Experimental Prenatal Treatment of 21-Hydroxylase Deficiency

Because treatment of 21OHD centers on glucocorticoid suppression of the HPA axis, suppressing the fetal HPA axis has been proposed by administering transplacental glucocorticoids to the mother. Female fetuses affected with CAH begin to become virilized at around 6 to 8 weeks' gestation, the time at which the testes of normal male fetuses produce testosterone, causing fusion of the labioscrotal folds, enlargement of the genital tubercle into a phallus, and the formation of the phallic urethra. The adrenals of female fetuses with 21OHD may produce androgen concentrations that approach those of a normal male, resulting in varying degrees of masculinization of the external genitalia; suppressing fetal adrenal steroidogenesis in a female fetus with 21OHD can theoretically ameliorate the virilization. Dexamethasone has been used for this purpose, but such treatment remains experimental and highly controversial.⁴⁰ This approach has been suggested when the parents are known to be heterozygotes by having previously had an affected child. However, even in such pregnancies, only one in four fetuses will have 21OHD, and, as prenatal treatment is not needed for male fetuses with 21OHD, only one in eight pregnancies of heterozygous parents would harbor an affected female fetus that might potentially benefit from prenatal treatment. Treatment must be started at about 6 weeks postconception (8 weeks of amenorrhea); fetal sexing by fetal DNA in the mother's blood may be done at about this time, allowing non-treatment or early cessation of dexamethasone treatment of male fetuses. However, in female fetuses, chorionic biopsy for DNA diagnostics cannot be done until 12 to 13 weeks, and turnaround times in DNA laboratories are slow if the mutations carried by both parents are not established previously. Thus seven of eight pregnancies may be treated needlessly to treat one affected female fetus.⁴⁰ Some advanced centers might avoid treating male fetuses by identifying Y-chromosome DNA in maternal circulation by 6 weeks; however, this only reduces, but does not eliminate, the number of fetuses needlessly exposed to dexamethasone, and its general applicability is not yet established.

The ethics of such prenatal treatment remains highly controversial.^{40,279,280} The rationale is that dexamethasone, which is not metabolized by placental 11 β HSD2, will cross the placenta, suppress fetal ACTH, and consequently suppress adrenal steroidogenesis. However, it is not known precisely when the fetal hypothalamus begins to produce CRH, when the fetal pituitary begins to produce ACTH, whether all fetal ACTH production is regulated by CRH, or whether these hormones are suppressible by dexamethasone in the early fetus. Although there is evidence that pharmacologic doses of glucocorticoids do not harm pregnant women, few data exist for the fetus. Pregnant women with diseases such as nephrotic syndrome and systemic lupus erythematosus are generally treated with prednisone, which does not reach the fetus because it is inactivated by placental 11 β HSD. Treatment of a fetus with 21OHD requires the use of fluorinated steroids that escape metabolism by 11 β HSD, and few data are available about the long-term use of such agents throughout gestation.

The usual protocol uses dexamethasone doses of 20 μ g/kg of maternal body weight (max 1.5 mg/day); for a 60-kg woman, this is 1.2 mg, which is about 6 times physiologic replacement. However, the fetus normally develops in the presence of very low cortisol concentrations of only about 20 to 60 nmol/L (0.7–2.0 μ g/dL),^{281,282} which is only about 10% of the corresponding maternal level. Thus the doses used in prenatal treatment appear to achieve effective glucocorticoid concentrations that are around 60 times physiologic for the fetus. The potential benefits of prenatal treatment are reduction or elimination of virilization of external genitalia and brain, reducing the risk of gender confusion and the need for surgery. Animal studies indicate prenatally administered dexamethasone increases risks of palatal clefting; impairs brain, kidney; and islet cell development; decreases birthweight; and increases risks of hypertension.^{40,283} Human studies have been limited in methodology or size, but studies in Sweden found that prenatally treated children without 21OHD had poorer working memory and poorer self-perception of scholastic competence, and increased self-rated social anxiety²⁸⁴; there were also mild effects on sociability²⁸⁵ and gender role behavior in boys,²⁸⁶ leading the Swedish investigators to discontinue further research on this treatment.²⁸⁷ Alternative approaches, such as preimplantation genetic diagnosis, also carry some risks. Thus the risks of prenatal treatment appear to outweigh the benefits,²⁸⁰ and all medical societies that have examined this issue as of 2018 recommend that such treatment only be done with fully informed parental consent under Institutional Review Board (IRB)-approved research protocols, in centers that see enough such patients to achieve meaningful results.⁴⁰

Experimental Postnatal Treatment of 21-Hydroxylase Deficiency

Growth is compromised in most children with 21OHD. The use of short-acting glucocorticoids and mineralocorticoid supplementation help, but adult heights are typically 1 SD or more below predicted heights.⁴⁰ The loss of height in 21OHD is partially caused by the effect of sex steroids on epiphyseal closure and partially caused by glucocorticoid-induced resistance to the action of growth hormone; the most crucial times when height is lost are during the first 2 years of life and during the pubertal growth spurt. Consequently, several research studies have addressed optimizing the final height of children with CAH.⁴⁰

Antiandrogens and Aromatase Inhibitors. These drugs have been tried in the presence of low-dose mineralocorticoids and lower doses of glucocorticoids.⁴⁰ Because estrogen is the key hormone in promoting epiphyseal fusion, inhibiting the conversion of androgen to estrogen with an aromatase inhibitor (testolactone) promotes growth, whereas the antiandrogen (flutamide) ameliorates virilization. This approach permits use of physiologic replacement doses of hydrocortisone (8 mg/m²/day), rather than the usual supraphysiologic doses of 12 to 15 mg/m²/day, favoring normal growth. Similarly, trials are underway with abiraterone to inhibit P450c17, thus interfering with the synthesis of all sex steroids. The drugs are expensive and not approved for this use, long-term safety and efficacy are not established, and antiandrogens are potentially hepatotoxic. Thus like all experimental therapies, these approaches should only be pursued in controlled, prospective trials approved by Institutional Review Boards.⁴⁰

Growth Hormone and Gonadotropin-Releasing Hormone Agonist Therapy. Growth-promoting drugs have been proposed in children near the age of puberty as pharmacologic growth hormone therapy may partially overcome the effects of higher doses of glucocorticoids, and GnRH agonist will delay the progression of puberty, permitting more time to grow.

Small preliminary studies with these agents are promising, but both agents are expensive and neither is approved for this use; controlled prospective trials are needed.⁴⁰

Adrenalectomy. Because the adrenal carrying severe *CYP21A2* mutations cannot produce aldosterone or cortisol, it has been argued that these affected glands do more harm than good, and should be removed. Among 18 adrenalectomized patients, five had adrenal crises when therapy was suboptimal and two became hypoglycemic during intercurrent illnesses.⁴⁰ As a result of the high risk of postoperative morbidity and mortality, this approach is not recommended.⁴⁰

Lesions in Isozymes of P450c11

11 β -Hydroxylase Deficiency

11 β -Hydroxylase deficiency (11OHD) is the hyperandrogenic form of CAH. There are two isozymes of 11-hydroxylase. P450c11 β , encoded by the *CYP11B1* gene, is expressed in the zonae fasciculata and glomerulosa, where it catalyzes the 11 β -hydroxylation of 11-deoxycortisol to cortisol and that of DOC to corticosterone; it also has some 18-hydroxylase activity, but has no 18-methyl oxidase activity.^{10,42} P450c11 α S (aldosterone synthase) encoded by the *CYP11B2* gene, is found only in the zona glomerulosa and catalyzes 11 β -hydroxylation, 18-hydroxylation, and 18-oxidation; thus it is the sole enzyme required to convert DOC to aldosterone.²⁸⁸ The *CYP11B1* and *CYP11B2* genes are 93% identical and closely linked on chromosome 8q22, but, unlike the *CYP21A1P* and *CYP21A2* genes in the HLA locus, their genetic recombination is rare.^{10,42} Severe deficiency of P450c11 β decreases the secretion of cortisol, causing CAH and virilization of affected females. The defect in the pathway to cortisol results in accumulation of 11-deoxycortisol and the defect in the 17-deoxy pathway in the synthesis of corticosterone in the fasciculata may lead to overproduction of DOC; elevated concentrations of 11-deoxycortisol that are hyperresponsive to ACTH establish the diagnosis. Because DOC is a mineralocorticoid, these patients can retain sodium. Although DOC is less potent than aldosterone, it is secreted at high levels in 11OHD, so that salt is retained and the serum sodium remains normal. Overproduction of DOC frequently leads to hypertension; as a result, 11OHD is often termed the *hypertensive form of CAH* when detected in older children. However, newborns often manifest mild, transient salt loss,²⁸⁹ as a result of the normal newborn resistance to mineralocorticoids (Fig. 14.18); this may lead to incorrect diagnosis and treatment. Thus there may be a poor correlation between DOC concentrations, serum potassium, and blood pressure or between the degree of virilization in affected females and the electrolyte and cardiovascular manifestations. Newborns may also have elevated concentrations of 17OHP, presumably as a “back-up” phenomenon of high concentrations of 11-deoxycortisol inhibiting P450c21, so that 11OHD may be detected in newborn screening for 21OHD.²⁵⁷ The diagnosis is established by demonstrating elevated basal concentrations of DOC and 11-deoxycortisol, which hyperrespond to ACTH; a normal or suppressed plasma renin activity is also a hallmark of this disease.

11OHD appears to cause about 5% of CAH in persons of European ancestry, but is more common in both Moslem and Jewish Middle Eastern populations,^{290–292} and accounts for up to 13.5% of CAH in Turkey,²⁹³ where 13 different *CYP11B1* mutations have been found.²⁹⁴ Over 100 *CYP11B1* mutations have been reported.^{291,295} Common *CYP11B1* mutations include R448H among Moroccan Jews, and Q356X and G379V in Tunisian Arabs.²⁹¹ A milder, nonclassic form of 11OHD, analogous to nonclassic 21OHD, has been reported

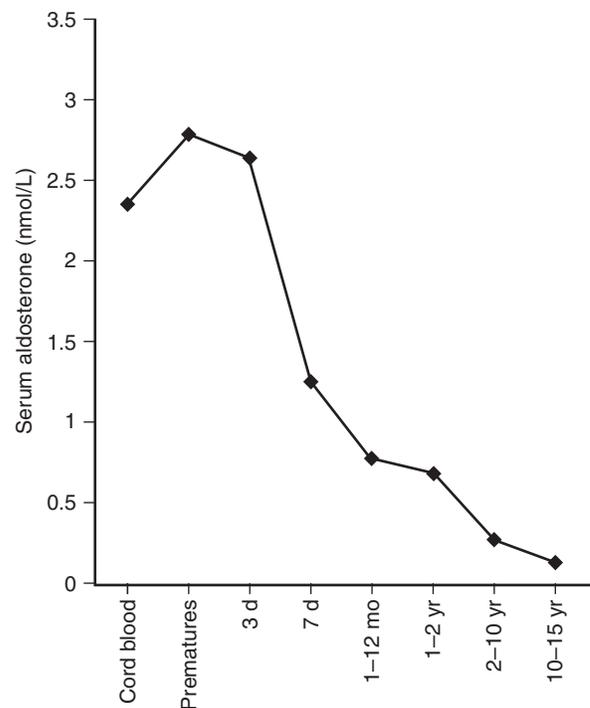

Fig. 14.18 Concentrations of aldosterone as a function of age.

in otherwise asymptomatic women with hirsutism, virilism, and menstrual irregularities, and in men with sexual precocity.^{291,296,297} However, true nonclassic 11OHD is rare; only two of five hyperandrogenic women who had 11-deoxycortisol values more than 3 times higher than the 95th percentile, in response to stimulation with ACTH, had mutations of P450c11 β , all of which retained 15% to 37% of normal activity.²⁹⁸ Repeated ACTH testing in two of the three women who lacked mutations showed much lower (but still elevated) 11-deoxycortisol values. Thus just as in the case of nonclassic 3 β HSD deficiency, an abnormal steroid response to ACTH is not sufficient to diagnose a genetic lesion. Treatment of 11OHD entails glucocorticoid replacement with doses similar to those used in 21OHD, but without mineralocorticoid replacement.

Corticosterone Methyl Oxidase Deficiencies

P450c11 α S is expressed exclusively in the zona glomerulosa where it catalyzes 11 β -hydroxylase, 18-hydroxylase, and 18 methyl oxidase activities. Disorders of P450c11 α S cause the so-called corticosterone methyl oxidase (CMO) deficiencies, wherein aldosterone biosynthesis is impaired, whereas the zona fasciculata continues to produce corticosterone and DOC.^{42,299} The absence of aldosterone biosynthesis will generally result in a salt-wasting crisis in infancy, at which time the normal secretory rate of DOC is insufficient to meet the newborn's mineralocorticoid requirements (similarly to the newborn with 11OHD). These infants typically present with hyponatremia, hyperkalemia, and metabolic acidosis, but the salt-wasting syndrome is typically less severe than in patients with 21OHD or lipid CAH because of the persistent secretion of DOC. These patients may recover spontaneously and grow to adulthood without therapy,³⁰⁰ probably reflecting the increasing sensitivity to mineralocorticoid action with advancing development, shown by the age-related decrease in serum aldosterone (see Fig. 14.18). Consistent with this, plasma renin activity is markedly elevated in affected children but may be normal in affected adults.

CMOI deficiency results from a complete loss of P450c11AS activity so that no 18-hydroxylase or 18 methyl oxidase activity persists, eliminating the biosynthesis of 18OH-corticosterone and aldosterone, while preserving the biosynthesis of corticosterone by P450c11 β . Thus the diagnosis for CMOI deficiency is usually based on an increased ratio of corticosterone to 18OH-corticosterone.⁴² CMOII deficiency results from amino acid replacement mutations in P450c11AS that selectively delete the 18-methyl oxidase activity, while preserving the 18-hydroxylase activity: serum 18OH-corticosterone is high and aldosterone is low.^{42,299} The diagnosis of CMOII deficiency requires an increased 18OH-corticosterone and very low aldosterone concentration. CMOII deficiency is common in Sephardic Jews of Iranian origin, where all affected individuals appear to be homozygous for two different mutations, R181W and V385A.³⁰¹ Family members who were homozygous for only one of these mutations were clinically unaffected; both mutations are required to cause disease. The clinical and hormonal findings in CMOI and CMOII overlap, and these syndromes should be regarded as different degrees of severity on a continuous clinical spectrum,^{302,303} similar to the overlapping clinical spectrum of 21OHD.

Glucocorticoid-Suppressible Hyperaldosteronism

Although *CYP11B* gene conversions are rare, an unusual gene duplication causes glucocorticoid-suppressible hyperaldosteronism. A homologous recombination event creates a third *CYP11B* gene that fuses the 5' flanking DNA of the *CYP11B1* gene for P450c11 β onto the *CYP11B2* gene for P450c11AS, thus placing the regulation of P450c11AS under the control of ACTH rather than the renin-angiotensin system, so that these patients make P450c11AS in response to physiology that should stimulate P450c11 β .^{304–306} The excess P450c11AS causes hyperaldosteronism and hypertension; this is then suppressible by glucocorticoid suppression of ACTH, which normally suppresses P450c11 β , hence the name "glucocorticoid-remediable hypertension"; this disorder appears to account for about 2% of hypertension.³⁰⁷

Lesions in Isozymes of 11 β -Hydroxysteroid Dehydrogenase

Cortisone and prednisone are inactive prohormones that must be reduced to cortisol or prednisolone to bind to and activate the GR. The interconversion of these keto- and hydroxysteroids is catalyzed by the two isozymes of 11 β -hydroxysteroid dehydrogenase, 11 β HSD1 (encoded by *HSD11B1*) and 11 β HSD2 (encoded by *HSD11B2*). Both enzymes are reversible in vitro, hence both can act as either an oxidase or reductase, depending on the availability of cofactors, but under physiologic situations, 11 β HSD1 generally acts to activate cortisone to cortisol, whereas 11 β HSD2 reverses this activation.^{10,16,71,73} 11 β HSD1 is primarily expressed in liver and fat, and 11 β HSD2 is expressed in mineralocorticoid-responsive tissues where it inactivates cortisol, permitting low concentrations of aldosterone to activate MRs (which also bind cortisol); 11 β HSD2 is inactive against aldosterone, DOC, and fludrocortisol. Interest in these enzymes extends far beyond their deficiency states, as they play central roles in metabolism;^{70,71} this has stimulated interest in using inhibitors of 11 β HSD1 to treat the metabolic syndrome, but such agents are not yet clinically available.³⁰⁸

Lesions in 11 β HSD1—(Apparent) Cortisone Reductase Deficiency

Defective 11 β HSD1 activity, diagnosed by reduced ratios of urinary metabolites of cortisol to those of cortisone, impairs cortisol feedback at the hypothalamic/pituitary axis, increasing the

secretion of ACTH and consequently increasing adrenal C19 steroid secretion, resulting in hyperandrogenism, sexual precocity, and polycystic ovaries. These patients may have heterozygous mutations (K187N, R137C) in the *HSD11B1* gene encoding 11 β HSD1; because 11 β HSD1 normally functions as a dimer, the presence of some mutant protein can exert dominant negative effects.³⁰⁹ Alternatively, a genetic lesion may be found in the *H6PDH* gene,³¹⁰ which encodes H6PDH, the enzyme that generates the NADPH used by 11 β HSD1 in the lumen of the endoplasmic reticulum. Although it was initially thought that mutations in both 11 β HSD1 and H6PDH interacted to cause this disease,³¹¹ mutations of H6PDH in patients appear to manifest with a more severe phenotype and are sufficient to cause this disorder, and only a few cases are caused by mutations in *HSD11B1*.^{73,309,310,312–314}

Lesions in 11 β HSD2—Apparent Mineralocorticoid Excess

Patients with apparent mineralocorticoid excess (AME) have hypervolemic hypertension, salt retention, and hypokalemic alkalosis—the classic picture of hyperaldosteronism—but with suppressed plasma renin activity and without measurable serum mineralocorticoids because of recessive mutations of 11 β HSD2.⁶⁸ About 30 different mutations in 11 β HSD2 have been described in about 60 patients with AME, and heterozygous carriers may have an increased risk of hypertension.³¹⁵ Typical features of children with AME include failure to thrive, delayed puberty, polydipsia, polyuria, muscle weakness, and hypertension. The hypertension is severe, often causing end-organ damage at an early age. Diagnosis is made from the high ratio of urinary metabolites of cortisol to cortisone. Treatment includes antagonism of the MR with spironolactone, correction of the hypokalemia, low-salt diets, and diuretics, but is only partially successful, and 10% of patients die from cerebrovascular accidents.³¹⁶

PAPSS2 Deficiency

The adrenal, gonad, and brain make DHEA, but only the adrenal effectively sulfates DHEA to DHEAS, catalyzed by SULT2A1; DHEAS may be desulfated back to DHEA by steroid sulfatase. SULT2A1 uses PAPS as its sulfate donor, which is in turn synthesized by PAPSS2 (see Section II). Sulfation by SULT2A1 predominates, especially in the zona reticularis; steroid sulfatase activity plays a relatively minor role in the adrenal, and its deficiency causes X-linked ichthyosis. SULT2A1 deficiency was suspected in a girl with mild vertebral deformities, premature pubarche, advanced bone age, and hirsutism; her DHEA, androstenedione, and testosterone were elevated but DHEAS was absent. This patient's *SULT2A1* gene was normal, but there was compound heterozygosity for PAPSS2 mutations.^{56,317,318} PAPSS2 deficiency depletes the adrenal of PAPS, increasing production of unconjugated DHEA, which is acted on by hepatic 3 β HSD1, yielding androgens. PAPSS2 deficiency had been reported in a Pakistani family with a rare skeletal defect termed "spondyloepimetaphyseal dysplasia (SEMD)/brachyolmia type 4," but endocrine studies had not been done in those individuals;^{319,320} these and other similar patients^{321–323} had complete loss of PAPSS2 activity.

ADRENAL INSUFFICIENCY

Many conditions will cause adrenal insufficiency, including CAH, hypopituitarism with ACTH deficiency, and primary adrenal disorders.³²⁴ Primary adrenal insufficiency is commonly termed *Addison disease*, but this is a vague term that encompasses many disorders. Up to World War II, most patients with "Addison disease" had tuberculosis of the adrenal, but over 80% of contemporary adult patients have autoimmune adrenalitis,

TABLE 14.8 Causes of Adrenal Insufficiency**PRIMARY ADRENAL INSUFFICIENCY**

therefore the term Addison disease is now widely used to indicate an autoimmune or idiopathic cause.

The spectrum of adrenal disorders presenting in infants, children, and adolescents differs from that presenting in adulthood (Table 14.8). CAH and autoimmune adrenal disease represent the largest proportions of cases, but some of the inherited developmental and metabolic causes of adrenal failure are also fairly common.^{160,325} Diagnosing some of these disorders is important for assessing potential associated features, initiating long-term management, and instituting genetic counseling.^{324,326} Adrenal disorders are typically divided into chronic and acute causes, but many acute presentations reflect an undiagnosed underlying chronic or developmental process (Table 14.9). Acute presentations may be triggered by intercurrent illness, trauma, or surgery, with poor fluid and sodium intake. Another way to group adrenal disorders consists of syndromic versus nonsyndromic forms, with syndromic forms being associated with additional signs and symptoms of other organ systems.

Acute Primary Adrenal Insufficiency

Acute adrenal crisis occurs most commonly in the child with undiagnosed chronic adrenal insufficiency who is subjected to an additional severe stress, such as major illness, trauma, or surgery. The major presenting symptoms and signs include abdominal pain, fever, hypoglycemia with seizures, weakness, apathy, nausea, vomiting, anorexia, hyponatremia, hypochloremia, acidemia, hyperkalemia, hypotension, shock, cardiovascular collapse, and death.³²⁴ Treatment consists of fluid and electrolyte resuscitation, ample doses of glucocorticoids, chronic glucocorticoid and mineralocorticoid replacement, and treatment of the precipitating illness.

Massive adrenal hemorrhage, with shock caused by blood loss, can occur in large infants who have had a traumatic delivery. A

 Weight loss

flank mass is usually palpable and can be distinguished from renal vein thrombosis by microscopic rather than gross hematuria; the diagnosis is then confirmed by CT or ultrasonography. Massive adrenal hemorrhage is more commonly associated with meningococemia (Waterhouse-Friederichsen syndrome). Meningitis is often, but not always, present. The characteristic petechial rash of meningococemia can progress rapidly to large ecchymoses; the blood pressure drops and respirations become labored, frequently leading rapidly to coma and death. Immediate intervention with intravenous fluids, antibiotics, and glucocorticoids is not always successful. A similar adrenal crisis may also occur rarely with septicemia from *Streptococcus*, *Pneumococcus*, *Pseudomonas*, diphtheria, and methicillin-sensitive and resistant isolates of *Staphylococcus aureus*.³²⁷ Adrenal hemorrhage has also been reported with the antiphospholipid syndrome and in patients on anticoagulant therapy.

Chronic Primary Adrenal Insufficiency

Autoimmune Disorders

Autoimmune adrenalitis is most commonly seen in adults 25 to 45 years old, about 60% to 70% of whom are women, with an adult prevalence of about 1 in 25,000.³²⁸ Autoimmune destruction of other endocrine tissues is frequently associated with autoimmune adrenalitis. Chronic adrenal insufficiency is suggested by poor weight gain or weight loss, weakness, fatigue, anorexia, hypotension, hyponatremia, hypochloremia, hyperkalemia, frequent illnesses, nausea, and vague gastrointestinal complaints (see Table 14.9), reflecting chronic deficiency of both glucocorticoids and mineralocorticoids. Early in the course of autoimmune adrenalitis, one may see signs of glucocorticoid deficiency (weakness, fatigue, weight loss, hypoglycemia, anorexia) without signs of mineralocorticoid deficiency (hyponatremia, hyperkalemia, acidosis, tachycardia, hypotension, low voltage on electrocardiogram, small heart on chest x-ray), or evidence of mineralocorticoid deficiency without glucocorticoid deficiency. Thus an initial clinical presentation that spares one category of adrenal steroids does not mean it will be spared in the long run. The symptoms listed in Table 14.9 can be seen in chronic adrenal insufficiency that is either primary or secondary. In primary chronic adrenal insufficiency, the low concentrations of plasma cortisol stimulate

the hypersecretion of ACTH and other POMC peptides, including the various forms of MSH; consequently, chronic primary adrenal insufficiency is also characterized by hyperpigmentation of the skin and mucous membranes, whereas secondary adrenal insufficiency is not. Such hyperpigmentation is most prominent in skin exposed to sun and in flexor surfaces, such as knees, elbows, and knuckles. The diagnosis is suggested by the aforementioned signs and symptoms, verified by a low morning cortisol level with a high ACTH, and confirmed by a minimal response of cortisol to a 60-minute intravenous ACTH test. Hyponatremia, hyperkalemia, low aldosterone, and elevated PRA suggest a disturbance in mineralocorticoid production. Associated findings may include the appearance of a small heart on chest x-ray, anemia, azotemia, eosinophilia, lymphocytosis, and hypoglycemia during fasting. Treatment of chronic primary adrenal insufficiency consists of physiologic glucocorticoid and mineralocorticoid replacement therapy.

Autoimmune adrenalitis is strongly associated with specific HLA haplotypes and with polymorphisms in the gene for cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4), which may be broadly involved in susceptibility to autoimmune disease.^{329–331} The diagnosis of autoimmune chronic adrenal insufficiency is based largely on finding circulating antibodies directed against adrenal cells or adrenal cellular contents. In many cases, the adrenal antigens are steroidogenic cytochrome P450 enzymes, especially P450_{sc}, P450_{c17}, and P450_{c21}.³²⁸ It is not clear how these enzymes reach immune cells to elicit an antibody response, but autopsy studies show infiltration of the adrenal cortex.¹⁶⁰ Thus it is likely that cell-mediated immunity is responsible for destruction of adrenocortical cells, resulting in a secondary discharge of cellular contents (including P450 enzymes) into the circulation, with subsequent development of secondary “marker” antibodies against these P450s. About half of adult patients with lymphocytic adrenalitis will also have autoimmune disease of another endocrine tissue with high titers of antibodies directed against specific contents of the affected tissue. This finding has led to the definition of specific autoimmune polyendocrine syndromes (APSs), some of which are more prevalent in childhood.³³¹

Type 1 Autoimmune Polyendocrine Syndrome (APS1). Also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia (APECED), APS1 is characterized by chronic mucocutaneous candidiasis, autoimmune Addison disease, and hypoparathyroidism. At least two of these features must be present to make the diagnosis, and their age of onset can be highly variable. In general, chronic mucocutaneous candidiasis appears in early childhood and affects the mouth and nails. Acquired hypoparathyroidism can present with clinical hypocalcemia during mid- or late childhood, although in some cases hypocalcemia may be masked by untreated adrenal insufficiency. The adrenal disorder usually presents in childhood or adolescence;³³² autoimmune adrenal disease may be a presenting feature in about 5% of cases³³³ and is found in more than 60%, predominantly in males (~2m:1f).³³² Additional autoimmune features of this condition include alopecia and vitiligo; gastritis, chronic diarrhea, and malabsorption, with or without pernicious anemia; hypergonadotropic hypogonadism, especially in women; and less commonly hepatitis, thyroiditis, interstitial nephritis, myositis, dental enamel hypoplasia, acquired asplenia, keratoconjunctivitis, and type 1 diabetes mellitus. Keratoconjunctivitis is an important associated feature that requires careful monitoring and treatment to prevent blindness. Oral or esophageal squamous cell carcinoma occurs in 10% of individuals as adults.³³³ APS1 is rare in most populations, but is common among people of Finnish (1:25,000), Sardinian (1:14,000), and Iranian Jewish (1:9,000) ancestry.³³¹ APS1 is caused by recessively inherited mutations in a 58-kDa transcription factor called *autoimmune regulator* (AIRE).^{334,335} More than 100 different mutations in the AIRE

gene have been described, although the homozygous or compound heterozygous R257X change is especially common in the Finnish population, whereas a 13-bp deletion (p.C322del13) is prevalent in persons from Norway.³³¹ The AIRE gene is expressed in thymic epithelial cells and rare peripheral dendritic cells that mediate the ectopic presentation of otherwise tissue-restricted peptides and promote self-tolerance of autoreactive thymocytes. In addition, AIRE seems to induce specific regulatory T cells in the thymus that are able to suppress autoimmunity. Deletion of AIRE in mice results in ectopic expression of peripheral tissue antigens in thymic medullary epithelial cells, resulting in the development of an autoimmune disorder similar to APS1/APECED.^{331,336} In general, autoimmune polyendocrinopathies are treated by hormone replacement therapy. Follow-up visits are recommended annually and screening of family members is advised. APS1 is also discussed in detail in Chapter 22.

Type 2 Autoimmune Polyendocrine Syndrome (APS2). Also known as Schmidt’s syndrome, APS2 refers to the relatively common association of autoimmune adrenalitis with thyroiditis and/or type 1 diabetes.³²⁸ APS2 is more common in females (3:1 ratio), is HLA-linked, and is generally seen in young or middle-aged adults, but can present at almost any age. Primary (hypergonadotropic) ovarian failure is seen in up to one-quarter of postpubertal females with APS2, but primary testicular failure is rare.¹⁶⁰ Pernicious anemia, hepatitis, vitiligo, and alopecia may also be seen, but the hypoparathyroidism and mucocutaneous candidiasis typical of APS1 are not seen in APS2. APS2 is associated with the same HLA markers as idiopathic autoimmune adrenalitis, which may simply be a form of APS2. But the heritability of APS2 is complex. APS2 and the subsequent X-linked immunodysregulation, polyendocrinopathy and enteropathy (IPEX) syndrome are discussed in detail in Chapter 22.

X-Linked Immunodysregulation, Polyendocrinopathy, and Enteropathy (IPEX). IPEX is a rare syndrome caused by mutations in the FOXP3 gene; more than 70 mutations have been described.³³¹ IPEX comprises of early-onset type 1 diabetes, autoimmune enteropathy manifesting with diarrhea and malabsorption, and dermatitis.³³⁷ Eosinophilia and elevated immunoglobulin (Ig)E levels may be seen. Kidney disease, autoimmune thyroiditis, alopecia, as well as autoimmune hepatitis, and exocrine pancreatitis, hemolytic anemia, and thrombocytopenia may be late manifestations. The disease is mostly lethal in infancy because of infections, and allogeneic bone marrow transplantation may offer the only cure.³³⁸

Immunotherapy-Related Autoimmune Disease. Immunotherapy has been highly successful with many cancers, but immunotherapy may be associated with immunotoxicity and autoimmunity.³³⁹ Autoimmune manifestations caused by immune checkpoint inhibitors (ICIs) depend on the pathway(s) targeted. ICIs disrupt the maintenance of immunological tolerance to self-antigens. Adverse events have been reported against multiple organ systems, including the gastrointestinal tract, skin, and all endocrine glands. Frequently observed endocrine manifestations are hypo- and hyperthyroidism, hypophysitis, autoimmune diabetes mellitus, and primary adrenal insufficiency.³⁴⁰ Use of the monoclonal antibody, ipilimumab, which blocks CTLA-4, has been associated with hypophysitis, whereas programmed cell death protein-1–antibody therapy is often associated with hypothyroidism.³³⁹ ICI-related hypophysitis often leads to life-threatening secondary adrenal insufficiency, necessitating prompt glucocorticoid replacement therapy, and should be considered or treated before starting any therapy for concomitant hypothyroidism. Primary adrenal insufficiency is rare with single-agent ICI treatment, but risk may exceed 4% with combination therapies.³⁴⁰

Adrenal Hypoplasia Congenita

Adrenal hypoplasia congenita, (AHC) also known as *congenital adrenal hypoplasia* or *adrenal dysgenesis*, is a disorder of adrenal development resulting in primary adrenal insufficiency. This condition can occur with several different inheritance patterns, and with a variety of associated or syndromic features.

X-Linked Adrenal Hypoplasia Congenita. This most common form of AHC is caused by mutations of the *NR0B1* gene encoding DAX1 on chromosome Xp21. In this most common form of primary adrenal hypoplasia, the definitive zone of the fetal adrenal does not develop, and the fetal zone is vacuolated and cytomegalic. About half of boys with AHC present with salt-loss and glucocorticoid insufficiency in early infancy; the rest present more insidiously with chronic adrenal insufficiency throughout childhood.³²⁵ Hypogonadotropic hypogonadism and incomplete pubertal development are associated features, although early puberty, with subsequent pubertal arrest, has been reported in rare cases. An underlying defect in spermatogenesis may also be present.

DAX1 is a nuclear transcription factor involved in adrenal and testicular development, as well as being expressed in pituitary gonadotropes. About two-thirds of boys with AHC have point mutations,³²⁵ the other one-third have *NR0B1* gene deletions either in isolation or as part of a contiguous gene deletion syndrome involving a telomeric X-linked mental retardation locus (*ILIRAPL1*) and/or centromeric genes for glycerol kinase deficiency (*GKD*) and sometimes ornithine transcarbamylase (*OTC*) and Duchenne muscular dystrophy (*DMD*). An adult-onset form of AHC caused by point mutations has also been described.³⁴¹

Boys with AHC respond well to glucocorticoid and mineralocorticoid replacement therapy. Testosterone treatment to induce secondary sexual characteristics is needed in adolescence; spontaneous fertility is rare and attempts to induce spermatogenesis with gonadotropins are rarely successful. Female carriers are unaffected, but half of their sons will be affected. Close monitoring and genetic counseling can help to prevent life-threatening adrenal crises in other family members or future pregnancies. Thus a family history of adrenal failure, unexplained death, or pubertal abnormalities in the male relatives of a boy with adrenal insufficiency should suggest AHC; indeed, a substantial proportion of boys with (sporadic) adrenal hypoplasia have DAX1 mutations.^{195,325,342}

Autosomal Forms of Adrenal Hypoplasia. In addition to X-linked AHC, autosomal recessive forms of adrenal hypoplasia have been reported and are yielding to genetic analysis. Mutations in SF1 (*NR5A1*), which were discussed earlier as a disorder of steroidogenesis that resembles lipoid CAH, are sometimes classified as a form of adrenal hypoplasia.^{342,343} However, SF1 mutations affect the gonad more severely than the adrenal, and have not been reported in phenotypic males with adrenal hypoplasia.³²⁵ Primary adrenal failure has also been associated with Pena-Shoekir syndrome type I (*DOK7*, *RAPSN*), pseudotrisomy 13, Meckel syndrome (*MKS1*), hydrolethalus syndrome (*HYLS1*), Galloway-Mowat syndrome (*WDR73*), the Pallister-Hall syndrome (*GLI3*), and with defects in *WNT3*.^{4,344}

Triple A (Allgrove) Syndrome. This disorder consists of (1) ACTH-resistant adrenal (glucocorticoid) deficiency (80% of individuals), (2) achalasia of the cardia (85%) and (3) alacrima (90%). The alacrima is the earliest and most consistent symptom, and the achalasia and adrenal insufficiency develop over the first 2 decades, although the achalasia is usually noted first. Mineralocorticoid insufficiency is reported in about 15% of cases, and up to 60% of patients develop progressive

neurological symptoms, such as intellectual impairment, sensorineural deafness, peripheral and cranial neuropathies, optic atrophy, parkinsonism, and autonomic dysfunction.¹⁴⁶ About 80% of affected patients have autosomal recessive mutations in *AAAS*, which encodes a WD-repeat protein termed ALADIN^{345,346}; the basis of the disease in patients lacking *AAAS* mutations is not completely solved yet. ALADIN colocalizes to the cytoplasmic side of the nuclear pore, where it interacts with and participates in the nuclear translocation of ferritin heavy chain protein, FTH1, thus rendering cells progressively susceptible to oxidative damage.³⁴⁷ Deficiency of ALADIN impairs the redox potential of adrenal cells and inhibits steroidogenesis.³⁴⁸ ALADIN is also involved in the regulation of mitotic controllers, essential for the formation of the mitotic spindle.³⁴⁹ Clinical findings of the *AAAS* can be quite variable even within the same family. Adrenal insufficiency is rarely the presenting feature. Thus a detailed family history of achalasia, alacrima, or neurological disorders is important when evaluating a patient with primary adrenal failure and may guide directly to the correct underlying disorder.

IMAGE Syndrome. Primary adrenal hypoplasia and neonatal adrenal crisis are also part of the IMAGE syndrome (intrauterine growth retardation, metaphyseal dysplasia, adrenal hypoplasia, genitourinary anomalies).³⁵⁰ A large, multigenerational family, with multiple, well-characterized individuals,³⁵¹ has been studied by linkage analysis, identifying a dominant missense mutation in the *CDKN1C* gene as the cause of this disorder.³⁵² In addition, four other, unrelated patients had four different missense mutations in *CDKN1C*.³⁵² The *CDKN1C* gene encodes the Wilms' tumor suppressor p57KIP2, which inhibits several cyclin-dependent kinases. This gene lies in the imprinted region of chromosome 11p15.5, so that only the maternal allele is expressed. Different mutations in this same gene cause Beckwith-Wiedemann overgrowth syndrome.³⁵³ The Beckwith mutations inhibit cell cycle, whereas the IMAGE mutations do not, and, when expressed in *Drosophila*, the Beckwith mutations have no effect on eye development, but the IMAGE mutations cause restricted growth.³⁵² Thus mutations in the same gene cause both the IMAGE adrenal hypoplasia syndrome and the Beckwith-Wiedemann adrenal hyperplasia syndrome.³⁵⁴ A *CDKN1C* missense mutation has also been described in a patient with Silver Russell syndrome sharing growth restriction but no other features with IMAGE syndrome.³⁵⁵

MIRAGE Syndrome. MIRAGE syndrome³⁵⁶ is characterized by myelodysplasia, infections, restricted growth, adrenal hypoplasia, genital anomalies, and enteropathy, and is associated with poor prognosis. Heterozygous *SAMD9* mutations (on chromosome 7q) have been identified in affected individuals, of which some survived longer, but developed a myelodysplastic syndrome (MDS). These mutations cause gain function of the growth repressor *SAMD9*. In some patients, progressive loss of mutated *SAMD9* by somatic adaptive changes in the bone marrow led to monosomy 7 and thereby rescued the negative effect on growth resulting in prolonged survival; but at the price of MDS.³⁵⁷

MCM4 Mutations. In the Irish Traveler population, the *MCM4* gene encoding minichromosome maintenance complex component 4 has also been found in patients presenting with primary adrenal insufficiency. These patients found in a genetically isolated population present with isolated cortisol deficiency, growth failure, increased chromosomal breakage, and natural killer cell deficiency.³⁵⁸ They may be more susceptible to infections and have an increased risk for neoplasias, but longer follow-up and better understanding of the underlying pathomechanism is needed.

Adrenocorticotrophic Hormone Resistance Syndromes

Hereditary unresponsiveness to ACTH, also termed familial glucocorticoid deficiency (FGD), can present as an acute adrenal crisis, precipitated by an intercurrent illness in an infant, or with the signs and symptoms of chronic adrenal insufficiency in childhood. Several different recessively inherited causes of FGD have been identified so far; these include *MC2R*, *MRAP1*, *StAR*, *CYP11A1*, *NNT*, *MCM4*, and *TXNRD2*. Unlike individuals with autoimmune adrenalitis, adrenal hypoplasia, or other forms of destruction of adrenal tissue, patients with hereditary unresponsiveness to ACTH typically continue to produce mineralocorticoids, because production of aldosterone by the adrenal zona glomerulosa is regulated principally by the renin-angiotensin system. Thus the presenting picture consists of failure to thrive, lethargy, pallor, hyperpigmentation, and hypoglycemia, often associated with seizures. Rare cases may also entail electrolyte abnormalities or increased plasma renin activity, leading to misdiagnosis as a different form of adrenal insufficiency.

MC2R Mutations: Familial Glucocorticoid Deficiency

Type 1. The ACTH receptor is a 7-transmembrane, G protein-coupled member of the family of melanocortin receptors termed MC2R.^{359,360} MC2R mutations appear to be the most common cause of ACTH resistance (25%), with several dozen reported cases, but the statistical distribution of these cases is unclear, as many different clinical criteria have been applied.¹⁸⁵

Most MC2R mutations are missense mutations, which lead to a retention of the receptor in the endoplasmic reticulum. Interestingly, one constitutively active mutation (F278C) of the MC2R protein has been described in a patient with Cushing syndrome.³⁶¹ However, all other patients harboring MC2R mutations present with isolated glucocorticoid deficiency and hyperpigmentation, often early after birth to up to 2 years of age; hypoglycemia is common and ACTH levels are grossly elevated, accounting for the hyperpigmentation. Mineralocorticoid and sex steroid production are usually not affected. However, absent adrenarche caused by low DHEAS is observed in many and establishes a role for ACTH in adrenarche.³⁶² Tall stature, increased head circumference, and advanced bone age have been reported in some cases; these might be secondary effects of grossly elevated ACTH levels affecting MC1R in the growth plate or stimulating estradiol synthesis. Alternatively, stimulated growth hormone axis before treatment could also be responsible.³⁶⁰ Treatment with replacement doses of glucocorticoids typically prevents adrenal crises, but may not suppress elevated ACTH levels completely; nevertheless, the use of supraphysiologic doses of steroids to suppress ACTH should be avoided.

MRAP Mutations: Familial Glucocorticoid Deficiency

Type 2. The MC2R accessory protein, MRAP1, is a small transmembrane protein that forms unusual antiparallel homodimers and serves two functions: it facilitates trafficking of MC2R from the endoplasmic reticulum to the cell membrane, and it interacts with MC2R on the cell surface to facilitate receptor action.³⁶³ Both MRAP1 and the related MRAP2 protein serve similar functions with other members of the MCR family.³⁶⁴ Whereas MRAP1 collaborates with MC2R, MRAP2, which is abundantly expressed in the hypothalamus, collaborates with MC4R and prokineticin receptors (PKRs), and is important in energy homeostasis and thus severe obesity. MRAP1 mutations are a common cause of FGD accounting for about 10% of cases, but MRAP1 mutations are clinically indistinguishable from MC2R mutations.^{195,365} In contrast, human MRAP2 mutations have been described in nonsyndromic severe obesity.

Nicotinamide Nucleotide Transhydrogenase Mutations.

Nicotinamide nucleotide transhydrogenase (NNT) is a protein of the inner mitochondrial membrane that generates NADPH from the energy of the mitochondrial proton gradient. Mitochondrial steroidogenic enzymes (e.g., CYP11A1 or CYP11B2/1) require NADPH for their activity. In addition, NNT and NADPH are important for the cellular balance of reactive oxygen species (ROS). First described in 2012,³⁶⁶ mutations in NNT have now been found in about 10% of FGD patients.^{195,367} Similarly to MC2R and MRAP1 deficiency, they cause isolated cortisol deficiency and may only be distinguished by genetic testing.³⁶⁷

Other Forms of Familial Glucocorticoid Deficiency.

FGD caused by mutations in other genes and proteins disrupting the oxidative stress system in mitochondria include *TXNRD2*,³⁶⁸ *GPX1*, and *PRDX3*.³⁶⁷ Furthermore, mild mutations in STAR that cause nonclassic lipoid CAH^{184,187} or in CYP11A1 may be mistaken for FGD.^{185,367} Overall, high-throughput sequencing of patients and families presenting with an FGD phenotype have revealed disease-causing mutations in about two-thirds of the patients, whereas the rest still remains without genetic diagnosis.

Metabolic Disorders

Metabolic disorders can also cause chronic primary adrenal insufficiency, including adrenoleukodystrophy (Schilder disease), peroxisome biosynthesis disorders (e.g., Zellweger syndrome spectrum), disorders of cholesterol synthesis and metabolism (e.g., Wolman disease/CESD (discussed in Section VI), SLOS), and mitochondrial disorders (e.g., Kearns-Sayre syndrome).

Adrenoleukodystrophy. Adrenoleukodystrophy (ALD) is a peroxisomal disease and is the most common metabolic cause of adrenal failure. Most cases are caused by mutations in the peroxisomal membrane protein ALDP encoded by the *ABCD1* gene on chromosome Xq28^{369,370}; ALDP belongs to the superfamily of ATP-binding cassette transporters. There are many clinical forms of ALD, including the childhood cerebral form (CCALD) with cerebral demyelination, the adolescent cerebral form, the adult cerebral form, adrenomyeloneuropathy, with axonopathy of the pyramidal and somatosensory tracts, and peripheral neuropathy, the olivo-ponto-cerebellar form, and a form presenting only with Addison disease.³⁷¹ CCALD is the most common phenotype. The prevalence of this condition is generally reported to be between 1:20,000 to 100,000, although the overall frequency may be as high as 1:17,000.³⁷² A rare autosomal recessive form of this condition also exists, which usually presents in infancy (see later).

ALDP imports activated acyl-CoA derivatives of very long chain fatty acids (VLCFA) into peroxisomes where they are shortened by β -oxidation.^{373,374} Consequently, ALD is characterized by high ratios of C26 to C22 VLCFA in plasma and tissues, permitting the diagnosis of individual patients and affected fetuses.³⁷⁵ Carriers can usually be detected by VLCFA screening, although genetic analysis may be necessary in some cases. Symptoms of X-linked CCALD commonly develop in mid-childhood, adrenomyeloneuropathy presents in adulthood.³⁷⁶ The same ALDP mutation can cause both ALD and adrenomyeloneuropathy, hence it is likely that other genetic loci are also involved.³⁷⁷ The earliest findings in CCALD are associated with the central nervous system leukodystrophy and include behavioral changes, poor school performance, dysarthria, and poor memory progressing to severe dementia. Symptoms of adrenal insufficiency usually appear after symptoms of white matter disease, but adrenal insufficiency may be the initial finding in up to 20% of children or young

adults.^{372,378,379} In contrast, adrenomyeloneuropathy typically begins with adrenal insufficiency in childhood and adolescence, and signs of neurologic disease follow 10 to 15 years later. About 1% to 3% of female carriers of X-linked ALD may develop neurological symptoms or adrenal dysfunction. Because screening is accurate and the diagnosis has long-term implications, VLCFA should be analyzed in all boys presenting with adrenal failure where the diagnosis is not clear. In fact, some countries, like the United States, have recently started including ALD in their newborn screening program as not to miss the window of opportunity for allogeneic hematopoietic stem cell transplantation for treating CCALD (<https://adrenoleukodystrophy.info/clinical-diagnosis/newborn-screening>). Lifetime prevalence of adrenal insufficiency in ALD males is about 80%, risk is highest in the first 10 years (almost 50%) and decreases to 5% after the age of 40 years.³⁸⁰ At onset of hypocortisolism mineralocorticoid production often is still intact and therefore does not require replacement therapy until showing deficiency.

Dietary therapy with so-called *Lorenzo's oil* (a 4:1 mixture of glyceryl-trioleate and glyceryl-trierucate) improves VLCFA levels, but it has been ineffective for the treatment of established cerebral disease, although a role in preventing the onset of cerebral disease has not been evaluated.^{372,377} Other therapeutic options include hematopoietic stem cell transplantation,^{372,374} which is most successful for early cerebral disease with a reported 5- to 8-year survival rate of 56%.³⁸¹ Lovastatin treatment decreases plasma C24:0 and C26:0, but is no longer recommended because it has no effect on C26:0 in cells or on VLCFAs.³⁸²

Peroxisome Biogenesis Disorders. Peroxisome biogenesis disorders (PBDs) are a group of autosomal recessive conditions caused by mutations in PEX proteins. Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease form the "Zellweger spectrum" and are clinically distinct from rhizomelic chondrodysplasia punctata caused by *PEX7* gene mutations.^{383,384} These disorders are characterized by developmental delay, hypotonia, neurosensory deafness, optic atrophy, and dysmorphic facial development. Patients often develop seizures, especially those with neonatal adrenoleukodystrophy. The diagnosis can be confirmed by the presence of C26:1, increased C26:0, and an increased ratio of C26:C22 and C24:C22 VLCFA. Most children with the severe forms of Zellweger syndrome and neonatal ALD do not survive past 2 years, although other variants of the Zellweger spectrum are associated with longer survival.³⁸⁵

Smith-Lemli-Opitz Syndrome. SLOS is an autosomal recessive defect in cholesterol biosynthesis resulting from abnormalities in the sterol Δ -7-reductase gene, *DHCR7*.³⁸⁶ The incidence of SLOS is estimated from 1:13,000 to 1:80,000. More than 190 mutations have been described, but two predominate: the c.964G>C mutation is mostly found in North America and Western Europe, whereas the W151X mutation is frequently found in Central and Eastern Europe, suggesting founder effects for these two mutations.³⁸⁷ The clinical features of SLOS include microcephaly, developmental delay, a typical facial appearance (short nose with broad nasal bridge and anteverted nares, long philtrum, microretrognathia, blepharoptosis, low-set, posterior-rotated ears, cleft and/or high-arched palate), proximal thumbs, and syndactyly of the second and third toes (>97%). Cardiac, renal, lung, and gastrointestinal abnormalities are also common. Genital anomalies include hypospadias, cryptorchidism, and even ambiguous genitalia in males. Adrenal insufficiency is present in some cases, especially during times of stress or when LDL-derived cholesterol sources are inadequate (e.g., dietary insufficiency/bile salt depletion).³⁸⁸ The clinical spectrum of SLOS is extremely broad, likely

reflecting differences in residual intrauterine cholesterol biosynthesis and/or differences in the transplacental supply of cholesterol supporting fetal development.³⁸⁷ SLOS may be suspected in utero by low maternal estriol and ultrasound findings. Postnatal biochemical analysis of sterol Δ -7-reductase activity, coupled with genetic analysis, can confirm the diagnosis. Alternatively, LC-MS/MS is a good method for sterol detection that can be used for diagnostic confirmation of SLOS. This approach may be adopted for newborn screening for SLOS via dried blood samples in the future. Life expectancy varies with disease severity. Dietary cholesterol supplementation, ranging from 20 to 300 mg/kg/day, has become an established therapeutic intervention. Beneficial effects include providing cholesterol to tissues outside the central nervous system (CNS) and downregulating HMG-CoA reductase, probably suppressing 7-DHC synthesis. Although this may result in amelioration of the extra CNS phenotype, a beneficial effect on brain is unlikely as plasma cholesterol does not cross the blood-brain barrier. Adding simvastatin to cholesterol supplementation did not really improve outcome.³⁸⁷

Mitochondrial Disorders. Disordered mitochondrial function can be associated with primary adrenal dysfunction.^{389,390} Typical clinical features include lactic acidosis, cataracts, sensorineuronal deafness, and myopathy/ophthalmoplegia. Adrenal failure is rare in childhood, but subclinical adrenocortical insufficiency may be found in adults with multisystem disease, and is a poor prognostic factor. The Kearns-Sayre syndrome results from large-scale deletions of mitochondrial DNA and can be associated with additional endocrinopathies, such as hypothyroidism, hypogonadism, diabetes, growth failure, and hypoparathyroidism.

Other metabolic disorders have also been reported to cause adrenal insufficiency, including Niemann-Pick disease type B (not to be confused with the type C disease, discussed in Section VI), a lysosomal lipid storage disease caused by mutations in the sphingomyelin phosphodiesterase 1 (*SMPD1*) gene, manifesting with hepatosplenomegaly and pulmonary disease.

Sphingosine-1-Phosphate Lyase. Sphingosine-1-phosphate lyase (SGPL1) deficiency is a recently described syndromic form of autosomal recessive adrenal insufficiency that manifests in combination with steroid-resistant nephrotic syndrome.^{391,392} Other associated features are ichthyosis, hypothyroidism, cryptorchidism, neurological symptoms, bone malformation, and immunodeficiency. SGPL1 is the enzyme responsible for the final step in the metabolism of sphingolipids. Mutations in upstream components of this pathway lead to sphingolipidoses, such as Gaucher, Niemann-Pick, Fabry, Krabbe, Sandhoff, and Tay-Sachs diseases, and GM1-gangliosidosis, which are lysosomal storage disorders resulting in the accumulation of sphingolipids in organs. Sphingolipidoses are generally progressive, multisystem disorders, some of which have a renal phenotype, but adrenal phenotypes have not been described. With SGPL1 deficiency sphingosine-1-phosphate and other precursors accumulate, leading to adrenal dysfunction and disrupted steroidogenesis.³⁹² The clinical phenotype with SGPL1 mutations has been broader than expected,³⁹¹⁻³⁹⁶ possibly caused by differences among genetic mutations and residual enzyme activity.

Other Causes

Hemorrhage and infections, discussed earlier as causes of acute primary adrenal insufficiency, may spare some adrenal tissue, leaving severely compromised, rather than totally absent, adrenal function. The result, as with autoimmune adrenalitis, is a chronic disorder with insidious onset of the broad range of nonspecific findings described earlier. Tuberculosis, fungal

infections (e.g., histoplasmosis, coccidiomycosis), viral infections (e.g., human immunodeficiency virus [HIV], cytomegalovirus), metastases, amyloidosis, and sarcoidosis may cause a similar clinical picture. Cortisol biosynthesis can also be inhibited by drugs, such as aminoglutethimide, etomidate, suramin, ketoconazole, or anti-HIV treatments; these drugs can cause adrenal insufficiency, and must be used with caution.

Secondary Adrenal Insufficiency

ACTH is required for adrenal cellular growth and for transcription of genes for steroidogenic factors, hence any impairment of ACTH synthesis, release, or action can cause secondary adrenal insufficiency. Examples include hypothalamic defects, hypopituitarism, disorders of POMC synthesis and processing, and suppression of the hypothalamic-pituitary axis, following exogenous steroid treatment.

Most forms of secondary adrenal insufficiency affect glucocorticoid and androgen synthesis rather than mineralocorticoid release, as angiotensin II is the primary drive to the zona glomerulosa. However, the clinical and biochemical assessment may be complicated, as glucocorticoids are necessary for renal free water clearance and concomitant vasopressin (AVP, ADH) insufficiency may be present. In fact, treatment of secondary adrenal insufficiency can unmask a previously inapparent deficiency of ADH and thus precipitate clinical diabetes insipidus, so close attention must be given to fluid and electrolyte balance, when steroid replacement is introduced. Conversely, the hypothyroidism resulting from thyroid-stimulating hormone (TSH) deficiency will result in slowed metabolism of the small amount of cortisol produced, and therefore protects the patient from the symptoms of adrenal insufficiency. Treatment of hypothyroidism with thyroxine will accelerate metabolism of these small amounts of cortisol, thus unmasking adrenal insufficiency caused by ACTH deficiency and, on occasion, can precipitate an acute adrenal crisis. Therefore careful evaluation of the pituitary-adrenal axis is required in hypopituitarism with secondary hypothyroidism. Many clinicians will choose to “cover” a patient with small doses of glucocorticoids (one-fourth to one-half of physiologic replacement) during initial treatment of such secondary hypothyroidism. Finally, it is important to appreciate that combined deficiency of growth hormone and ACTH will strongly predispose the patient to hypoglycemia, as both hormones act to raise plasma glucose. This effect is especially important in infancy and early childhood, when children are vulnerable to hypoglycemia during periods of prolonged fasting.

Hypothalamic Causes

Hypothalamic causes of ACTH insufficiency include tumors and radiotherapy. Tumors, such as craniopharyngioma, are associated with ACTH deficiency in about 25% of patients.^{397,398} The frequency may be higher in tumors, such as germinoma and astrocytoma. Adrenal insufficiency is rarely the presenting complaint but may contribute to the clinical picture. After surgery and/or radiation therapy, the great majority of patients with hypothalamic tumors will have ACTH deficiency as part of their surgical or radiation-induced hypothalamic-pituitary damage. Therefore all such patients should receive glucocorticoid coverage during treatment, irrespective of the status of the HPA axis at the time the tumor is identified. Because treatment of secondary adrenal insufficiency can precipitate diabetes insipidus, close attention to water balance is essential. ACTH insufficiency can also result following whole-brain irradiation for brain tumors and other central malignancies. This may involve both hypothalamic and pituitary mechanisms. The frequency of ACTH

insufficiency in such cases is much lower than following the treatment of hypothalamic tumors but may only manifest some years after treatment.³⁹⁹

Adrenocorticotrophic Hormone Deficiency

ACTH may be deficient as part of a multiple pituitary hormone deficiency (MPHD, panhypopituitarism) or as isolated ACTH insufficiency. MPHD can result from pituitary surgery or radiotherapy, from an infiltrative process (e.g., Langerhans cell histiocytosis), or from a poorly understood form of hypothalamic dysfunction. In most cases, growth hormone secretion is lost first, followed in order by gonadotropins, TSH, and ACTH, so ongoing vigilance and assessment of these patients is required for many years. MPHD can also result from disorders of hypothalamic-pituitary development involving transcription factors, such as HESX1, LHX4, and SOX3. Associated features, such as optic nerve hypoplasia (HESX1) and cerebellar abnormalities (LHX4), may help to focus the diagnosis. Impaired ACTH secretion has also been described in individuals with PROP1 mutations, one of the most frequent genetic causes of MPHD. This finding can occur many years after presentation with growth hormone, TSH, and gonadotropin deficiency, highlighting the importance of long-term follow-up of patients with pituitary disorders.^{400,401}

Patients with MPHD often have a relatively mild form of adrenal insufficiency. Mineralocorticoid secretion is normal, whereas cortisol secretion is reduced but not absent. However, adrenal reserve is severely compromised by the chronic under-stimulation of steroidogenic enzyme biosynthesis. Because some cortisol synthesis continues, the diagnosis may not be apparent unless a CRF or metyrapone test of pituitary ACTH production capacity and an intravenous ACTH test of adrenal reserve are performed. This can be especially true when TSH deficiency is a component of hypopituitarism, as outlined earlier; treatment of secondary hypothyroidism with thyroxine will accelerate metabolism of these small amounts of cortisol, thus unmasking adrenal insufficiency caused by ACTH deficiency and, on occasion, can precipitate an acute adrenal crisis.

Isolated ACTH insufficiency is a rare condition that can be caused by recessively inherited mutations in the *TPIT* gene. *TPIT* encodes a T-box factor (TBX19) that regulates transcription of the POMC promoter in corticotropes.⁴⁰² These patients usually present with severe, early-onset ACTH insufficiency.^{403,404} Hypoglycemia and prolonged jaundice are frequently present, and neonatal death may result.⁴⁰⁵ As this defect is confined to POMC synthesis in the corticotropes, the additional features of generalized POMC deficiency (outlined later) are not present. *TPIT* mutations are not found in approximately half of patients with isolated ACTH insufficiency, suggesting that other causes are yet to be found.⁴⁰⁶ Hypocortisolemia caused by isolated ACTH insufficiency has also been described with hippocampal (memory) defects and hair abnormalities (alopecia) as part of the “Triple H syndrome,” a possible autoimmune association.⁴⁰⁷

Disorders of Proopiomelanocortin

Defects in POMC synthesis and processing can also cause abnormal ACTH production and action. In patients with POMC mutations, plasma ACTH and cortisol concentrations are usually extremely low, but depending on the genetic defect, plasma ACTH concentrations may also be elevated reflecting the production of an immunoreactive but bioinactive protein.⁴⁰⁸ Recessively inherited mutations or deletion of the *POMC* gene will affect multiple POMC peptides, including MSH and β -endorphin. Thus red hair, pale skin, and obesity are associated features of this form of secondary adrenal insufficiency.⁴⁰⁹ These clinical signs may be more subtle in

individuals with naturally dark hair and pigmented skin, or red hair may darken in adulthood.⁴¹⁰ Mutations in prohormone convertase 1 (PC1, *PCKS1*), which is required for the processing of POMC to ACTH, cause abnormal cleavage and processing of several hormone systems, including the generation of bioactive ACTH from POMC.⁴¹¹ Patients with this rare recessive disorder can have hypocortisolemia together with abnormal glucose metabolism, obesity, hypogonadotropic hypogonads, and persistent malabsorptive diarrhea.^{411,412} These patients need glucocorticoid replacement therapy for adrenal insufficiency and their severe obesity and hyperphagia may be successfully treated by setmelanotide, an MC4R agonist.⁴¹³

Long-Term Steroid Therapy

Long-term glucocorticoid therapy can suppress *POMC* gene transcription and the synthesis and storage of ACTH. Furthermore, long-term therapy apparently decreases the synthesis and storage of CRF and diminishes the abundance of receptors for CRF in the pituitary. Therefore recovery of the HPA axis from long-term glucocorticoid therapy entails recovery of multiple components in a sequential cascade, and hence often requires considerable time (see section on Glucocorticoid Therapy and Withdrawal). Patients successfully withdrawn from glucocorticoid therapy or successfully treated for Cushing disease may exhibit a fairly rapid normalization of plasma cortisol values, while continuing to have diminished adrenal reserve for over 12 months. Inhaled steroids, nasal sprays, and even steroid eye drops can cause suppression of the adrenal axis, so vigilance may be needed following their withdrawal or at time of additional stress (e.g., surgery, intercurrent illness).^{414–416} Treatment with cortisone and prednisone during pregnancy will only result in minimal suppression of the fetal adrenal, because of the protective effects of placental 11 β HSD; dexamethasone treatment in pregnancy can affect fetal adrenal steroidogenesis.

ADRENAL EXCESS

Cushing Syndrome

The term “Cushing syndrome” describes any form of glucocorticoid excess; “Cushing disease” designates hypercortisolism caused by pituitary overproduction of ACTH. The related disorder caused by ACTH of nonpituitary origin is termed the “ectopic ACTH syndrome.” The term “Cushing syndrome” is sometimes used to refer specifically to hypersecretion of cortisol from adrenal tumors, but this is ambiguous and should be avoided. Other causes of Cushing syndrome include adrenal adenoma, adrenal carcinoma, and multinodular adrenal hyperplasia. All of the aforementioned are distinct from iatrogenic Cushing syndrome, which is the similar clinical constellation resulting from the chronic administration of suprphysiologic quantities of ACTH or glucocorticoids.

Clinical Findings

The physical features of Cushing syndrome result from chronic hypercortisolism with or without hyperandrogenism. Central obesity, “moon facies,” hirsutism, and facial flushing are seen in over 80% of adults with Cushing syndrome. Striae, hypertension, muscular weakness, back pain, “buffalo hump” fat distribution, psychological disturbances, acne, and easy bruising are commonly described (35%–80%). However, these are the signs and features of advanced Cushing syndrome. When annual photographs of such patients are available, it is often apparent that these features can take 5 years or longer to develop. Thus the classic “Cushingoid appearance” will usually not be the initial picture seen in the child with Cushing syndrome. The earliest, most reliable indicators of hypercortisolism in children

TABLE 14.10 Findings in 39 Children With Cushing Disease

Sign/Symptom	# of Patients	%
Weight gain	36/39	92
Growth failure	31/37	84

(From Devoe, D. J., Miller, W. L., Conte, F. A., et al. (1997). Long-term outcome in children and adolescents after transsphenoidal surgery for Cushing's disease. *J Clin Endocrinol Metab*, 82, 3196–3202.)

are weight gain and growth arrest⁴¹⁷ (Table 14.10). Cumulative data from three large studies of pediatric Cushing disease identified weight gain at presentation in 91/97 (94%) cases and growth failure in 82/95 (86%) cases.^{417–419} Thus any overweight child who stops growing should be evaluated for Cushing syndrome. Glucocorticoids suppress growth by increasing hypothalamic secretion of somatostatin, suppressing growth hormone secretion and IGF-1 production, and by acting directly on the epiphyses to inhibit sulfation of cartilage, inhibit mineralization, and inhibit cell proliferation. In contrast, children with simple dietary obesity often grow more rapidly and are tall for their age (presumably because of chronic secondary hyperinsulinism). The obesity of Cushing disease in children is initially generalized rather than centripetal, and a buffalo hump is evidence of long-standing disease. Psychological disturbances, especially compulsive overachieving behavior, are seen in about 40% of children and adolescents with Cushing disease,⁴¹⁷ and are distinctly different from the depression typically seen in adults.⁴²⁰ Emotional lability has been described in approximately 30% of cases.⁴¹⁸ An underappreciated aspect of pediatric Cushing is the substantial degree of bone loss and undermineralization in these patients.^{417,421,422} Thus Cushing disease is generally diagnosed in young adults because the diagnosis was missed, rather than absent, during adolescence. Rarely, Cushing syndrome caused by adrenal carcinoma or the ectopic ACTH syndrome can produce a rapid fulminant course.

Cushing Disease

Although generally described in great detail and illustrated with striking photographs in endocrine texts, Cushing disease is fairly rare in adults.⁴²³ Furthermore, about 25% of patients referred to large centers for Cushing disease are children, and many patients first seen as adults actually experience the onset of symptoms in childhood or adolescence. For example, Harvey Cushing's original patient was a young woman of 23 years whose clinical features indicated long-standing disease, and who was only 144 cm tall,⁴²⁴ suggesting disease onset around age 11 years. In adults and children over 7 years of age, the most common cause of Cushing syndrome is true Cushing disease (adrenal hyperplasia caused by hypersecretion of pituitary ACTH).⁴²⁵ Boys are more frequently affected than girls in the prepubertal period, although the sex ratios are equal during adolescence and women have a higher incidence of Cushing

ACTH, Adrenocorticotropic hormone.

(From Miller, W. L., Townsend, J. J., Grumbach, M. M., & Kaplan, S. L. (1979). An infant with Cushing's disease due to an adrenocorticotropic-producing pituitary adenoma. *J Clin Endocrinol Metab*, 48, 1017–1025.)

disease in adulthood.⁴²⁶ In infants and children under 7 years, adrenal tumors predominate. Among 60 infants under 1 year of age with Cushing syndrome, 48 had adrenal tumors⁴²⁷ (Table 14.11).

Among adults, over 90% of patients with Cushing disease have identifiable pituitary microadenomas.^{420,428} These tumors are generally 2 to 10 mm in diameter, are not encapsulated, have ill-defined boundaries, and are frequently detectable with a contrast-enhanced pituitary MRI. These tumors are often identifiable only by minor differences in their appearance and texture from surrounding tissue, thus the frequency of surgical cure is correlated with the technical skill of the surgeon. Among children and adolescents, about 80% to 85% of those with Cushing disease have surgically identifiable microadenomas.^{417,429,430} Although removal of the tumor usually appears curative, 20% of such “cured” patients suffer relapse and again manifest Cushing disease within about 5 years so that the net cure rate is 65% to 75%.^{417–419,431,432}

The high cure rate of transsphenoidal microadenomectomy in Cushing disease indicates that the majority of such patients have primary disease of the pituitary itself, rather than secondary hyperpituitarism resulting from hyperstimulation of the pituitary by CRF or other agents. Careful follow-up studies of these patients confirm this.^{417,430,431} In most postoperative patients, the circadian rhythms of ACTH and cortisol return to normal, ACTH and cortisol respond appropriately to hypoglycemia, cortisol is easily suppressed by low doses of dexamethasone, and the other hypothalamic-pituitary systems return to normal.

However, some patients with Cushing disease have no identifiable microadenoma, and some “cured” patients relapse. This suggests that this smaller population of patients may have a primary hypothalamic disorder, or that some of the pituitary tissue responsible for ACTH-hypersecretion was not excised.⁴³³ Present clinical investigation suggests that Cushing disease is usually caused by a primary pituitary adenoma, but that sometimes it may be caused by hypothalamic dysfunction. Microsurgery can be curative in the former, but not the latter. Unfortunately, no diagnostic maneuver is available to distinguish the two possibilities; thus transsphenoidal exploration remains the preferred initial therapeutic approach to the patient with Cushing disease.

Whole-exome sequencing of ACTH-secreting microadenomas has identified recurrent gain-of-function mutations in the gene coding ubiquitin-specific protease 8 (*USP8*), a deubiquitinase that regulates the turnover of EGF receptors and other membrane proteins.⁴³⁴ To date, these somatic mutations have been found mostly in adult female patients. This and similar advances may lead to more targeted medical therapies.

Cushing Disease: Treatment. Transsphenoidal surgery offers the best initial approach for rapid and complete cure of most patients, but alternative approaches may be necessary in younger children if the sphenoid sinus is not yet aerated. Short-term consequences of transsphenoidal surgery include transient diabetes insipidus and cerebrospinal fluid rhinorrhea.^{418,419,435} Persistent panhypopituitarism is rare, but the effects of hypercortisolism on growth hormone secretion may remain for 1 to 2 years after treatment, and growth hormone deficiency can occur even in those children who have not received irradiation.^{418,419,435} Final height may be reduced by 1.5 to 2.0 SD by the long-term hypercortisolism;^{417,436} treatment with growth hormone may ameliorate this growth loss in patients with growth hormone insufficiency.^{437,438} Management of hypocortisolemia during the postoperative period is important, because the HPA axis will be suppressed. Careful monitoring for recovery of the axis is necessary over several months, until stress responsiveness returns.

The management of nonresponsive or relapsed Cushing disease is challenging. Repeat transsphenoidal surgery is typically the first approach, especially if there is evidence of a distinct lesion or lateral hypersecretion of ACTH. Second-line approaches include subtotal hypophysectomy, Gamma Knife irradiation, dopamine agonists (cabergoline), somatostatin analogs (pasireotide), adrenalectomy, and drugs that target the adrenal (mitotane), steroidogenesis (ketoconazole, metyrapone, etomidate), or GRs (mifepristone). All have significant disadvantages, especially in children. Subtotal hypophysectomy has the potential to eliminate pituitary secretion of growth hormone, TSH, and gonadotropins, causing growth failure, hypothyroidism, and failure to progress in puberty, respectively. Although hypothyroidism is easily treated with oral thyroxine replacement, growth hormone deficiency requires very expensive replacement therapy. Sex steroid replacement can be used to achieve secondary sexual characteristics at the age of puberty; however, gonadotropin replacement will be needed to achieve fertility. Pituitary irradiation has been touted to avoid many of these problems and is effective in treating Cushing disease, but growth-hormone deficiency occurs in most cases and additional endocrinopathies can occur with time.⁴³⁹ The interval from radiotherapy to cure can be more than 1 year, during which time therapeutic blockade of hypercortisolemia is necessary to prevent the ongoing effects of Cushing disease on growth, weight, and bone mineralization. Furthermore, large doses of radiation increase the risk of cerebral arteritis, leukoencephalopathy, leukemia, glial neoplasms, and bone tumors involving the skull; stereotactic radiotherapy may reduce these potential effects, but few data exist yet in children.

Bilateral laparoscopic adrenalectomy represents definitive therapy for patients with persistent Cushing disease; pituitary irradiation may be used when future fertility is not an issue. In addition to the obvious effects of eliminating normal production of glucocorticoids and mineralocorticoids, removal of the adrenal also eliminates the physiologic feedback inhibition of the pituitary. In some adults with residual pituitary adenomas, this results in the development of pituitary macroadenomas, producing very large quantities of ACTH. These can expand and impinge on the optic nerves and can produce sufficient POMC to yield enough MSH to produce profound darkening of the skin (Nelson syndrome), but this is rarely seen in children. There is relatively little pediatric experience with ketoconazole and other drugs that inhibit steroidogenesis, but these may provide a useful form of therapy for selected patients or for controlling hypercortisolemia in the short-term.⁴⁴⁰ Metyrapone is not useful for long-term therapy; mitotane, an adrenolytic agent, may be used to effect a “chemical adrenalectomy,” but its side effects of nausea, anorexia, and

vomiting are severe. Etomidate may be useful in the acute setting for severe or life-threatening Cushing disease before surgery.^{441,442} Mifepristone has been reported to successfully treat the symptoms associated with hypercortisolism in Cushing syndrome in both adult and pediatric patients.^{443,444}

Other Endogenous Causes of Cushing Syndrome

Adrenal Tumors. Adrenal carcinomas are the typical cause of Cushing syndrome in infants and small children (see Table 14.11); the first report of a pediatric adrenocortical carcinoma is of a 6-year-old girl who died in 1688.⁴⁴⁵ These tend to occur more frequently in girls, for unknown reasons. Adrenal adenomas almost always secrete cortisol with minimal secretion of mineralocorticoids or sex steroids. In contrast, adrenal carcinomas tend to secrete both cortisol and androgens, and are often associated with progressive virilization.^{446,447} Adrenal adenoma or carcinoma may be associated with hemihypertrophy, sometimes as part of the Beckwith-Wiedemann syndrome, with overproduction of IGF-2. Additional genetic associations include germline mutations or loss heterozygosity of the tumor suppressor gene *p53*, sometimes as part of the Li-Fraumeni syndrome, as well as mutations in the canonical Wnt/ β -catenin pathway.^{448–450} DNA sequencing of adrenal adenomas causing ACTH-independent Cushing syndrome in adults has also revealed sporadic gain-of-function mutations in *PRKACA*, the gene encoding the catalytic subunit of cAMP-dependent protein kinase (PKA), as well as in the phosphodiesterases that normally inactivate cAMP, *PDE11A*, and *PDE8B*.⁴⁵¹

CT and MRI are useful in the diagnosis of adrenal tumors, and steroid analysis can be informative at the time of presentation and for monitoring for potential relapse. The treatment for both adenoma and carcinoma is surgical, and complete resection is needed for cure. In some cases, the histologic differentiation of adrenal adenomas and carcinomas is difficult, but a worse prognosis is associated with increased tumor size, capsular and/or vascular invasion, retroperitoneal lymph nodes, metastases, or failure to normalize hormonal values postoperatively.^{447,452–454} Although a few patients with residual or metastatic disease have done well with adjunctive therapy with mitotane or other chemotherapeutic strategies, the general prognosis remains poor. To improve outcome for such rare diseases, patients should be enrolled in clinical trials and international registries.

Adrenocorticotrophic Hormone-Independent Multinodular Adrenal Hyperplasias. This group of generally rare and benign adrenal hyperplasias includes ACTH-independent macronodular adrenocortical hyperplasia (also known as massive macronodular adrenocortical disease) and micronodular hyperplasias, mostly primary pigmented nodular adrenocortical disease (PPNAD). Traditionally, macronodular disorders have been associated with nodules greater than 1 cm and micronodular disorders encompass nodules that are less than 1 cm; however, in the genomic era it is increasingly recognized that such designations can be arbitrary.

In childhood, bilateral macroadenomatous hyperplasia is mostly seen with McCune-Albright syndrome caused by somatic mutations in the guanine nucleotide-binding protein, alpha-stimulating polypeptide (*GNAS*) 1 gene. Patients present typically with the triad of polyostotic fibrous dysplasia, café-au-lait skin spots, with irregular margins, and gonadotropin-independent sexual precocity. However, as the disorder is caused by somatic cell mutations, rather than germ line mutations, its manifestations are clinically heterogeneous and may include other endocrine disorders, such as thyrotoxicosis, hyperparathyroidism, pituitary gigantism, and hyperprolactinemia. Cushing syndrome is rare in McCune-Albright syndrome and usually presents before 6 months of age. Most

cases of macronodular adrenocortical hyperplasia resulting in Cushing syndrome are sporadic, isolated, and occur in middle age. The etiology of such lesions has been linked to the ectopic formation of hormone receptors, such as vasopressin, serotonin, and LH/hCG, as well as to the local production of ACTH from the adrenal cortex itself.^{455–457} Another cause is germline mutations in tumor suppressor genes, including armadillo repeat containing 5 gene (*ARMC5*), multiple endocrine neoplasia type 1 (*MEN1*), adenomatous polyposis coli (*APC*), and fumarate hydratase (*FH*).^{458–461}

The group of micronodular benign adrenal hyperplasias includes PPNAD and isolated micronodular adrenocortical disease. PPNAD, characterized by the secretion of both cortisol and adrenal androgens,^{462,463} is a rare entity seen in infants, children, and young adults, with females affected more frequently. It is usually seen as part of the “Carney complex,” which is a form of multiple endocrine neoplasia (MEN), consisting of pigmented lentigines and blue nevi on the face, lips, and conjunctiva, and a variety of tumors, including schwannomas and atrial myxomas, and occasionally growth hormone-secreting pituitary adenomas, Leydig cell tumors, calcifying Sertoli cell tumors (which may secrete estrogens), and medullary carcinoma of the thyroid.^{463,464} Typical features of Cushing syndrome are often seen in the pediatric population.⁴⁶⁵ The adrenals are not truly hyperplastic but consist of discrete pigmented nodules surrounded by atrophic tissue, which permits their identification by MRI or CT. Because the hypercortisolism is resistant to suppression with high doses of dexamethasone and because both glucocorticoids and sex steroids are produced, PPNAD is clinically difficult to distinguish from the ectopic ACTH syndrome, but plasma ACTH assays are usually diagnostic. Complete adrenalectomy is usually indicated, although some successes have been reported with subtotal resections.

Carney complex, like other MEN disorders, is typically autosomal dominant. Loss of heterozygosity and mutations in a regulatory subunit of protein kinase A (*PRKARIA*) have been found in 73% of patients with Carney complex,^{466–470} or as sporadic germline or somatic events in isolated adrenal tumors (isolated PPNAD).⁴⁷¹ In general, patients with Carney Complex harboring mutations in *PRKARIA* manifest at a younger age and have more myxomas, schwannomas, thyroid tumors, and gonadal tumors than patients without mutations in *PRKARIA*. Patients with isolated PPNAD typically carry the *PRKARIA* mutations c.709-7del6 or c.1A>G/p.M1V, which is important for genetic counseling and screening.⁴⁷⁰

Patients with micronodular benign adrenal hyperplasia without Carney Complex and *PRKARIA* mutations may harbor mutations in other cAMP signaling proteins. Mutations in the gene encoding phosphodiesterase 11A4 (*PDE11A*) have been reported in individuals with isolated micronodular adrenocortical disease and PPNAD and mutations in phosphodiesterase 8B (*PDE8B*) in isolated micronodular adrenocortical disease.^{470,472} Both *PDE11A* and *PDE8B* catalyze the hydrolysis of cAMP and cyclic guanosine monophosphate and are expressed in several endocrine tissues, including the adrenals. As noted earlier, sporadic mutations in *PRKARIA*, *PDE11A*, and *PDE8B* have also been associated with isolated adrenal adenomas causing with ACTH-independent Cushing syndrome. Thus abnormalities in signaling pathways play an important role in adrenal hyperplasia and tumorigenesis.⁴⁷³

The Ectopic Adrenocorticotrophic Hormone Syndrome. The ectopic ACTH syndrome is most commonly seen in adults with oat cell carcinoma of the lung, carcinoid tumors, pancreatic islet cell carcinoma, and thymoma, but it may also be seen in children. Ectopically produced POMC and ACTH are derived from the same gene that produces pituitary

POMC but is not sensitive to glucocorticoid feedback in the malignant cells. This phenomenon permits distinction between pituitary and ectopic ACTH by suppressibility of the former by high doses of dexamethasone. Although the ectopic ACTH syndrome is rare in children, it has been described in infants younger than 1 year of age. Associated tumors have included neuroblastoma, pheochromocytoma, islet cell carcinoma of the pancreas, and neuroendocrine tumors of the thymus.⁴⁷⁴ The ectopic ACTH syndrome is typically associated with ACTH concentrations 10 times higher than those seen in Cushing disease. However, both adults and children with this disorder may show little or no clinical evidence of hypercortisolism, probably caused by the typically rapid onset of the disease and to the general catabolism associated with malignancy. Unlike patients with Cushing disease, adults and children with the ectopic ACTH syndrome frequently have hyporeninemic hypokalemic alkalosis, presumably because the extremely high levels of ACTH stimulate the production of DOC by the adrenal fasciculata, and/or stimulate the production of aldosterone by adrenal glomerulosa. Rare intracranial, nonpituitary tumors may produce ectopic ACTH but be mistaken for pituitary Cushing disease because of their location.^{475,476}

DICER1 Syndrome and Infant Cushing Disease. Mutations in *DICER1*, the gene encoding the DICER1 ribonuclease that participates in the generation of small interfering RNAs (siRNAs) and microRNAs,⁴⁷⁷ were first discovered in pleuropulmonary blastoma (PPB),⁴⁷⁸ and subsequently reported in pituitary blastoma,⁴⁷⁹ and other embryonal tumors.⁴⁸⁰ The PPB familial tumor and dysplasia syndrome [OMIM #601200] is a pleiotropic tumor predisposition syndrome. Pituitary blastoma has been described in over a dozen cases of infants with Cushing disease,^{481,482} and may be autosomal recessive or associated with an inherited germ line mutation plus a somatic mutation, both in *DICER1*; among the few cases reported, the prognosis has been poor.

Approach to the Child With Endogenous Cushing Syndrome

Cushing syndrome in children is usually suggested by weight gain, growth arrest, mood change, and change in facial appearance (plethora, acne, hirsutism). The diagnosis in children may be subtle and difficult when it is sought at a relatively early point in the natural history of the disease. For initial screening, three laboratory investigations are recommended: (1) diurnal ACTH and cortisol profiles from blood (the latter may be performed on saliva), (2) 24-hour UFC measurements, and (3) the overnight 1 mg dexamethasone suppression test.⁴⁶³ Absolute elevations above the "upper limits of normal" for concentrations of plasma ACTH and cortisol are often absent. Rather than finding morning concentrations of cortisol greater than 20 µg/dL or of ACTH greater than 50 pg/mL, it is more typical to find mild, often equivocal elevations in the afternoon and evening values. This loss of the diurnal rhythm, evidenced by continued secretion of ACTH and cortisol throughout the afternoon, evening, and nighttime, is usually the earliest reliable laboratory index of Cushing disease. A single plasma cortisol measurement obtained at midnight from an indwelling venous catheter, while the patient remains asleep, should be less than 2 µg/dL in normal individuals, and more than 2 µg/dL in Cushing disease.⁴⁸³ Similarly, late-night free cortisol values, measured in saliva, should normally be less than around 1 ng/mL (2.8 nmol/L) at 11 PM.⁴⁸⁴ Interpretation of late-night salivary samples can be influenced by factors ranging from a disordered sleep pattern to gingival disease. Thus samples should be collected under optimal conditions (e.g., after rinsing one's mouth but before brushing one's teeth) to avoid false positive results. Salivary samples are stable at room temperature for several days but can be frozen if longer term storage is required.

The values for ACTH and cortisol are typically extremely high in the ectopic ACTH syndrome, whereas cortisol is elevated, but ACTH is suppressed in adrenal tumors and in multinodular adrenal hyperplasia (Table 14.12). In all forms of Cushing syndrome, monitoring of the 24-hour UFC assists in

TABLE 14.12 Diagnostic Values in Various Causes of Cushing Syndrome

deciding whether further investigations are warranted. A normal 24-hour UFC value is generally less than 70 $\mu\text{g}/\text{m}^2/\text{day}$ (with radioimmunoassays). Several repeat collections are advisable, and it is important to use normal ranges adjusted for size, as well as age, as children with simple obesity have higher cortisol secretion rates. Another baseline test is the low-dose (1 mg) dexamethasone overnight suppression test with a cut-off for cortisol lower than 1.8 $\mu\text{g}/\text{dL}$ (50 nmol/L). If both the 24-hour UFC and the low-dose dexamethasone overnight suppression test are normal, the diagnosis of Cushing syndrome is usually excluded. An exception is patients with intermittent or periodic cortisol hypersecretion who need longer follow-up and repeat testing for diagnosis of Cushing syndrome.

Once the diagnosis of Cushing syndrome is established, further investigations may be needed to find the origin of disease. Low- and high-dose dexamethasone suppression tests can be useful when done with care. To achieve reliable results in pediatric patients, children should be hospitalized, preferably on a pediatric clinical research ward. Two days of baseline (control) data should be obtained. Low-dose dexamethasone (20 $\mu\text{g}/\text{kg}/\text{day}$, up to a maximum of 2.0 mg) should be given, divided into equal doses given every 6 hours for 2 days, followed by high-dose dexamethasone (80 $\mu\text{g}/\text{kg}/\text{day}$) given in the same fashion. Eight AM and 8 PM (or midnight) values for ACTH and cortisol and 24-hour urine collections for 17OHCS, 17-ketosteroid (17KS), free cortisol, and creatinine (to monitor the completeness of the collection) should be obtained on each of the 6 days of the test. Measurements of either UFC or 17OHCS are probably equally reliable if the laboratory has established good pediatric standards. Because of variations caused by episodic secretion of ACTH, the 8 AM and 8 PM blood values should be drawn in triplicate at 8:00, 8:15, and 8:30.

In patients with exogenous obesity or other non-Cushing disorders, cortisol, ACTH, and urinary steroids will be suppressed readily by low-dose dexamethasone. Plasma cortisol should be less than 1.8 $\mu\text{g}/\text{dL}$, ACTH less than 20 pg/mL, and 24-hour urinary 17OHS less than 1 mg/g of creatinine. Patients with adrenal adenoma, adrenal carcinoma, or the ectopic ACTH syndrome will have values relatively insensitive to both low- and high-dose dexamethasone, although some patients with multinodular adrenal hyperplasia may respond to high-dose suppression with a paradoxical rise in cortisol following dexamethasone, as has been reported with the Carney complex.^{485,486} Patients with Cushing disease classically respond with suppression of ACTH, cortisol, and urinary steroids during the high-dose treatment, but not during the low-dose treatment. However, some children, especially those early in the course of their illness, may exhibit partial suppression in response to low-dose dexamethasone. Thus if the low dose that is given exceeds 20 $\mu\text{g}/\text{kg}/\text{day}$ or if the assays used are insufficiently sensitive to distinguish partial from complete suppression, false-negative tests may result.

Petrosal sinus sampling is widely used in adults with Cushing disease, to distinguish pituitary Cushing disease from the ectopic ACTH syndrome. The smaller vascular bed in children increases the risk of this procedure, but inferior petrosal venous sampling has been used with some success in adolescents in an attempt to localize pituitary adenomas before surgery.⁴⁸⁷ Such approaches should only be undertaken in highly specialized centers; jugular venous sampling may provide an alternative approach, although extensive data in the pediatric population are not available.⁴⁸⁸ In general, the diagnosis of Cushing disease is considerably more difficult to establish in children than in adults. In addition to laboratory tests, imaging studies may help in establishing the exact diagnosis of Cushing syndrome. An adrenal CT scan or MRI may visualize an adrenal

cortex tumor or a macro-/micronodular adrenal hyperplasia, whereas adrenal ultrasound often fails and therefore should not be trusted as a diagnostic tool for adrenal disorders. MRI is also the preferred method for visualizing the hypothalamus and the anterior pituitary for lesions.

Primary Hyperaldosteronism

Aldosterone is normally produced in glomerulosa cells in response to depleted intravascular volume via the renin-angiotensin system and/or high plasma potassium. In primary aldosteronism, the adrenal constitutively produces aldosterone in the absence of angiotensin II or hyperkalemia. Primary aldosteronism is the most common form of secondary hypertension, affecting around 10% of all hypertensive patients. In addition to the adverse cardiovascular outcomes associated with hypertension, excess aldosterone is an independent risk factor for cardiovascular disease and renal damage, likely owing to the direct effects of aldosterone on tissues other than the kidney.⁴⁸⁹

Clinical Findings

Primary aldosteronism is classically characterized as presenting with hypertension, polyuria, hypokalemic alkalosis, and low plasma renin activity because of autonomous production of aldosterone. Aldosterone-producing adenomas are well described in adults but are rare in children. Familial cases of primary aldosteronism have also been described, including glucocorticoid-remediable aldosteronism (GRA) (see Section VI). Primary aldosteronism exists across a continuum of disease severity, ranging from mild to severe, suggesting current estimates of disease prevalence may underrepresent the true burden of disease. Early in the course of disease, primary aldosteronism may simply present with increased blood pressure without corresponding hypokalemia or low renin activity.⁴⁹⁰

Differential Diagnosis

Since the initial description of primary aldosteronism, a number of distinct etiologies have been described, including (1) unilateral aldosterone-producing adenomas (APAs, Conn syndrome), accounting for 30% to 40% of cases; (2) bilateral idiopathic hyperaldosteronism, accounting for 60% to 70% of cases; and rarer forms, such as (3) familial hyperaldosteronism (FH), and (4) primary nodular adrenal hyperplasias, as described earlier.

Aldosterone-Producing Adenomas (Conn syndrome).

Recurrent somatic mutations causing APAs, most commonly in the gene encoding the K^+ channel *KCNJ5* (also known as *Kir3.4*) have been identified recently.^{491–494} Multicenter studies have identified two somatic mutations in *KCNJ5* (G151R or L168R) in 38% of all APAs.⁴⁹⁵ Such mutations are more prevalent in females and at a younger age, and manifest with higher preoperative aldosterone levels.⁴⁹⁶ These *KCNJ5* mutations affect the ion selectivity filter of the K^+ channel, causing an increase in Na^+ influx and permanent depolarization of the zona glomerulosa cell membrane.⁴⁹² Membrane depolarization leads to activation of voltage-gated Ca^{2+} channels, which increases intracellular Ca^{2+} , thus providing the normal signal for aldosterone production and glomerulosa cell proliferation. Recently, exome sequencing studies have identified additional recurrent somatic mutations that arise independently of mutations in *KCNJ5*, including in *ATP1A1*, *ATP2B3*, *CACNA1D*, and *CTNNA1*.^{497–499} *ATP1A1* encodes the alpha subunit of the Na^+/K^+ ATPase and accounts for ~5% of APAs. *ATP2B3* encodes a Ca^{2+} ATPase and accounts for around 2% of APAs. *CACNA1D* encodes a voltage-gated calcium channel and may

account for 11% of APAs. Each of these channel-associated mutations have been functionally linked to depolarization of zona glomerulosa cells and aldosterone hypersecretion. It remains unclear, however, whether they are sufficient to drive the hyperplastic response leading to the APA. *CTNNB1* is the gene encoding β -catenin, a canonical member of the Wnt signaling pathway. In addition to APAs, activating mutations in exon 3 of *CTNNB1* have been associated with both nonsecreting adrenal adenomas and adrenocortical carcinomas.⁵⁰⁰

Bilateral Idiopathic Hyperaldosteronism. Bilateral idiopathic hyperaldosteronism accounts for 60% to 70% of cases, although it can sometimes present as unilateral disease. Bilateral idiopathic hyperaldosteronism is generally considered a disease of adults, but it may initially present earlier in life. Despite its high prevalence, the underlying pathophysiology remains poorly understood. Although patients with bilateral idiopathic hyperaldosteronism have increased sensitivity to angiotensin II, it remains unknown why such lesions are unresponsive to angiotensin II receptor antagonists. Somatic mutations in *KCNJ5* are associated with APAs; however, germline mutations in *KCNJ5* are associated with bilateral adrenal hyperplasia (as in cases of FH Type III, later).

Familial Hyperaldosteronism. Four subtypes of autosomal-dominant FH have been described. FH type I, characterized by severe hypertension presenting in the first 2 decades of life is glucocorticoid-suppressible hyperaldosteronism (described in Section VI). FH type II, caused by mutations in *CLCN2*,⁵⁰¹ most closely resembles sporadic forms of primary aldosteronism, though in contrast to the familial form, no genetic mutations have yet to be linked to this sporadic condition. FH type III has been associated with germline mutations in *KCNJ5* and classically presents as severe hypertension and hypokalemia early in life. Recently, FH type IV has been associated with germline mutations in *CACNA1H* (encoding the α subunit of a T-type calcium channel, Cav3.2), presenting with primary aldosteronism in the first decade of life. Rarely, de novo germline mutations in *CACNA1H* have also been described in children presenting with the constellation of primary aldosteronism, cerebral palsy, epilepsy, and neurological abnormalities.^{500,502}

Cellular Origins of Primary Aldosteronism. Immunohistochemical analysis of normal adrenal glands for CYP11B2 (aldosterone synthase) expression has revealed the existence of aldosterone-producing cell clusters (APCCs) that arise under the adrenal capsule and extend into the zona fasciculata. APCCs were initially described adjacent to APAs, suggesting they may represent a precursor lesion. Genomic analysis of 23 APCCs and normal adjacent adrenal tissue revealed mutations previously linked to aldosterone-producing lesions in 35% of cases, with *CACNA1D* and *ATP1A1* being affected most commonly; mutations in *KCNJ5* were not found in APCC lesions.⁵⁰³ Among adrenals from autopsied normotensive Japanese subjects, the incidence of having at least one APCC was around 30%.⁵⁰⁴ Among APCCs found in normal adrenals from kidney donors, 12% were found in donors younger than 19 years old, and 40% in donors younger than 35 years old, suggesting that primary aldosteronism may often originate in adolescence and young adulthood.⁵⁰⁵

Approach to the Child With Hyperaldosteronism

The diagnostic task is to differentiate primary aldosteronism from physiologic secondary hyperaldosteronism occurring in response to another physiologic disturbance. Any loss of sodium, retention of potassium, or decrease in blood volume will result in hyperreninemic secondary hyperaldosteronism. Renal tubular acidosis, treatment with diuretics, salt-wasting

nephritis, or hypovolemia caused by nephrosis, ascites, or blood loss are typical settings for physiologic secondary hyperaldosteronism. Although the constellation of hypertension, hypokalemic alkalosis, and low plasma renin activity may point toward primary aldosteronism, patients suspected of having this condition but not meeting these criteria may benefit from careful evaluation in a clinical research setting, where the effects of sodium loading and other interventions on aldosterone levels and renin activity can be formally assessed.⁴⁹⁰

Virilizing and Feminizing Adrenal Tumors

Most virilizing adrenal tumors are adrenal carcinomas producing a mixed array of androgens and glucocorticoids; virilizing and feminizing adrenal adenomas are quite rare. Virilizing tumors in boys will have a presentation similar to that of SVCAH. There will be phallic enlargement, erections, pubic and axillary hair, acne, increased muscle mass, deepening of the voice, and scrotal thinning, but the testicular size will be prepubertal. Elevated concentrations of testosterone in young boys alter behavior, with increased irritability, rambunctiousness, hyperactivity, and rough play, but without evidence of libido. Diagnosis is based on hyperandrogenemia unsuppressible by glucocorticoids. The treatment is surgical; all such tumors should be handled as if they are malignant, with care exerted not to cut the capsule and seed cells onto the peritoneum. The histologic distinction between adrenal adenoma and carcinoma is difficult, especially in pediatric patients.

Feminizing adrenal tumors are extremely rare in either sex. P450aro, the enzyme aromatizing androgenic precursors to estrogens, is not normally found in the adrenals but is found in peripheral tissues, such as fat, and is also found in some adrenal carcinomas. It is not known whether most feminizing adrenal tumors exhibit ectopic adrenal production of this enzyme, whether some other enzyme mediates aromatization in the tumor, or whether these are truly androgen-producing, virilizing tumors occurring in a setting where there is unusually effective peripheral aromatization of adrenal androgens. Feminizing adrenal (or extraadrenal) tumors can be distinguished from true (central) precocious puberty in girls by the absence of increased circulating concentrations of gonadotropins and by a prepubertal response of LH to an intravenous challenge of GnRH (luteinizing hormone-releasing factor [LRF], GnRH). In boys, such tumors will cause gynecomastia, which will resemble the benign gynecomastia that often accompanies puberty. However, as with virilizing adrenal tumors, testicular size, and the gonadotropin response to LRF testing will be prepubertal. The diagnosis of a feminizing tumor in a pubertal boy can be extremely difficult, but it is usually suggested by an arrest in pubertal progression and can be proved by the persistence of circulating plasma estrogens after administration of testosterone.

Other Disorders

Familial Glucocorticoid Resistance

Familial glucocorticoid resistance is a rare disorder caused by mutations in the α -isoform of the GR. Decreased glucocorticoid action results in grossly increased ACTH secretion, which, in addition to stimulating the production of cortisol, also stimulates the production of other adrenal steroids. Thus these patients may present with fatigue, hypertension, and hypokalemic alkalosis, suggesting a mineralocorticoid excess syndrome, and also have symptoms of hyperandrogenism.^{506,507} In contrast, they typically lack Cushingoid features with biochemical hypercortisolism. Circadian rhythmicity of the HPA axis is

maintained and resistance to dexamethasone suppression is observed. Patients have been described who are homozygous for missense mutations,⁵⁰⁸ heterozygous for a gene deletion,⁵⁰⁹ or homozygous for a wholly null mutation.⁸⁶ Heterozygous point mutations with incomplete dominant negative activity or multiple effects on GR α action have also been described.⁵¹⁰ Point mutations may interfere with GR α -dependent transcriptional regulation through altered DNA binding, impaired ligand binding, delayed nuclear localization, abnormal nuclear aggregation, and disrupted interaction with coactivators, depending on the position of the mutation.⁵⁰⁶ Thus familial glucocorticoid resistance is usually a syndrome of partial resistance to the action of glucocorticoids. Treatment consists of supraphysiologic doses of dexamethasone that will elicit a physiologic response with the poorly functioning receptor, usually starting with 0.25 to 0.5 mg/day at bedtime and titrating to the suppression of morning ACTH and thus androgens, blood pressure, and serum potassium levels.⁵⁰⁷ The dose of dexamethasone may be reduced to a minimum according to individual needs. Hypertension may require additional treatment with aldosterone antagonists.

Pseudohypoaldosteronism

Pseudohypoaldosteronism (PHA) is a salt-wasting disorder of infancy characterized by hyponatremia, hyperkalemia, and increased plasma renin activity in the face of elevated aldosterone concentrations, reflecting aldosterone resistance.⁵¹¹ The more common, more severe, systemic, autosomal recessive form of PHA ("pseudohypoaldosteronism Type II") is caused by inactivating mutations in any of the three subunits (α , β , γ) of the amiloride-sensitive sodium channel, ENaC (encoded by the *SCNN1A*, *B* and *G* genes).⁵¹² This condition is often associated with lower respiratory tract congestion, cough and wheezing (but not pulmonary infections), and clear rhinorrhea, as ENaC mutations increase the volume of airway fluid.⁵¹³ PHA type II persists into adulthood, requiring vigorous salt-replacement therapy throughout life. Gain-of-function mutations caused by carboxy-terminal truncation of β -ENaC cause Liddle syndrome, an autosomal dominant form of salt-retaining hypertension.⁵¹²

Autosomal dominant renal Type 1 pseudohypoaldosteronism (PHA type I) is caused by inactivating mutations in the MR (encoded by the *NR3C2* gene).⁵¹⁴ More than 50 different mutations have been found in this receptor, which interfere with mineralocorticoid binding and gene transcription.⁵¹⁵ PHA type I is milder than the recessive forms of PHA caused by ENaC mutations and remits with age, but requires sodium replacement therapy in infancy and childhood. Rarely, point mutations in the MR have been found in association with an autosomal dominant form of severe hypertension, which begins in adolescence and worsens in pregnancy.⁵¹⁶ In these cases, alterations in the structure of the ligand-binding domain of the MR result in mild constitutive activation, as well as permitting binding and activation of the receptor by progesterone.

An acquired, transient form of PHA is rarely seen in infants with obstructive uropathy, especially shortly following surgical relief of the obstruction, or with urinary tract infections. The lesion is renal tubular, resembling renal tubular acidosis, type 4,⁵¹⁷ so that mineralocorticoid treatment is generally ineffective; salt replacement generally suffices, while the renal lesion resolves. The etiology of mineralocorticoid resistance in such cases is poorly understood.

GLUCOCORTICOID THERAPY AND WITHDRAWAL

Glucocorticoids are so termed because of their major actions to increase plasma concentrations of glucose. This occurs by their

diverse insulin counterregulatory actions and induction of the transcription of the genes encoding the enzymes of the Embden-Meyerhof glycolytic pathway and other hepatic enzymes that divert amino acids, such as alanine, to the production of glucose. Since their introduction into clinical medicine in the early 1950s, glucocorticoids have been used to attempt to treat a substantial number of diseases. At present, their rational use falls into two broad categories: replacement in adrenal insufficiency and pharmacotherapeutic use. The latter category is largely related to the antiinflammatory and immunosuppressive properties of glucocorticoids but also includes their actions to cause growth arrest and induce apoptosis in normal and leukemic leukocytes, lower plasma calcium concentrations, and reduce increased intracranial pressure.

Virtually all of these actions are mediated through GRs, which are found in most cells. There are three principal variants of GRs (α , β and γ) that are generated through alternative splicing patterns from the same mRNA transcript from the *GR* gene. GR α is the most abundant, correlates with the levels of GR protein, and is thought to be the primary form that mediates glucocorticoid action. However, emerging evidence indicates that the other GRs may have a more important role than originally appreciated. For example, GR β and GR γ have dominant-negative activity over GR α , and may contribute to the development of steroid resistance that may occur during therapy.^{518,519} Furthermore, despite the initial simple appearance of the hormone-receptor relationship, receptor bound glucocorticoids exert surprisingly diverse activities that can be specific to particular tissues. This diversity is mediated by a variety of mechanisms, including differences in the receptor shape in different tissues, resulting in distinct transcriptional activities.⁵²⁰ This can be seen by comparing mRNA expression profiles across different tissues and cell types in response to the same glucocorticoid signal. These molecular differences in GR across different cellular contexts are the mechanism for the different tissue responses to glucocorticoids, such as promoting visceral adipose tissue expansion, while simultaneously inhibiting growth of muscle and bone. Other features of Cushing syndrome are similarly attributable to tissue-specific differences in the transcriptional activity of specific glucocorticoid-sensitive genes. Although complicating our understanding of glucocorticoid action, this diversity may permit development of drugs that are more selective for certain GR isoforms, thus maintaining therapeutic efficacy, while mitigating adverse side effects,^{521,522} similarly to the development of selective estrogen receptor modulators (SERMs).⁵²³

Nevertheless, the only differences among the currently available glucocorticoid preparations are their ratio of glucocorticoid to mineralocorticoid activity, their capacity to bind to various binding proteins, their molar potency, and their biologic half-life. An important exception to this paradigm is the use of the potent synthetic glucocorticoid dexamethasone for reducing increased intracranial pressure and brain edema. Neurosurgical experience indicates that the optimal doses for this action are 10 to 100 times those that would thoroughly saturate all available receptors, suggesting that this action of dexamethasone may represent activity that is not mediated through the GR. However, receptor-independent glucocorticoid activity of physiologic levels of glucocorticoids has yet to be identified.

In the normal population, there is a wide interindividual variation in glucocorticoid sensitivity which is, at least in part, explained by genetic variants of the *GR* gene.⁵⁰⁷ Several single nucleotide polymorphisms have been associated with changes in glucocorticoid sensitivity. The A3669G (rs6198) polymorphism, present in about 35% of the normal population, is associated with glucocorticoid insensitivity and a more active immune system with an increased risk for autoimmune disease.^{524,525} The ER22/23EK polymorphism (rs6189) and

rs6190) present in about 7% of the population and is associated with mild glucocorticoid resistance and a healthier metabolic profile.⁵²⁶ In contrast, polymorphisms N363S (rs1695) and Bcl1 (rs41423247) present in about 8% and 45% of people, respectively, are associated with mild glucocorticoid hypersensitivity yielding a less fortunate metabolic profile (more body fat, less lean mass, increased cholesterol, and insulin resistance etc.).⁵⁰⁷ Some of the variability in glucocorticoid sensitivity is explained by GR subtypes arising from posttranslational modifications, such as phosphorylation, ubiquitination, sumoylation, and acetylation.⁵²⁰ These processes contribute to the broad range of glucocorticoid responsiveness to specifically regulate glucocorticoid-dependent genes.⁵²⁷ Thus individual glucocorticoid sensitivity plays a role in modulating risk for diseases (cardiovascular, autoimmune, metabolic) and may also affect responsiveness to glucocorticoid treatment.

Mechanisms of Glucocorticoid Action

The GR was the first nuclear hormone receptor to be cloned,⁵²⁸ revealing a series of functional domains in the protein that turned out to be prototypical for the nuclear receptor family. The ligand binding domain (LBD) is located at the C-terminus of the protein, which also interacts with coactivator proteins. The LBD of GR is highly homologous to the MR LBD. Subtle structural differences between MR and GR confer specificity for aldosterone binding to MR, but cortisol is able to bind to both receptors. Sensitive tissues, like the kidney, express HSD11B2, which inactivates cortisol to cortisone, protecting MRs from being activated by cortisol. The DNA binding domain (DBD), which is conserved among nuclear receptors, is centrally located in the GR protein. The DBD facilitates receptor dimerization and contains two zinc-finger motifs that can bind to the major groove of DNA. The N-terminal domain of GR is the least conserved and enables interactions with coregulators.

Unbound GRs exist predominantly in the cytoplasm; when intracellular glucocorticoid levels increase, more GRs become bound by hormone and translocate into the nucleus. Rather than being a passive process, the binding of glucocorticoids induces changes in the shape of GR that expose nuclear localization motifs, promoting facilitated trafficking of the hormone-receptor complex into the nucleus. Once in the nucleus, the liganded GR acts by (1) binding to defined sequences of DNA (glucocorticoid response elements; GREs), (2) interactions with cofactors and coregulators, and (3) engagement of the glucocorticoid/GR complex with transcriptional machinery. The sum of these actions regulates the expression of GR target genes. GR access to GREs in the DNA is also influenced by chromatin structure, further contributing to tissue-specific activity of glucocorticoids. GRs can bind to GREs as a GR monomer or dimer ("simple") or associated with another transcription factor ("composite"), or GR can "tether" to a GRE by binding to another protein that is bound to the GRE. Thus GR does not need to bind to DNA directly to regulate target genes. GREs can be found in the classic "promoter proximal" location in target genes and also at significant distances from the target gene, which then loop into closer proximity to the regulated gene. This can complicate the assignment of GREs to particular GR target genes, but adds to the multiple levels by which glucocorticoids can regulate gene expression. Similarly, posttranslational modifications of GR further refine glucocorticoid action on target genes. Together, these variables enable tissue and cell-specific glucocorticoid activity, as well as a capacity for fine-tuned regulation of the transcription levels of target genes in response to dynamic physiologic needs.

Replacement Therapy

Glucocorticoid replacement therapy is complicated by undesirable side effects with even minor degrees of overtreatment or undertreatment. Overtreatment can cause the signs and symptoms of Cushing syndrome; and even minimal overtreatment can impair growth. Undertreatment will cause the signs and symptoms of adrenal insufficiency (see Table 14.9) only if the extent of undertreatment (dose and duration) is considerable. However, undertreatment may impair the individual's capacity to respond to stress. Glucocorticoid replacement therapy is most commonly used in CAH caused by 21OHD; however, in this setting, undertreatment will lead to overproduction of adrenal androgens, which will promote virilization and hasten epiphyseal maturation and closure, thus compromising ultimate adult height. Therefore when formulating a program of adrenal replacement therapy for the growing child, one should use the lowest doses possible that achieve the therapeutic goal.

To optimize pediatric glucocorticoid replacement therapy, astute physicians have gauged their therapy to resemble the endogenous secretory rate of cortisol. Several studies indicate that the cortisol secretory rate is 6 to 8 mg/m²/day in children and adults,^{144,145} but data are not available for infants and children under 5 years. The range of normal values varies considerably, indicating that therapy must be tailored and individualized for each patient to achieve optimal results. The management of this delicate balance between overtreatment and undertreatment of the child, requiring replacement therapy, is thus confounded by considerable variation in the "normal" cortisol secretory rate among different children of the same size and the probability that most therapeutic guidelines err on the side of overtreatment. However, several additional factors must be considered in tailoring a specific child's glucocorticoid replacement regimen.

The specific form of adrenal insufficiency being treated significantly influences therapy. When treating autoimmune adrenalitis or any other form of "Addison disease," it is prudent to avoid overtreatment. This will eliminate the possibility of glucocorticoid-induced iatrogenic growth retardation and often permits the pituitary to continue to produce normal to slightly elevated concentrations of ACTH. This ACTH will continue to stimulate the remaining functional adrenal steroidogenic machinery and also provide a fairly convenient means of monitoring the effects of therapy. In contrast, when treating severe, virilizing CAH, the adrenal should be suppressed more completely, as essentially all adrenal steroidogenesis will result in the production of unwanted androgens, with their consequent virilization and rate of advancement of bony maturation that is more rapid than the rate of advancement of height. However, overtreatment will also compromise growth and could have long-term adverse implications, including for bone density, body composition, and metabolism.

The presence or absence of associated mineralocorticoid deficiency is an important variable. Children with mild degrees of mineralocorticoid insufficiency, such as those with SV CAH, may continue to have mildly elevated ACTH values, suggesting insufficient glucocorticoid replacement in association with elevated PRA. In some children, the ACTH is elevated in response to chronic, compromised hypovolemia, attempting to stimulate the adrenal to produce more mineralocorticoid. In such children, without overt signs and symptoms of mineralocorticoid insufficiency, mineralocorticoid replacement therapy ensures euvolemia, permitting one to decrease the amount of glucocorticoid replacement needed to suppress plasma ACTH and urinary 17KS. This reduction in glucocorticoid therapy reduces the likelihood that adult height will be compromised

and mitigates against other potential adverse effects of excess glucocorticoids.

The specific formulation of glucocorticoid used is also of great importance. Extremely potent, long-acting glucocorticoids, such as dexamethasone or prednisone, may be used in the treatment of adults but are rarely appropriate for replacement therapy in children. As children are continually growing and changing their weights and body surface areas, it is necessary to adjust their dose frequently; small, incremental changes are more easily done with relatively weaker glucocorticoids. The use of short-acting steroids permits the patient to have physiologically low nighttime glucocorticoid activity, facilitating rest, growth, and pituitary stimulation, as well as mimicking the natural circadian oscillations in cortisol levels. As ACTH and cortisol concentrations are high in the morning and low in the evening, it is intellectually and logically appealing to attempt to duplicate this circadian rhythm in replacement therapy. Such circadian oscillations in glucocorticoid secretion are seen in most species, including those that do not have prolonged periods of fasting, suggesting that other physiologic processes are affected by this rhythmicity. A circadian molecular clock is embedded in several important glucocorticoid signaling pathways.^{529–532} However, the clinical data are insufficient to recommend diurnal variation in steroid dosing, although most clinicians chose to mimic the diurnal rhythm by giving higher doses in the morning.⁵³³

Pharmacologic Therapy

Pharmacologic doses of glucocorticoids are used in a variety of clinical situations, including immune suppression in organ transplantation, tumor chemotherapy, treatment of “autoimmune” collagen, vascular and nephrotic syndromes, regional enteritis, and ulcerative colitis. Asthma, pseudotumor cerebri, dermatitis, certain infections, neuritis, and certain anemias are also often treated with glucocorticoids. The choice of glucocorticoid preparation to be used is guided by the pharmacologic parameters described earlier and in Table 14.7, and by custom (e.g., the use of betamethasone rather than dexamethasone to induce fetal lung maturation in impending premature deliveries). There is substantial variation in the relative glucocorticoid and mineralocorticoid activities of each steroid, depending on the assay used,⁵³⁴ hence Table 14.7 is an integration of multiple studies, and can only be taken as a rough guide. Furthermore, dosage equivalents among various glucocorticoids can be misleading. Virtually all handbooks of therapy publish tables of equivalency for the most commonly used pharmaceutical preparations of glucocorticoids; a similar set of equivalencies is shown in Table 14.7. Because most preparations of glucocorticoids are intended for pharmacotherapeutic use rather than replacement therapy, and because the most common indication for pharmacologic doses of glucocorticoids is for their antiinflammatory properties, virtually all tables of glucocorticoid equivalencies are based on antiinflammatory, immunosuppressive equivalencies. However, the differences in the plasma half-life and ability to bind to plasma proteins result in different biologic equivalencies when one assesses, for example, antiinflammatory versus growth-suppressant equivalencies. Thus dexamethasone is widely reported as being about 30 times more potent than cortisol when its antiinflammatory capacities are measured, but the growth suppressant activity of dexamethasone is about 80 times that of cortisol (see Table 14.7). The variables discussed earlier explain why there is little unanimity in recommendations for designing a glucocorticoid treatment regimen. However, an understanding of these variables will permit appropriate monitoring of the patient and encourage the

TABLE 14.13 Complications of High-Dose Glucocorticoid Therapy

Short-Term Therapy	Long-Term Therapy
Gastritis	Gastric ulcers
Growth arrest	Short stature
↑ Appetite	Weight gain
Hypercalciuria	Osteoporosis, fractures
Glycosuria	Slipped epiphyses
Immune suppression	Ischemic bone necrosis
Masked symptoms of infection, esp. fever and inflammation	Poor wound healing
Toxic psychoses	Catabolism
	Cataracts
	Bruising (capillary fragility)
	Adrenal/pituitary suppression
	Toxic psychosis

physician to vary the treatment according to the responses and needs of the individual child.

Pharmacologic doses of glucocorticoids administered for more than 1 or 2 weeks will cause the signs and symptoms of iatrogenic Cushing syndrome. These are similar to the glucocorticoid-induced findings in Cushing disease, but may be more severe (but lack adrenal androgen effects) because of the high doses involved (Table 14.13). The frequency of these adverse effects has stimulated broad interest in the development of more selective GR analogues, discussed earlier, but none have yet reached clinical use. Until more targeted approaches become available, alternate-day therapy can often be tried to decrease the toxicity of pharmacologic glucocorticoid therapy, especially suppression of the HPA axis and suppression of growth. The basic premise of alternate-day therapy is that the disease state can be suppressed with intermittent therapy, while there is significant recovery of the HPA axis during the “off” day. Thus alternate-day therapy requires the use of a relatively short-acting glucocorticoid administered only once in the morning of each therapeutic day to ensure that the off day is truly off. Long-acting glucocorticoids, such as dexamethasone, should not be used for alternate-day therapy; results are best with oral prednisone or methyl prednisolone.

Commonly Used Glucocorticoid Preparations

Numerous chemical derivatives and variants of the naturally occurring steroids are commercially available in a huge array of dosage forms, vehicles, and concentrations. Choosing the appropriate product can be simplified by considering only the most widely used steroids listed in Table 14.7.

There are four relevant considerations in the choice of which drug to use. First, the glucocorticoid potency of the various drugs is generally calculated and described according to the antiinflammatory potency, but this may not be the appropriate consideration in many cases. Second, the growth-suppressant effect of a glucocorticoid preparation may be significantly different from its antiinflammatory effect. This is because of differences in half-life, metabolism and protein binding, and receptor affinity (potency). Third, the mineralocorticoid activity of various glucocorticoid preparations varies widely. Glucocorticoids can bind to both GR and MR. Mineralocorticoid activity is intimately related to the activity of 11 β HSD2, which metabolizes glucocorticoids, but not mineralocorticoids, to forms that cannot bind the receptor. Thus the relative mineralocorticoid potency of various steroids is determined by both their affinity for MR and their resistance to the activity of 11 β HSD2. An understanding that some commonly used glucocorticoids, such as cortisol, cortisone, prednisolone, and prednisone, have significant mineralocorticoid activity is especially important when large doses of glucocorticoids are used as “stress doses” in a patient on replacement therapy. Such stress

doses of the glucocorticoid preparation may provide sufficient mineralocorticoid activity to meet physiologic needs; therefore mineralocorticoid supplementation is not needed and sustained administration of very high doses of these preparations have the potential to result in signs of mineralocorticoid excess. Fourth, the plasma half-life and biologic half-life of the various preparations may be discordant and will vary widely depending on binding to plasma proteins, hepatic metabolism, and hepatic activation. The plasma half-life of intravenously administered cortisol (hydrocortisone) is variable (mean of 75–100 min) and more than 90% of orally administered hydrocortisone is absorbed within an hour.^{535,536} Cortisone and prednisone are biologically inactive (and even have mild steroid antagonist actions), until they are metabolized by hepatic 11 β HSD1 to their active forms, cortisol, and prednisolone. Thus the glucocorticoid potency of these preparations is affected by hepatic function. Cortisone and prednisone are cleared more rapidly in patients receiving drugs, such as phenobarbital or phenytoin, that induce hepatic enzymes and are cleared more slowly in patients with liver failure.

In addition to these chemical considerations in the choice of glucocorticoid, the route of administration is important. Glucocorticoids are available for oral, intramuscular, intravenous, intrathecal, intraarticular, inhalant, and topical use; topical preparations include those designed for use on skin, mucous membranes, and conjunctiva. Each preparation is designed to deliver the maximal concentration of steroid to the desired tissue, while delivering less steroid systemically. However, all such preparations are absorbed to varying extents, so that the widely used inhalant preparations used to treat asthma can, in sufficient doses, cause growth retardation and other signs of Cushing syndrome and, in rare cases, result in adrenal insufficiency when abruptly stopped. In general, and in contradistinction to many other drugs, orally administered steroids are absorbed rapidly, but incompletely, whereas intramuscularly administered steroids are absorbed slowly, but completely. Thus if the secretory rate of cortisol is 8 mg/m² of body surface area, the intramuscular or intravenous replacement dose of cortisol (hydrocortisone) would be 8 mg/m². However, the dosage equivalents listed in Table 14.7 and similar tables are only general approximations, and doses must be tailored to the clinical response.

ACTH can also be used for glucocorticoid therapy by its action to stimulate endogenous adrenal steroidogenesis. Although intravenous and intramuscular ACTH are extremely useful in diagnostic tests of adrenal function, the use of ACTH as a therapeutic agent is no longer favored, principally because it will stimulate synthesis of mineralocorticoids and adrenal androgens, as well as glucocorticoids. Furthermore, the need to administer ACTH parenterally further diminishes its usefulness. Intramuscular ACTH(1-39) in a gel form is recommended for and is the treatment of choice for infantile spasms and possibly also for other forms of epilepsy in infants resistant to conventional anticonvulsants. Whether this action is mediated by ACTH itself, by ACTH-induced adrenal steroids, or by ACTH-responsive synthesis of novel “neurosteroids”⁵³⁷ in the brain has not been determined. When pharmacologic doses of ACTH are used therapeutically, as in infantile spasms, the patient should be given a low-sodium diet to ameliorate steroid hypertension. Although greatly elevated concentrations of ACTH, as in the ectopic ACTH syndrome, will cause pituitary suppression, treatment with daily injections of ACTH results in less hypothalamic-pituitary suppression than does treatment with equivalent doses of oral glucocorticoids, presumably because the effect on the adrenal is transient. Also adrenal suppression obviously does not occur in ACTH therapy. Because the effects of ACTH on adrenal steroidogenesis are highly variable, it is even more difficult to determine dosage equivalencies for

ACTH and oral steroid preparations than it is among the various steroids, as discussed earlier. A very rough guide from studies in adults is that 40 units of ACTH(1-39) gel is approximately equivalent to 100 mg of cortisol.

Withdrawal of Glucocorticoid Therapy

Withdrawal of glucocorticoid therapy can be difficult and can lead to symptoms of glucocorticoid insufficiency. When glucocorticoid therapy has been used for 10 days or less, therapy can be discontinued abruptly, even if high doses have been used.⁵³⁸ Although only one or two doses of glucocorticoids are needed to suppress the HPA axis, this axis recovers very rapidly from short-term suppression. When therapy has persisted for 2 weeks or longer, recovery of HPA function is slower, and tapered doses of glucocorticoids are indicated. Acute discontinuation of therapy in such patients will lead to symptoms of glucocorticoid insufficiency, the so-called steroid withdrawal syndrome. This symptom complex does not include salt loss, as adrenal glomerulosa function, regulated principally by the renin-angiotensin system, remains normal. However, blood pressure can fall abruptly, as glucocorticoids are required for the action of catecholamines in maintaining vascular tone. The most prominent symptoms of the steroid withdrawal syndrome include malaise, anorexia, headache, lethargy, nausea, and fever. In reducing pharmacologic doses of glucocorticoids, it might appear logical to reduce the dosage precipitously to “physiologic” replacement doses. However, this is rarely successful and occasionally disastrous. Even when given physiologic replacement, patients who have been receiving pharmacologic doses of glucocorticoids will experience steroid withdrawal. Long-term pharmacologic glucocorticoid therapy inhibits synthesis of GR, so that physiologic concentrations of glucocorticoids will elicit subphysiologic cellular responses, resulting in the steroid withdrawal syndrome. Thus it is necessary to taper gradually from the outset. The duration of glucocorticoid therapy is a critical consideration in designing a glucocorticoid withdrawal program. Therapy for a couple of months will completely suppress the HPA axis but will not cause adrenal atrophy. Therapy of years’ duration may result in almost total atrophy of the adrenal fasciculata/reticularis, and hence may require a withdrawal regimen that takes months.

Procedures for tapering steroids are empirical. Their success is determined by the length and mode of therapy and by individual patient responses. Patients who have been on alternate-day therapy can be withdrawn more easily than those receiving daily therapy, especially daily therapy with a long-acting glucocorticoid, such as dexamethasone. In patients on long-standing therapy, a 25% reduction in the previous level of therapy is generally recommended weekly. If the patient has been on daily therapy equivalent to 100 mg of cortisol for many months, a tapering protocol over 8 to 10 weeks may be needed. A protocol of 75% of the previous week’s dose would thus be 75 mg/day for the first week, 56 mg/day for the second, then 42, 31.5, 24, 18, 13.5, 10, 7.5, 5.5 mg/day, then off treatment. A more practical regimen based on the sizes of available tablets would be 75, 50, 37.5, 25, 17.5, 12.5, 10, 7.5, and 5 mg/day. Most patients can be tapered more rapidly, but all patients need to be followed closely. When withdrawal is done with steroids other than cortisol, measurement of morning cortisol values can be a useful adjunct. Morning cortisol values of 10 μ g/dL or more indicate that the dose can be reduced safely.

Even after the successful discontinuation of therapy, the HPA axis is not wholly normal. Just as in the patient successfully treated for Cushing disease, the HPA axis may be incapable of responding to severe stress for 6 to 12 months, after successful withdrawal from long-term, high-dose glucocorticoid therapy.

Thus evaluation of the hypothalamus and pituitary by a CRF or metyrapone test (when available), and evaluation of adrenal responsiveness to pituitary stimulation with an intravenous low-dose ACTH test, should be done at the conclusion of a withdrawal program, and 6 months thereafter. The results of these tests will indicate if there is a need for “steroid coverage” in acute surgical stress or illness.

Stress Doses of Glucocorticoids

The cortisol secretory rate increases significantly during physiologic stress, such as trauma, surgery, or severe illness. Patients receiving glucocorticoid replacement therapy or those recently withdrawn from pharmacologic therapy need coverage with “stress doses” of steroids in such situations. However, the specific indications for this coverage and the appropriate dosage are controversial and difficult to establish; most practitioners prefer to err on the “safe” side of steroid overdosage. This is the safest tactic in the short term but can have a significant effect on growth over a period of years and, if frequently used, may prolong the time needed for the HPA axis to recover.

It is generally said that doses 3 times physiologic replacement are needed for “the stress of surgery,” but this stress varies greatly. In the past, much “surgical stress” had to do with pain, fluid loss, hypovolemia, and fever, but these are managed better in contemporary pediatric services. Modern techniques of anesthesiology; better anesthetic, analgesic, and muscle-relaxing drugs; and increased awareness of the particular needs of children in managing intraoperative fluids and electrolytes have greatly reduced surgical stress. Serum cortisol does not exceed 10 ug/dL (276 nmol/L) in adrenally intact children undergoing anesthesia and minor surgery.⁹⁴ When used, stress dosing should be given in constant doses at 6-hour intervals.⁵²⁹ Although it remains appropriate and necessary to give about 3 times physiologic requirements during such periods of stress, it is probably not necessary to give higher doses. Similarly, it is not necessary to triple a child’s physiologic replacement regimen during simple colds, upper respiratory infection, otitis media, or after immunizations.

The preparation of the hypoadrenal patient on replacement therapy for surgery requires coordination with the anesthesia team. The best approach is to place a stress dose of 25 mg hydrocortisone per square meter in the intravenous fluid, so that the glucocorticoid is delivered continuously during surgery, rather than being given a single bolus at the beginning of the procedure. It appears that the greatest stress is at the time of anesthesia reversal, rather than at the time of anesthesia induction.⁹² Regular therapy at 2 to 3 times physiologic requirements can then be reinstated on the day after the surgical procedure.

Mineralocorticoid Replacement

Replacement therapy with mineralocorticoids is indicated in salt-losing CAH and in syndromes of adrenal insufficiency that affect the zona glomerulosa. Only one mineralocorticoid, oral 9 α -fluorocortisol (Fluorinef), is currently available. There is no parenteral mineralocorticoid preparation so that hydrocortisone plus salt must be used.

Because of increasing mineralocorticoid sensitivity with age (see Fig. 14.18), mineralocorticoid doses are similar in children and adults. Newborns are quite insensitive to mineralocorticoids and often require substantially larger doses than adults. The adult replacement dose of 9 α -fluorocortisol is usually 0.05 to 0.10 mg daily, but newborns with CAH may require up to 0.4 mg. Sodium must be available to the nephrons for mineralocorticoids to promote reabsorption of sodium, thus

the newborn with salt-losing CAH must be treated with both mineralocorticoids and sodium chloride. Similarly, mineralocorticoids will cause hypertension only by retaining sodium.

Cortisol has mineralocorticoid activity: approximately 20 mg of intravenous cortisol has a mineralocorticoid action equivalent to 0.1 mg of 9 α -fluorocortisol. Thus stress doses of cortisol provide adequate mineralocorticoid activity, and mineralocorticoid replacement can be interrupted. Additional 9 α -fluorocortisol is not needed until the supraphysiologic stress doses of cortisol are decreased. Because 9 α -fluorocortisol can be administered only orally and because this may not be possible in the postoperative period, the appropriate drug for glucocorticoid replacement is cortisol, which has mineralocorticoid activity, rather than synthetic steroids, such as prednisone or dexamethasone, which have little mineralocorticoid activity.

CONCLUDING REMARKS

Because the adrenal cortex is principally concerned with steroid synthesis, most of its disorders reflect genetic lesions in adrenal development and steroidogenesis. Overproduction and underproduction of steroids, having varied and complex physiologic actions, lead to complex phenotypes and clinical presentations. These primary, genetic disorders typically present themselves in infancy and childhood. In contrast, secondary disorders, such as Cushing disease (usually a disorder of the pituitary) and Addison disease (usually a disorder of cellular immunity), may be seen at any age. Thus the pediatric endocrinologist must have a detailed understanding of the cell biology, genetics, and biochemistry of steroid hormone biosynthesis. Improvements in the speed, accuracy, and economy of DNA sequencing now permits direct genetic diagnosis of many genetic diseases. However, it is unlikely that measurements of steroid hormones will become obsolete in the foreseeable future, and an understanding of steroid physiology will always be needed to understand clinical presentations, formulate differential diagnoses, choose genes for study, and monitor therapy. Thus genetics will continue to enhance clinical physiology, but will not replace it.

INTRODUCTION

Endocrine neoplasms comprise a variety of benign and malignant tumors that arise from the endocrine glands or other neuroendocrine tissues, such as the paraganglia. Most childhood endocrine tumors, typified by papillary thyroid carcinoma, are sporadic and not attributable to an identifiable germline mutation whereas others, epitomized by catecholamine-producing tumors (Table 15.1) and medullary thyroid carcinoma (MTC), are familial and occur within the context of a broader hereditary tumor syndrome. In familial endocrine neoplasms, the mode of inheritance is autosomal dominant and mutations are primarily inactivating mutations causing loss of function in a tumor suppressor gene. Advances in genetic testing and research have led to the ongoing discovery of novel tumor-susceptibility genes, in addition to a better understanding of the underlying pathophysiology of these unique disorders. Knowledge regarding genotype-phenotype relationships continues to evolve, as has clinical practice regarding the age of performing predictive genetic testing, screening for endocrine tumors in an asymptomatic carrier, and the timing of therapeutic intervention. Given the rapidly changing field, it is beneficial for patients with an endocrine tumor to be evaluated in programs with known multidisciplinary expertise. In addition, the results of genetic testing and formal genetic counseling should be fully incorporated

into treatment planning and long-term follow-up. This chapter reviews the pathophysiology, diagnosis, and management of pediatric endocrine tumors and the most common genetic syndromes associated with their diagnosis.

GENETIC COUNSELING AND TESTING

A diagnosis of an endocrine tumor in a child, especially one that is neuroendocrine in origin, should raise concern for the possibility of an underlying genetic predisposition. Genetic counseling is a process of communication that promotes understanding, decision-making, and coping related to the impact of genetic disease.¹ It should be incorporated into all stages of care, both at diagnosis and during long-term follow-up, because patients' needs change over time and also because genetic testing and management recommendations are likely to evolve.

Genetic testing, nicely exemplified in multiple endocrine neoplasia (MEN) type 2,² is a multistep process that begins with a patient who already has clinical manifestations of disease. In most cases, such as in MEN1 and MEN2A, this is likely to be a parent or another blood relative, but in other heritable disorders with low disease penetrance, such as the familial paraganglioma (PGL) syndromes, genetic testing of the family may actually begin with the child who is the index case. Genetic

TABLE 15.1 Major Disorders and Genes Associated With Pheochromocytoma and Paraganglioma

Hereditary Syndrome	Gene (Chromosome)	Tumor Type	Clinical Phenotype ^a	Earliest Age ^b	Screening Guidelines ^c
Multiple endocrine neoplasia type 2A (MEN2A)	<i>RET</i> (10q11.21)	PHEO/rare PGL & composite PHEO ^d	<ul style="list-style-type: none"> • Adrenergic • Malignancy rare • Background of adrenal medullary hyperplasia 	8 ⁴⁵⁵	Start by age 11 yrs. in codon 634 mutations; by age 16 yrs. in other codons
Multiple endocrine neoplasia type 2B (MEN2B)	<i>RET</i> (10q11.21)	PHEO/rare PGL	<ul style="list-style-type: none"> • Adrenergic • Malignancy rare • Background of adrenal medullary hyperplasia 	10 ³⁵⁵	Start by age 11 yrs. in codon 918 and 883 mutations

Familial paraganglioma syndrome 3 (PGL3)	<i>SDHC</i> (1q23.3)	PGL (primarily head & neck/ thorax)	<ul style="list-style-type: none"> • Nonfunctional or noradrenergic • Malignancy rare 	13 ⁴⁵⁷	Start by age 10 yrs ^f
Familial paraganglioma syndrome 4 (PGL4)	<i>SDHB</i> (1p36.13)	PGL (Abdominal/ pelvic >head & neck)/PHEO	<ul style="list-style-type: none"> • Noradrenergic or nonfunctional • Malignancy ~25% 	3 ⁴⁵⁸	Start by age 5 yrs ^g
Familial paraganglioma syndrome 5 (PGL5)	<i>SDHA</i> (5p15.33)	PGL/PHEO	<ul style="list-style-type: none"> • Nonfunctional or noradrenergic • Malignancy uncommon 	8 ²²⁸	Start by age 10 yrs ^h
von Hippel-Lindau disease (VHL)	<i>VHL</i> (3p25.3)	PHEO/PGL	<ul style="list-style-type: none"> • Noradrenergic • Malignancy rare 	2 ⁴⁴⁴	Start by age 5 yrs

HTN, Hypertension; PGL, paraganglioma; PHEO, pheochromocytoma.

^aNoradrenergic tumors exclusively secrete norepinephrine/normetanephrine, whereas adrenergic tumors secrete both epinephrine and norepinephrine, in addition to their metabolites (metanephrine and normetanephrine). Nonfunctional tumors are parasympathetic tumors that arise in the head and neck.

^bEarliest age of diagnosis of PHEO/PGL and reference.

^cData from consensus guidelines and other relevant publications.^{55,63,65–67,235,236} The age to start annual screening (blood pressure; fractionated plasma or 24-hour urine metanephrines) and the frequency/type of radiologic screening (for *SDHx* carriers) is not an absolute and should be tailored to patient symptoms, physical examination (blood pressure), biochemical test results, and family preference. Consider testing in young women of childbearing age who plan to become pregnant and in any patient before an elective surgical procedure, assuming they have not been recently screened.

^dA composite PHEO is a mixed tumor comprised of PHEO and a developmentally related neurogenic tumor, such as neuroblastoma, ganglioneuroma, or ganglioneuroblastoma.⁶

^eThere are parent-of-origin effects in PGL1, such that children develop clinical disease only if a mutation is inherited from their father. In children with maternal transmission of an *SDHD* mutation, routine screening is not needed, although comprehensive testing should be considered at least once, as there are reports of maternally inherited *SDHD* mutations causing disease.

^fThe authors also consider head and neck ultrasonography for screening of cervical PGL, in addition to biennial (or less frequent) whole-body magnetic resonance imaging (MRI) as recommended by others.

^gGiven the higher rate of malignancy, earlier screening is recommended for *SDHB* mutation carriers. In addition to biochemical screening, the authors consider ultrasound of the abdomen/pelvis starting at age 5 years and biennial whole-body MRI when the patient is old enough to tolerate an MRI without sedation.

^hDisease penetrance in young *SDHA* mutation carriers is extremely low^{228,459} and thus intensive screening during childhood may not be warranted.

testing serves multiple purposes, including confirmation of the genetic cause of an endocrine tumor, identification of asymptomatic patients who are at risk for clinical disease, and guidance regarding clinical management and family planning.³ When ordering predictive genetic testing, it is important to understand how the results will be used in patient management. In some cases (e.g., MEN2), knowledge of the genotype will lead to a disease-preventing intervention (early thyroidectomy), whereas in other hereditary syndromes, such as MEN1 and von Hippel-Lindau (VHL) disease, it will only lead to an earlier diagnosis.

The process of genetic testing in children is engrained with various ethical, legal, and psychosocial implications.^{4,5} Despite the

clear medical benefits afforded from an early diagnosis, genetic testing in children has the potential for harm to the patient and family: alteration of the child's self-image and of the parents' perception of the child, modification of the patient's outlook on life, worry about the potential for genetic discrimination, changes in family relationships, early "medicalization" of an otherwise healthy child, and concerns regarding future reproductive issues. Timely medical benefit to the child should be the primary justification for genetic testing. In all cases where the risks versus benefits of genetic testing are unclear, the provider should respect the decision of the family. There are several online resources regarding genetic counseling and testing, including the National Society of Genetic Counselors (www.nsgc.org), the National Cancer

Institute's "The Genetics of Cancer" website (www.cancer.gov/cancertopics/genetics), and the internet site *GeneReviews*[®] (<https://www.ncbi.nlm.nih.gov/books/NBK1116/>).

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Pheochromocytomas (PHEOs) and PGLs are neuroendocrine tumors (NETs) that arise from neural crest-derived paraganglion cells. PHEO (Fig. 15.1) is the term used for a

catecholamine-producing tumor that evolves from chromaffin cells in the adrenal medulla, whereas PGLs (Fig. 15.2) are extra-adrenal tumors that arise from both sympathetic and parasympathetic paraganglia located in the autonomic nervous system outside the cerebrospinal axis.^{6–8} Historically, the term *PHEO* was used interchangeably with PGL, but it is best to maintain a distinction between these two neoplasms because of underlying differences in genetics, clinical presentation, and malignant potential (see Table 15.1).

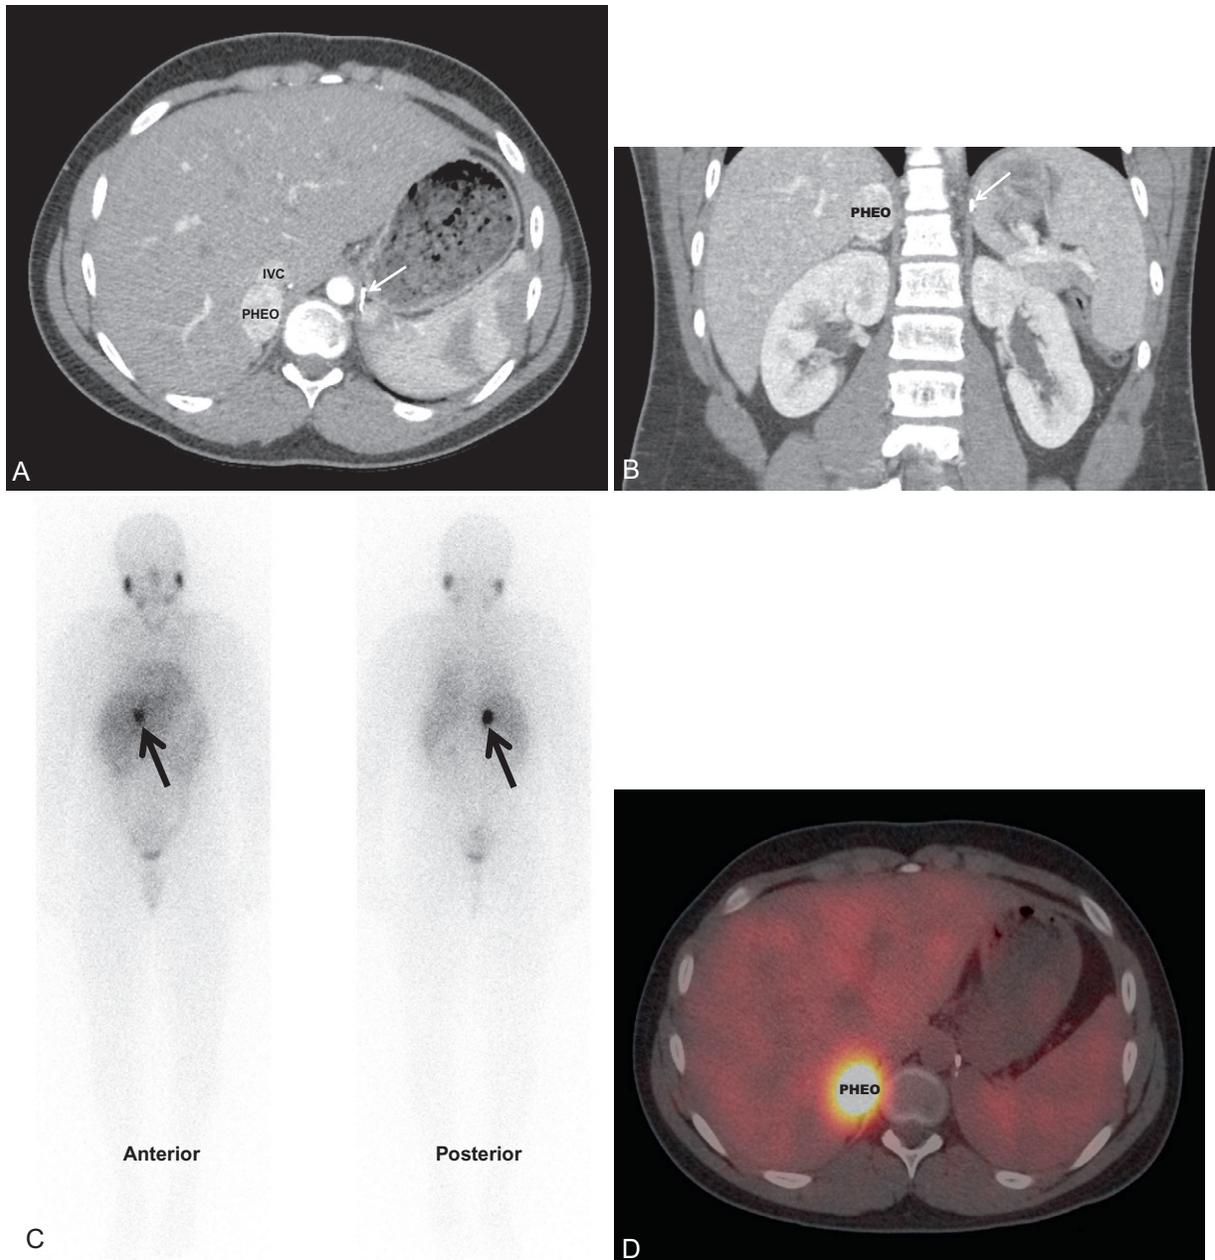

Fig. 15.1 A normotensive 14-year-old male with von Hippel-Lindau disease and a history of a left pheochromocytoma and abdominal paraganglioma diagnosed at the age of 7 years was found to have elevated normetanephrine levels after screening. Axial computed tomography (CT) postcontrast (A) with coronal reconstruction (B) identified a vascular neoplasm arising from the superior right adrenal gland (arrow, surgical clips from previous adrenalectomy). Metaiodobenzylguanidine (MIBG) scan confirmed the functional nature of the tumor and ruled out other synchronous tumors. Planar (C) and fused single photon emission CT/CT axial images (D) in the same patient, 24 hours after the administration of ¹²³I MIBG. IVC, Inferior vena cava; PHEO, pheochromocytoma.

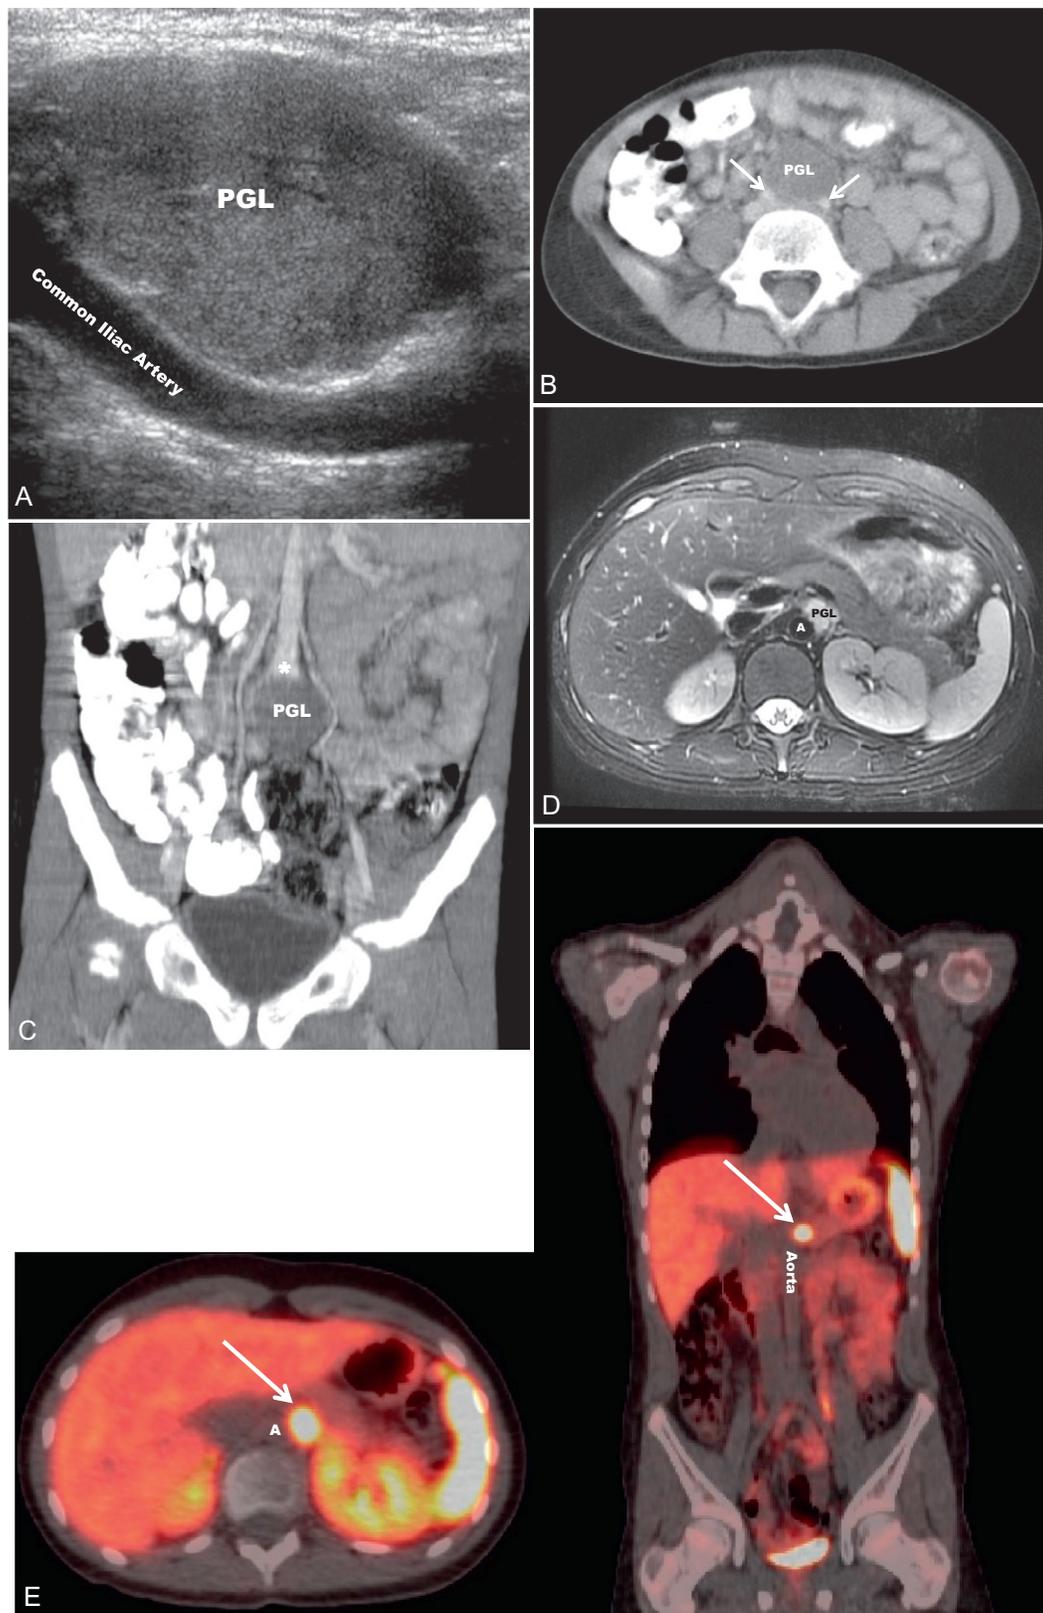

Fig. 15.2 A 6-year-old female with a paraganglioma (PGL) and an *SDHB* mutation presented with severe hypertension during a well-child examination. A, Abdominal ultrasound (sagittal view) revealed a homogeneous, hypervascular 3.3-cm mass next to the common iliac arteries. Axial computed tomography (CT) postcontrast (B) (arrows, common iliac arteries) with coronal reconstruction (C) confirmed a tumor at the aortic bifurcation (asterisk). A 13-year-old boy with an *SDHB* mutation developed elevated blood pressures and abnormal norepinephrine, normetanephrine, and chromogranin A levels during prospective screening. T2-weighted axial images from abdominal magnetic resonance imaging (D) revealed a 2-cm paraaortic mass (PGL) between the origins of the celiac axis and superior mesenteric artery that was T2 hyperintense. This was subsequently confirmed via functional imaging with ⁶⁸Ga-DOTATATE positron emission tomography/CT (E) to be a paraganglioma (arrows). A, Aorta.

PHEO/PGL are rare tumors with an annual incidence in the United States of 500 to 1600 cases per year.⁹ Around 10% of PHEO/PGL are diagnosed during childhood at an average age of 13 years; there is a slight predominance in boys, particularly when diagnosed under the age of 10 years.^{10–22} Less than 2% of children diagnosed with hypertension will harbor a catecholamine-producing neoplasm.^{23,24}

PGL occur in all locations where paraganglia are found (from the skull base to the pelvis) and are either functioning (sympathetic) or nonfunctioning (parasympathetic) neoplasms, depending on the site of origin and underlying pathophysiology^{6,11,25–27} (see Table 15.1). PGL arising in the head and neck region, which are rarer in children,^{11,28} are almost exclusively nonfunctioning, parasympathetic tumors, whereas most intraabdominal PGL (commonly occurring within the organ of Zuckerkandl [see Fig. 15.2] in a periaxillary location, or around the renal hilum⁶) are sympathetic and thus secretory tumors. The majority of PHEO/PGL diagnosed during childhood are functional and synthesize and secrete catecholamines (dopamine, norepinephrine, and/or epinephrine) and their metabolites (including 3-methoxytyramine, normetanephrine, and metanephrine, respectively)^{25,29,30} (Fig. 15.3). All functioning PHEO/PGL contain chromaffin tissue, which refers to the brown-black color resulting from the oxidation of catecholamines after staining with chromium salts. Multicentric tumors are common in childhood presentations of PHEO/PGL.^{10,11,13,15,20–22,31}

Biosynthesis and Actions of Catecholamines

Dopamine, norepinephrine, and epinephrine (collectively known as *catecholamines*) are chemical neurotransmitters and hormones that play important roles in the regulation of numerous physiologic processes and the development of neurologic, psychiatric, endocrine, and cardiovascular diseases.^{32–35} The catecholamines are comprised of a catechol (1,2-dihydroxybenzene) moiety and a side-chain amine group. They are synthesized from the amino acid tyrosine, which is converted to 3,4-dihydroxyphenylalanine (dopa) by the enzyme tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis (see Fig. 15.3). Subsequent enzymatic decarboxylation and hydroxylation of dopa yields dopamine and norepinephrine, respectively, and norepinephrine is subsequently converted to epinephrine via the cytosolic enzyme phenylethanolamine N-methyltransferase (PNMT).

The catecholamines are synthesized and stored in granules within the adrenal medulla, where they are released via exocytosis into the systemic circulation in response to stressful stimuli. Dopamine and norepinephrine are also produced by postganglionic neurons in the sympathetic nervous system. Epinephrine is made only in the adrenal medulla, where it represents the predominant catecholamine (~80%) because PNMT expression is dependent upon and regulated by high local concentrations of glucocorticoids (as occurs only in the adrenal medulla, surrounded by the cortisol-synthesizing adrenal cortex, with a distinct concentration gradient towards the adrenal medulla).^{32,36,37} The effects of catecholamines are terminated via rapid reuptake into nerve terminals by the norepinephrine transporter and via metabolism by two major enzymes: monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT)^{25,32,35} (see Fig. 15.3).

The complex actions of norepinephrine and epinephrine are mediated by the G-protein-coupled α - and β -adrenergic receptors, whereas dopamine binds to a different class of G-protein-coupled dopamine receptors (five distinct receptors [D1–D5]) that are divided into two families: D1-like and

D2-like)^{32–34} (Table 15.2). The initial classification of adrenergic receptors was based upon epinephrine's ability to both excite (α -receptor) and inhibit (β -receptor) smooth muscle. Specific agonists and antagonists characterize the adrenergic receptor subtype (α_1 , α_2 , β_1 , β_2 , and β_3) and can be used as therapeutic agents. The D2 receptor is the primary dopamine receptor that is targeted for drug therapy.

Clinical Presentation

The clinical presentation of pediatric PHEO/PGL is highly variable. Children with these tumors can come to attention because of symptomatic catecholamine hypersecretion, symptoms caused by tumor mass effect (e.g., pain), an incidental radiographic finding, or because of prospective screening in one of the associated hereditary tumor syndromes^{6,8,12,38–41} (see Table 15.1). PHEO/PGL may also arise in the setting of cyanotic congenital heart disease.^{42,43} Given their neuroendocrine origin, PHEO/PGL can very rarely cosecrete other hormones that result in a clinical syndrome of ectopic hormone excess, primarily Cushing syndrome, because of overproduction of adrenocorticotropic hormone (ACTH).^{25,44}

The clinical presentation of a functioning PHEO/PGL depends on inherent differences in catecholamine production, as well as individual patient sensitivities to catecholamines.⁴⁵ Signs and symptoms of catecholamine excess include: hypertension, which is typically sustained in the majority of pediatric cases; severe headaches; paroxysmal episodes with the classic triad of headaches, palpitations, and diaphoresis (less common in children); orthostatic hypotension and syncope; pallor; tremor; and/or anxiety.^{7,13,17,18,23,25,26,38,44,46} PHEO/PGL in children can also cause nonspecific signs and symptoms, such as blurred vision; abdominal pain, constipation, diarrhea and other gastrointestinal symptoms; weight loss; hyperglycemia; polyuria and polydipsia; low-grade fever; and behavioral problems, attention deficit hyperactivity disorder, and/or a decline in school performance.^{13,17,18,23,25,26,46–49} Bladder PGL can present with hematuria and paroxysmal symptoms during micturition.^{44,50}

Complications of catecholamine excess can include hypertensive crisis, cardiomyopathy (takotsubo cardiomyopathy), arrhythmias, pancreatitis, severe constipation and intestinal pseudoobstruction, stroke, seizures, and even multisystem crisis and death.^{26,44,46,48,51–53} Symptoms of parasympathetic PGL (usually located in the head and neck region) include hearing loss, pulsatile tinnitus, neck mass, and other symptoms of mass effect, such as voice hoarseness, pharyngeal fullness, and dysphagia.⁵⁴

Up to 80% of the pediatric population with PHEO/PGL have a hereditary predisposition syndrome (see Table 15.1 and later section),^{6,10,11,14,20–22,31,55} and a subset of these will be diagnosed only after a tumor is identified during a screening program. Compared with sporadic disease, hereditary PHEO/PGL identified during the course of prospective presymptomatic screening are smaller and less symptomatic (or even asymptomatic) tumors.^{56–58} In all cases of pediatric PHEO/PGL, genetic counseling and testing should be pursued^{39,55,59–62}; identifying a germline mutation early after diagnosis appears to have a positive impact on the management and clinical outcome of patients with heritable disease.⁶¹ The American Association of Cancer Researchers developed guidelines for screening the pediatric population with hereditary PHEO/PGL syndromes,⁶³ and others have also published screening recommendations in pediatric populations with MEN2^{64,65} and VHL disease.^{66,67}

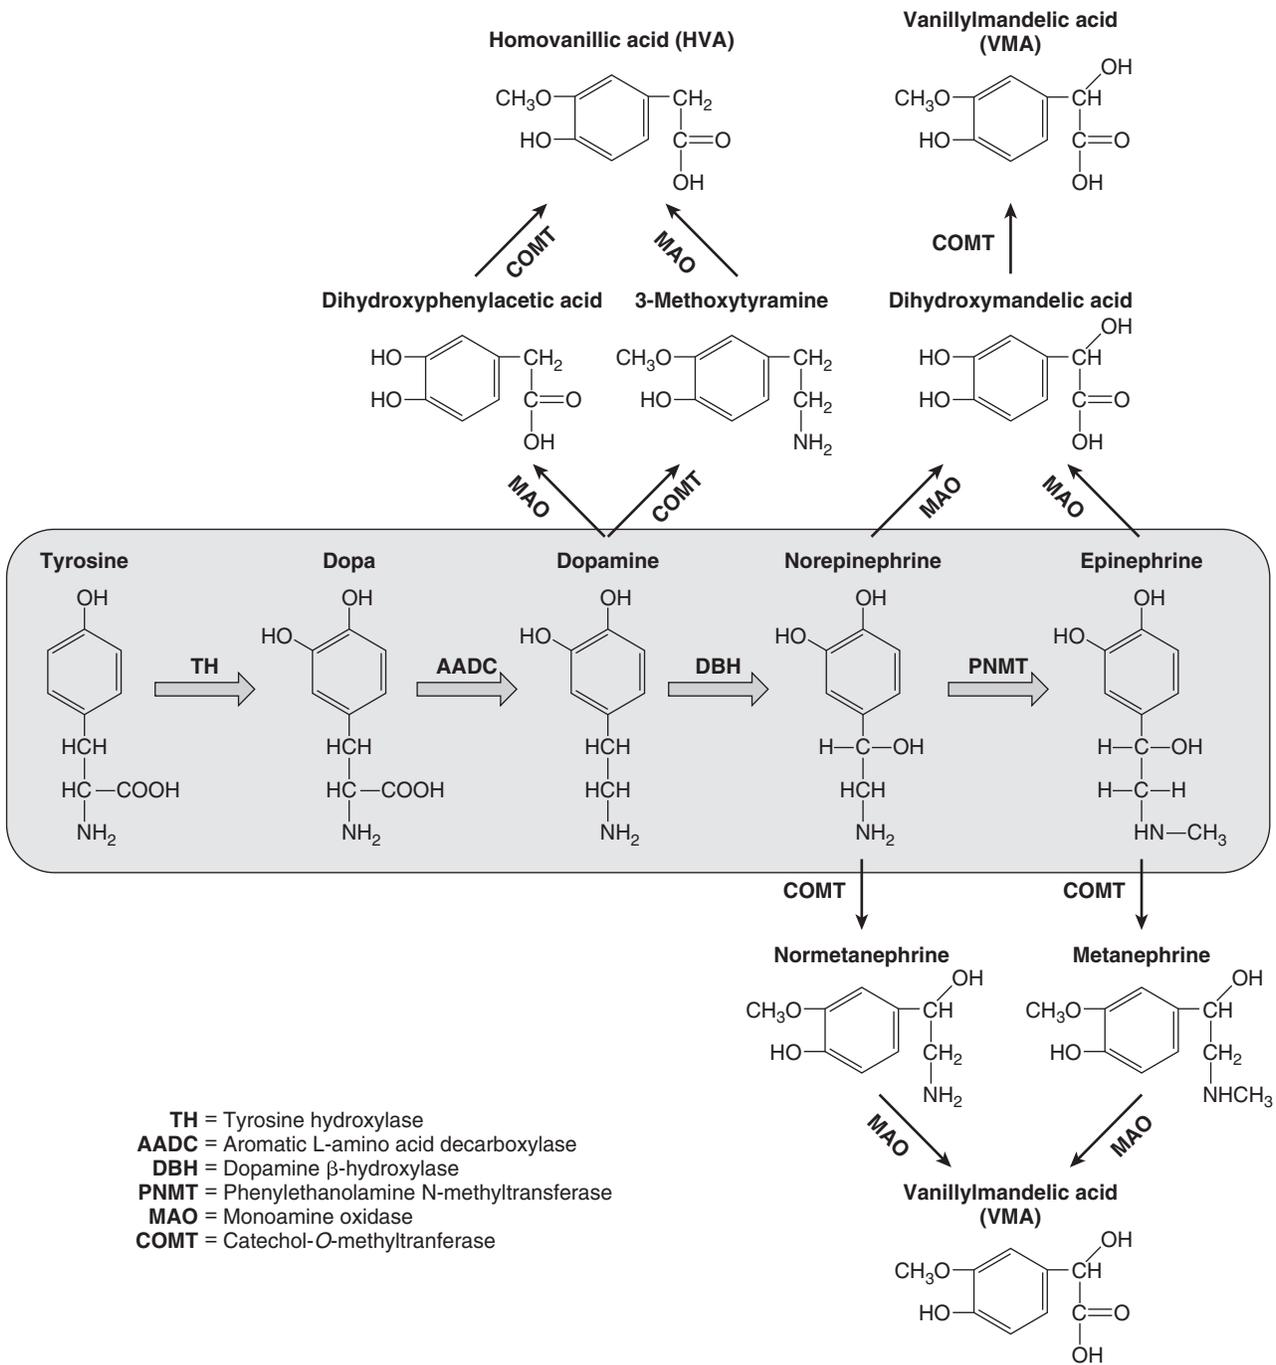

Fig. 15.3 The catecholamines are synthesized from the amino acid tyrosine, which is converted to 3,4-dihydroxyphenylalanine (dopa) by the enzyme tyrosine hydroxylase (TH), the rate-limiting step in catecholamine biosynthesis. Subsequent enzymatic decarboxylation (aromatic L-amino acid decarboxylase; AADC) and hydroxylation (dopamine β-hydroxylase; DBH) yields dopamine and norepinephrine, respectively, and norepinephrine is subsequently converted to epinephrine via the cytosolic enzyme phenylethanolamine N-methyltransferase (PNMT). The catecholamines are metabolized by two major enzymes: monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT).

Evaluation

Biochemical Diagnosis

The diagnosis of PHEO/PGL has been simplified by advances in the assays used to detect and quantify levels of catecholamines and their metabolites in blood and urine. The measurement of fractionated plasma and/or urine metanephrines

(metanephrine and normetanephrine) is the most sensitive test (approaching 100% sensitivity) for the diagnosis of PHEO/PGL and should be the primary diagnostic test^{7,25,59,68-72} (Fig. 15.4).

The high sensitivity of metanephrine testing is based upon the fact that there is continuous intratumoral metabolism of catecholamines, a process that occurs independently of catecholamine release, which can occur intermittently or at

TABLE 15.2 Catecholamine Receptor Classification, Function, and Pharmacology

Receptor Type	Primary Pharmacologic Agonist(s)	Primary Pharmacologic Antagonist(s)	Major Biologic Effects
α_1	Phenylephrine, midodrine	Doxazosin, prazosin, terazosin, etc.	Vasoconstriction; promotes cardiac growth and structure
α_2	Clonidine, methyl dopa, tizanidine	Yohimbine	Inhibition of norepinephrine release; vasoconstriction; inhibits adrenal catecholamine release and modulates CNS dopamine neurotransmission
β_1	Dobutamine	Atenolol, bisoprolol, esmolol, metoprolol, etc.	Increases heart rate and contractility
β_2	Albuterol, levalbuterol, salmeterol, terbutaline, etc.	Propranolol (prototypic β_2 antagonist that is also a β_1 antagonist) and others	Smooth muscle relaxation (arteriolar and venous dilation; relaxation of tracheobronchial muscles)
β_3	Mirabegron	Investigational	Metabolic effects in adipose tissue and skeletal muscle
D1-like (D_1 and D_5)	Levodopa	No primary agents	Vasodilation; increased renin secretion; promotes norepinephrine and epinephrine release; various CNS functions
D2-like (D_2 , D_3 , and D_4)	Bromocriptine, cabergoline, pramipexole, ropinirole	Aripiprazole, chlorpromazine, haloperidol, metoclopramide, prochlorperazine, etc.	Decreases prolactin secretion; decreases renin secretion; inhibits norepinephrine and epinephrine release; various CNS functions

low rates.⁶⁹ An elevation of metanephrines greater than 4-fold above the reference range is associated with almost 100% probability of the presence of a catecholamine-secreting tumor⁷³; however, a PHEO/PGL can still be present with metanephrine levels more than two times the upper limit of normal, especially in the setting of hereditary disease.⁷⁴ Any drugs known to interfere with these assays (e.g., acetaminophen, tricyclic antidepressants, phenoxybenzamine, and decongestants, among others⁵⁹) should be discontinued before testing. Dietary restrictions need not be routinely used but should be considered if the assay used measures only deconjugated normetanephrines or if a dopamine-secreting tumor is suspected.⁷⁵ The measurement of the catecholamine metabolites vanillylmandelic acid (VMA) and homovanillic acid (HVA) is no longer recommended for the evaluation of PHEO/PGL. However, testing for HVA and VMA in spot urine samples remains a critical component of the evaluation of neuroblastoma, where these analytes have a high sensitivity and specificity for tumor detection.⁷⁶

In patients with mildly elevated metanephrine levels, in whom a false positive test result is suspected, consideration should be given to measuring these plasma analytes drawn from patients in the supine position, 30 minutes after an indwelling needle or catheter is inserted into the vein.^{7,59,71} Clonidine suppression and glucagon stimulation tests^{59,77,78} have been a component of the diagnostic algorithm in adults but are rarely required and have not been validated in the diagnosis of childhood PHEO/PGL.

Catecholamine-producing tumors can be subclassified as being either noradrenergic or adrenergic based upon their pattern of catecholamine release.^{79,80} Noradrenergic PHEO/PGL secrete norepinephrine and normetanephrine, as seen in VHL disease and in tumors associated with the hereditary PGL/PHEO syndromes.^{19,22,59,79,81,82} Adrenergic tumors secrete both epinephrine and norepinephrine and their metabolites, and these tumors are more commonly PHEO that arise

sporadically or within the clinical context of MEN2 or neurofibromatosis type 1 (NF1).^{59,69,79,81,82} This differential secretion of catecholamines is caused by decreased expression of PNMT in noradrenergic tumors secondary to PNMT promoter hypermethylation.^{81,83}

Dopamine-secreting tumors are rare and are typically extraadrenal succinate dehydrogenase (*SDH*)x-associated PGLs, as well as head and neck PGLs.^{84–86} The measurement of methoxytyramine, a metabolite of dopamine, (see Fig. 15.3) may help to identify more aggressive tumors, particularly in the context of an *SDHx* mutation,⁸⁷ but this test is not widely available. A dopamine-secreting tumor should be considered in normotensive patients identified to have a mass that appears consistent with a PHEO/PGL, in which case dopamine and its metabolites, HVA and methoxytyramine (if available), should be measured.^{85,87–89} For prospective screening in patients with a known *SDHx* mutation, total catecholamines should be checked in addition to total metanephrines because of this possibility.

Chromogranin A is a major secretory protein present in the soluble matrix of chromaffin granules that serves as a tumor marker that may correlate with PHEO/PGL size and malignant potential.^{19,68,90} Chromogranin A also appears to be a useful marker in the biochemically silent, *SDHB*-related PGL,^{27,86} making it a potentially useful test in the screening of asymptomatic *SDHx* mutation carriers. However, chromogranin A can be falsely elevated in many circumstances, including concomitant use of proton-pump inhibitors and serotonin reuptake inhibitors, renal failure, and pancreatic disorders,⁹¹ so caution is needed in the interpretation.

Radiographic Studies

Once a diagnosis of catecholamine excess is established from biochemical testing, radiographic studies should be performed to identify the location of the tumor(s)^{26,71} (see Figs. 15.1, 15.2, and 15.4).

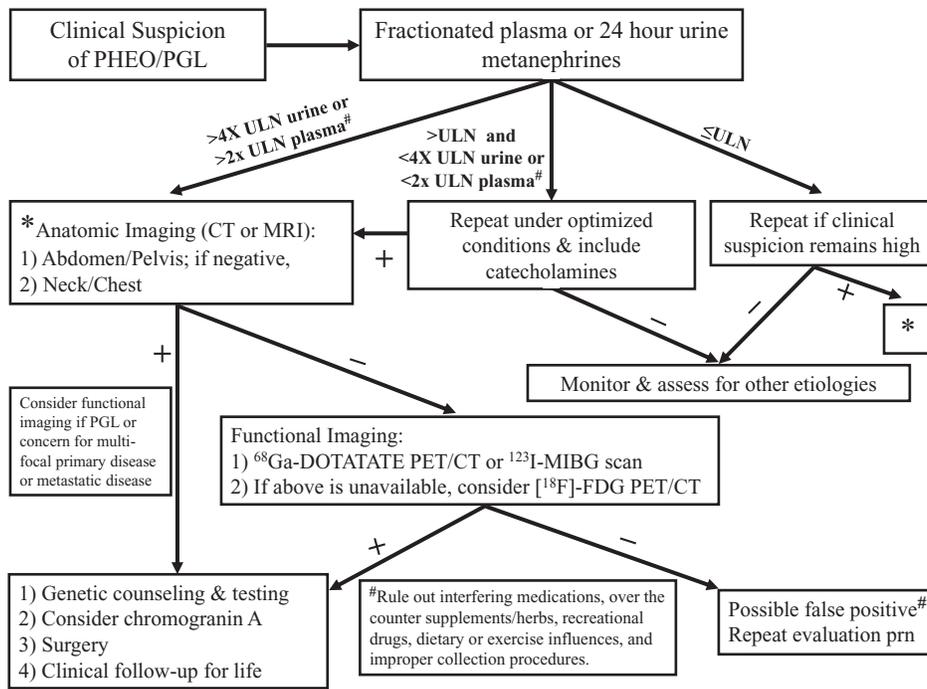

Fig. 15.4 Diagnosis of pediatric pheochromocytoma (PHEO) /paraganglioma (PGL). ULN, Upper limit of normal. (Modified from Waguespack, S.G., Rich, T., Grubbs, E., et al. (2010). A current review of the etiology, diagnosis, and treatment of pediatric pheochromocytoma and paraganglioma. *J Clin Endocrinol Metabol*, 95(5), 2023–2037.)

Initial imaging studies should include anatomic cross-sectional imaging of the abdomen and pelvis (computed tomography [CT] or magnetic resonance imaging [MRI]), followed by imaging of the neck and chest if the initial studies are unrevealing^{25,69} (see Fig. 15.4). CT and MRI have similar diagnostic sensitivities, and so the imaging test of choice is best determined by local practices and patient preference.^{71,92} Abdominal ultrasound (US) may also be considered in young children, if local expertise permits (see Fig. 15.2). PHEO/PGL are highly vascular (and hence enhancing) neoplasms that commonly contain necrotic, cystic, and/or hemorrhagic areas. On CT, the noncontrast Hounsfield units are almost exclusively greater than 10, and on MRI, PHEO/PGL exhibit a classic hyperintense appearance on T2-weighted images (called the *lightbulb sign*) and no loss of signal intensity on in and out of phase imaging^{25,93} (see Fig. 15.2).

Nuclear medicine, or functional imaging can be useful in certain circumstances to diagnose PHEO/PGL (especially to confirm the diagnosis in an extraadrenal tumor) or to evaluate the patient for multifocal or metastatic disease, particularly in those patients with risk factors for malignancy and a noradrenergic phenotype.^{21,94–97} There are several nuclear medicine scans that can be helpful.⁹⁸ Metaiodobenzylguanidine (MIBG) is a synthetic compound that bears structural similarity to norepinephrine (except it also has a guanidine side chain that resists metabolism), and it accumulates preferentially in adrenergic tissues, namely because of reuptake via the norepinephrine transporter system.^{99,100} MIBG used for diagnostic purposes is radiolabeled with either ¹²³I or ¹³¹I, although ¹²³I MIBG is the agent of choice because of its superior imaging properties and substantially lower radiation dose because it is not a β emitter.^{98,103} ¹²³I MIBG scanning (see Fig. 15.1) can confirm the

catecholamine-producing nature of a tumor, localize tumors not seen with cross-sectional imaging, and potentially identify other sites of disease, although its sensitivity is not that high and therefore its use is limited for this reason, unless considering treatment with ¹³¹I-MIBG for metastatic disease.^{59,69,70,94,104} Before ¹²³I-MIBG scanning, care should be taken to ensure that the patient is not taking medications (e.g., decongestants, calcium-channel blockers, or labetalol) that are known to decrease MIBG uptake, and potassium iodide should be administered to block thyroid uptake of radioactive iodine.^{100,105} Because of the limitations of MIBG testing, the use of other nuclear imaging modalities that incorporate positron-emission tomography (PET) with CT imaging have become more commonplace, especially [18F] fluorodeoxyglucose (FDG) PET/CT and ⁶⁸Ga-DOTATATE PET/CT^{69,92,98,106–109} (see Fig. 15.2). ⁶⁸Ga-DOTATATE PET/CT has become the functional imaging modality of choice, given its specificity for somatostatin receptors commonly found on NETs, such as PHEO/PGL and its superior sensitivity over FDG-PET/CT and ¹²³I-MIBG imaging.^{97,106,108,109}

Genetic Issues

Knowledge regarding the hereditary causes of catecholamine-producing tumors is rapidly expanding.^{8,41,110} The syndromes most commonly associated with pediatric PHEO/PGL are VHL disease, followed by the hereditary PGL/PHEO syndromes, particularly those caused by mutations in *SDHB* (PGL4) and *SDHD* (PGL1), then *NF1* and *MEN2*^{10,11,20–22,31} (see Table 15.1 and separate sections later in the chapter). Additional genes associated with the development of PHEO/

PGL, but with a much lower prevalence, include fumarate hydratase (*FH*)¹¹¹; hypoxia-inducible factor 2 alpha (*HIF2A*, also known as [aka] *EPAS1*)¹¹²; kinesin family member 1B (*KIF1B*)¹¹³; *MEN1*¹¹⁴; MYC associated factor X (*MAX*)¹¹⁵; prolyl hydroxylase domain 1 (*PHD1*, aka *EGLN2*) and 2 (*PHD2*, aka *EGLN1*)^{116,117}; succinate dehydrogenase complex assembly factor 2 (*SDHAF2*)¹¹⁸; succinate dehydrogenase complex, subunit A (*SDHA*)¹¹⁹; succinate dehydrogenase complex, subunit C (*SDHC*)¹²⁰; and transmembrane protein 127 (*TMEM127*)¹²¹. Recently, even more genes have been described as associated with PHEO/PGL and further research is needed to determine causation. These include BRCA1-associated protein-1 (*BAP1*)¹²²; malate dehydrogenase 2 (*MDH2*)¹²³; MER protooncogene, tyrosine kinase (*MERTK*)¹²⁴; MET protooncogene (*MET*)¹²⁴; solute carrier family 25 member 11 (*SLC25A11*)¹⁰¹; and others. Family history, clinical presentation of the patient, and differences in the biochemical phenotype (noradrenergic versus adrenergic) help to prioritize genetic testing,^{39,83} but the availability of next-generation sequencing has led to the development of validated targeted gene panels that are now more commonly used,¹¹⁰ especially when testing an index case.⁸³

Based on genomic analysis, the PHEO/PGL susceptibility genes are now divided into two major clusters: cluster 1 (a pseudohypoxia subtype, subdivided into tricarboxylic acid [TCA] cycle-dependent and *VHL/EPAS1*-dependent) and cluster 2 (a kinase signaling subtype).^{41,111,125} Most pediatric PHEO/PGL will fall into cluster 1 (*SDHx*, *VHL*) instead of cluster 2 (*NF1*, *RET*).^{22,31} PHEO/PGL that arise in the context of *VHL* or the hereditary PGL syndromes (cluster 1) occur at younger ages and are typically noradrenergic tumors, producing almost exclusively norepinephrine and normetanephrine.^{19,22,82,83} Adrenergic tumors (which secrete epinephrine and metanephrine, in addition to norepinephrine and normetanephrine) are seen in cluster 2 (*MEN2*, *NF1*) and sporadic cases.

Management

Surgical Therapy

Surgical resection is the mainstay in the treatment of PHEO/PGL. A preoperative biopsy is not indicated and potentially dangerous.¹²⁶ The procedure of choice for most PHEO is laparoscopic adrenalectomy, either using transperitoneal or retroperitoneal approaches.^{59,127,128} Laparotomy should be contemplated in patients with large PHEO and/or a concern for underlying malignancy based upon the clinical presentation, genetic background, or radiographic appearance of the tumor.^{128,129} In the setting of bilateral PHEO or known hereditary PHEO, a cortical-sparing procedure should be performed to minimize the risk of the life long glucocorticoid and mineralocorticoid replacement and the attendant risks of primary adrenal insufficiency.^{102,129–134} Because it is extremely difficult to preserve a vascularized portion of adrenal cortex sufficient to prevent corticosteroid dependence without also leaving some residual adrenal medulla, there is a risk for recurrent PHEO in the remnant. Recent data suggest that recurrence rates after cortical-sparing surgery are 10% or less.^{102,131,132,135} The surgical approach for removal of a PGL depends upon the location of the tumor, but in selected cases of abdominal disease can also be performed laparoscopically. Head and neck PGL can be expectantly monitored, if small, or treated with surgery or radiation.^{129,136}

It is important that the anesthesiologist have experience with the intraoperative management of PHEO/PGL because

dysrhythmias can occur and blood pressures can be quite labile.^{137,138} Both intravenous antihypertensive medications (e.g., nitroprusside, phentolamine, esmolol, labetalol, etc.) and vasopressors (e.g., phenylephrine and norepinephrine) should be readily available for intraoperative use. The greatest risk for hypertension occurs during anesthesia induction and manipulation of the tumor, whereas hypotension is most likely to occur after ligation of the adrenal vein, when the abrupt decline in catecholamine concentrations leads to vasodilation.¹²⁹ Postoperatively, the patient should be monitored for the two major complications of hypotension and hypoglycemia.^{7,129,137,138} In patients who have had a cortical-sparing adrenalectomy in the context of bilateral PHEO resection, stress glucocorticoids should be provided perioperatively and a high-dose cosyntropin stimulation test obtained to determine the need for ongoing adrenal steroid replacement.

Medical Preparation for Surgery

Once the diagnosis of a PHEO/functioning PGL has been confirmed, medical therapy to normalize the blood pressure and mitigate the signs and symptoms of catecholamine excess should be initiated (Table 15.3). If surgery is planned, medical treatment should be taken for at least 10 to 14 days before surgery to minimize the potential complications that may arise from acute catecholamine surges.^{16,26,59,137} No universal algorithm exists for the medical management of a PHEO/PGL before surgery. For adults, the Endocrine Society guidelines recommend first-line therapy with an α -adrenergic receptor blocker and second-line therapy with a calcium channel blocker.⁵⁹ Limited data exist for children, but small studies suggest these regimens are safe.¹³⁹

Effective α -receptor blockade improves symptoms, lowers blood pressure, and expands the vascular bed and blood volume. Tachycardia without hypotension is a sign of good alpha blockade and should be treated with addition of a β -adrenergic receptor blocker rather than a dose reduction of the alpha blocker. Beta blockers should not be started without good alpha blockade because of the theoretical risk of reflex hypertension from uncontrolled α -adrenergic receptor activity. Phenoxybenzamine is a noncompetitive α -receptor antagonist that has a long half-life; therefore it may also increase the risk of postoperative hypotension.^{7,16,70,140} Selective α 1-receptor blockers, such as prazosin and doxazosin, can also be used.^{16,59,140,141} Although labetalol and carvedilol, drugs with both α - and β -receptor antagonist activity, sound like attractive options for preoperative blockade, they are not recommended for primary medical treatment because of their lower α -adrenergic receptor blockade relative to their β -antagonist activity.^{59,141} Symptomatic postural hypotension may be seen at the beginning of medical therapy, particularly with large biochemically active tumors, so it is imperative to start at low doses and increase the dose and/or frequency every few days, until the blood pressure is normal for age and height and the patient is minimally orthostatic. Phenoxybenzamine is only supplied as a single dose (10-mg capsule) and so it will need to be compounded by the pharmacy to allow for the administration of the lower doses needed in younger children. Phenoxybenzamine is also an expensive drug, which makes the selective α 1-receptor blockers a more attractive option in many cases.

Metyrosine is a competitive inhibitor of tyrosine hydroxylase, the rate-limiting step of catecholamine biosynthesis (see Fig. 15.3) and it can also be used as part of the preoperative preoperative regimen, although data in children are limited.^{141,142} However, not all centers use metyrosine routinely because of its

TABLE 15.3 Preoperative Medical Management of Pheochromocytoma/Sympathetic Paraganglioma

Drug Class	Drug	Mechanism of Action	Initial Pediatric Dose
α-adrenergic receptor blockers	Doxazosin	α ₁ -antagonist	0.5–1 mg daily
	Phenoxybenzamine	α ₁ - and α ₂ -antagonist	0.2–0.25 mg/kg/d divided BID (max 10 mg BID)
	Prazosin	α ₁ -antagonist	0.05–0.1 mg/kg/d divided TID (max 1 mg TID)
β-adrenergic receptor blockers	Atenolol	β ₁ - antagonist	0.5–1 mg/kg/d daily or BID (max 50 mg daily)
	Metoprolol	β ₁ - antagonist	1–2 mg/kg/d divided BID (max 50 mg BID)
Calcium channel blockers	Propranolol	β ₁ - and β ₂ -antagonist	1–2 mg/kg/d divided BID or TID (max 80 mg daily)
	Amlodipine	Calcium channel blocker	0.1 mg/kg/d (<6 years); 2.5–5 mg daily (age ≥6 years)
	Nifedipine (sustained release)	Calcium channel blocker	0.25–0.5 mg/kg/d daily or BID (max 60 mg total daily dose)
Inhibitors of catecholamine synthesis	Metyrosine	Tyrosine hydroxylase inhibitor	125–250 mg QID

BID, Twice per day; *QID*, four times a day; *TID*, three times per day.

cost and potential significant side effects (sedation, diarrhea, and extrapyramidal manifestations) and unclear benefit in most cases.^{39,129} A few days before surgery, oral salt loading (either via increased dietary intake or with sodium chloride tablets) is recommended to expand the blood volume to mitigate postoperative hypotension. Some centers also routinely admit patients for intravenous fluids before PHEO/PGL resection,¹⁴¹ and this can be considered for very symptomatic children with large tumors.

Prognosis and Follow-Up

The long-term prognosis of most children diagnosed with PHEO/PGL is excellent. In all cases, however, there is risk of the development of synchronous and/or metachronous tumors in both adrenal glands, as well as extraadrenal sites. In fact, up to 50% of patients diagnosed with a childhood PHEO/PGL will develop an additional primary tumor in their lifetime (25% at 9 years and 50% at 31 years postdiagnosis),¹¹ underscoring the need for life-long follow-up and appropriate genetic counseling and testing.⁶⁰

Malignancy in PHEO/PGL is defined as the presence of metastases in a site where chromaffin cells and paraganglia are not normally located (primarily bones but also lymph nodes, liver, and/or lungs).^{19,22,30} In fact, the most recent World Health Organization (WHO) guidelines removed the term malignant PHEO/PGL in favor of metastatic PHEO/PGL.⁶ There is no single histologic feature or immunohistochemical profile that is independently able to predict metastatic potential in a resected PHEO/PGL, but histopathologic scoring systems (Pheochromocytoma and the Adrenal Gland Scaled score¹⁴³ and grading system for adrenal PHEO and PGL^{144,145}) have tried to create predictions for features more frequently noted in metastatic tumors. Unfortunately, these scoring systems are limited by a lot of inter- and intraobserver variability.¹⁴⁶ The most reliable features of an increased risk of metastatic potential include extraadrenal location, size greater than 5 cm, and a germline *SDHB* mutation.^{11,55,147,148} The highest risk for malignancy and death in the pediatric population is in *SDHB*-related sympathetic PGL, which represents a majority of metastatic tumors.^{11,19–22,148,149}

Based upon data from a British tumor registry, the incidence of malignant disease in children is estimated to be 0.02 per million per year.¹² Approximately 9% to 16% of pediatric PHEO/PGL become metastatic,^{10,11,13,21} although some referral centers report a much higher malignancy rate (up to 65%) in pediatric PHEO/PGL,^{19,38} likely reflecting a referral bias. On the other hand, the latency period between diagnosis and confirmation of metastatic disease is 9 years on average¹⁹; thus the true rate of malignancy may be higher than previously recognized because it can only be identified during long-term systematic follow-up. Children with metastatic disease typically demonstrate a more indolent clinical course with average overall survival of more than 6 years after the diagnosis of metastatic disease.^{11,19}

Because PHEO/PGL can have unpredictable clinical behavior and because children are at risk for the development of metachronous primary tumors, delayed metastatic disease, and local recurrence, long-term follow-up with biochemical screening and intermittent imaging studies is required for all children with PHEO/PGL.^{11,12,39,60,63} For asymptomatic children with an identified genetic mutation predisposing them to the development of a PHEO/PGL, annual biochemical screening is advised, with the age of initial screening determined by the specific gene mutation (see Table 15.1). Furthermore, occasional cross-sectional imaging, typically MRI because of the lack of radiation exposure, is recommended periodically for follow-up of patients at high risk of recurrence or malignant disease (e.g., abdominal PGLs) or at risk for developing a PHEO/PGL that may not be identified on biochemical testing alone (e.g., the hereditary PGL-PHEO syndromes).

MEDULLARY THYROID CARCINOMA

MTC is a malignant NET that arises from the calcitonin-producing, parafollicular C-cells of the thyroid gland.^{6,150,151} In childhood, MTC comprises 5% or less of thyroid malignancies and has an annual incidence of 0.3 cases/million/year¹⁵²; it is the most common thyroid cancer in patients younger than 5 years of age. In the pediatric population, MTC has a fairly equal female:male ratio,¹⁵³ unlike the differentiated thyroid carcinomas, which are much more frequent in girls than

boys.¹⁵² Pediatric MTC almost always results from an inherited or de novo activating mutation in the *rearranged during transfection* (*RET*) protooncogene^{154–157} and is diagnosed in the context of either MEN2A or MEN2B, depending on the specific mutation.^{2,65,158–161} Because of the close association of MTC with a germline *RET* deoxyribonucleic acid (DNA) variant, genetic testing is recommended in all cases.⁶² Although sporadic nonhereditary tumors account for 70% to 75% of adult MTC cases,^{6,159} such tumors are rare in children. Sporadic MTC is primarily associated with somatic (not germline) mutations in *RET* (specifically the p.M918T mutation) and *RAS*.^{65,159,161}

RET is a member of the cadherin superfamily and encodes a receptor tyrosine kinase that has an extracellular binding domain and an intracellular tyrosine kinase domain (Fig. 15.5). The endogenous ligands (which activate *RET* via a high-affinity ligand-binding coreceptor, GFR α) are members of the glial cell derived neurotrophic factor (GDNF) family, which are involved in the regulation of neural tissue development.¹⁶² The *RET* protein, therefore plays a crucial role in the development of neural crest-derived cells, the urogenital system, and the central and peripheral nervous systems, notably the enteric nervous

system.^{163,164} In MEN2, ligand-independent constitutive activation of the *RET* receptor tyrosine kinase, either as a dimer (because of mutations in the extracellular cysteine-rich domain; MEN2A) or monomer (because of mutations in the intracellular tyrosine kinase domain; MEN2B), stimulates multiple downstream pathways that promote cell growth, proliferation, survival, and differentiation.¹⁶¹

Hereditary MTC is typically multifocal, bilateral, and located in the middle to upper regions of the thyroid lobes (Fig. 15.6), an area where C-cells are the most highly concentrated.^{6,151,165} Microscopic examination and calcitonin staining of the thyroid will often identify C-cell hyperplasia, the initial stage in an oncologic cascade that leads to the development of microscopic noninvasive MTC and ultimately lymph node and distantly metastatic disease because of frankly invasive carcinoma^{2,151,166–168} (see Fig. 15.6). Patients with familial MTC have an age-related progression of malignant disease, with lymph node and distant metastases typically occurring years after the onset of C-cell hyperplasia.^{166,168} The cervical and mediastinal lymph node basins are the most common sites of metastatic disease, whereas distant sites for MTC spread include the lungs, liver, and bone/bone marrow.

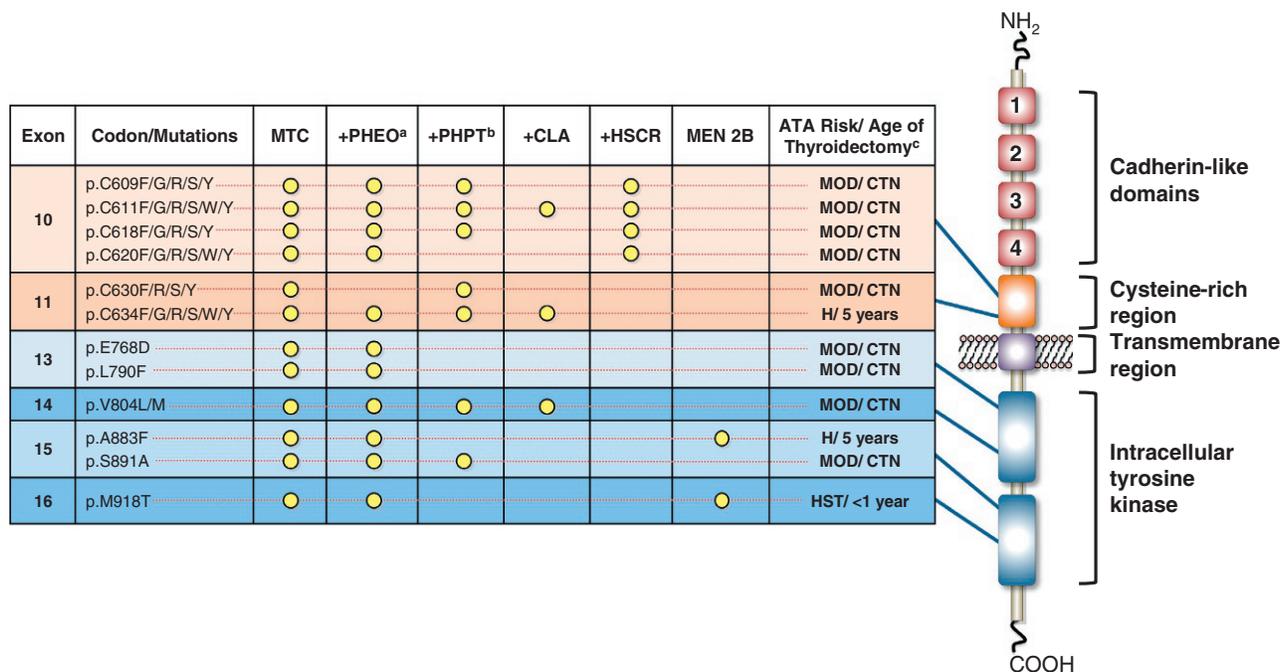

Fig. 15.5 The *RET* receptor tyrosine kinase, commonly mutated *RET* codons, associated MEN2 phenotypes, and the 2015 ATA risk stratification and recommendations regarding the timing of thyroidectomy and prospective screening for other MEN2 manifestations.⁶⁵ ATA, American Thyroid Association; CTN, basal serum calcitonin level; CLA, cutaneous lichen amyloidosis; H, ATA high risk; HSCR, Hirschsprung disease; HST, ATA highest risk; MEN2, multiple endocrine neoplasia Type 2; MOD, ATA moderate risk; MTC, medullary thyroid carcinoma; PHEO, pheochromocytoma; PHPT, primary hyperparathyroidism. ^a Annual screening for PHEO is recommended at age 11 years for mutations in *RET* codons 634, 883, and 918 and at age 16 years for *RET* codons 609, 611, 618, 620, 768, 790, 804, and 891. Patients with mutations not yet known to be associated with PHEO can be screened periodically. ^b Annual screening for PHPT is recommended at age 11 years for mutations in *RET* codon 634 and at age 16 years for *RET* codons 609, 611, 618, 630, 804, and 891. Patients with mutations not yet known to be associated with PHPT can be screened periodically. ^c Age of thyroidectomy is the age by which surgery should be considered for presymptomatic *RET* carriers. The age of testing for the presence of a *RET* mutation should be pursued at an earlier age after appropriate genetic counseling and based upon the family's wishes. CTN denotes that timing of thyroidectomy can be determined by the basal serum calcitonin level, in addition to the preference of the parent/guardian after multidisciplinary input. For a more comprehensive list of *RET* mutations, the reader is referred elsewhere.^{65,327} (Modified from Waguespack, S.G., Rich, T.A., Perrier, N.D., Jimenez, C., Cote, G.J. (2011). Management of medullary thyroid carcinoma and MEN2 syndromes in childhood. *Nat Rev Endocrinol*, 7(10), 596–607.)

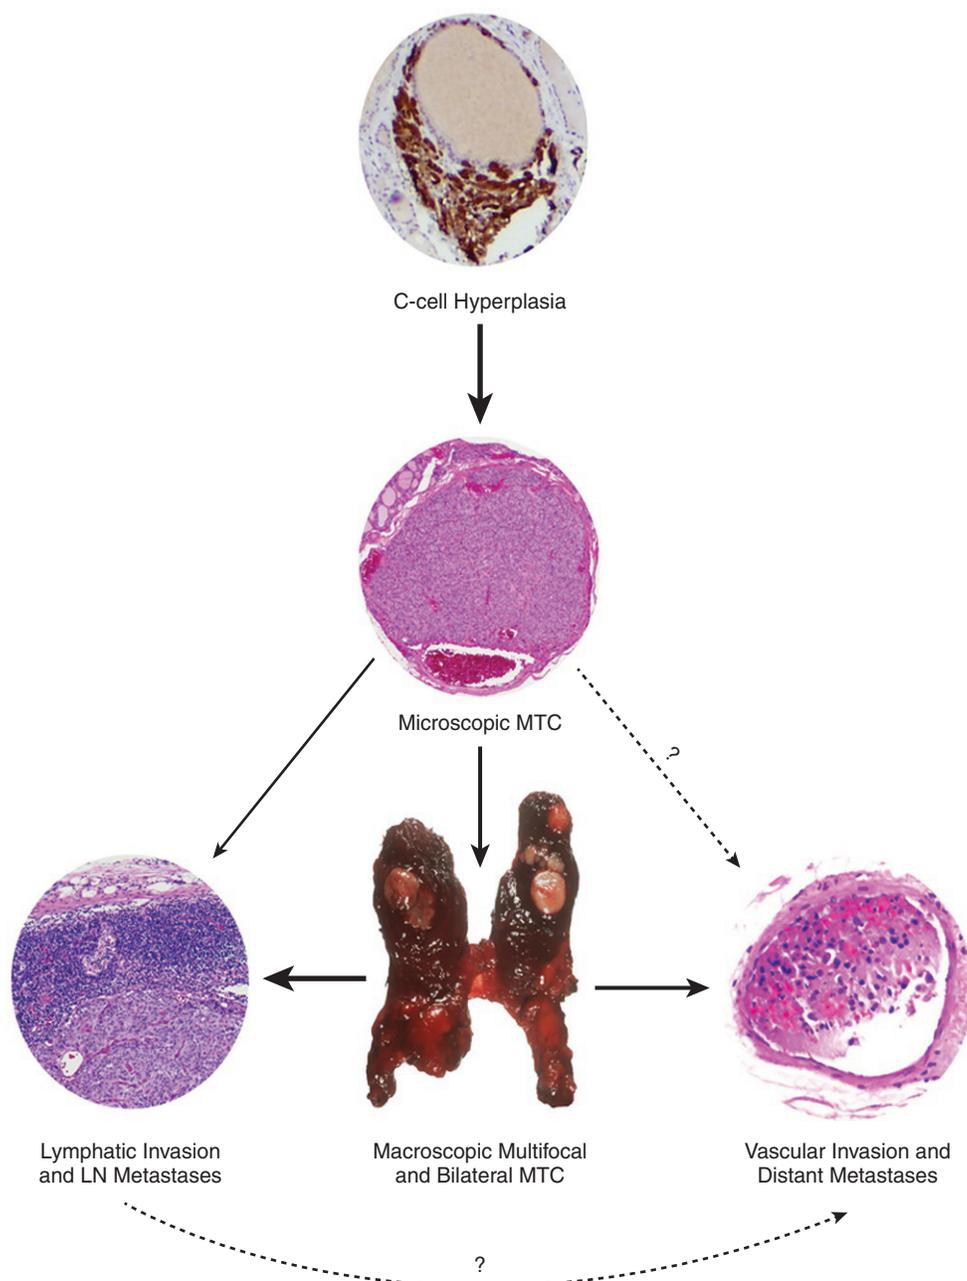

Fig. 15.6 A germline *RET* mutation causes C-cell hyperplasia, the initial stage in an oncologic cascade that ultimately leads to the development of microscopic noninvasive MTC and possibly lymph node and distant metastatic disease caused by frankly invasive carcinoma. The weight of the arrows denotes the hypothetical probability of the event occurring in the typical pediatric patient with a *RET* codon 634 mutation. *LN*, Lymph node; *MTC*, medullary thyroid carcinoma. (From Waguespack, S.G., Rich, T.A., Perrier, N.D., Jimenez, C., Cote, G.J. (2011). Management of medullary thyroid carcinoma and MEN2 syndromes in childhood. *Nat Rev Endocrinol*, 7(10), 596–607.)

Clinical Presentation

Children with sporadic MTC present similar to other thyroid malignancies, typically with a palpable thyroid nodule and/or cervical lymphadenopathy; diarrhea also can rarely be the initial clinical presentation (primarily attributed to extremely high calcitonin levels). On the other hand, children with hereditary disease because of a germline *RET* mutation less frequently present with overt clinical disease, except for MTC associated with MEN2B, which is a diagnosis that remains uniformly delayed.^{169,170} Therefore in the current era, the

predominant presentation of MTC during childhood is one of the presymptomatic identification of a *RET* mutation and the ultimate identification of microscopic MTC after early thyroidectomy.

Evaluation and Management

There are several guidelines and review papers available to assist the clinician in the specific evaluation and management of the child with suspected or proven MTC.^{2,64,65,159,160,171–173} Similar to other pediatric thyroid malignancies, surgery is the

cornerstone of therapy and the only chance for MTC cure. Given the higher surgical complication rates in children¹⁷⁴ and the unique aspects of the medical and surgical care of patients with MTC, treatment should be pursued at tertiary care centers with multidisciplinary, high-volume expertise.^{65,173,175} Apart from the decision of when to intervene, the thyroid surgeon must incorporate knowledge regarding the patient's *RET* genotype and clinical data into the decision-making process to determine the optimal surgical approach.² Meticulous and safe removal of all thyroid tissue, including the posterior capsule, is the goal of a prophylactic/early thyroidectomy for the MEN2 patient without clinical MTC.¹⁷¹ Routine central compartment (level VI) neck dissection is not performed in the setting of a purely prophylactic procedure because lymph node metastases are exceedingly rare in that setting.^{65,166,171,176–179} However, if the operation is for a structurally evident hereditary tumor (especially if the calcitonin level exceeds 40 pg/mL) or for sporadic MTC, total thyroidectomy and a concomitant central neck dissection should be performed.⁶⁵ Dissection of the lateral cervical lymph node compartments (levels IIA–V) is generally performed, only in cases where there is clinical evidence of lateral neck involvement, although some centers base this decision on the preoperative calcitonin level.

Fortunately, life-threatening MTC rarely occurs during childhood and primarily only in the clinical context of MEN2B. In advanced MTC, response rates to traditional cytotoxic chemotherapy (dacarbazine, vincristine, and cyclophosphamide) are low. More recently, two targeted molecular therapies (vandetanib and cabozantinib) that inhibit *RET* and other receptor tyrosine kinases have been approved in adults for the treatment of metastatic MTC.^{159,180} Studies using these drugs in children with MEN2B have suggested comparable efficacy and safety.^{181–183} Novel therapeutics that selectively inhibit the *RET* kinase in tumors with a *RET* mutation or fusion are showing promise in clinical trials that commenced in 2017.¹⁸⁰

Prognosis

Overall, the prognosis of childhood MTC is good, with 5- and 15-year survival rates of 97% and 89%, respectively.¹⁸⁴ In general, positive lymph node status and a higher stage at diagnosis predict lower disease-free survival and higher mortality in MTC.^{153,176,179,185,186} As the tumor stage increases, the risk of both locoregional and distant metastases rises,^{153,187} although lymph node metastases may still occur when the tumor is less than 1 cm in size.^{188,189} Patients with MEN2B have an especially guarded prognosis, with a fifth of patients dying at a median age of 25 years (range <1–59 years), albeit not always caused by MTC.¹³¹

Many children who present with clinical MTC already have metastatic disease at diagnosis. Consequently, the majority of cases of childhood MTC not diagnosed before lymph node metastases occur represent incurable yet indolent cancers. The aggressiveness of the clinical course can be predicted by the specific *RET* mutation (see MEN2 section later), the child's clinical presentation, and by the use of the serologic tumor markers, calcitonin and carcinoembryonic antigen (CEA). The loss of calcitonin expression, a CEA level out of proportion to calcitonin, and a rapid CEA and/or calcitonin doubling time are all harbingers of an aggressive disease course.^{65,173,185,190,191}

HEREDITARY ENDOCRINE NEOPLASIA SYNDROMES

Carney Complex

First described in 1985,¹⁹² the Carney complex (CNC) is a genetically and clinically heterogeneous familial lentiginosis syndrome with autosomal dominant inheritance. It is characterized by blue nevi and/or spotty skin pigmentation affecting the lips, conjunctiva, and other mucosal surfaces (Fig. 15.7); myxomas of the breast, heart, and skin; endocrine tumors and/or

Fig. 15.7 Carney complex and primary pigmented nodular adrenocortical disease (PPNAD). A, A 10-year-old female with adrenocorticotropic hormone (ACTH)-independent Cushing syndrome and the Carney complex demonstrates facial rounding, plethora, and classic facial lentiginosis. B, Gross pathologic specimen of the right adrenal gland in another patient with PPNAD and the Carney complex.

overactivity, classically primary pigmented nodular adrenocortical disease (PPNAD)¹⁹³ and pituitary growth hormone/prolactin hypersecretion; and psammomatous melanotic schwannoma, among other clinical manifestations.^{192,194–196} Two or more distinct genetic loci are associated with CNC: the gene *PRKARIA*^{197,198} on chromosome 17q24.2 and an unknown gene on chromosome 2p16.¹⁹⁹ *PRKARIA* encodes for the RI- α subunit of protein kinase A, the major mediator of intracellular cyclic adenosine monophosphate (cAMP) signaling. Most *PRKARIA* mutations are inactivating point mutations, and about 30% of CNC patients have de novo disease.²⁰⁰ In patients with CNC, the overall *PRKARIA* mutation detection rate is 62%.²⁰⁰

The major endocrine phenotype of the CNC is PPNAD, occurring either alone or with other CNC manifestations, in 60% of cases²⁰⁰; adrenocortical carcinoma also has been rarely reported.²⁰¹ PPNAD is a rare form of ACTH-independent hypercortisolism pathologically associated with multiple small (<1 cm) black or brown nodules (containing lipofuscin) in an otherwise atrophic cortex.^{193,201} (see Fig. 15.7). The median age of onset is 34 years (with about 20% of cases occurring during childhood), and there is a female predominance after puberty.²⁰⁰ The hypercortisolism is typically insidious in its onset, and a pathognomonic finding in PPNAD-related Cushing syndrome is the paradoxical increase in glucocorticoid excretion on the second day of high-dose dexamethasone administration during the Liddle test.²⁰² Adrenal imaging is of limited value for the confirmation of PPNAD because the lesions are small, but it can suggest diffuse micronodular disease on contrast-enhanced CT.^{203,204} The treatment of symptomatic PPNAD is usually bilateral adrenalectomy, although this may not be necessary in all patients.²⁰¹

Growth-hormone hypersecretion (causing gigantism or acromegaly, depending on the age of onset) is the primary pituitary phenotype of the CNC, occurring in 10% to 12% of CNC patients.^{192,200} Pathologically, this may be associated with an adenoma or hyperplasia.^{205–207} Concomitant hyperprolactinemia is prevalent and is similarly caused by underlying hyperplasia or frank adenomas in rare cases.^{205,208} Subtle abnormalities in growth hormone and prolactin secretion may be identified in up to 75% of patients with CNC.²⁰⁶ Corticotroph adenomas have also been described in rare cases.^{207,209} Thyroid neoplasia occurs in 25% of CNC patients with most being benign nodules, although differentiated thyroid carcinoma (both papillary and follicular carcinomas) have been identified in 2.5% of cases.²⁰⁰ Involvement of the thyroid occurs around a median age of 33 years (range 12–57 years) and can be associated with thyrotoxicosis.²¹⁰ Males with CNC are at risk for testicular tumors, primarily bilateral large-cell calcifying Sertoli cell tumors (LCCSCT), clinically identified in 33% to 41% of patients.^{200,206} Similar to the Peutz-Jeghers syndrome (see later), gynecomastia and/or testicular enlargement may be a clinical presentation of LCCSCT,²¹¹ which can be malignant in very rare cases.¹⁹⁵

Once CNC is diagnosed clinically or an asymptomatic child is found to harbor a germline *PRKARIA* mutation, prospective monitoring for the development of the tumors and endocrine disorders characteristic of the syndrome can be undertaken using published recommendations for screening.^{195,196,206}

Familial Isolated Pituitary Adenomas

Hereditary pituitary adenomas can occur as a distinct entity within families who do not have MEN1, and the term *familial isolated pituitary adenomas* (FIPA) was first proposed in 2006.²¹²

FIPA is defined by the occurrence of pituitary adenomas in two or more members of the same family with no other clinical manifestations suggestive of MEN1 or CNC.²¹³ With all hormonal subtypes represented, pituitary tumors occurring within FIPA families present similarly to sporadic pituitary adenomas, and there can be significant intrafamilial clinical heterogeneity.²⁰⁷

AIP-Associated Familial Isolated Pituitary Adenomas

In a subset of FIPA kindreds, the disorder was ultimately identified to be caused by germline mutations in the aryl hydrocarbon receptor-interacting protein (*AIP*) gene (chromosome 11q13.2).^{214,215} Mutations in *AIP* represent only 15% to 30% of FIPA cases and disease penetrance is incomplete, estimated to be less than 30%.^{207,213,216} FIPA individuals with *AIP* mutations have tumors that are larger (overwhelmingly macroadenomas) and diagnosed at a much younger age compared with *AIP*-negative patients.^{215,217,218} Median age of diagnosis is 16 to 23 years and 50% to 60% of cases present during childhood or adolescence.^{217,218} The vast majority of *AIP*-mutated adenomas are somatotroph or mammosomatotroph adenomas, which typically present with gigantism in up to 30% of cases (especially males) and are more recalcitrant to the typical therapies prescribed for gigantism/acromegaly.^{207,213,215,217} In patients younger than age 18 years presenting with an apparently sporadic pituitary macroadenoma, especially a somatotroph adenoma, 20% may harbor a germline *AIP* mutation.²¹⁹ In a large series of pediatric patients with macroprolactinomas, 9% of tested cases were found to have an *AIP* mutation, and these children responded similarly well to a dopamine agonist as sporadic cases.²²⁰

Given the relatively recent characterization of *AIP*-related FIPA, there are no evidence-based consensus guidelines as to the timing of genetic testing for *AIP* mutations in sporadic pituitary adenoma cases or for at-risk members of an affected kindred with an *AIP* mutation. Recommendations for prospective clinical screening in asymptomatic *AIP*-mutation carriers are also not well established, but some experts have proposed an approach to care that includes educating patients about symptoms of pituitary disease and performing an annual hormonal and auxologic evaluation.^{213,216,221} Because of the low clinical penetrance of *AIP* mutations and the high likelihood of functioning pituitary tumors, which most likely would be identified via biochemical testing and review of the growth chart in children, it is unclear if routine screening MRI is indicated.

Hereditary Paraganglioma-Pheochromocytoma Syndromes

Hereditary paraganglioma-pheochromocytoma syndromes (HPS) are characterized primarily by the development of parasympathetic and sympathetic PGL and PHEO.⁴⁰ Five autosomal dominantly inherited HPS syndromes (PGL1-5) have been described (see Table 15.1) and are caused by germline mutations in discrete genes encoding any of the subunits of the succinate dehydrogenase enzyme gene (*SDHA*, *SDHB*, *SDHC*, and *SDHD*) or a protein necessary for the flavination of *SDHA* (*SDHAF2*): PGL1 (*SDHD*),²²² PGL2 (*SDHAF2*),¹¹⁸ PGL3 (*SDHC*),¹²⁰ PGL4 (*SDHB*),²²³ and PGL5 (*SDHA*).¹¹⁹

The *SDHx* genes comprise the subunits for complex II of the mitochondrial respiratory chain that, when mutated, lead to stabilization of hypoxia inducible factor 1 with a subsequent state of pseudohypoxia.²²⁴ The clinical phenotype somewhat

differs among the five syndromes and remains poorly characterized in some cases, such as PGL5 (*SDHA*). As an example, mutations in *SDHD* primarily cause benign parasympathetic head and neck PGL (also referred to as *glomus tumors* or *chemodectomas*), whereas mutations in *SDHB* are associated more with abdominal PGL and a higher risk of malignancy (see Table 15.1 and Fig. 15.2). In all cases, penetrance of the clinical phenotype is less than 100% and increases with age.^{28,40,55,225–228} Mutations in *SDHD* (and also *SDHAF2*) demonstrate parent-of-origin effects, with disease occurring only when the mutation is inherited from the father,^{40,229} although recent reports of PHEO/PGL development in individuals with maternal inheritance of an *SDHD* mutation have been published.²³⁰ Besides PGL and PHEO, *SDHx*-related tumors include gastrointestinal stromal tumors (GIST), a finding that has also been denoted the Carney-Stratakis syndrome or dyad.²³¹ Other nonparanglial neoplasms attributed to an *SDHx* mutation include clear cell renal cell carcinoma, pituitary adenomas, and other NETs.^{28,40,207,225,232,233} The association of PHEO/PGL and pituitary adenoma occurring in the context of a germline *SDHx* mutation has been named the “3PAs.”²³⁴ The optimal screening program for children with HPS (see Table 15.1) remains poorly defined but generally includes annual physical examination/blood pressure monitoring, annual plasma or urine metanephrines, and biennial whole body MRI.^{55,63,235} Similar to presymptomatic screening in other tumor-predisposition syndromes, MRI is the preferred imaging modality in HPS.²³⁶

Hyperparathyroidism-Jaw Tumor Syndrome

The hyperparathyroidism-jaw tumor (HPT-JT) syndrome is a heritable disorder with incomplete penetrance characterized by parathyroid neoplasia/primary hyperparathyroidism (PHPT) associated with ossifying fibromas of the maxilla and/or mandible. First reported in 2002, *CDC73* (chromosome 1q31.2; formerly known as *HRPT2*) is the only known gene in which mutations cause HPT-JT syndrome, and *CDC73* mutations are identified in about 60% of HPT-JT syndrome kindreds.²³⁷ PHPT caused by a single benign parathyroid adenoma is the most common clinical manifestation, but parathyroid carcinomas are prevalent, representing 10% to 15% of cases.²³⁸ The youngest age of diagnosis of PHPT has been age 7 years.²³⁹ Ossifying fibromas, also known as *cementoossifying fibromas*, can be locally aggressive and occur in 30% to 40% of individuals with HPT-JT syndrome²³⁸; they are chiefly treated with surgical extirpation. Other clinical manifestations of the HPT-JT syndrome include renal lesions (cysts, hamartomas, and nephroblastoma [Wilms tumor]) and uterine tumors.^{240,241} Prospective clinical monitoring of asymptomatic individuals with a *CDC73* mutation is recommended (starting at age 5–10 years) and includes annual biochemistries to assess for PHPT and imaging (panoramic dental x-ray and renal US) every 5 years; female adolescents of reproductive age should get a pelvic US if any abnormal uterine bleeding occurs.^{64,238}

Multiple Endocrine Neoplasia Type 1

MEN1 is an inherited tumor syndrome characterized by glandular hyperplasia and benign or malignant neoplasms occurring in two or more endocrine glands, classically the parathyroids, pituitary, and neuroendocrine pancreas^{242–247} (Table 15.4). MEN1 tumors can be hormonally active or nonfunctioning and multifocality is common, except for pituitary tumors. Patients are also at risk for developing adrenocortical tumors (ACTs), PHEO, extraabdominal NETs (thymus

and bronchopulmonary), benign tumors of the skin (angiofibromas, collagenomas, lipomas), central nervous system (CNS) tumors (meningiomas and ependymomas), and/or uterine leiomyomas.^{114,242,246–250} Breast cancer risk in women with MEN1 may be heightened.²⁵¹

The hereditary nature of multiple endocrine adenomas and the link to a monogenic disorder was first proposed by Wermer in 1954.^{247,252} The precise genetic cause of the syndrome was identified and confirmed in 1997.^{253–256} The *MEN1* gene is a tumor suppressor gene that encodes a ubiquitous nuclear protein (menin), which plays a role in transcriptional regulation, genome stability, cell division, and proliferation.^{245,257,258} Most patients with MEN1 inherit the mutation from an affected parent, but about 10% of individuals with MEN1 represent de novo disease;^{255,257,259} about one-quarter of patients younger than age 21 years will represent index cases.^{249,260}

MEN1 represents a prime example of the “two-hit” mechanism of disease (Fig. 15.8), which was first described by Knudson in hereditary retinoblastoma²⁶¹ and is applicable to any disease caused by inactivating mutations of a tumor suppressor gene. An inherited heterozygous germline *MEN1* mutation is insufficient to induce tumor formation. Consequently, a somatic mutation (the second hit) in the wild-type *MEN1* allele is required to cause disease. This second hit usually deletes the only normally functioning *MEN1* gene, leading to a loss of heterozygosity at the *MEN1* locus in tumor DNA and attenuating the ordinary constraints by menin on cell growth. More than 90% of tumors from MEN1 patients have loss of heterozygosity caused by a subchromosomal rearrangement or deletion of the entire chromosome; other mechanisms for the second hit include point mutations and small insertions/deletions within the wild-type *MEN1* gene.^{244,245,257} To date, there have been several hundred unique germline mutations of the *MEN1* gene characterized, and these occur via multiple mechanisms and are distributed throughout the *MEN1* gene without hot spots.^{258,262} Testing by direct DNA sequencing identifies most *MEN1* mutations, but approximately 5% to 10% of people with MEN1 do not have a mutation in the coding region or splicing sites of *MEN1*.²⁵⁷ Such patients may represent a phenocopy (see section on MEN4) or they may harbor a mutation in untranslated regions or introns or a large gene deletion, the latter of which requires other technologies, such as multiplex ligation-dependent probe amplification (MLPA) to detect.²⁵⁸

Clinical Presentation and Management

Most children will be diagnosed with MEN1 after the identification of a germline *MEN1* mutation, as a result of cascade genetic testing in a known MEN1 family.²⁶³ The clinical presentation of MEN1-related disease is highly variable, even among members of the same kindred, and will depend on the location and functionality of the underlying tumor(s). Not surprisingly, functional tumors typically present 5 to 10 years earlier than nonsecretory neoplasms.²⁶⁴ Despite the variable expressivity, there is almost complete penetrance of the phenotype, such that MEN1 clinical and biochemical manifestations will generally develop in 80% and more than 98% of patients, respectively, by the fifth decade of life.^{243,248,259,264} Penetrance of the clinical phenotype in children with MEN1 has been previously estimated to be less than 1% before age 5 years, 7% by age 10 years, 28% by age 15 years, and 52% by age 20 years²⁵⁹ (Fig. 15.9). Most of the more recent studies found similar high penetrance in childhood. In two studies, 73% to 78% of patients younger than age 21 years had at least one MEN1

TABLE 15.4 Earliest Clinical Manifestations and Suggested Biochemical/Imaging Screening Protocol for Neuroendocrine and Adrenocortical Tumors in Children with Multiple Endocrine Neoplasia 1^a

Tumor	Earliest Age of Diagnosis (Years) With Reference	Age to Begin Screening (Years)	Clinical Signs/Symptoms of Disease	Biochemical ^b and Imaging Tests Used for Screening Asymptomatic Patients	
Pituitary	5 ^{c,460}	5–10	No symptoms, headaches, visual loss, abnormal linear growth, delayed puberty, galactorrhea, menstrual irregularity	Prolactin, IGF-1	Pituitary MRI (start at 15 years and then every 3 years)
Parathyroid	4 ^{d,249} 8 ^{e,249}	5–10	No symptoms, nephrolithiasis, polyuria, difficulty concentrating, fatigue, poor appetite, abdominal pain, constipation	Total calcium, intact PTH	No routine imaging indicated
Thymic	16 ²⁷⁷	15	No symptoms, chest/shoulder pain, cough, dyspnea, wheezing, hemoptysis	No routine biochemical testing (unless lesion or clinical syndrome identified)	Chest MRI (start at 15 years and then every 3 years)
Bronchial	15 ²⁶⁵				
Gastric	NA	NA	No symptoms	No routine biochemical testing	No routine imaging
Duodenal/pancreatic					
-Insulinoma	5 ²⁴⁹	5	Confusion, loss of consciousness, neuroglycopenic symptoms, weakness, seizures	Glucose, insulin	No routine imaging (only once diagnosis made)
-Gastrinoma	7 ²⁴⁹	15	Peptic ulcer disease, dyspepsia, abdominal pain, diarrhea	Gastrin ^f	No routine imaging (will typically not identify duodenal tumors)
-Nonfunctional	12 ⁴⁶¹	15	No symptoms	Chromogranin A, pancreatic polypeptide ^g	Abdominal MRI (start at age 15 years and then every 3 years) or endoscopic ultrasound
-Other functional	NA	NA	Diabetes, skin rash, weight loss, stomatitis, anemia (glucagonoma) Watery diarrhea, hypokalemia, achlorhydria (VIPoma)	No routine biochemical testing	No routine imaging
Adrenocortical	3 ²⁴⁹	15	Virilization (primary sign), Cushing syndrome, hypertension, abdominal/back pain	No routine biochemical testing (unless lesion or clinical syndrome identified)	Abdominal MRI (done in conjunction with screening for pancreatic NETs)

IGF-1, Insulin-like growth factor 1; MEN, multiple endocrine neoplasia; MRI, magnetic resonance imaging; NETs, neuroendocrine tumors; PTH, parathyroid hormone; PHPT, primary hyperparathyroidism.

^aData from consensus guidelines and other relevant publications.^{64,246,249,262,265,289,293,312} The age to start and the frequency of radiologic screening is not an absolute and should be tailored to patient symptoms and whether or not they already have clinical manifestations of MEN1. In current practice, the authors typically start clinical and biochemical screening at age 5 years and imaging in asymptomatic patients around age 15 years.

^bScreening laboratories should always be done after an overnight fast.

^cThis patient had a mammosomatotroph tumor, cosecreting prolactin and growth hormone.

^dBiochemical PHPT only.

^eSymptomatic PHPT.

^fGastrin levels will be elevated in patients taking a proton-pump inhibitor, which should be stopped at least 7 days before testing.

^gThese tests have a low diagnostic accuracy but, if significantly elevated, should prompt imaging.

clinical manifestation.^{249,260} In another series, 54.5% of children monitored using a specific screening program developed at least one clinical manifestation of MEN1 by a median age of 22.5 years (range 12–31 years), 83% of whom were clinically asymptomatic.²⁶³ However, another study documented a much lower penetrance (12%) of the MEN1 clinical phenotype before the age of 19 years.²⁶⁵ In contrast with MEN2, as discussed subsequently, there are no clear genotype-phenotype correlations in MEN1, so a provider cannot rely on the specific mutation or family history to predict the age of onset, severity, or type of clinical manifestation.^{245,259,264}

In the absence of treatment, MEN1-associated endocrine tumors are associated with higher mortality (50% probability of death by the age of 50 years.), and the cause of death in 50% to 70% of patients with MEN1 is usually a malignant tumor process or sequela of the disease.^{246,266,267} Currently, the greatest risk of mortality in MEN1 is chiefly from malignant duodenopancreatic and thymic NETs.^{246,249,264,266}

The specific management of each MEN1-associated endocrine neoplasm is generally similar to that for the respective sporadic tumors occurring in patients without MEN1, with notable exceptions for the parathyroid and pancreas (see later).

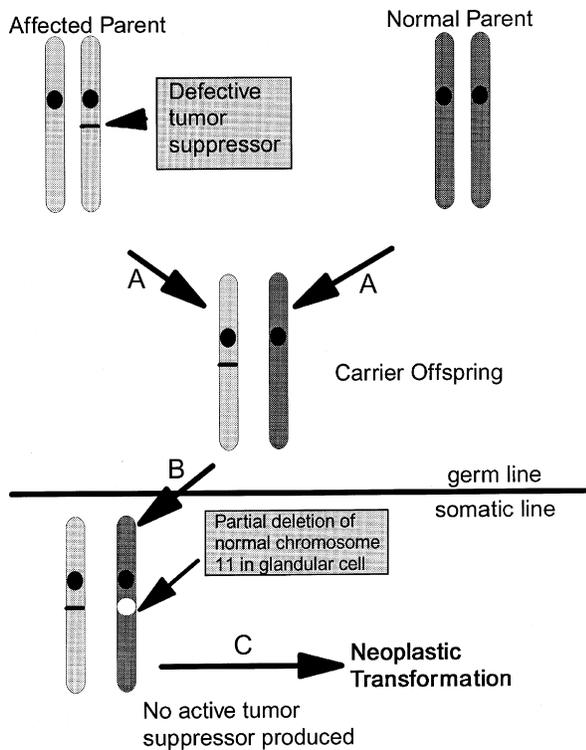

Fig. 15.8 “Two-hit” theory of tumorigenesis as exemplified by multiple endocrine neoplasia (MEN)1. A, An affected parent passes a mutated *MEN1* gene to an offspring, who inherits a normal (wild-type) gene from the other parent. B, Loss of heterozygosity in a somatic cell (a “second hit” that typically occurs via a subchromosomal rearrangement or deletion of the entire chromosome) disrupts the function of the remaining normal *MEN1* allele. C, The absence of menin tumor suppressor activity in a cell then leads to tumor formation.

This section will therefore focus more on the unique aspects of these disorders as they relate to MEN1 in children. As with most hereditary tumor syndromes, patients with MEN1 and their families should be managed by a multidisciplinary team consisting of relevant specialists with experience in the management of endocrine tumors.^{246,247}

Primary Hyperparathyroidism

PHPT is the most prevalent and earliest endocrine manifestation of MEN1.^{248,249,264} It is diagnosed in 75% to 91% of cases of MEN1 patients with clinical manifestations before age 21 years, with or without other MEN1 manifestations; most diagnoses are made after 10 years of age.^{248,249,263,265} MEN1 patients have multigland parathyroid hyperplasia rather than single gland adenomas. The majority of children with MEN1-related PHPT are asymptomatic, and nephrolithiasis is the major presenting sign of symptomatic disease.^{249,263}

The diagnosis of PHPT is based on an elevated serum calcium level in the setting of an inappropriately normal or frankly elevated PTH level; at times, the PTH can be elevated with a normal calcium level.²⁶³ Given the multifocal parathyroid hyperplasia in MEN1 patients, preoperative imaging is generally not beneficial.^{251,268} However, in the case of reoperation, localization studies, such as technetium (^{99m}Tc) sestamibi scan (typically with concomitant single-photon emission CT [SPECT] imaging), US, contrast-enhanced CT, four-dimensional (4D)-CT, or less commonly MRI can be helpful for surgical planning.^{269–271}

Surgical removal of the hyperfunctioning parathyroid glands is the definitive treatment of PHPT in MEN1 patients,

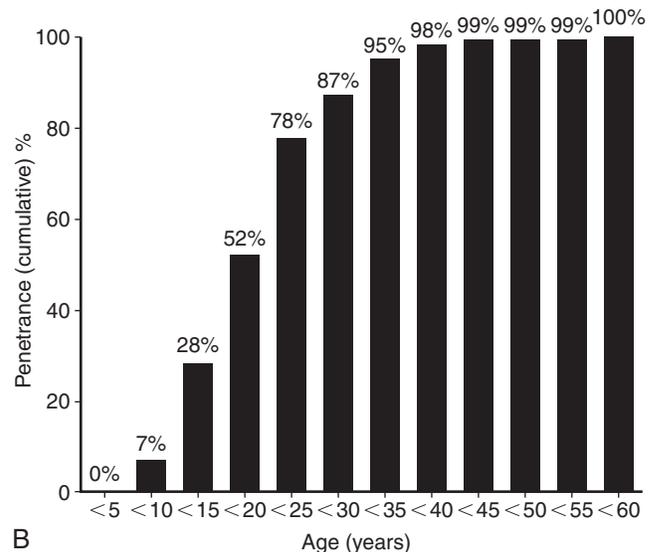

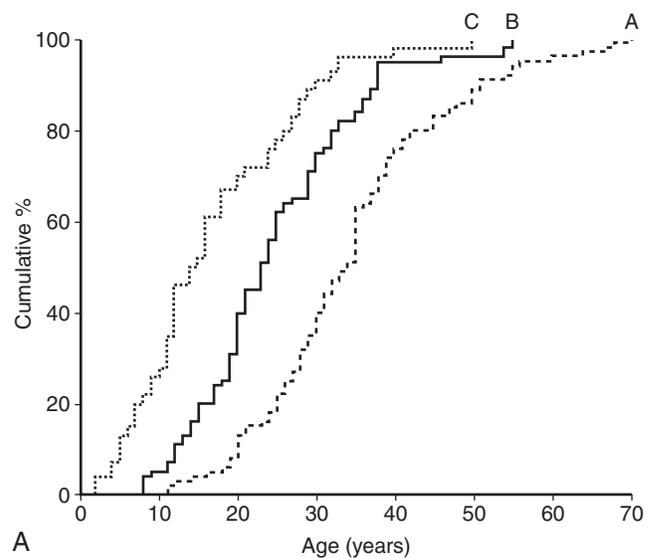

Fig. 15.9 Penetrance of the multiple endocrine neoplasia (MEN)1 phenotype. Age distributions (A) and age-related penetrance (B) of MEN1 clinical manifestations in 201 carriers of a mutated *MEN1* gene. Group A patients presented with clinical symptoms at the age depicted. Group B patients were asymptomatic but had positive biochemical screening at the age depicted. Group C patients were asymptomatic with negative biochemical screening with the age of their last biochemical testing shown. Patients in Groups B and C were significantly younger than Group A ($P < .001$). The age-related penetrance (B) is the proportion of mutation carriers who have developed a clinical manifestation by a given age. (From Bassett, J.H., Forbes, S.A., Pannett, A.A., et al. (1998). Characterization of mutations in patients with multiple endocrine neoplasia type 1. *Am J Hum Genet*, 62(2), 232–244).

but the surgical approach remains controversial.^{242,272} Subtotal (3.5 gland) parathyroidectomy with transcervical thymectomy or total (four gland) parathyroidectomy with transcervical thymectomy and parathyroid autotransplantation to the nondominant forearm are the primary options for surgical therapy. Resection of less than three glands results in the highest risk of persistent and recurrent disease (odds ratio [OR], 3.11; 95% confidence interval [CI] = 2.00–4.84).^{273,274} Although the risk for persistent or recurrent HPT is not significantly different between a subtotal versus total procedure,

the risk for permanent hypoparathyroidism is significantly lower with subtotal parathyroidectomy,²⁷³ which makes this the preferred approach.^{246,272} However, some studies have shown equivalent outcomes between the two procedures in young patients.²⁷⁵ In patients operated for PHPT before age 21 years, 67% remain normocalcemic at last follow-up, whereas 22% have persistent hypercalcemia and 11% have hypoparathyroidism.²⁴⁹ At the initial surgery, concomitant transcervical thymectomy is recommended to remove any potential ectopic parathyroid glands and to prophylactically remove the bulk of the thymus, which is at risk for the development of a thymic NET.^{246,273,274,276,277}

Surgical indications for asymptomatic PHPT in children with MEN1 remain poorly developed, and the risk of permanent hypoparathyroidism must be balanced against the risks of PHPT. In addition to the calcium level, factors, such as surgical experience, patient or parent preference, and availability of long-term monitoring of calcium levels, should be considered in the timing of surgery.²⁴⁶ In select MEN1 patients with PHPT for whom surgery is not feasible, medical treatment with the calcimimetic agent, cinacalcet, can be considered.^{251,263,278}

Pituitary Adenomas

Pituitary tumors are the second most common clinical manifestation in children, occurring in 29% to 55% of MEN1 patients with penetrance of the MEN1 phenotype younger than 21 years of age, a little over half of whom will be symptomatic.^{207,248,249,263,265} Diagnosis before age 10 years is unlikely. Similar to adults, prolactinomas are the most prevalent, although all subtypes of pituitary adenomas have been reported.^{248,249,263,265,279–281}

In MEN1, there does seem to be a higher prevalence of pituitary adenomas in females, a higher rate of invasiveness and macroadenomas (especially in males), and more pluripotent tumors.^{249,279,281–285} Hypersecreting MEN1-related pituitary tumors may be more resistant to standard medical therapies,^{220,279,281,282} although other data suggest that medical treatment is equally effective compared with the general population.²⁵¹ There is no increased risk of death from having an MEN1-associated pituitary tumor,^{266,282} although one case of pituitary carcinoma occurring in the context of MEN1 has been published.²⁸⁰

Duodenopancreatic Neuroendocrine Tumors

NETs that arise from the neuroendocrine cells of the duodenum and pancreas represent the third most common clinical manifestation of MEN1 in children, reported to be present in 9% to 42% of all patients with MEN1 manifestations occurring before age 21 years.^{248,249,260,263,265} These gastrointestinal (GI) NETs can often be multifocal in the setting of MEN1. Gastrinomas primarily occur in the duodenum (within the so-called *gastrinoma triangle*), whereas other hormonally active tumors arise from the pancreatic islet cells at various locations throughout the pancreas.^{6,128,246,284} Furthermore, pancreatic NETs can ectopically secrete growth hormone–releasing hormone and ACTH.^{285,286} Nonfunctioning pancreatic NETs by definition are not associated with clinical symptoms from hormonal hypersecretion and thus are diagnosed via routine imaging.²⁴⁹ Such tumors can overproduce clinically silent hormones, such as pancreatic polypeptide and chromogranin A,^{6,287,288} although these serologic markers have a low diagnostic accuracy.^{289,290}

Because NETs can be small and grow slowly, localization can be challenging and often multiple techniques may need to be used.^{289,291,292} Guidelines recommend multiphasic CT,

MRI, and/or endoscopic ultrasound (EUS) for the evaluation of pancreatic NETs.^{128,246,287,293} EUS affords the highest diagnostic sensitivity, especially with smaller tumors,^{251,260,289} but this improved sensitivity may not change management because small tumors less than 2 cm in size are typically monitored in the absence of symptomatic hormonal hypersecretion.²⁹³ NETs generally express somatostatin receptors. Thus somatostatin receptor scintigraphy, especially ⁶⁸Ga-DOTATATE PET/CT, also plays an important role in the management of pancreatic NETs, especially in the identification of metastatic disease.^{128,287,289,291,294} FDG-PET is not routinely recommended because of the low proliferation rate of these neoplasms, but poorly differentiated tumors can be localized with FDG-PET.^{128,287} A diagnosis of a malignant NET would be extraordinarily rare in childhood. Guidelines regarding the diagnosis and management of NETs are available.^{128,250,287}

Insulinoma. Insulinomas are the most frequent functioning pancreatic NET in children with MEN1, having been reported to account for 54% to 78% of pancreatic NETs in large published series and diagnosed in 12% to 25% of all patients with MEN1 manifestations that occur at younger than age 21 years.^{248,249,265} Patients present with hypoglycemic symptoms that improve with glucose intake, thus fulfilling Whipple's triad. Two main symptoms attributed to hypoglycemia include loss of consciousness or coma (55%) and weakness (45%), associated with seizures in some cases.²⁴⁹ The gold standard diagnostic test is a 72-hour fast. The diagnosis is established if the serum glucose is less than 55 mg/dL with a concomitant insulin of 3 μ U/mL or higher by immunochromiluminescent assay (ICMA), c-peptide of 0.2 nmol/L or higher, and no detectable oral hypoglycemic in the blood.²⁹⁵ One-third of insulinoma patients will develop hypoglycemia at 12 hours, 80% at 24 hours, 90% at 48 hours, and 100% by 72 hours.²⁹⁶ Because medical treatment with frequent carbohydrate meals, diazoxide, and/or somatostatin analogs is not always successful, surgery is considered the standard of care.^{128,296} In contrast with other functioning NETs, insulinomas have a lower malignant potential.²⁹⁷

Gastrinoma. Gastrinomas occur primarily in the duodenum and are usually multiple, small (<1 cm) tumors that result in elevated gastric acid production and recurrent peptic ulcer disease, referred to as the *Zollinger-Ellison syndrome* (ZES).^{246,293} Other symptoms can include diarrhea and steatorrhea. They are the most common functional tumor in adults with MEN1.²⁴⁸ Exceedingly rare during childhood and occurring in 0% to 7% of patients (0% to 22% of pancreatic NETs) in series that include children,^{248,249,260,263,265} gastrinomas are usually diagnosed during the second decade of life in pediatric patients.

The diagnosis is established by an increased serum fasting gastrin concentration (often \geq 1000 pg/mL) and elevated basal gastric acid secretion (gastric pH < 2).^{6,287,298,299} Patients with borderline hypergastrinemia should be considered for the secretin stimulation test; after a 2-U/kg intravenous bolus,³⁰⁰ a rise in gastrin of 120 pg/mL or more from baseline affords the highest diagnostic sensitivity and specificity.³⁰¹ False positive elevations of gastrin can occur because of use of proton-pump inhibitors or antacids, conditions of autoimmune chronic atrophic gastritis with achlorhydria, and/or chronic renal insufficiency.^{302,303} Patients should therefore be off proton-pump inhibitors for at least 1 week before testing, but this may not be possible in highly symptomatic patients.^{287,299} Hypercalcemia can also stimulate gastrin secretion.²⁹⁹

Medical therapy with a potent oral proton-pump inhibitor is the primary treatment of gastrinoma in MEN1 patients.^{246,293}

Some patients may also require the addition of an H₂ receptor antagonist. The role of surgery in treating MEN1 patients with gastrinoma is controversial. Tumors are generally multiple and in the duodenum, so cure is less likely, unless extensive surgery is undertaken. If surgery is performed, both duodenal inspection and lymph node dissection are required.²⁸⁴ For pancreatic gastrinomas or lesions larger than 2 cm, surgery should be considered to reduce the risk of lymph node or hepatic metastasis.²⁹³

Other Functional Pancreatic Neuroendocrine Tumors.

Glucagonomas secrete glucagon and have not been previously described in children with MEN1, outside of a single case of an apparently silent glucagonoma.²⁶³ The classic glucagonoma syndrome is characterized by a skin rash in the groin and extremities (called *necrolytic migratory erythema*) in 70% of patients, mild diabetes mellitus in 87%, weight loss in almost all patients, stomatitis, and anemia.^{288,293}

VIPomas, which also have not been reported during childhood, are very rare tumors that secrete vasoactive intestinal peptide (VIP) and are associated with the Verner-Morrison syndrome of watery diarrhea, hypokalemia, and achlorhydria (i.e., pancreatic cholera).^{288,293}

Nonfunctioning Pancreatic Neuroendocrine Tumors. In children with MEN1, nonfunctioning pancreatic NETs represent the second most common NET arising in the duodenum/pancreas (40% of pancreatic NETs; 9% of all cases) and are identified via imaging alone.²⁴⁹ With improved screening methods, they have been identified in 42% of adolescents subjected to testing and represented 75% of pancreatic NETs,²⁶⁰ and so their true penetrance may be underestimated in older studies that primarily include functional, and thus symptomatic, tumors. Epidemiologic studies have shown that 27% of patients with nonfunctioning pancreatic NETs measuring 2.1 to 3.0 cm have metastasis compared with 11% of those 2 cm or less.³⁰⁴ More importantly, nonfunctioning tumors are now understood to confer an increased risk of death in MEN1 patients, comparable with thymic NETs and functioning pancreatic NETs, except insulinomas.^{266,267} Although controversies remain as to the indications for surgical therapy, general consensus is that tumors 2 cm (or larger) or tumors that demonstrate a relatively rapid rate of growth should be considered for resection.^{128,246,247,293,305}

Other Clinical Manifestations

Thymic, Bronchial and Gastric Neuroendocrine Tumors. In MEN1, NETs also occur outside of the duodenum and pancreas and can be found in the thymus, bronchopulmonary system, and stomach. Historically referred to as *carcinoid tumors*, the preferred term is *NET*.^{6,128} The diagnosis of such tumors almost universally occurs in adulthood, but one case of a malignant thymic NET has been reported in a 16-year-old MEN1 patient,^{249,277} and a bronchial NET has been found in a 15-year-old girl.²⁶⁵

Thymic NETs are more prevalent in smokers and males (male/female ratio 20:1), whereas bronchial NETs are more prevalent in women (male/female ratio 1:4).^{306,307} Bronchial NETs behave more indolently compared with thymic tumors, which impart a significant increased risk for death in MEN1 patients.²⁶⁶ Thymic NETs can still develop despite previous prophylactic transcervical thymectomy,^{251,277} presumably because the entire thymus is not removed via a cervical approach, underscoring the importance of continuing prospective screening even if thymectomy has already been performed. Thymic and

bronchial NETs can ectopically secrete growth hormone–releasing hormone and ACTH.^{277,285,286}

Gastric NETs are well-differentiated tumors with malignant potential that arise from the enterochromaffin-like cells of the stomach mucosa.³⁰⁸ Type II gastric NETs are those that occur in MEN1, developing secondary to chronic hypergastrinemia in the setting of gastrinoma/ZES.³⁰⁹ Given the rarity of gastrinoma in childhood, type II gastric NETs have not been reported in a pediatric patient.

Adrenocortical Tumors. Unilateral and bilateral ACTs are reported in 10% to 26% of MEN1 patients, with a mean age at diagnosis of an adrenal lesion of around 45 years of age^{310,311}; in children with clinical MEN1 younger than age 21 years, the prevalence ranges from 0% to 4%.^{248,249,263,265} Adrenocortical hyperplasia, adenomas, and adrenocortical carcinoma are the types of adrenal lesions seen; PHEO has also been reported in adults with MEN1. Most ACTs are nonfunctioning, and functioning tumors primarily present with hypersecretion of aldosterone or cortisol, although hyperandrogenism/virilization is seen in children.^{249,310} In the large MEN1 series published by Goudet et al. and in the study by Gatta-Cherifi and colleagues, all cases of ACT arising in childhood before age 20 years presented with hyperandrogenism and were classified as malignant.^{249,310}

Cutaneous Manifestations. Often underappreciated as a component of the MEN1 phenotype, skin manifestations (Fig. 15.10) include angiofibromas, collagenomas, and lipomas.¹⁹⁴ More commonly identified in older MEN1 patients, the dermatologic manifestations can also be found in children, even as an initial manifestation of disease.²⁶³ Angiofibromas are benign tumors of blood vessels and connective tissue, similar to those seen in tuberous sclerosis. They present as pink to tan, dome-shaped papules that occur on the face, especially the nose. Collagenomas are well-defined, skin-colored cutaneous papules that have a predilection for the neck and trunk. The prevalence rates of angiofibromas, collagenomas, and lipomas in MEN1 patients are 64% to 88%, 63% to 72%, and 3% to 34%, respectively.¹⁹⁴ In general, MEN1-related skin lesions do not require treatment, although lipomas can grow quite large and may need to be resected because of local symptoms.

Genetic Testing and Presymptomatic Screening

An integrated program of both genetic counseling/testing of at-risk individuals and clinical screening of MEN1 mutation carriers is undertaken with the assumption that an earlier diagnosis and treatment may help to reduce morbidity and mortality. Guidelines for the care of MEN1 patients based on systematic reviews of the medical literature and developed by experts in the field were introduced in 2001 and updated in 2012.^{243,246} Subsequent publications have proposed alterations to the 2012 screening guidelines, especially as relate to nonfunctioning pancreatic NETs.^{64,249,265,289,293,312}

At the present time, there is no specific therapy that will prevent a MEN1-associated disease nor are any prophylactic therapies warranted. In addition, an earlier identification of asymptomatic disease may potentially lead to premature and unnecessary treatment that may in fact have a negative long-term impact. Thus the goal of screening in MEN1 is primarily to detect a clinical manifestation at an earlier stage, specifically so that treatment can be rendered before malignancy develops in high-risk organs or serious ramifications from hormone hypersecretion occur. Because of the long latency for disease manifestations, many unaffected individuals will potentially

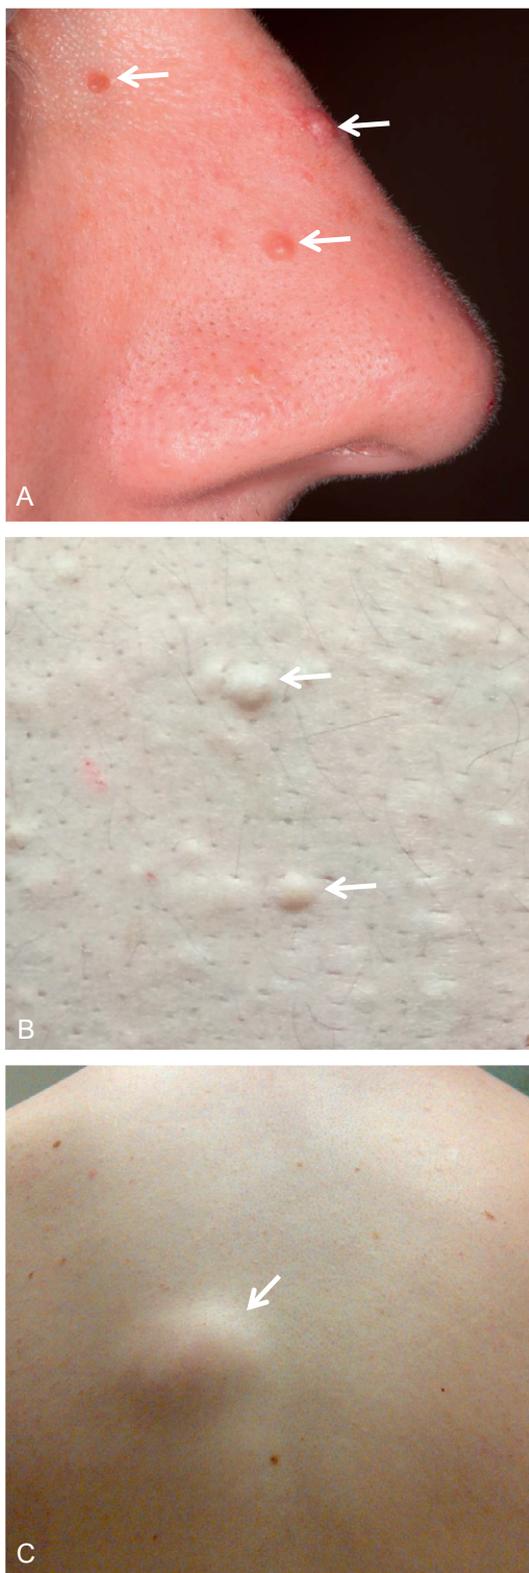

Fig. 15.10 Dermatologic manifestations of multiple endocrine neoplasia (MEN)1. Angiofibromas (A), collagenomas (B), and lipomas (C) are more commonly identified in adult MEN1 patients, but they can also develop in children, even as an initial manifestation of disease. Angiofibromas are telangiectatic papules characterized by fibrous tissue and vascular proliferation and distributed primarily on the nose and adjacent cheeks. Collagenomas are cutaneous stromal lesions that represent areas of excess collagen and tend to occur on the upper torso, neck, and shoulders. Lipomas are benign neoplasms that contain mature fat cells enclosed by thin fibrous capsules.

undergo years of episodic testing, which may have psychosocial and financial consequences,⁵ and this must be kept in mind as a prospective screening program is planned for any given MEN1 patient. In all cases, patient/parent preference, risks of screening, local resources, and clinical judgment should be considered when prospectively monitoring a patient with MEN1.

MEN1 germline mutation testing should be offered to all index patients and first-degree relatives of those individuals with a known MEN1 mutation, regardless of symptomatology.²⁴⁶ Because relevant MEN1 disease has been diagnosed in children as young as 5 years of age (see Table 15.4), current practice is to offer testing at the earliest opportunity, but only after comprehensive genetic counseling so that patients and families with MEN1 receive the medical and genetic information they require.⁵

Subsequent to genetic diagnosis, a specific screening program should be devised to detect the development of tumors in presymptomatic patients, understanding that the optimal ages to begin screening for disease have not been clearly established. Table 15.4 summarizes a suggested MEN1 screening program based upon consensus guidelines and adapted from recent publications on the subject.^{64,246,249,262,265,289,293,312}

Debate remains as to the optimal screening procedures, which could be less intensive than what is currently prescribed.^{247,262,265,312} Although annual laboratory evaluation is used by most clinical centers, not all centers order radiographic screening for presymptomatic children and young adults, as the 2012 guidelines proposed, and the frequency and type of imaging (CT, MRI, EUS) is an important area that warrants further research. Important to note are the real risks of using CT (which exposes MEN1 patients to a significant ionizing radiation dose over the course of their lives³¹³) in a hereditary tumor disorder, especially one that requires a somatic second hit for tumorigenesis to occur. Therefore given the lengthy follow-up period required in MEN1 patients, MRI is generally preferred over CT to reduce the risks from ionizing radiation,^{249,262,293} although CT still plays an important role, especially in surgical planning.

Multiple Endocrine Neoplasia Type 2

The original description of MEN2A is attributed to Sipple when he reported the case of a 33-year-old man who died of intracranial hemorrhage and was found on autopsy to have bilateral PHEO, bilateral MTC, and probable parathyroid hyperplasia.³¹⁴ In 1962 Cushman proposed an association between these endocrine tumors,³¹⁵ and MEN2 was subsequently named as a distinct clinical syndrome by Steiner et al.³¹⁶ Linkage analysis studies in large MEN2 kindreds led to the localization of the putative gene to chromosome 10.^{317,318} Ultimately, mutations in the *RET* protooncogene (chromosome 10q11.21) were found to cause MEN2A.^{154,155}

The original characterization of the MEN2B phenotype in the English literature was made by Williams and Pollock in 1966,³¹⁹ and MEN2B was further distinguished as a variant of hereditary MTC with a mucosal neuroma phenotype.³²⁰ In 1994 MEN2B was reported to also be secondary to activating mutations in *RET*.^{156,157}

As a result of the initial collaborative efforts of the International *RET* Mutation Consortium, it quickly became apparent that only a limited number of mutations were associated with MEN2 and that strong genotype–phenotype correlations were present¹⁵⁸ (see Fig. 15.5). Because of the very high penetrance of MTC in individuals with a *RET* mutation, there was a rapid incorporation of genetic testing into management algorithms for patients with MTC and their families. Predictive genetic testing thus ushered in the era of performing total prophylactic

thyroidectomies for presymptomatic individuals carrying a high-risk *RET* germline mutation.¹⁶⁵

Multiple Endocrine Neoplasia 2A

MEN2A accounts for 90% to 95% of MEN2 cases and is characterized by the lifetime development of MTC in more than 90% of *RET* mutation carriers. Depending on the specific mutation, PHEO and/or PHPT occur in 0% to 50% and 0% to 20% of individuals with MEN2A, respectively^{65,160}; rare cases of adrenal ganglioneuroma have also been described.³²¹ Furthermore, activating mutations in *RET* are also associated with Hirschsprung disease³²² and cutaneous lichen amyloidosis,^{194,323} a dermatologic disorder of intense pruritus and secondary skin changes that is typically located in the interscapular region of the back. Although historically discussed as a separate syndrome, familial medullary thyroid carcinoma (FMTC), in which MTC is the only clinical manifestation of a germline *RET* mutation, is now considered to be a variant of MEN2A.^{65,160}

In MEN2A, mutations are located mostly in the extracellular cysteine-rich domain of the *RET* protooncogene, usually in exon 10 (codons 609, 611, 618, or 620) or exon 11 (codon 634), but mutations can also be found in the intracellular tyrosine kinase domain^{65,158,177,324,325} (see Fig. 15.5). Codon 634 mutations account for the vast majority of classical MEN2A cases, but more recently, the prevalence of mutations in other codons (especially codon 804) has increased.^{325,326} As molecular testing becomes widespread in patients with MTC, more *RET* mutations and DNA variants are being identified, which is contributing to an everchanging spectrum of the MEN2A genotype and phenotype.^{160,327}

Medullary Thyroid Carcinoma in Multiple Endocrine Neoplasia 2A. MEN2A-related MTC, when identified during childhood, is usually diagnosed after early thyroidectomy directed by genetic testing results and is usually a microcarcinoma <1 cm in size.^{176,328,329} Most children with MEN2A will have a positive family history; *de novo* *RET* mutations represent only 2% to 9% of cases.^{330,331} A strong genotype-phenotype relationship is present, such that the rapidity with which a mutation carrier will develop MTC can be estimated, but the natural history of MTC in MEN2A can be highly variable, even among members of the same kindred.^{2,158,327,332,333} Patients with mutations in *RET* codon 634 have the highest risk of MTC, followed by those with mutations in codons 609, 611, 618, 620, or 630, whereas mutations in other codons impart the lowest risk for early-onset MTC.^{65,160,168,334} However, once MTC is diagnosed, overall survival and the development of distantly metastatic disease are similar among patients with high- and moderate-risk *RET* mutations,³³⁵ further suggesting that the genotype drives the age of onset of MTC more than it does its clinical aggressiveness after diagnosis.¹⁷³

Pheochromocytoma in Multiple Endocrine Neoplasia 2A. MEN2-associated PHEO is an adrenergic tumor that usually arises within a background of adrenal medullary hyperplasia,^{167,336–338} although some groups prefer the term *microPHEO* to indicate medullary proliferations smaller than 1 cm.³³⁹ With a diagnosis most likely during the fourth decade of life, PHEO develops primarily because of codon 634 mutations and to a much lesser degree with mutations in exon 10 (codons 609, 611, 618, and 620) and other codons.^{82,102,158,336,340–344} Typically, a PHEO is diagnosed synchronously with MTC or only after MTC is identified; in more contemporary studies, it is the initial clinical presentation in up to 15% of cases.^{102,343} Guidelines currently recommended prospective metanephrine screening for PHEO in children with MEN2A, starting at age 11 years, in

patients with a codon 634 mutation, and at age 16 years in all others⁶⁵ (see Table 15.1).

Primary Hyperparathyroidism in Multiple Endocrine Neoplasia 2A. Patients with MEN2A are at risk of developing PHPT because of parathyroid adenomas and hyperplasia. PHPT is chiefly associated with codon 634 mutations and less commonly described in other *RET* mutations.^{65,133,344–346} Onset during childhood is extraordinarily rare but has been described in a child as young as 5 years of age.³⁴⁷ Usually PHPT is diagnosed in the fourth decade of life, and therefore it is rarely the first manifestation of MEN2A.^{133,160,344} Screening for PHPT is recommended at age 11 years, in children with a codon 634 mutation, and at age 16 years in all others⁶⁵ (see Fig. 15.5).

Multiple Endocrine Neoplasia 2B

MEN2B is a completely penetrant disease that accounts for 5% to 10% of MEN2 cases.³⁴⁸ MEN2B is almost always (>95%) because of a single mutation in exon 16 (p.M918T) that is located in the intracellular tyrosine kinase domain of the *RET* receptor^{158,324} (see Fig. 15.5). Rare MEN2B cases can be attributed to double *RET* mutations involving codon 804 or a mutation in codon 883 (p.A883F, exon 15).^{65,348} Carriers of the p.A883F mutation have a later onset of disease and a more indolent natural history compared with those who harbor the p.M918T mutation.³⁴⁹ Unlike MEN2A, 84% to 90% of MEN2B cases arise as a result of a *de novo* mutation, with the child having unaffected parents.^{131,169,350,351} Because of this and because of the rarity of the syndrome, the diagnosis of MEN2B is almost always delayed, even in the presence of obvious clinical features that can start as early as infancy.^{169,170}

MEN2B is characterized by the development of MTC (100% of cases), PHEO (up to 50% of cases; rare cases of adrenal ganglioneuroma have also been described³²¹), and a highly penetrant and characteristic clinical phenotype (100% of cases; Fig. 15.11).^{131,169,170,348,350,352,353} Although the clinical phenotype is present in all patients, individual manifestations have a variable presentation and are age dependent.¹⁷⁰ Multiple mucosal neuromas¹⁹⁴ are a major clinical manifestation and occur on the lips, tongue, and/or conjunctiva, in addition to the urinary system and gastrointestinal tract. The symptoms of intestinal ganglioneuromatosis include constipation and feeding problems in infancy and the development of megacolon. A second component of the MEN2B phenotype is musculoskeletal abnormalities, including a marfanoid body habitus, narrow long facies, pes cavus, pectus excavatum, high-arched palate, scoliosis, and/or slipped capital femoral epiphysis. Other clinical features include joint laxity, hypotonia or proximal muscle weakness, thickened lips, ophthalmologic findings (inability to make tears in infancy [alacrima], thickened and everted eyelids [ectropion], mild ptosis, and prominent corneal nerves), and pubertal delay. The oral manifestations of MEN2B are highly penetrant and often lead to the clinical diagnosis. PHPT is not a feature of MEN2B.³⁴⁴

Medullary Thyroid Carcinoma in Multiple Endocrine Neoplasia 2B. MTC that occurs in MEN2B is an aggressive malignancy with a very early onset of metastasis (lymph node disease has been documented within the first year of life¹⁸⁹), a high cancer stage (defined by the tumor, node, and metastasis [TNM] classification system) at diagnosis, and an average age of MTC onset (second decade of life) that is about 10 years earlier than that observed in MEN2A.^{131,170,176,243,340,348,354} Earlier MTC onset is observed in those children with MEN2B with severe intestinal manifestations, who also seem to have a poorer prognosis than those without these intestinal manifestations.³⁵² Morbidity and

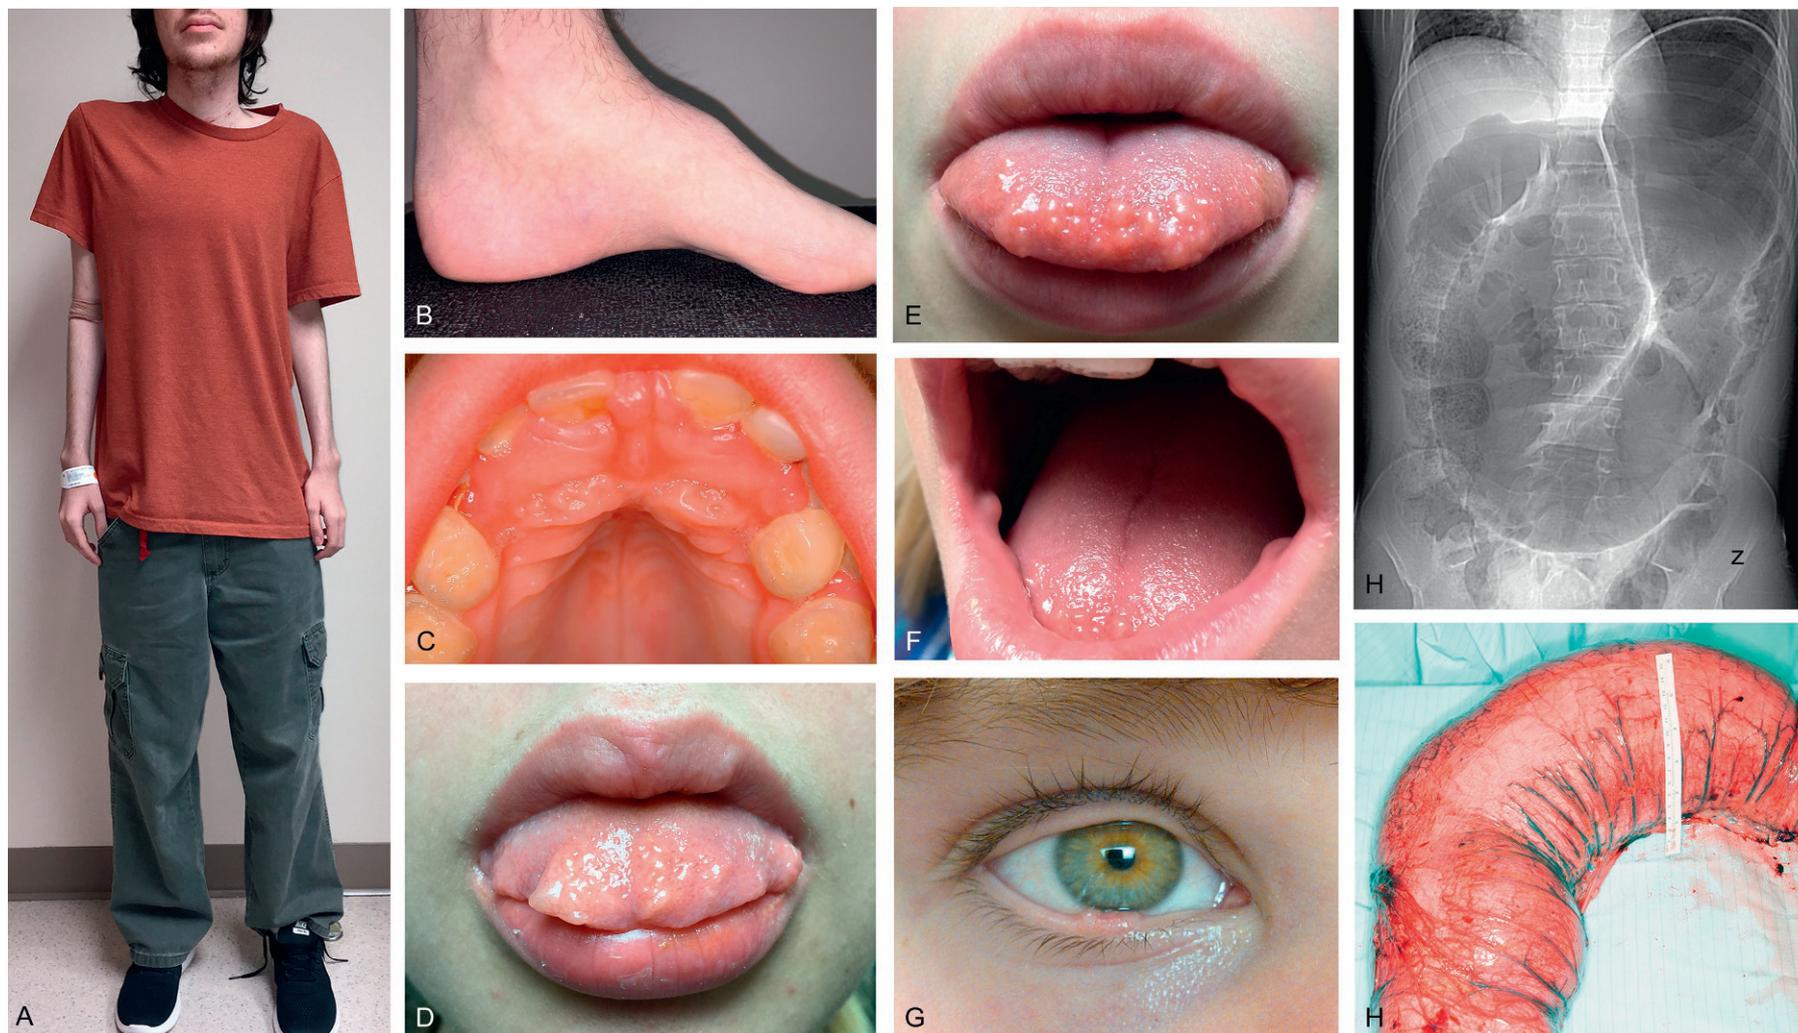

Fig. 15.11 The pathognomonic clinical phenotype of MEN2B: (1) marfanoid body habitus (A) and other skeletal features including scoliosis (A), pes cavus (B), and high-arched palate (C); (2) thickened lips and neuromas affecting the tongue (D) and (E), the oral mucosa (F), the conjunctiva (G), and other mucosal surfaces; (3) ophthalmologic signs including ptosis and everted upper eyelids (ectropion) (G); and (4) gastrointestinal problems primarily related to impaired colonic motility caused by diffuse intestinal ganglioneuromatosis that can lead to megacolon (H). For additional clinical manifestations of MEN2B, please refer to the text. (From Castinetti, F., Moley, J., Mulligan, L., Waguespack, S.G. (2018). A comprehensive review on MEN2B. *Endocr Relat Cancer*, 25(2), T29–T39)

mortality rates are much higher in MEN2B, although the higher mortality rate may reflect the earlier onset of disease and more advanced tumor stage at presentation, rather than an intrinsically more aggressive carcinoma.^{173,185,348,353} Clinical outcomes are improving in the current era because of improved diagnosis and treatment at a younger age and thus a lower stage of MTC.³⁵¹

Pheochromocytoma in Multiple Endocrine Neoplasia 2B.

Compared with the more heterogeneous MEN2A population, patients with MEN2B have a higher lifetime risk (~50%) of developing PHEO.^{131,342} The clinical phenotype of the disease is no different than that seen in MEN2A, although the median age of diagnosis is around 25 years, about a decade earlier than MEN2A.^{102,131,343,344,351} Two other notable differences between MEN2A and MEN2B are that PHEO is even less likely to be diagnosed before MTC and that historical mortality from PHEO is lower compared with death from MTC.^{131,336,342,355} Despite an aggressive MTC phenotype and a constitutively activated RET tyrosine kinase, the risk of malignant PHEO in patients with MEN2B is exceedingly rare (0%–3%).^{131,147,343} To date, the youngest documented case of MEN2B-associated PHEO was in a 10-year-old child.³⁵⁵ Contemporary guidelines recommend initiation of screening at age 11 years.⁶⁵

Timing of Thyroidectomy in Multiple Endocrine Neoplasia 2

When MTC metastasizes beyond the thyroid, it usually becomes an incurable disease that may ultimately cause shortened survival. Given that MEN2 can be easily diagnosed through predictive genetic testing, hereditary MTC has become one of the few malignancies that can be prevented (via prophylactic thyroidectomy) or cured (via early thyroidectomy) before it becomes clinically apparent. In experienced surgeons' hands, children who have a total thyroidectomy performed before the onset of metastatic disease have an excellent chance of remaining disease free; cure is also possible even for children with high-risk MEN2, despite surgery not being performed at the earliest prescribed ages.^{131,176,179,329,350,351,353,356,357} In reality, many thyroidectomy specimens from children with MEN2A harbor microscopic, nonmetastatic MTCs that are often cured after early thyroidectomy^{328,329,357,358}; in those not cured after initial surgery, calcitonin may remain abnormal but without structural evidence of disease.^{328,357} For most children with MEN2B, cure is unobtainable because of the fact that most surgeries in this population are therapeutic, not prophylactic, given the oft-delayed clinical diagnosis; however, in children diagnosed and treated before age 1 year, biochemical cure is achieved in 83% of cases.¹³⁰

There is widespread agreement that the therapeutic goal in a child with MEN2 is to remove the at-risk thyroid before incurable MTC metastasis occurs, while minimizing potential medical and surgical morbidity. Recommendations regarding the timing of surgical intervention have evolved over the last 25 years. Previously based on genotype alone, contemporary practice is to offer an early thyroidectomy in children at an age dictated by genotype, and in the case of mutations less likely to cause MTC in early childhood, basal calcitonin levels^{65,173} (see Fig. 15.5). Although thyroid US is frequently incorporated into clinical decision making, it is an insensitive test for the diagnosis of MTC and should therefore not be used independently to determine the age of surgery.³⁵⁸

In the American Thyroid Association (ATA) guidelines published in 2015, the disease-causing *RET* mutations were stratified into three major risk categories: highest risk (codon 918), high risk (codons 634 and 883), and moderate risk (all others)⁶⁵ (see Fig. 15.5). Recent studies have suggested that the ATA moderate risk mutations are a heterogeneous group and that further subdivisions in this category may be needed to better inform the risk for MTC development.¹⁶⁸ Total thyroidectomy is recommended within the first year of life in carriers of the highest risk mutation and at or before age 5 years for those with high-risk mutations. With all other (moderate risk) *RET* mutations, the detection of an elevated calcitonin level can be used to help decide surgical timing, noting that some ATA moderate risk mutations may be more virulent than others.^{168,334} Calcitonin levels under 30 to 40 pg/mL are associated with an exceedingly low risk of lymph node metastasis,^{173,176,359} and thus operating on a child just as the calcitonin is rising should result in a long-term cure.³⁵⁷ Ultimately, decisions regarding the age of surgery should be made by a multidisciplinary team experienced in MEN2 management and the child's parent(s)/guardian(s). Notably, an elevated calcitonin level does not reliably portend a diagnosis of MTC¹⁷⁶; false positive elevations can be found in nonneoplastic conditions, such as chronic kidney disease, autoimmune thyroiditis, and hyperparathyroidism.^{65,191} Conversely, MTC can be identified pathologically even in the presence of a normal calcitonin level.^{357,358}

Multiple Endocrine Neoplasia Type 4

MEN4 is a syndrome of multiple endocrine tumors that is caused by germline mutations in the *CDKN1B* gene on chromosome 12p13.1, which encodes the cyclin-dependent kinase inhibitor p27^{Kip1} and plays a critical role in regulating cell proliferation.³⁶⁰ Homozygous mutations in rat *Cdkn1b* were originally identified to cause MENX, a multitumor syndrome in the rat that has phenotypic features of both MEN1 and MEN2.^{360,361} Subsequently, studies in humans without a proven *MEN1* mutation confirmed that a small subset will have heterozygous mutations in the human homologue *CDKN1B*, and these patients have an MEN1-like phenotype, subsequently called *MEN4*.³⁶² Individuals with a germline *CDKN1B* mutation are at risk for developing tumors of the parathyroid glands (the main clinical manifestation), pituitary, adrenals, and/or GI neuroendocrine system, among others.^{360–362} Although MEN4 is a very rare cause of multiple endocrine neoplasia, mutational screening of the *CDKN1B* gene should be considered in patients with a clinical diagnosis of MEN1, but negative *MEN1* genetic testing.^{246,362} The optimal surveillance strategy has not been established but at a minimum should include periodic testing for PHPT and other functioning endocrine tumors.⁶⁴

X-Linked Acrogigantism

X-linked acrogigantism (X-LAG) is the most recently characterized hereditary disorder associated with pediatric pituitary tumors. It is a disorder with X-linked inheritance that is characterized by pituitary gigantism with an onset during the first few years of life (<4 years of age).³⁶³ The disease is caused by inherited or de novo (most common) germline microduplications on chromosome Xq26.3 that includes the responsible gene, *GPR101*, which encodes for an orphan G-protein-coupled

receptor.^{364,365} Somatic mosaicism for the Xq26.3 microduplication leading to the X-LAG phenotype has also been reported in male simplex cases.³⁶⁵ A germline and somatic *GPR101* missense variant (p.E308D) has also been identified in some cases of acromegaly,³⁶⁴ although it remains uncertain if this DNA variant plays a causative role in the pathogenesis of somatotroph adenomas.²⁰⁷

Clinically, X-LAG patients present with marked growth hormone excess that is associated with hyperprolactinemia in about 80% to 90% of cases; histologically, mixed somatotroph–lactotroph adenomas and/or pituitary hyperplasia are identified.^{364,365} In distinct contrast with *AIP*-associated FIPA, X-LAG is characterized by a female preponderance, with 24/33 reported cases being female.²⁰⁷ Interestingly, all female probands published to date represent de novo cases and vertical transmission of a *GPR101* duplication from an affected parent to a daughter has not yet been reported.³⁶³

OTHER TUMOR SYNDROMES ASSOCIATED WITH ENDOCRINE NEOPLASIA

Adenomatous Polyposis Coli-Associated Polyposis

The *adenomatous polyposis coli* (*APC*)-associated polyposis conditions result from dominantly inherited germline mutations in the *APC* tumor suppressor gene (chromosome 5q22.2) and include the clinical syndromes of familial adenomatous polyposis (FAP, including the now historical Gardner and Turcot syndromes), attenuated FAP, and gastric adenocarcinoma and proximal polyposis of the stomach (GAPPS).³⁶⁶ Patients with an *APC* mutation are at greatest risk for colon cancer but may also develop endocrine neoplasia. Compared with the general population, ACTs are at least twice as prevalent (16% of patients) in FAP, and similar to sporadic adrenal neoplasia, *APC*-associated ACTs may be hormonally active or nonfunctioning and may rarely be malignant.^{367–369} Patients with an *APC* mutation also have up to a 12% lifetime risk for thyroid malignancy.³⁷⁰ The primary subtype is papillary thyroid carcinoma, classically the cribriform-morular histologic variant,³⁷¹ and it is a diagnosis almost exclusively made in young women during the third decade of life.³⁷⁰ Outside of thyroid palpation, opinions regarding screening for thyroid cancer in an *APC*-associated polyposis condition are varied; routine surveillance for adrenal tumors is not recommended.^{235,366,372}

Beckwith-Wiedemann Syndrome

The Beckwith-Wiedemann syndrome (BWS) is a congenital overgrowth disorder caused by dysregulation of gene transcription in an imprinted domain on chromosome 11p15 that includes genes, such as *CDKN1C* and *IGF2*, which are strong regulators of fetal growth.^{373,374} Clinical findings are pleiotropic and include macrosomia and hemihyperplasia, macroglossia, visceromegaly, embryonal tumors (e.g., Wilms tumor, hepatoblastoma, neuroblastoma, pancreatoblastoma, and rhabdomyosarcoma), omphalocele, neonatal hypoglycemia, ear creases/pits, ACTs/adrenal cytomegaly, and renal abnormalities (e.g., medullary dysplasia, nephrocalcinosis, medullary sponge kidney, and nephromegaly). A variety of malignant tumors, typically restricted to childhood onset, have been associated with BWS and occur in 7.4% of all cases.³⁷⁵ ACT, both benign and malignant, are among the more common neoplasms identified in BWS, representing up to 8% of benign and 7% of malignant tumors.³⁷⁶ Fetal adrenocortical cytomegaly (a component of the underlying visceromegaly)

and adrenal cystic lesions also occur.^{376,377} PHEO and thyroid carcinoma are additional endocrine tumors that have been reported.^{375–377} Various protocols have been suggested for tumor surveillance in BWS and algorithms have been developed for the management of children with an identified adrenal mass.³⁷⁷ Children with paternal uniparental disomy appear at highest risk for the development of ACTs and thus screening with abdominal US should be focused more on these children, as well as those with negative molecular tests.^{374,375}

Carney Triad

The Carney triad was originally described in 1977 as the association of gastric epithelioid leiomyosarcoma (later renamed GIST), PGL, and pulmonary chondroma.³⁷⁸ Over time, the phenotype has expanded to include clinically nonfunctioning ACTs and esophageal leiomyomas.^{379,380} The Carney triad affects primarily young women (85%) with a mean age of onset of 20 years (7–48 years).³⁸⁰ Because of incomplete expression of the phenotype, PGL is not present in all patients suspected to have the Carney triad.³⁷⁹ PHEO can occur in a minority of patients, and the aortopulmonary body is a common site for the development of PGL, although PGL occur equally in the head and neck, thorax, and abdomen.³⁸⁰

Although the Carney triad is not a heritable disorder in the traditional sense, about 10% of patients will be identified to have a germline DNA variant in the *SDHA*, *SDHB*, or *SDHC* genes.³⁸¹ Furthermore, hypermethylation of *SDHC* appears to be the main molecular characteristic of the Carney triad.³⁸²

DICER1 Syndrome

Germline mutations in the *DICER1* gene cause the DICER1 syndrome, a rare autosomal dominant disorder with decreased penetrance, characterized by a variety of benign and malignant tumors,^{6,383–385} including pleuropulmonary blastoma (PPB), ovarian sex cord-stromal tumors (primarily Sertoli-Leydig cell tumor but also juvenile granulosa cell tumor and gynandroblastoma), cystic nephroma, and thyroid gland neoplasms (multinodular goiter and differentiated thyroid cancer). Other tumors that are less commonly observed include ciliary body medulloepithelioma, botryoid-type embryonal rhabdomyosarcoma of the cervix or other sites, nasal chondromesenchymal hamartoma, renal sarcoma, pituitary blastoma, and pineoblastoma.

DICER1 (chromosome 14q32.13) is a gene encoding an endoribonuclease that cleaves noncoding small ribonucleic acid (RNA) precursors to generate mature microRNAs that are involved in the posttranscriptional regulation of gene expression. Mutations in *DICER1* were first identified in familial PPB³⁸⁶ and then subsequently found to cause a pleiotropic tumor syndrome, including various other tumor types.³⁸⁷ The *DICER1* syndrome normally results from a germline inactivating mutation, followed by a somatic second hit primarily involving the RNase IIIb catalytic domain of *DICER1*.^{383,385,388} Most of the germline mutations are inherited but 10% to 20% may arise de novo.³⁸³ Somatic mosaic *DICER1* mutations, often accompanied by second somatic truncating mutations or loss of heterozygosity, can also cause the *DICER1* syndrome.³⁸⁹

Thyroid nodules appear to be one of the most common manifestation in patients with germline *DICER1* mutations, and there is a significantly increased risk of multinodular goiter compared with family controls and at least a 16-fold elevated risk of thyroid cancer compared with the general population.³⁹⁰ Familial multinodular goiter may in fact be the only clinical manifestation,^{391,392} and in the child being evaluated

for possible syndromic nodular goiter, macrocephaly may be a clue to the presence of a germline *DICER1* mutation.³⁹³ Similar to nonsyndromic thyroid nodular disease, females are more affected, and by the age of 40 years, the cumulative incidence of multinodular goiter or thyroidectomy is 75% in women and 17% in men.³⁹⁰ Differentiated thyroid cancer occurs in less than 3% of *DICER1* carriers and is a low-risk tumor that does not appear to be more clinically aggressive.^{390,394} Although exposure to chemotherapy or radiation was originally felt to contribute to the risk of thyroid cancer, a germline *DICER1* mutation alone appears sufficient to increase the thyroid cancer risk.^{383,390} Surveillance for thyroid tumors in children with the *DICER1* syndrome include periodic thyroid ultrasonography, starting by age 8 years and then every 3 years or more frequently, if being treated for another tumor,^{383,384} although some centers recommend physical examination alone, starting at age 10 years in children not exposed to alkylating chemotherapy.³⁹⁵

Pituitary blastomas, occurring in less than 1% of patients with a *DICER1* mutation, are extremely rare and aggressive neoplasms that arise from the fetal anterior pituitary and clinically present at an age younger than 24 months with ACTH-dependent Cushing disease and/or ophthalmoplegia because of mass effect.^{6,388} Because this tumor is so rare, it is unclear that routine surveillance is necessary in all cases, although some centers advocate for MRI screening.³⁹⁵ Regardless, assessing for and recognizing the signs and symptoms of a pituitary blastoma (rapid weight gain, ophthalmoplegia) should lead to an early diagnosis.

Li-Fraumeni Syndrome

Li-Fraumeni Syndrome (LFS) is a highly penetrant cancer-predisposition syndrome caused by autosomal dominantly inherited germline mutations in the tumor suppressor gene *TP53* (tumor protein p53; chromosome 17p13.1).³⁹⁶ Soft tissue and bone sarcomas, premenopausal breast cancer, ACTs, and brain tumors represent the core tumors of LFS.^{397–399} The prototypical endocrine tumor associated with LFS is ACT (both benign and malignant), although several cases of thyroid carcinoma have also been reported, especially in Brazilian kindreds.^{400,401} The adrenal cortex is the third most common site of neoplasia development in LFS.³⁹⁷ ACTs have an early age of onset, with the diagnosis most common in very young children, who may in fact represent the proband for an LFS kindred.^{397,402,403} In southern Brazilian families, the *TP53* mutation p.Arg337His is associated with a higher susceptibility to isolated ACT in children (median age of diagnosis 3 years; range 4 months to 13.5 years),⁴⁰⁴ although cancer risk also appears increased for adult carriers of this mutation.⁴⁰² Children with an ACT typically present with virilization,^{404,405} but at all ages, these tumors can present with other signs/symptoms of adrenocortical hyperfunction (such as Cushing syndrome) and/or with symptoms because of tumor mass effect, particularly in the case of nonfunctioning tumors. Cancer screening recommendations, which include monitoring for the development of an ACT, are available.³⁹⁹

Lynch Syndrome (Hereditary Nonpolyposis Colon Cancer)

Lynch syndrome is a disorder with autosomal dominant inheritance that is secondary to mutations in DNA mismatch repair genes and characterized by an increased risk for colorectal cancer and various other malignancies.⁴⁰⁶ A diagnosis of adrenocortical carcinoma has been reported in individuals and families with Lynch syndrome,^{407,408} although to date there

has not been a pediatric presentation of ACT occurring in this context.

Neurofibromatosis Type 1

NF1, also known as Von Recklinghausen disease, is an autosomal dominant disorder caused by mutations in the *NF1* gene, a tumor suppressor gene located on chromosome 17. Café-au-lait macules, neurofibromas (cutaneous and plexiform), axillary and inguinal freckling, optic pathway gliomas, skeletal dysplasia, and Lisch nodules (benign hamartomas) of the iris are the main clinical features.⁴⁰⁹ NF1 patients are at an increased risk of developing PHEO/PGL and other NETs.

The prevalence of a catecholamine-producing tumor in NF1 patients is 2% to 6%.^{134,297,410} PHEO (up to 17% bilateral) represent the majority of NF1-associated cases but intraabdominal and pelvic PGL are diagnosed in up to 6%.^{134,410} Mean age of diagnosis is in the fifth decade of life,^{134,411} and NF1-associated PHEO are typically characterized by an adrenergic phenotype.^{411,412} Malignancy is uncommon but does occur in 5% to 12% of cases.¹³⁴ Rarely, a composite PHEO (a mixed tumor consisting of PHEO and a developmentally related neurogenic tumor, such as neuroblastoma, ganglioneuroma, or ganglioneuroblastoma) may occur in the setting of NF1.⁶

Gastrointestinal NETs occur in less than 10% of NF1 patients and are almost exclusively duodenal somatostatinoma that occur in the periampullary region and present clinically as a result of the tumor itself (pain, jaundice, bleeding) rather than a somatostatinoma syndrome.^{6,297,413} NF1-associated somatostatinomas are typically diagnosed during the fifth decade of life.⁴¹³ Other types of NETs that have been reported in NF1 patients include insulinomas, gastrinomas, and nonfunctioning pancreatic NETs.^{297,414,415} Case reports of PHPT caused by benign and malignant parathyroid tumors and ACTs have also been reported to occur in NF1.^{369,416,417} Finally, a unique endocrinopathy associated with NF1 in children with infiltrating optic pathway gliomas is the clinical syndrome of gigantism caused by unregulated growth hormone secretion.⁴¹⁸

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome (PJS) is an autosomal dominantly inherited syndrome with incomplete penetrance characterized by hamartomatous polyps in the GI tract and mucocutaneous hyperpigmentation.^{419,420} It is caused primarily by inactivating mutations in the *STK11* (*LKB1*) gene (chromosome 19p13.3). Individuals with PJS are at increased risk for various malignancies over the course of their lives, chiefly luminal GI cancers (colorectal >stomach >small bowel) and breast cancer, followed by pancreatic cancer, gynecologic malignancies, and lung cancer.^{419,421} Several case reports of differentiated thyroid cancer have been published,⁴²² but it remains unclear if this is a random occurrence or a direct association with PJS.

Patients with PJS are at risk for unique gonadal tumors that may clinically present with an endocrinopathy during childhood: Sertoli cell tumors of the testis in males and ovarian sex cord tumors with annular tubules (SCTATs) in females. Testicular Sertoli cell tumors in PJS are benign lesions that typically occur in prepubertal boys (mean age 6.8 years) who present with gynecomastia and bilateral (rarely unilateral) testicular enlargement.²¹¹ The microscopic findings are distinctive and the term *intratubular large cell hyalinizing Sertoli cell neoplasia* has also been proposed.²¹¹ Calcifications are unusual and not extensive in these lesions, although large-cell calcifying Sertoli cell tumors (similar to those identified in the Carney

complex) can also occur within the PJS spectrum.⁴²³ The gynecomastia is caused by estrogen overproduction secondary to high levels of aromatase activity,²¹¹ making the use of an aromatase inhibitor the optimal approach to medically treating such cases.⁴²⁴ SCTAT is a distinctive neoplasm that has morphologic features that lie between those of a Sertoli cell tumor and a granulosa cell tumor.⁴²⁵ When occurring in the PJS, these tumors are typically small, calcified, multifocal, and bilateral lesions, as compared with non-PJS SCTATs. SCTAT is almost always a benign neoplasm with a mean age of diagnosis of 27 years (range 4–57 years).⁴²⁵ Clinical presentation is often caused by estrogen overproduction and manifested by menstrual irregularity in postmenarchal women and sexual precocity in prepubertal girls. Abdominal pain and a palpable adnexal mass can also be presenting features, and SCTAT can also be an incidental finding.⁴²⁵ Annual physical examination (assessing for gynecomastia/testicular enlargement in boys and precocious puberty in girls) is recommended for children with PJS.³⁷²

PTEN Hamartoma Tumor Syndrome

The *PTEN* hamartoma tumor syndrome (PHTS) results from germline mutations in the *PTEN* (phosphatase and tensin homolog) tumor suppressor gene (chromosome 10q23.31) and is inherited in an autosomal dominant manner.⁴²⁶ Penetrance is high (>80%) and the clinical diagnosis may be missed because of a variable phenotypic presentation and associated tumors that have a high background population prevalence.²³⁵ The PHTS comprises the clinical spectrum of Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome, *PTEN*-related Proteus syndrome, and Proteus-like syndrome.⁴²⁷ Cowden syndrome (CS), the most common PHTS phenotype and one that has established diagnostic criteria, is a multiple hamartoma syndrome with an increased risk for both benign and malignant tumors arising from the thyroid follicular cell and, in women, the breast and endometrium; pathognomonic skin manifestations include papillomatous papules, facial trichilemmomas, and acral keratoses.^{426,427} Macrocephaly (occipitofrontal circumference >2 standard deviations [SDs]/97.5th percentile) is a nearly universal finding in children with a *PTEN* mutation, and neurodevelopmental disorders are common (autism spectrum disorder in 50%).⁴²⁸ Thyroid neoplasia eventually occurs in the majority of individuals with CS and includes multinodular goiter, follicular adenomas, and differentiated thyroid carcinoma (papillary and follicular thyroid carcinomas).^{429–431} Follicular carcinomas appears to be overrepresented in *PTEN* mutation-positive patients (youngest reported age is 7 years), but papillary carcinomas are also common.^{430–432} The risk of thyroid neoplasia begins during childhood, and one-quarter of children with PHTS have abnormal thyroid imaging.⁴²⁸ Surveillance of children with the PHTS include annual physical examination and periodic thyroid US.^{235,384,427}

Tuberous Sclerosis Complex

The tuberous sclerosis complex (TSC) is an autosomal dominant, multiorgan hamartomatous disorder characterized by abnormalities of the skin (hypomelanotic macules, confetti skin lesions, facial angiofibromas, shagreen patches, fibrous cephalic plaques, unguis fibromas); brain (cortical dysplasias, subependymal nodules and subependymal giant cell astrocytomas, seizures, intellectual disability/developmental delay); kidney (angiomyolipomas, cysts, renal cell carcinomas); heart (rhabdomyomas, arrhythmias); and lungs (lymphangiomyomatosis).⁴³³ The two

known genes that cause the TSC include *TSC1* (chromosome 9q34.13) and *TSC2* (chromosome 16p13.3), which encode for the proteins hamartin and tuberlin, respectively.^{433,434} Various endocrine neoplasms occurring within the context of the TSC have been reported, including functional pituitary adenomas, parathyroid hyperplasia and adenomas, pancreatic NETs, and case reports of PHEO and papillary thyroid cancer.^{435–438} The pancreatic NETs can be benign or malignant and functioning or nonfunctioning, with a large proportion of these cases associated with *TSC2* gene mutations.^{436,438} Insulinomas appear to be overrepresented in TSC patients and so a low threshold should exist for clinical evaluation in those with classic signs or symptoms of hypoglycemia or worsening neurologic symptoms.⁴³⁵

Von Hippel-Lindau Disease

VHL disease is an autosomal dominant, highly penetrant disorder caused by germline mutations in *VHL* (chromosome 3p25.3), a tumor suppressor gene first identified in 1993,⁴³⁹ and characterized by a variable clinical phenotype that includes hemangioblastomas of the retina (also called *retinal angiomas*) and CNS; renal cysts and clear cell renal cell carcinoma; PHEO/PGL; pancreatic cysts, cystadenomas, and pancreatic NETs; endolymphatic sac tumors; and cystadenomas of the epididymis in males and broad ligament of the uterus in females.^{440–442} About 20% of patients with VHL do not have an affected parent and thus either harbor a de novo mutation or inherit a *VHL* mutation from a parent with germline mosaicism; genetic testing is highly reliable, identifying a mutation in almost all clinically affected individuals.⁴⁴⁰ The majority of VHL mutations are small deletions/insertions or point mutations but large deletions comprise 11% of *VHL* pathogenic variants.⁴⁴⁰

Although the median age of PHEO/PGL diagnosis in VHL is age 28 years, up to 20% of pediatric patients (median age 12 years), primarily those individuals with missense mutations of the *VHL* gene, will be diagnosed with a PHEO/PGL (see Fig. 15.1).^{74,443} PHEO is much more common than PGL and malignancy is rare.^{74,441} These tumors can be one of the earliest clinical manifestations of VHL, having been diagnosed as young as age 2 years,⁴⁴⁴ and it can also be the sole clinical manifestation of VHL, as seen in VHL type 2C.^{440,441} Prospective screening is generally recommended to commence at the age of 5 years in children with missense mutations and/or a family history of PHEO/PGL^{39,66,67,74,440}; others have advocated for earlier testing.^{63,445} Although almost all VHL-related PHEO/PGL are functional noradrenergic tumors (see previous PHEO/PGL section), nonfunctional parasympathetic PGL occurring in the context of VHL have also been described.⁴⁴⁶

Pancreatic NETs develop in 15% of VHL patients.⁴⁴⁷ Few pediatric cases have been reported in the literature,⁴⁴⁸ and the youngest case was in a 10-year-old child.⁴⁴⁹ These tumors are clinically nonfunctioning (thus biochemical screening is unnecessary) and they can be malignant, especially with lesions up to 2.8 to 3 cm or with a fast tumor doubling time, and those in patients with germline missense mutations or a mutation in exon 3 of *VHL*.^{449–452} Prospective screening for pancreatic NETs is performed as a component of testing for other VHL intraabdominal manifestations and include intermittent US (typically starting at age 8 years) or MRI (starting at age 16 years),^{66,67,440,442,445} although some groups have recommended MRI starting at age 10 years.⁶³ Similar to MEN1, MRI is preferred over CT to minimize the lifetime exposure to ionizing radiation.⁴⁵³

Finally, testosterone-secreting ovarian steroid cell tumors have been described,⁴⁵⁴ and this diagnosis should be considered in women with VHL who present with an adnexal mass, amenorrhea, and/or hirsutism.

SUMMARY AND FUTURE DEVELOPMENTS

Although rare, childhood endocrine neoplasms, especially NETs, such as PHEO and MTC, are frequently associated with a known tumor predisposition syndrome. Advances in genomic medicine have improved our understanding of the etiology and pathophysiology of these disorders, which in turn has changed the way providers manage patients with the diseases discussed in this chapter. Because it is a rapidly evolving field, the reader should continue to seek the most current information for important clinical decisions regarding individual patient care. Future research will add to our knowledge regarding genotype-phenotype correlations; optimal screening strategies for asymptomatic children known to carry a disease-causing mutation; timing of interventions, such as early thyroidectomy in MEN2 and parathyroidectomy in MEN1; and the treatment of advanced or inoperable disease with newer targeted therapies.

Puberty is the stage of development during which secondary sexual characteristics appear and there is a transition from the sexually immature to the sexually mature stage. Adolescence is widely used as a generally synonymous term for puberty, but it is often used to convey an added cultural connotation as a psychosocial coming of age.

By the mid-1960s a general concept of the major factors involved in the initiation of puberty was established (Fig. 16.1).^{1,2} A decrease in sensitivity of the brain “gonadostat” to sex hormone negative feedback was thought to be the primary event. This signaled the hypothalamus to discharge neurohumors (then unidentified), which in turn stimulated the pituitary to release gonadotropins. The resultant rise in secretion of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), was thought to account directly for increased estrogen production by the ovary. A mature relationship was thought to develop in which the blood levels of estrogen and gonadotropins were regulated reciprocally via the gonadostat,³ much as a furnace is regulated by a thermostat. The pineal was identified as having gonadal suppressive properties. The increased adrenocortical secretion of 17-ketosteroids (17-KS), which becomes apparent at about the time of puberty (“adrenarche”), was thought to be caused by a pituitary factor stimulating adrenal androgens in synergism with adrenocorticotrophic hormone (ACTH).⁴

The rapid scientific advances since 1965 have permitted this concept to be tested in increasingly sophisticated ways. In the

subsequent decade, radioimmunoassay (RIA), originally developed by Yalow and Berson, was applied to the measurement of gonadotropins and sex steroids; the gonadotropin-releasing hormone (GnRH) for both LH and FSH was isolated, identified, and synthesized by Guillemin’s and Schally’s groups. Cyclic adenosine-3’,5’-monophosphate (cAMP), postulated by Sutherland to mediate the action of peptide hormones, was found to mediate gonadotropin effects on the ovarian follicle. The initial steps in the mechanism of action of steroid hormones were defined by Jensen, Gorski, and their groups. The landmark nature of many of these discoveries was recognized by the awarding of Nobel Prizes in Medicine to Sutherland in 1971 and to Yalow, Schally, and Guillemin in 1977.

Our present view of the mechanisms controlling puberty is more refined and complex than it once was, although the earlier schema is correct in a general sense. The gonadostat is a patently oversimplistic concept for a complex system that regulates the activity of the hypothalamic GnRH pulse generator, a functionally interconnected and synchronized network of GnRH neurons.⁵ The gonadostat setting seems to change throughout childhood in a biphasic manner. This concept is illustrated in Fig. 16.2.^{6,7} During most of fetal and perinatal life, the gonadostat is insensitive to negative feedback by sex steroid hormones; at this time the nascent neuroendocrine-gonadal axis functions at a pubertal level. The gonadostat becomes increasingly sensitive to negative feedback during infancy but does not become highly sensitive until midchildhood, at which time GnRH pulse generator activity is minimal. During late prepuberty, the gonadostat begins to relinquish its inhibition. This permits the onset of puberty. The changing set-point initially permits increasing, episodic secretion of GnRH. Increasing sensitivity of the pituitary gonadotropic cells to GnRH follows. The change in LH and FSH secretion is first detectable during sleep. Gradually, the gonads become increasingly sensitized to gonadotropin stimulation, grow at an increased rate, and bring about sustained rises in plasma sex steroid hormone levels. Some of these phenomena synergize with others, so that autoamplification occurs and the pace of change accelerates. Eventually, the set-point for gonadotropin release comes to vary sufficiently to encompass a positive feedback mechanism.

The data on which this model is based are presented later. The most recent data on the hormonal milieu and accompanying physical stages of normal puberty are then presented. Abnormal puberty is subsequently discussed: the causes, differential diagnosis, and management.

DEVELOPMENT OF THE FEMALE REPRODUCTIVE SYSTEM

Maturation of the Neuroendocrine-Ovarian Axis

Fetus

Neuroendocrine Unit. The anterior lobe of the pituitary gland, of stromal ectodermal origin, and the posterior lobe, of neural origin, differentiate by 11 weeks’ gestational age.⁸ By this time, GnRH neurons have migrated from the olfactory placode into place in the medial basal hypothalamus.⁹ Hypothalamic GnRH subsequently rises in parallel with fetal pituitary and serum LH and FSH.¹⁰ All peak at about 20 to

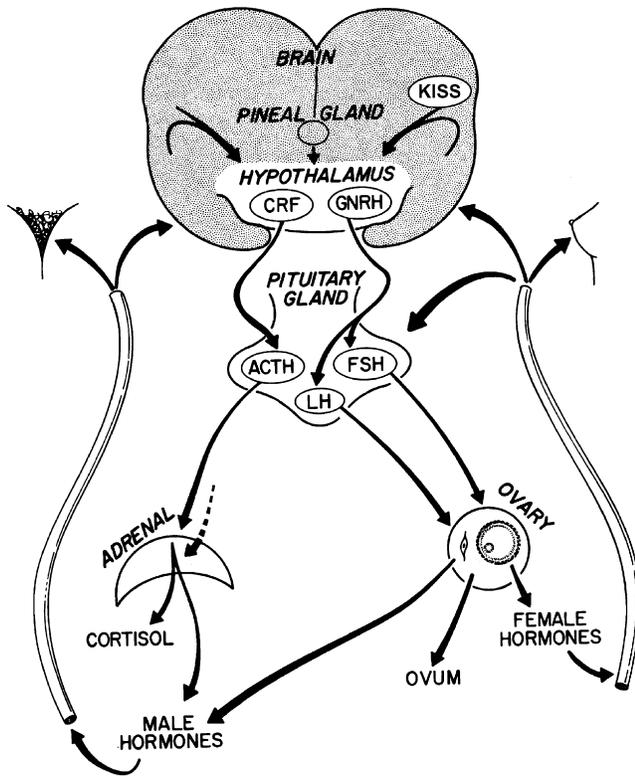

Fig. 16.1 Schematic representation of the neuroendocrine-ovarian axis involved in normal pubertal development. *ACTH*, Adrenocorticotropic hormone; *CRF*, corticotropin-releasing factor; *FSH*, follicle-stimulating hormone; *GnRH*, gonadotropin-releasing hormone; *KISS*, kisspeptin; *LH*, luteinizing hormone.

24 weeks, as the connections of the pituitary portal system become complete, to levels not again seen until menopause.¹¹ Serum LH and FSH levels are higher in human female than male fetuses.¹¹ In rats, GnRH-containing neurons develop earlier in females than in males,¹² and there are sexual dimorphisms in the degree of synapsing of specific tracts with

dendritic spines in the preoptic nucleus, one of the major GnRH-containing areas of the hypothalamus.^{13,14} These differences may be determined by gonadal sex steroid hormone output. In all species studied, fetal secretion of LH, particularly LH pulse frequency, is permanently desensitized to estradiol-progesterone negative feedback by fetal virilization.¹⁵ In the rat, this has been demonstrated to be mediated by permanent impairment of estradiol-induced progesterone receptor (PR) gene expression.¹⁶

In late gestation, fetal hypothalamic GnRH and pituitary gonadotropin secretion fall to low levels. These changes are likely explicable by the negative feedback effect of the high sex steroids produced by the fetoplacental unit. Meanwhile, maturation of the central nervous system (CNS) tracts that inhibit hypothalamic GnRH secretion and mediate gonadal negative feedback signals appears to progress throughout gestation.^{17,18}

The production of gonadotropins by the fetal pituitary seems to facilitate normal ovarian development. Hypophysectomy of rhesus fetuses has been reported to reduce the number of germ cells and oocytes, as well as the integrity of the rete ovarii.¹⁹ Therefore it seems that survival of gametes depends upon the secretions of the fetal pituitary.

Ovary. The ovaries differentiate in the urogenital ridge adjacent to the anlage of the adrenal cortex and the kidney. The granulosa cells are the homologues of the Sertoli cells of the testes. The theca, interstitial, and hilus cells are the homologues of the Leydig cells; hilus cells may even contain crystalloids like Leydig cells. Adrenocortical rests occasionally have been found in the hilus of the ovary.²⁰ Conversely, ovarian rests have been identified in the adrenal glands.²¹

The primitive germ cells migrate into the ovary from the yolk sac endoderm during the first month of gestation. The testes become histologically discernable by 8 weeks' gestation.²² The ovaries develop²³ in the absence of testicular development being switched on by the signaling cascade initiated by the *SRY* gene on the Y chromosome.^{24,25} Activation of the β -catenin signaling pathway by *Wnt-4* and *R-spondin1* permit forkhead (*Fox*) L2 transcription factor expression by germ cells to activate ovarian differentiation by sustaining oocyte and granulosa cell development and suppressing Sertoli and Leydig cell differentiation; they also support later aspects of follicle development.^{26,27} Steroidogenic factor-1 (*SF-1*) *WT-1*, *LIM-1*, and

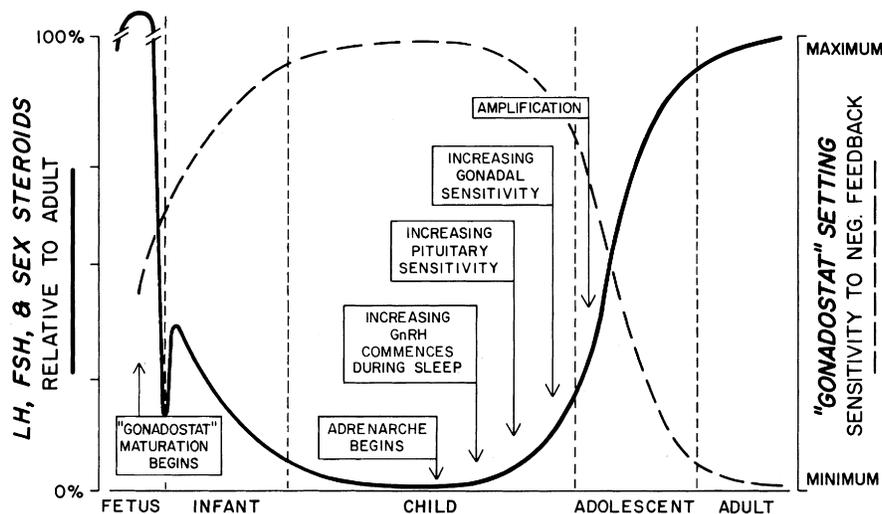

Fig. 16.2 The changing pattern of serum gonadotropins and sex hormones from fetal life to maturity in relationship to the apparent sensitivity of the central nervous system “gonadostat” to the negative feedback effect of sex hormones and the underlying hormonal events. *FSH*, Follicle-stimulating hormone; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone. (Modified from Grumbach, M., Grave, C., Mayer, F. (Eds.) (1974), *The Control of the Onset of Puberty*. New York, John Wiley & Sons.)

possibly *DAX-1* genes play roles in the formation of the ovaries.²⁸ Germ cell bone morphogenetic proteins (BMPs) are necessary for primordial germ cell proliferation.

Primitive germ cells undergo mitotic division to become oogonia, a process that is maximum at 8 to 12 weeks. Oogonia then undergo oogenesis, entering the prophase of meiosis to become primary oocytes beginning at 12 to 16 weeks.²⁹ The number of oocytes reaches a peak at 20 weeks when there are 6.8 million germ cells, of which 80% appear to be viable (Fig. 16.3).³⁰ When oocytes enter the diplotene stage of meiotic prophase they must be furnished with granulosa cells to form a primordial follicle, or else they undergo atresia.³¹

The ovary remains histologically undifferentiated until primordial follicles appear at about 16 weeks, when the epithelium of the secondary sex cords provides granulosa cells to the oocytes.²² However, the fetal ovary has the capacity for androgen and estrogen formation and signaling, although at a far lower level than the testes, by 12 weeks.^{22,32-35} Primordial follicles become primary follicles when the encircling granulosa cell layer becomes cuboidal. Primordial and small primary follicles (Fig. 16.4)^{36,37} are resting follicles, which are the major repository of germ cells.³⁸ This stock of germ cells is depleted only very slowly during childhood (see Fig. 16.3). Residence of primordial follicles in the ovarian cortex restrains their progression partly because of cortex mechanical rigidity.³⁹ Mechanical effects are mediated by the growth-restrictive Hippopotamus signaling pathway and by vascular permeability via the vascular endothelial growth factor signaling pathway.⁴⁰

Secondary follicles and preantral follicles, characterized, respectively, by organization of a distinct theca cell layer and proliferation of granulosa cell layers, then appear successively. Preantral follicles develop at 24 to 26 weeks.^{22,31} Antral (graafian) follicles appear near term, and those granulosa cells enveloping the oocyte to become the cumulus.^{37,41,42} Ovarian estrogen production appears to be virtually unresponsive to gonadotropins until early antral follicles develop at near term gestational age.^{18,43,44} One or two antral follicles of 1 to 2 mm in diameter are present in the ovary at term.^{18,22,31} At this time, ovarian follicle development is complete,^{37,41,42} and the complement of ova is greater than at any other time during postnatal life (see Fig. 16.3), totaling 2 million, of which half appear atretic.^{30,45}

Both X-chromosomes are active in oocytes,⁴⁶ and the oocytes secrete factors, such as growth differentiation factor-9 (GDF9),⁴⁰ necessary for the induction of the granulosa cell layer that is necessary for oocyte survival.^{41,47} Oocyte-specific chemokines and transcription factors then coordinately direct the formation of primordial follicles and their subsequent development to primary follicles.⁴⁰ GDF9 interaction with growth factors, such as BMP 9 and transforming growth factor beta (TGF- β), is then critical for primary follicle granulosa cell proliferation. Then preantral follicles develop when GDF9, in coordination with other growth factors, induces the theca cell layer from fibroblast-like stem cells.^{48,49} A host of local factors then regulate further follicle growth and development; for example, the forkhead transcription factor FOXL2, expressed specifically in granulosa cells, restrains GDF9 from prematurely activating follicle growth.⁵⁰

Estrogen receptor (ER) expression is critical for development of the granulosa cell layer.⁴⁰ Insulin and androgen promote the primordial-primary follicle transition. Only upon reaching the early antral follicle stage does further follicle development become strictly dependent on FSH action.

Follicle number is determined by the balance between survival and atresia of ovarian germ cells. The endowment of ovarian germ cells has been thought to be determined during fetal life since the germ cells of the ovary, unlike those of the testes, seem to be a nonrenewing population. However, female germline stem cells can replicate,⁵¹ which suggests that local environmental factors extrinsic to the oocyte hold it in a state of suspended animation.⁵² The endowment of follicles may also be influenced by circulating factors, such as toxins⁵³ and placental insufficiency.⁵⁴ Some clinical evidence suggests that fetal undernutrition slows the rate of atresia.⁵⁵ Studies in mice indicate that puberty appears to be a critical developmental window for the regulation of the follicle population because a wave of primordial follicle depletion is triggered by gonadotropin action on the intrinsic apoptotic pathway.⁵⁶

Placenta. The fetoplacental unit becomes the major source of sex hormones in the female fetus in the latter half of pregnancy: the fetal adrenal gland provides 17-KS as substrate for the formation of potent sex steroids by the placenta. Excess androgen, from any source, in the female fetus masculinizes genital

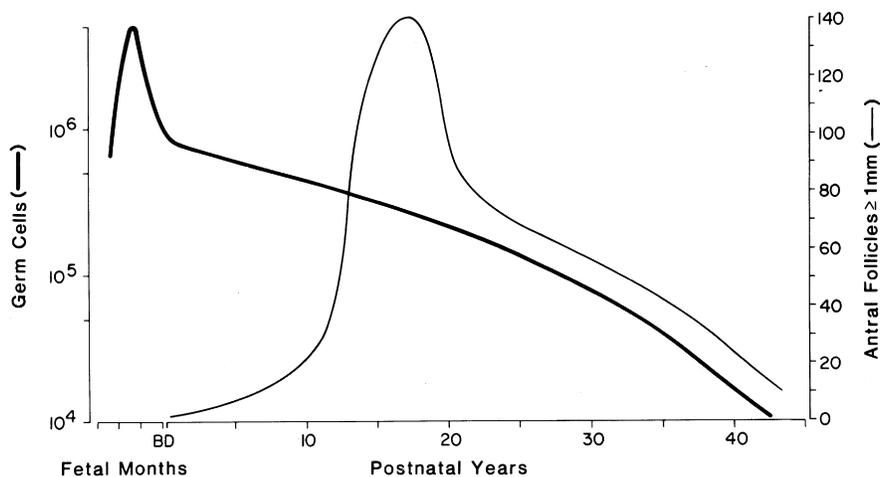

Fig. 16.3 The development of ovarian follicles from fetal life to maturity. Curves for total number of viable germ cells (*thick line*) and large antral follicles (*thin line*) smoothed from the data of Baker and Block. The number of germ cells is maximal at the fifth month of fetal life. The loss of germ cells is exponential throughout postnatal life. At puberty, a marked shift occurs in the pattern of development of follicles. An increased fraction grows to large antral size.

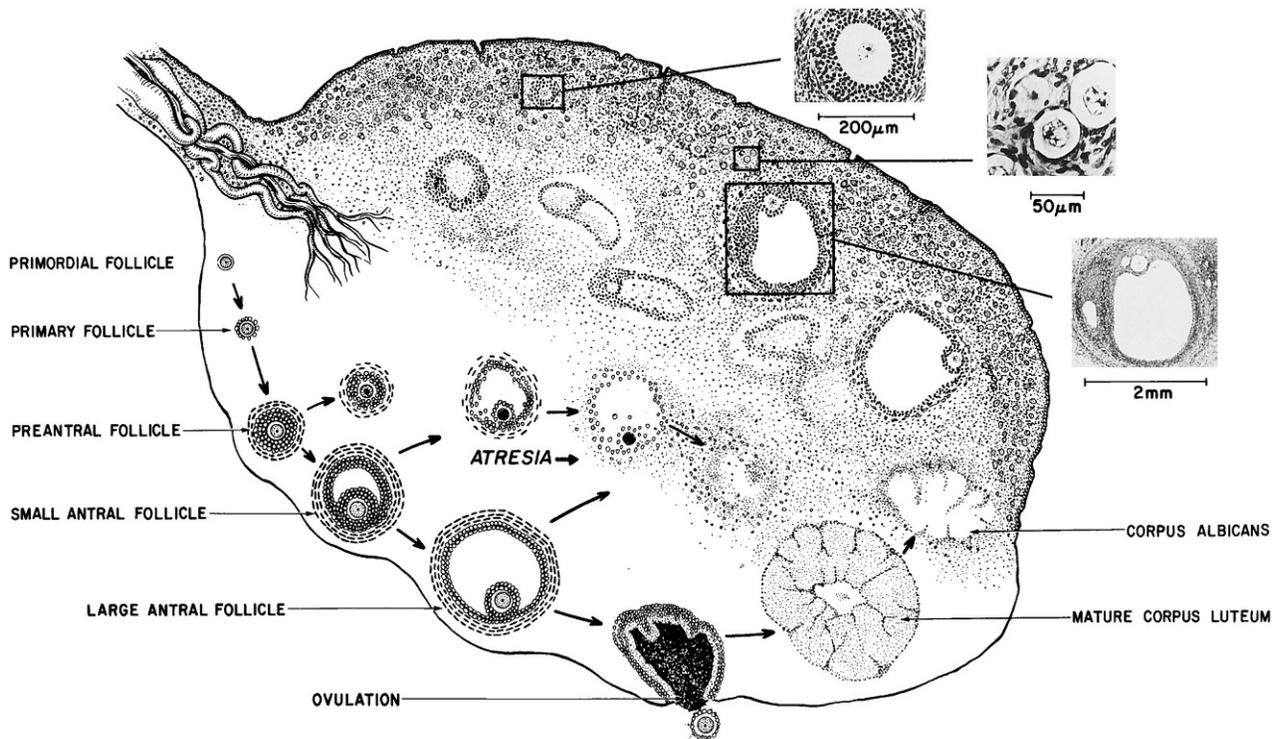

Fig. 16.4 The human ovary. The lower portion of the figure shows the classification of follicles. Preantral follicles contain as many as 300 granulosa cells, and their diameter ranges from 50 to 200 µm. The oocyte diameter increases from 25 or less to 80 µm. Antral (graafian, tertiary, or vesicular) follicles have a fluid-filled antrum and a full-grown oocyte, are lined with more than 300 granulosa cells, and have a well-developed theca. They are greater than 200 µm in diameter. The dimensions of the mature ovary are approximately 1.25 × 2.75 × 4 cm. The upper portion of the figure illustrates the histological appearance of the perimenarcheal ovary. (Photomicrographs from Peters, H. (1979). The human ovary in childhood and early maturity. *Eur J Obstet Gynecol Reprod Biol*, 9(3), 137; modified from Ross, G.T., Schreiber, J.R. (1978). The ovary. In: Yen, S.S.C., Jaffe, R. (eds.), *Reproductive Endocrinology*. Philadelphia, WB Saunders, p. 63.)

differentiation, as discussed in other chapters. This also programs for LH elevation and insulin resistance in adult life.¹⁵ Another factor predisposing to postnatal insulin resistance is placental insufficiency, via hypoxemia and resultant overactivation of fetal prostaglandin production and cortisol secretion.⁵⁷

Adolescent

The endocrinological changes of puberty actually begin in late preadolescence before secondary sex characteristics appear, as just reviewed. The underlying basic event is increasing secretion of hypothalamic GnRH. Puberty is the consequence of the hypothalamus releasing GnRH with increasing frequency and amplitude, first only at night, then gradually throughout the day.

Increased GnRH secretion in man was initially deduced when Kastin, Job, Grumbach and their collaborators demonstrated that preadolescent children had GnRH-releasable pituitary stores of LH and FSH (Figs. 16.6 and 16.9).⁸⁷ Subsequently, it was reported that in man, the output of an immunoreactive fragment of GnRH begins to rise in late childhood and increases to adult levels during puberty.^{73,88} Studies in the rat suggest that hypothalamic GnRH increases through puberty.⁸⁹

Knobil subsequently showed that puberty can be induced in the immature female rhesus monkey by administering GnRH in hourly pulses that yield blood levels of about 2000 pg/mL.⁹⁰

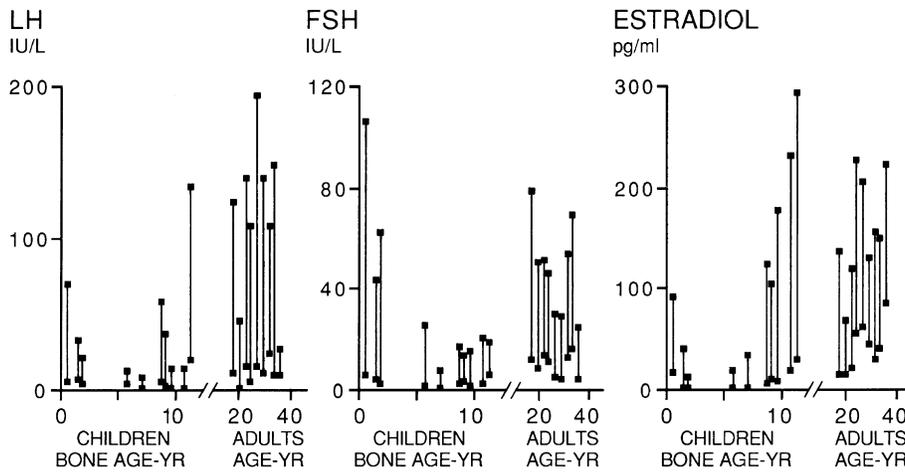

Fig. 16.6 Basal and peak responses to the gonadotropin-releasing hormone agonist nafarelin (1 mcg/kg subcutaneously) during development. Lines connect the basal and peak responses in control children. The responses are related to bone age in children and chronological age in adults. Note the biphasic pattern of the responses. They are high in infancy, lower in midchildhood, and rise again during puberty. The peak gonadotropin responses occur at approximately 4 hours, and peak estradiol responses occur at 20 hours. *FSH*, Follicle-stimulating hormone; *LH*, luteinizing hormone. (From Rosenfield, R.L., Burstein, S., Cuttler, L., et al. (1989). Use of nafarelin for testing pituitary-ovarian function. *J Reprod Med*, 34, 1044.)

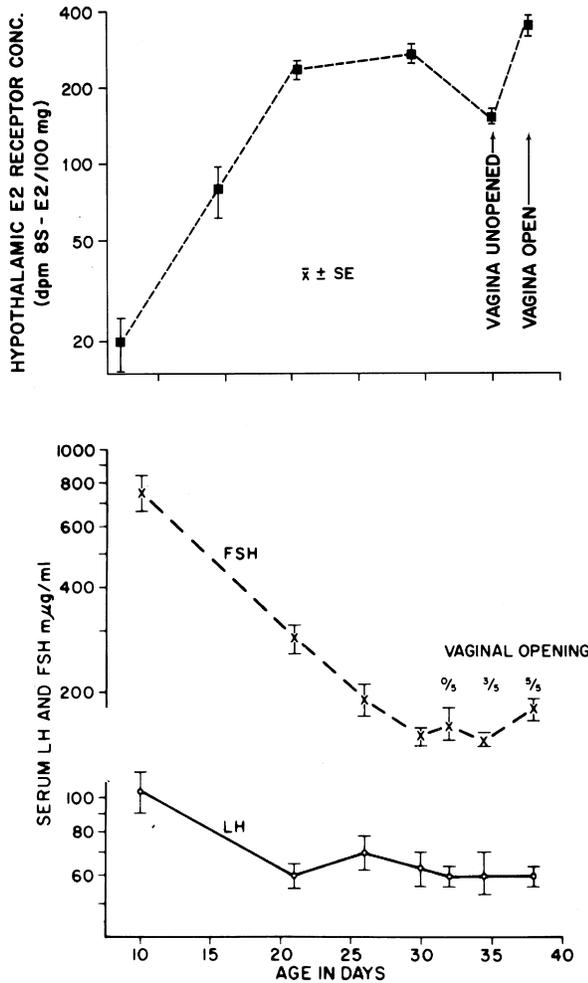

Fig. 16.7 Relationship of maturation of hypothalamic estrogen receptors (top) to serum gonadotropin levels (bottom) in the developing female rat. *FSH*, Follicle-stimulating hormone; *LH*, luteinizing hormone. (From Rosenfield, R.L. (1977). Hormonal events and disorders of puberty. In: Givens, J.R. (ed.), *Gynecologic Endocrinology*. Chicago, Year Book Medical. By permission of Mosby-Year Book.)

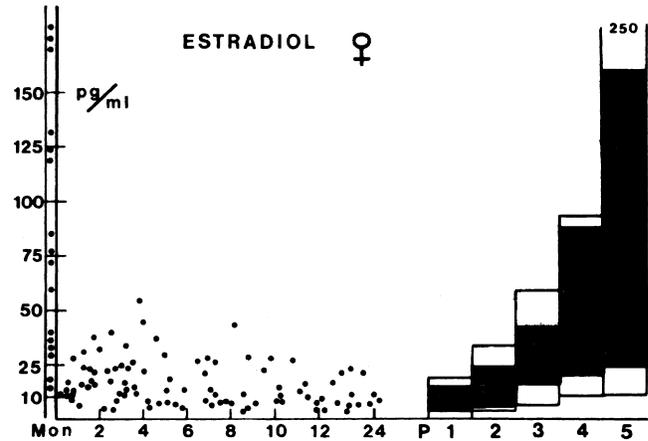

Fig. 16.8 The distribution of plasma estradiol levels in infant females compared with pubertal and adult female levels. The columns represent the normal ranges for the various stages of puberty. The area between 10th and 90th percentiles is dark. Stage P1 includes all prepubertal girls older than 2 years. The values between the ordinates were found between 2 and 5 days of age. (From Bidlingmaier, F., Knorr, D. (1978). Oestrogens: physiological and clinical aspects. *Pediatr Adolesc Endocrinol*, 4, 41-84.)

Prolonged administration of GnRH according to this regimen first gradually brings about transient increases in LH and FSH. This then induces cyclic follicular development. The resultant moderate estradiol surge is of such magnitude as to result in menarche because of withdrawal menstrual bleeding in an anovulatory cycle (Fig. 16.10). Continuation of the same GnRH regimen leads to development of normal monthly ovulatory menstrual periods. Physiological pulses of GnRH in man probably attain lower concentrations (200 pg/mL) and occur at slightly wider intervals than in monkeys.⁹¹ Consequently, LH pulses in mature women occur at intervals of approximately 1.5 hour during the follicular phases, slowing during the luteal phase.⁹²

Puberty begins in response to increased GnRH secretion. Serum LH first begins to rise disproportionately to FSH; this LH-FSH disparity is particularly evident during sleep, which is

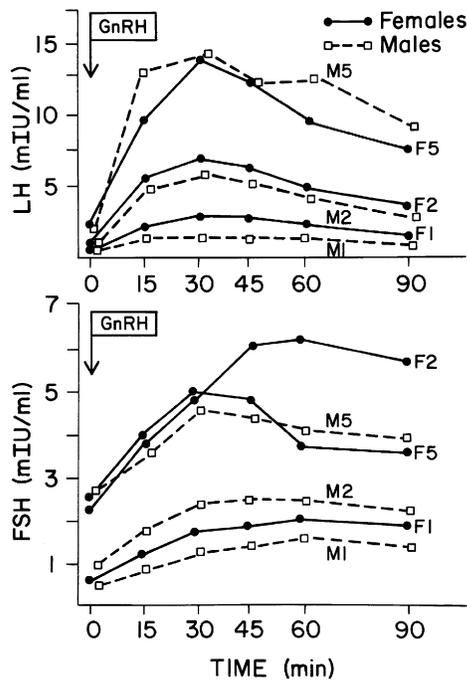

Fig. 16.9 The luteinizing hormone (LH) and follicle-stimulating hormone (FSH) responses to gonadotropin-releasing hormone (GnRH) bolus (50 mcg/kg/day) in males (M) and females (F) in prepuberty (age 5–6 years: F1, M1), early puberty (F2, M2), and later puberty (F5, M5). The responses to GnRH tend to progress with advancing puberty. However, early pubertal girls have a readily releasable FSH pool that is greater than that of more advanced adolescents. The peak responses of girls tend to be somewhat greater than those of boys at comparable stages. (Modified with permission from Ehrmann et al, Polycysticovary syndrome as a form of functional ovarian hyperandrogenism due to dysregulation of androgen secretion. *Endocr Rev.* 1995;16:322–353.)

reflected in responses to GnRH or GnRH agonist (Table 16.1). Puberty becomes clinically apparent as thelarche when estradiol levels are sustained >10 pg/mL.⁹³ It seems likely that a rise in inhibin-B as increasing ovarian follicles develop plays a key negative-feedback role in limiting further increase in FSH levels during puberty. FSH levels become less GnRH-dependent during puberty.⁷⁷ The mechanisms for differential regulation of FSH and LH are discussed later in this chapter.

Pubertal gonadotropin cycles seem to develop well before menarche^{7,94} and are capable of inducing cyclic estrogen production.^{94,95} Our working model of the nature of pituitary-ovarian dynamics in early puberty is illustrated in Fig. 16.11.

Puberty progresses as LH rises. Whereas serum FSH levels rise about 2.5-fold over the course of puberty, LH levels rise 25-fold or more.⁷⁷ The initial change in LH secretion at the beginning of puberty is a nightly increase in LH secretion that begins within 20 minutes of the onset of sleep. Subsequently, LH increases more with the onset of sleep, stays up longer, and falls less during waking hours. As the child approaches menarche, the daytime LH levels continue to increase until the diurnal rhythm is typically lost. FSH levels follow a similar pattern, although the FSH changes are less striking. The gonadotropin diurnal rhythm during puberty seems entirely related to sleep, unlike the cortisol circadian rhythm.⁹⁶ There is a delay of about 12 h between the peak LH level during sleep and the estradiol zenith, such that estradiol levels are maximal between late morning and early afternoon.^{97,98} The gonadotropin and estradiol rhythms in an early pubertal girl are shown in Fig. 16.12.⁹⁸

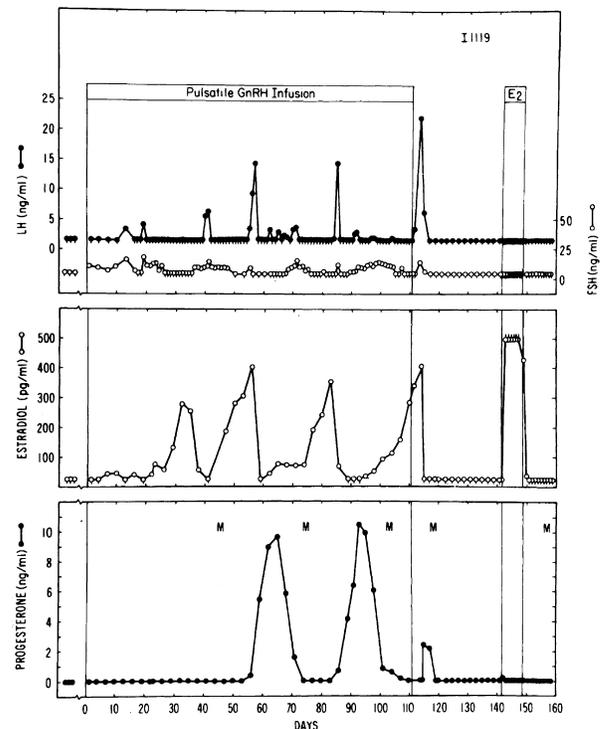

Fig. 16.10 Induction of puberty in a 13-month-old prepubertal rhesus monkey by an unvarying pulsatile gonadotropin-releasing hormone (GnRH) regimen (1 mcg/min \times 6 min hourly). Luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol (E2), and progesterone were undetectable before the GnRH infusion. On GnRH infusion, a rise in FSH was the first change detectable by midmorning sampling midway between GnRH pulses. A substantial E2 surge occurred approximately 1 month later. The subsequent LH surge was too modest to elicit ovulation, but menses (M) occurred a few days after subsidence of the week-long E2 surge—menarche resulting from an anovulatory cycle. Continuation of the GnRH led to the sustained occurrence of ovulatory menstrual cycles at 28-day intervals. An identical outcome results if an arcuate-lesioned adult animal undergoes this GnRH regimen. The third of the LH surges occurred 2 days after GnRH was discontinued. Progesterone secretion from the corpus luteum was blunted and transient in the absence of sustained LH secretion. A subsequent increase in plasma E2 produced by E2 implantation subcutaneously failed to elicit a gonadotropin surge, indicating that the animal had reverted to an immature state. Menarche eventually spontaneously recurred in such animals at the usual age (approximately 27 months). Small vertical lines beneath data points indicate values below the sensitivity of the assay. Note that gonadotropins and E2 were often undetectable (prepubertal range) during the induced puberty. (From Knobil, E. (1980). The neuroendocrine control of the menstrual cycle. *Recent Prog Horm Res.* 36, 53.)

Augmentation of the bioactivity of serum LH occurs during pubertal progression. Plasma LH bioactivity rises nearly fivefold more during the course of puberty than does LH as measured by polyclonal RIA.^{99,100} The change in bioactive LH is mirrored well by the “third-generation” monoclonal antibody-based immunometric (“pediatric”) assays that have very high specificity for bioactive LH epitopes. However, disparities in the ratio of bioactive to immunoreactive LH (B/I) persist with these assays, for reasons related to the molecular microheterogeneity of gonadotropins, which is discussed later. Serum FSH rises during puberty according to immunoassay more so than by bioassay.¹⁰¹

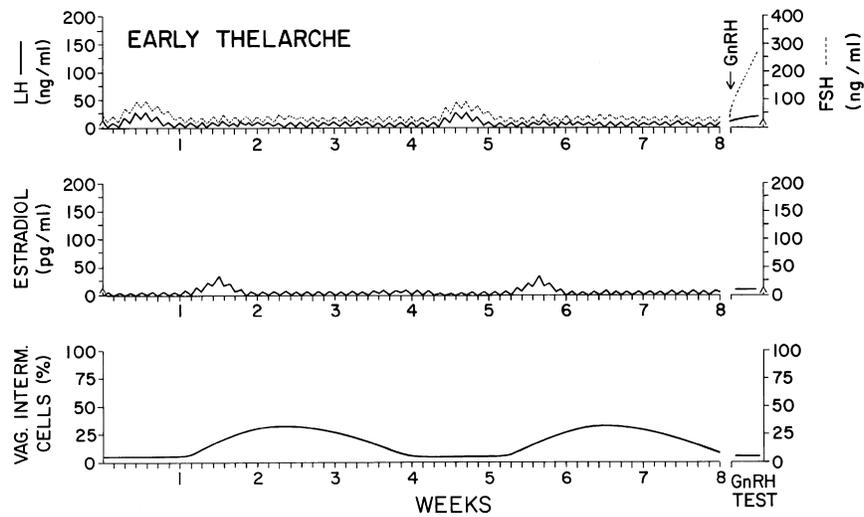

Fig. 16.11 Diagram depicting our working hypothesis of the hormonal patterns in girls during very early puberty. We conceptualize this pattern as occurring both cyclically in the earliest stage of normal puberty and occasionally in unsustained sexual precocity (i.e., most US cases of idiopathic premature thelarche). Daytime and nighttime serum concentrations of hormones (gonadotropins relative to the LER-907 standard) and the percentage of intermediate cells on vaginal smear are shown. The typical response to a gonadotropin-releasing hormone (*GnRH*) test is illustrated. Subclinical hormonal cycles lasting approximately 1 month result from a few days of increased follicle-stimulating hormone (*FSH*) and luteinizing hormone (*LH*) secretion. Because the drive to gonadotropin release is relatively weak, *FSH* and *LH* production are suppressed promptly and for long periods of time by the resultant modest amounts of estradiol (*E2*) secretion. Estradiol is detectable in plasma for only a few days a month. Maturation of the vaginal mucosa, however, is detectable for approximately 2 weeks after *E2* production has waned.

Estradiol output increases rapidly in the year approaching menarche.¹⁰² This seems to be the result of a variety of autoamplification phenomena that facilitate puberty, maturation of the dominant follicle, and ovulation. These are summarized in Box 16.1.^{103–116} These phenomena occur at all levels of the axis. The CNS is stimulated by preovulatory levels of

estradiol to increase *GnRH* pulse amplitude. At the pituitary level, there is the self-priming effect of *GnRH*, whereby a pulse of *GnRH* sensitizes the pituitary to have a greater *LH* response to a subsequent identical *GnRH* pulse. Critical patterns of estradiol and progesterone secretion enhance the pituitary *LH* and *FSH* responsiveness to *GnRH*. At the gonadal level, the cascade of events is augmented by the *FSH* induction of aromatase activity and progesterin production in granulosa cells, phenomena in which androgens play a synergistic role. Furthermore, *FSH* stimulates granulosa cell mitosis and induces *LH* receptors, phenomena in which estradiol may play a synergistic role. Subsequently, *LH* is able to further enhance the aromatase and

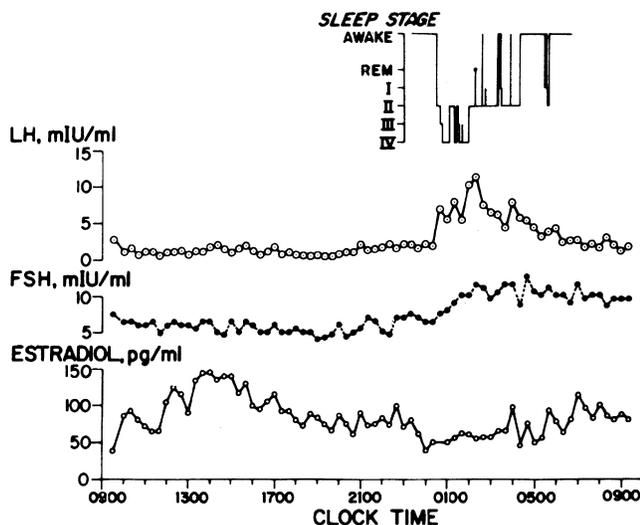

Fig. 16.12 The patterns of serum luteinizing hormone (*LH*), follicle-stimulating hormone (*FSH*), and estradiol (*E2*) typical of early female puberty. Note that daytime gonadotropin levels are in the prepubertal range. Note also the episodic nature of *LH* release at intervals of 1 to 3 hours. Estradiol levels are seen to fluctuate considerably in the course of the daytime, rising to peak levels about 12 hours after the maximum nocturnal gonadotropin surges. (From Boyar, R.M., Wu, R.H.K., Roffwarg, H., et al. (1976). Human puberty: 24-hour estradiol patterns in pubertal girls. *J Clin Endocrinol Metab*, 43, 1418.)

BOX 16.1 Autoamplification Processes Involved in Pubertal Progression, Follicle Maturation, and Ovulation^{38,99, 103–116}

Central nervous system *KISS1* and *GnRH* secretion increases^{103–104} via:

- *E2*-inducing progesterone receptors¹⁰⁵
- Progesterone synergization with *E2*¹⁰⁶

Pituitary *LH* and *FSH* responsiveness to *GnRH* increases via:

- *GnRH* self-priming¹⁰⁷
- Critical patterns of *E2* secretion-stimulating *LH/FSH* responsiveness^{108,109}
- Progesterone synergization with *E2*^{109–111}
- *LH* bioactivity increases⁹⁹

Gonadal responsiveness to *FSH* and *LH* increases via:

- *FSH*-inducing aromatase and progesterone in granulosa cells: androgens and progesterone synergization with this effect^{112–114}
- *FSH*-stimulated granulosa meiosis³⁸ and *FSH*-inducing granulosa *LH* receptors; *IGF-1* synergization^{115,116}

E2, Estradiol; *FSH*, follicle-stimulating hormone; *GnRH*, gonadotropin-releasing hormone; *IGF-1*, insulin-like growth factor-1; *KISS1*, kisspeptin; *LH*, luteinizing hormone.

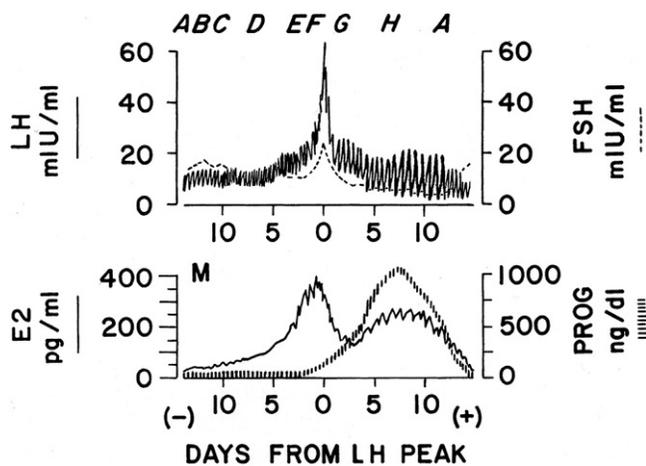

Fig. 16.13 Diagram of gonadotropin and female hormone levels during the normal menstrual cycle. The levels are centered in reference to the day of the midcycle luteinizing hormone (LH) peak (day 0). Letters A through F above the top panel correspond to stages of follicular development in Fig. 16.14. G and H are discussed in the text. M (bottom panel) shows time of menses. E2, Estradiol; FSH, follicle-stimulating hormone; PROG, progesterone. (Data from Abraham, G.E. (1974). (1984). Progesterone modulation of pulsatile luteinizing hormone secretion in normal women. *J Clin Endocrinol Metab*, 58, 378.)

progesterone effects. Progesterone itself plays a synergistic role in stimulating granulosa cell progesterone and prostaglandin synthesis in concert with both FSH and LH. In the rat, ovarian GnRH receptor sites also diminish just before ovulation,¹¹⁷ and at about this time the ovary changes its pattern of metabolism so that the secretion of androstenediol-3 β -monosulfate decreases to levels that are no longer inhibitory to LH secretion.¹¹⁸

The preovulatory gonadotropin surge occurs when all these cascading processes culminate in activation of the positive feedback mechanism, a unique feature of the female neuroendocrine system.^{119,120} Positive feedback refers to the neuroendocrine system acquiring the ability to secrete a midcycle surge of LH in response to the increasing estrogen secretion by a preovulatory follicle, that is, when the ovary signals via increasing estrogen secretion that it is prepared for ovulation.

Menarche does not necessarily indicate full maturation of the neuroendocrine-ovarian axis. As the studies of Knobil illustrate (see Fig. 16.10), menarche can be caused by estrogen-withdrawal bleeding—and it is about half of the time—but ovulatory cycles may follow in short order. General characteristics of the mature ovary are shown in Fig. 16.4.

The morphology of the normal adolescent ovary has long been considered polycystic, and histological examination typically has shown thecal luteinization.^{80,121} In the perimenarcheal period, the combination of a high number of follicles and mature gonadotropin stimulation leads to a greater number of 2 to 9 mm antral follicles within a year after menarche than at any other stage (see Fig. 16.3).³⁰ This often leads to a “multifollicular” ultrasonographic appearance^{82,122,123} that overlaps adult criteria for polycystic ovary morphology in one-third to one-half of normal adolescents (see section on polycystic ovary syndrome).¹²⁴

Adult

The follicular phase of each menstrual cycle recapitulates puberty in many respects. Gonadotropin and sex hormone levels are low during the premenstrual phase of the mature cycle (Fig. 16.13A).^{125,126} Gonadotropin concentrations then increase at the time of menstruation, FSH predominating in the early follicular phase, whereas nocturnal LH pulsation is slow¹²⁷ (Fig. 16.13B). LH pulsation increases to a circadian pattern around a stable baseline, and estradiol production slowly begins as antral follicles develop (Fig. 16.13C). Estradiol levels gradually increase and serum FSH levels fall reciprocally (Fig. 16.13D). Upon formation of a dominant follicle, serum estradiol concentrations increase geometrically. This selectively begins to amplify the pituitary’s LH response to GnRH as estradiol reaches about 90 pg/mL for over 3 days (Fig. 16.13E).

When the serum estradiol rises to over 200 to 300 pg/mL for 36 hours, the positive feedback mechanism is activated and the midcycle gonadotropin surge commences (Fig. 16.13F). Estradiol then appears to induce PR expression in the hypothalamus and pituitary.¹²⁹ An increase in progesterone to 100 ng/dL facilitates the LH surge, shortens the duration of time over which estradiol is required for the surge to 24 hours, and brings about an FSH surge. The mechanism of progesterone action involves inhibition of GnRH cleavage.¹¹¹ Androgens may also play a role in facilitating FSH and GnRH release.^{130,131} The LH surge is then primarily responsible for luteinizing the preovulatory ovarian follicle (see Fig. 16.13F). At this time, LH pulses become larger in amplitude but slower in frequency and their apparent bioactivity increases. Ovulation then results.

As the follicle is disrupted by ovulation, estrogen levels fall (Fig. 16.13G). Meanwhile, serum progesterone increases steadily as the corpus luteum begins to form, and comes to be sustained at very high levels for several days, along with a lesser increase in 17-hydroxyprogesterone (17-OHP) and a return of estradiol to late follicular phase levels (Fig. 16.13H).^{125,126,132} In response to the high progesterone level, LH pulses become slow and large.^{127,132} In the absence of increasing human chorionic gonadotropin (hCG) from a conceptus, the corpus luteum’s life span is exhausted and its production of progesterone and estradiol wanes. Subsequently, FSH begins to rise out of proportion to LH. Shortly after the sex steroids withdraw from the scene, the endometrium sloughs, giving rise to menstrual flow. Meanwhile, the follicular growth induced earlier by FSH begins to gain momentum and the next cycle begins.

Follicular (Proliferative) Phase Ovary. The hormonal functions of the follicle have dual purposes that must be closely coordinated: to change the milieu of the ovum to prepare for ovulation and to signal the pituitary to send the signal to ovulate, that is, the LH surge. Thus the ovary is the zeitgeber for the cycle; the normal cyclic pattern of ovarian hormone secretion induces the midcycle surge of pituitary gonadotropins, even in the presence of unchanging circadian pulses of GnRH.⁹⁰ Ovarian hormones also augment the amplitude of the GnRH response,^{103–106} which is a “fail-safe” mechanism that “guarantees” a preovulatory gonadotropin surge.

Ovarian follicular development and steroid secretion in relationship to changing gonadotropin levels are illustrated in Fig. 16.14.^{38,133–135} FSH and LH play major roles in granulosa and thecal cell differentiation, respectively, whereas a host of local factors modulate gonadotropin action. For example, follicular maturation in response to gonadotropins is enhanced by insulin-like growth factors (IGFs), TGF- β , and fibroblast growth factor, whereas it is inhibited by TGF- α .

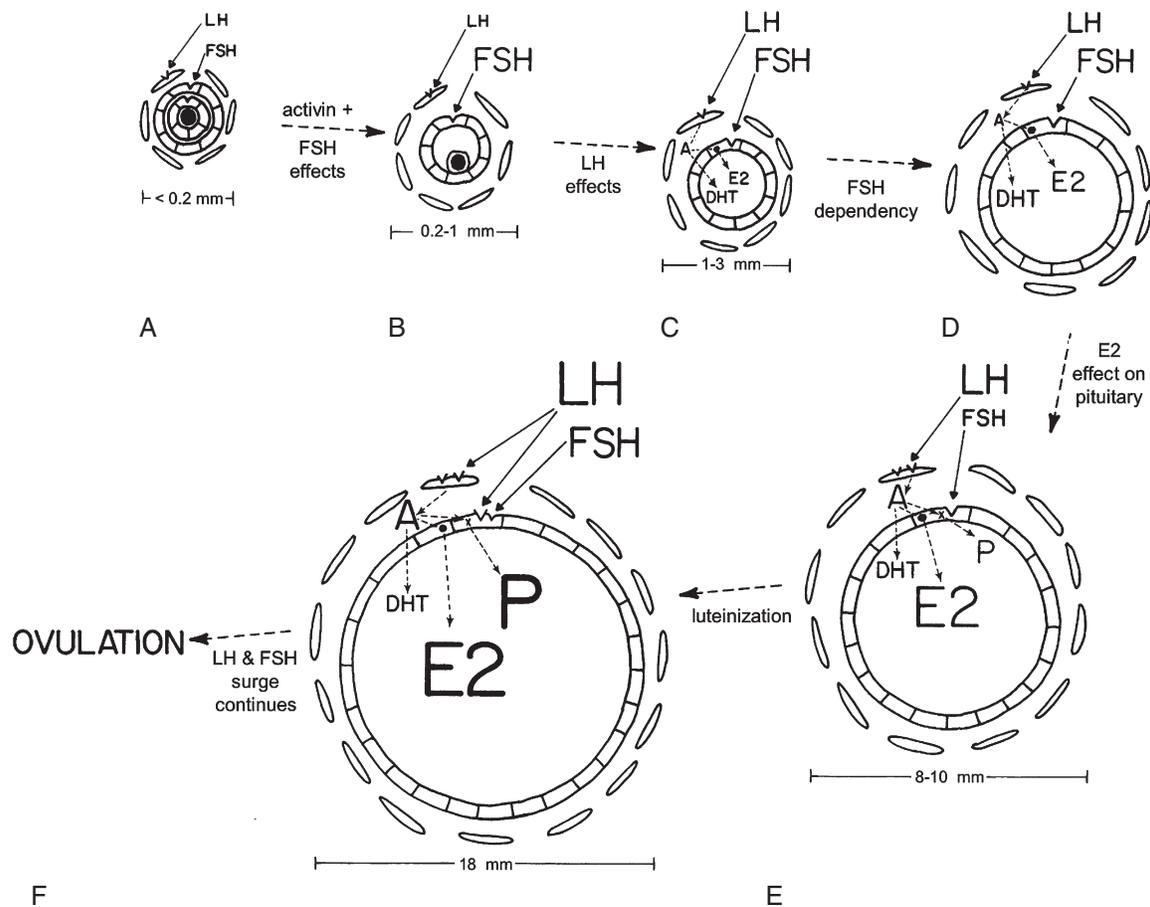

Fig. 16.14 Relationships among gonadotropins, the ovarian follicle, and ovarian steroids according to the two-cell two-gonadotropin model of ovarian steroidogenesis. A through F: Stages of ovarian follicular development found during the times of the menstrual cycle designated by the corresponding letters on Fig. 16.13. The size of the letters designating hormones relates to the magnitude of their serum and/or follicular concentrations. (A) Preantral follicle with luteinizing hormone (LH) and follicle-stimulating hormone (FSH) receptors in theca and granulosa cells, respectively. There is no antrum surrounding the ovum (stippled in center). (B) Small antral follicle. Activin upregulates FSH receptors, and FSH receptor activation is required to initiate antrum formation. (C) Larger antral follicle (≥ 1 mm). Aromatase activity (.) has been induced in granulosa cells. Interactions between theca and granulosa cells, the former producing androgens (androstenedione [A], and dihydrotestosterone [DHT] synthesis. (D) FSH-dependent granulosa cell multiplication (not shown) is responsible for more follicular growth and more E2 synthesis. (E) Estradiol enhances pituitary LH secretion in response to GnRH, while at the same time inhibiting pituitary FSH secretion. The increased LH induces more theca LH receptors and stimulates androgen production. Androgens serve as a substrate for E2 formation and synergize with FSH to stimulate progesterone (P) secretion. (F) In the preovulatory follicle, FSH induces LH receptors on the granulosa cell, which completes luteinization. Steroid secretion is augmented further. Then, increasing progesterone amplifies the positive feedback effect of E2 to initiate the preovulatory gonadotropin surge.

Primordial follicle growth and development is gonadotropin independent. Subsequently, granulosa cells of preantral follicles develop FSH receptors, and theca cells, which encircle granulosa cells, develop LH receptors (see Fig. 16.14A). Activin causes FSH-independent upregulation of FSH receptors in preantral follicles,¹¹⁶ although it opposes FSH stimulation of antral follicle development.³⁸ Primordial follicle growth is constitutively repressed by nuclear forkhead transcription factor Foxo3; when Foxo3 is released in response to stimulation of the PTEN-PI3K-Akt pathway, follicular growth progresses to the point where follicles become responsive to FSH.¹³⁶

Antrum formation requires a trace (prepubertal) amount of FSH receptor activation (see Fig. 16.14B).^{38,137-140} FSH stimulates androgen receptor expression in primary follicles, and androgens in turn stimulate further expression of FSH receptors and the early stages of follicular growth.¹⁴¹ Androgen action is also necessary for the development of a full complement of follicles, and androgen excess stimulates excessive follicle number.^{142,143} LH stimulates the appearance in theca cells of the enzymes necessary for androgen biosynthesis.¹⁴⁴ Evidence that theca cells of small antral follicles form estradiol is meager.¹⁴⁵

As antral follicles grow over 2.5 mm in diameter, their granulosa cells begin to form estradiol from androgen supplied by theca cells (see Fig. 16.14C).¹⁴⁶⁻¹⁵⁰ Androgen production at low levels may synergize with FSH to stimulate aromatase activity within the granulosa cells.^{112,151,152}

At this stage, follicles are increasingly FSH dependent and consequently uniformly FSH responsive.^{38,137} IGF-1 is required for follicular growth beyond the early antral stage in response to FSH.¹⁵³ Antral follicles do not grow over 5 mm in diameter without a pubertal degree of FSH stimulation.¹³⁹ By the midfollicular phase, the proliferation of FSH-responsive granulosa cells results in an accelerating rate of estradiol production and preferential conversion of androstenedione to estradiol rather than dihydrotestosterone (DHT) by these cells (see Fig. 16.14D).^{146-148,150,154,155} Estradiol itself clearly stimulates proliferation of granulosa cells and oocyte survival in rodents.¹⁵⁶ In humans, estradiol appears to promote antral growth independently of LH¹⁵⁷ and is synergistic with FSH in bringing about the development of the dominant follicle.^{158,159}

A dominant follicle is selected at the beginning of the menstrual cycle from a crop of follicles that were recruited

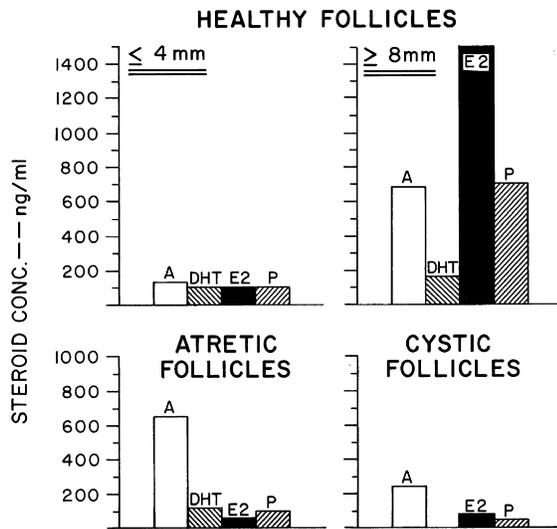

Fig. 16.15 Normal human antral fluid steroid concentrations. Healthy follicles are well populated by granulosa cells ($\geq 50\%$ of maximal complement). Healthy follicles seem capable of further development because many of them (75%) contain healthy-appearing oocytes (histologically intact germinal vesicles), 96% of which are viable in culture. Moderately large follicles (8 mm or larger in diameter) make their appearance only in the midfollicular phase of the cycle and contain follicle-stimulating hormone. Data are shown only for those large follicles well populated by granulosa cells, only one of which usually arises in the follicular phase of each menstrual cycle. Atretic follicles are small follicles beginning to show degenerative changes in the number of granulosa cells and appearance of the oocyte. Cystic follicles tend to be larger follicles with only a sparse granulosa cell lining. The testosterone content of antral fluid is about a third that of dihydrotestosterone (DHT) owing to the pattern of granulosa cell metabolism of androstenedione (A). E₂, Estradiol; P, progesterone. (Data from McNatty, K.P., Makris, A., Reinhold, V.N., De Grazia, C., Osathanondh, R., Ryan, K.J. (1979). Metabolism of androstenedione by human ovarian tissues in vitro with particular reference to reductase and aromatase activity. *Steroids*, 34, 429–443.)

2.5 months prior.³⁸ Recruitment of a group of follicles is normally promoted by the midcycle FSH surge and regresses with increasing corpus luteum progesterone secretion. Another wave of follicle growth in the late luteal phase is promoted by the rise of FSH as luteal progesterone and estradiol secretion wanes. The selected follicle is the one that is the most sensitive to FSH (lowest "FSH threshold"). FSH is critically important during the follicular phase for optimal development of this dominant follicle. By the midfollicular phase of the cycle this follicle becomes virtually the sole source of estradiol (see Fig. 16.14E). Typically, there is only one such follicle. Only this follicle continues to grow so as to reach a diameter of 10 mm or more. All other gonadotropin-dependent follicles undergo atresia.

At this stage, the rising estradiol level is suppressing FSH secretion and augmenting pituitary LH responsiveness to GnRH. FSH is more bioactive in the dominant follicle because it is more efficiently concentrated¹⁵⁴ and because local factors increase ovarian responsiveness to FSH. The increased LH causes further proliferation of thecal cells and an increase in their LH receptor content.¹¹³ Androgen production is consequently increased. This synergizes with FSH to both augment aromatase activity and bring about increasing progesterone secretion by the well-estrogenized granulosa cells of these follicles. Progesterone then enhances the synthesis of both itself and estradiol.^{113,115} The increased thecal androstenedione production is diverted much more to estradiol than to DHT biosynthesis. Antral fluid steroid concentrations reflect these changes (see Fig. 16.15).^{146,147,154}

Activin acts to prevent premature luteinization of granulosa cells, and activin tone seems to wane as the preovulatory phase approaches.^{38,116}

FSH next induces LH receptors in the granulosa cells, luteinizing them (see Fig. 16.14F).⁴⁰ Androgen and insulin synergize with FSH in this induction of LH receptors. LH then joins FSH in acting on luteinized granulosa cells to augment estradiol and progesterone production.

The LH and FSH surge then occurs in response to the positive feedback action of estradiol at both the CNS and pituitary levels, an effect amplified by the rising levels of progesterone. The final steps in follicle maturation ensue rapidly: the LH surge induces granulosa cell PR and prostaglandin synthase while inhibiting cyclin gene transcription,^{26,160} and the FSH surge upregulates vascular endothelial growth factor.¹⁶¹ In the absence of these critical steps, ovulation and follicular rupture do not occur. Then the follicle promptly becomes desensitized to LH and FSH and ceases to grow.¹⁶² This is followed by an inflammatory-type response. Protease activity, prostaglandin production, and vascular permeability increase; cell junctions loosen; and cumulus cells form a mucopolysaccharide envelope around the oocyte (cumulus expansion).

Oocyte meiotic maturation resumes in response to a specific phosphodiesterase,¹⁶³ forming the haploid gamete (secondary oocyte) and the first polar body in response to the LH surge.¹⁶⁴ Ovulation of the cumulus-oocyte complex then occurs. The presence of a favorable follicular steroidal milieu is necessary both for ovulation (a premature LH surge in a subject with an unripe follicle will not result in ovulation) and subsequent developmental competence of the oocyte.^{165,166} Meiosis will go to completion and the second polar body will be extruded only in response to contact with a sperm.

The processes stimulating dominant follicle emergence are delicately balanced by those preventing it. It seems critical that the intraovarian concentration of androgens not become excessive. Androgen excess interferes with follicle viability beyond about the 8-mm stage¹⁴⁸ and synergizes with FSH to cause premature luteinization.⁴⁰ These interfere with the emergence of dominant follicles. Follicles arrested in their growth become atretic, and atretic follicles contain relatively high concentrations of androgens (see Fig. 16.15). Progesterone also suppresses further differentiation of nondominant follicles¹⁶⁷ by some of the same mechanisms.¹⁶⁸ High concentrations of estrogen play a critical role in inhibiting selection of the dominant follicles in primates.¹⁶⁹ If there is interference with estrogenization, multiple large cystic follicles develop that are impaired in their ability to ovulate and undergo androgen-dependent atresia.^{170–172}

Anti-Müllerian hormone (AMH) and inhibins have emerged as other granulosa cell factors important in the regulation of follicular development. AMH is the major hormonal paracrine inhibitor of primordial follicle progression.⁴⁰ It is produced by the granulosa cells of small growing follicles. As follicles grow, intrafollicular AMH levels rise sufficiently to inhibit recruitment of primordial follicles to the primary follicle stage; it also inhibits P450c17 activity, GnRH release, and FSH stimulation of aromatase activity.^{40,173} Because estradiol inhibits AMH production,^{174,175} there exists an intrafollicular short negative feedback loop confining AMH expression to follicles up to about 8 mm in diameter. Thus AMH appears to act as a follicular gatekeeper, ensuring that each small antral follicle produces little estradiol before selection of the dominant follicle, which allows a direct ovarian-pituitary dialogue regulating the development of the follicle selected to undergo ovulation.¹⁷⁶

Inhibin-B is the predominant form of inhibin.^{177,178} It arises from granulosa cells in small follicles before aromatase is expressed¹⁷⁹ and is regulated by FSH in a sluggish negative feedback loop. It upregulates thecal steroidogenesis, as discussed later. Inhibin-A is a product of the preovulatory follicle (and corpus luteum) that responds to both LH and FSH.

Atresia is the fate of all except the few hundred follicles chosen for ovulation during an individual's life span. Most follicles beyond the primordial stage become atretic. Atresia occurs by the process of programmed cell death.³⁸ This apoptotic process has diverse determinants, including cell death inducer and repressor genes.^{135,180} FSH support becomes increasingly necessary for survival as the follicle matures, and it is normally only the follicle that has the lowest FSH threshold that escapes atresia.

Luteal (Secretory) Phase Ovary. Ovulatory rupture of the dominant follicle (see Fig. 16.13G) is followed by invasive proliferation of capillaries and fibroblasts from the theca that breaks down the separating basement membrane. The luteinized granulosa and theca cells then intermingle and complete the luteinization process by forming the corpus luteum.¹⁸¹

Histologically, luteinization is a process of lipid droplet accumulation that begins as the dominant follicle forms. The biochemical hallmark of the luteinized granulosa cell is the acquisition of LH receptors, with the subsequent capacity to form progesterone, 17-OHP, and estrogen in response to LH/hCG.^{182–184}

During its functional life span, the corpus luteum is normally the major source of the sex hormones secreted by the ovary. Corpus luteum function reaches its peak about 4 days after ovulation and begins to wane about 4 days before menstruation (see Fig. 16.13H). Loss of sensitivity to LH and estradiol heralds luteal senescence. Regression of the corpus luteum—luteolysis—occurs if pregnancy does not provide hCG. Luteolysis is probably mediated by prostaglandins. Transformation of the corpus luteum into an avascular scar, the corpus albicans, then occurs.

Early luteal phase increases in secretion of both estradiol and progesterone cause secretory transformation and hyperplasia of the endometrium, which is necessary for implantation of the fertilized egg. Later falloff in secretion of female hormones to a level insufficient to maintain the endometrium results in menstruation (see Fig. 16.13A). Withdrawal of progesterone is specifically responsible for constriction of spiral arteries, local prostaglandin accumulation, and subsequent ischemic necrosis of the endometrium. Normal menstrual flow then results from a complete slough of the secretory endometrium.

Documentation of ovulation can be accomplished by demonstrating collapse of the dominant follicle by ultrasonographic monitoring¹⁸⁵ or by assessing the luteal transition in the estradiol/progesterone ratio,¹⁸⁶ detecting the LH surge,¹⁸⁷ or demonstrating a normal midluteal phase rise of serum progesterone either directly¹⁸⁵ or indirectly by a rise in basal body temperature.¹⁸⁸ A significant rise in basal body temperature, averaging 0.55° C, usually occurs when serum progesterone reaches 400 ng/dL or more and continues as long as that level is maintained. While the results of these methods are correlated, LH surges are sometimes inadequate to stimulate a follicle sufficiently mature to develop into a normally functioning corpus luteum, particularly during adolescence^{124,189} (see Luteal Phase Defects).

Regulation of the Neuroendocrine-Ovarian Axis

Factors Controlling the Onset of Puberty

Pubertal onset is under the control of a complex regulatory network that is able to dynamically respond to numerous endogenous and environmental signals. GnRH neurons play a critical hierarchical role in the direct and indirect integration of these central and peripheral signals. Reproductive development is coupled with metabolic cues that may disrupt the maturational process. The mechanisms by which neuroendocrine and genetic factors control pubertal development remain unknown. Epidemiological studies indicate that nutrition, ethnicity, and genetic factors, are normally important in the pubertal process.¹⁹⁰ Environmental chemicals and chronic inflammatory disease can disrupt the process.^{190–193}

Evidence that there are genetic factors involved in the timing of puberty comes from multiple studies.^{194–204} It has been estimated that between 50% and 80% of the variation in the timing of puberty is genetically determined. Several large genome-wide association studies (GWAS) of age at menarche, examined pubertal timing in healthy females^{205–207} to identify the genes responsible. These studies demonstrated that there is significant genetic heterogeneity in pubertal timing in the general population that is likely to involve hundreds of common variants. The gene Lin-28 homolog B (*LIN28B*)²⁰⁸ was the first locus associated with age of menarche. *LIN28B* is the human ortholog of the *Caenorhabditis elegans* gene that controls developmental timing through micro ribonucleic acid (microRNA). Mutations in *LIN28B* have not been identified in humans with disorders of puberty.^{209,210} The 1000 Genomes Project studied genotype data in about 370,000 women and identified 389 independent signals ($P < 5 \times 10^{-8}$) for age at menarche,²¹¹ with effect sizes per allele ranging from 1 week to 5 months. These signals explain only about 7.4% of the population variance in age at menarche. Genes implicated in GnRH signaling, pituitary development, hormonal regulation, fatty acid biosynthesis, and energy homeostasis have been implicated.^{207,212–215} Although mutations in these genes have been shown to cause physiological interruptions in development, their role in the initiation of puberty remains unknown. Specifically, single nucleotide polymorphisms (SNPs) in the GnRH and GnRH receptor genes have not been associated with variations in the timing of puberty in the general population.²¹⁶

The key in the initiation of puberty is the activation of the hypothalamic GnRH pulse generator. The molecular events that control the pulse generator include a complex interplay between both inhibitory and stimulatory factors. The mechanism of central activation of puberty first appears to be a consequence of a removal of a restraint mechanism, with a rise in gonadotropin secretion (initially during sleep).²¹⁷ This restraint in the GnRH pulse generator is independent of the presence of gonads⁷⁰ and more intense in males.²¹⁸ A targeted gene approach in mice has confirmed that ER α (also termed ESR1) in Kiss1 neurons mediates feedback suppression of both Kiss1 expression and gonadotropin secretions during the prepubertal period.²¹⁹

However, the high levels of testosterone to which the male fetus was exposed during the period of sexual differentiation may be responsible for the more prolonged suppression of GnRH release in males than females. A role for decreased estrogen feedback sensitivity by the hypothalamic pulse generator near the time of puberty has also been shown.²²⁰

Recent evidence points to an important role for the kisspeptin 1 receptor (*KISS1R*), a G-protein-coupled receptor (previously known as GPR54), and its ligand, kisspeptin, an excitatory neuropeptide, as a signal for pubertal GnRH release. Expression of both proteins has been found to increase before pubertal onset in association with the increase in GnRH pulse generator activity in the hypothalamus.²²¹ Kisspeptin binding to its receptor on GnRH neurons stimulates GnRH secretion. Mice with knockout of *Kiss1r* were found to be infertile despite having normal GnRH neurons.^{222,223} Leptin and androgen synergistically upregulate this system, and estrogen antagonizes it.²²⁴ Mutations in *KISS1R* result in hypogonadotropic hypogonadism.^{213,222,225} However, mutations in *KISS1R* have not been found in boys with pubertal delay, nor have polymorphic sequences been associated with delay of pubertal development.²²⁶ Elegant studies in primates have demonstrated an increase in kisspeptin during pubertal development with a corresponding increase in *KISS1R* associated with an increase in LH. The maximum level of expression of kisspeptin and *KISS1R* in the hypothalamus in both males and females occurs at puberty.^{227,228} For each Tanner stage, girls tend to have higher kisspeptin levels than boys, potentially explaining their earlier onset of puberty.²²⁹

Chronic administration of kisspeptin to immature female rats induces precocious activation of the central axis.²²⁷ In addition, chronic treatment with kisspeptin restores pubertal development in a rat model of undernutrition.²³⁰ Kisspeptin may thus not only influence the priming of puberty, but also the integration of nutritional and energy status.²³¹ Although it is clear that kisspeptin activation of GnRH neurons occurs at puberty and that GnRH is increasingly sensitive to kisspeptin activation during development,^{232,233} other pathways contribute to GnRH activation since the hypogonadism associated with deficiency of *KISS1* or *KISS1R* is not complete.²³⁴

Neurokinin B (NKB) signaling seems to be critical for the initiation of puberty.²³⁵ Some kisspeptin neurons, KNDy neurons, coexpress NKB, dynorphin A, and their receptors (TAC3R and KOR), the primary function of which seems to be synchronizing kisspeptin neuron pulsatility.²³⁶ Receptors for NKB are also located on GnRH neurons, where they seem to modulate GnRH release or transport.²³⁷ Loss-of-function mutations in *TAC3* and its receptor *TACR3* in patients with normosmic GnRH deficiency and pubertal failure²³⁸ have identified a role for this neuropeptide in the control of GnRH secretion. Although kisspeptin directly regulates GnRH expression and secretion, NKB agonists failed to stimulate GnRH release in rodents. It appears most likely that a collaborative mechanism that includes both kisspeptin and NKB signaling to GnRH neurons is necessary for reproductive function in females.^{239,240} To investigate the interactions of kisspeptin and NKB in humans,

the effects of the coadministration of kisspeptin-54, NKB, and an opioid receptor antagonist, naltrexone, on LH pulsatility were studied. Subjects receiving kisspeptin and naltrexone increased LH and LH pulsatility, whereas NKB alone did not affect gonadotropins. NKB and kisspeptin given together had significantly lower increases in gonadotropins compared with kisspeptin alone. These results suggest significant interactions between the KNDy neuropeptides on GnRH pulse generation in humans.²⁴¹ Further, *Tacr3* knockout mice are infertile,^{242,243} although they appear to have reversible central hypogonadism.²⁴⁴ Interestingly, a mutation in *TAC3R* was found in one patient with constitutional delay of growth and pubertal development (CDGP) in a study of 50 patients,²⁴⁵ whereas none have been reported in *TAC3*.

Disrupting mutations in makorin ring finger protein 3 (MKRN3), a paternally expressed, imprinted gene located in the Prader-Willi syndrome locus, are associated with central precocious puberty.²⁴⁶ This indicates the presence of a GnRH release-inhibiting pathway centered in the arcuate nucleus.

Initiation of puberty involves coordinated changes in transsynaptic and glial-neuronal communication.²⁴⁷ Mediating pubertal restraint are the major inhibitory systems: gamma-aminobutyric acid (GABA)ergic,²⁴⁸ some opioidergic contribution,²⁴⁹ and gonadotrophin-inhibiting hormone (GnIH), an RFamide-related peptide (RFRP).²⁵⁰ The major excitatory systems involve glutamate and kisspeptin signaling, with glial cells facilitating GnRH secretion in diverse ways (Fig. 16.16).^{236,247}

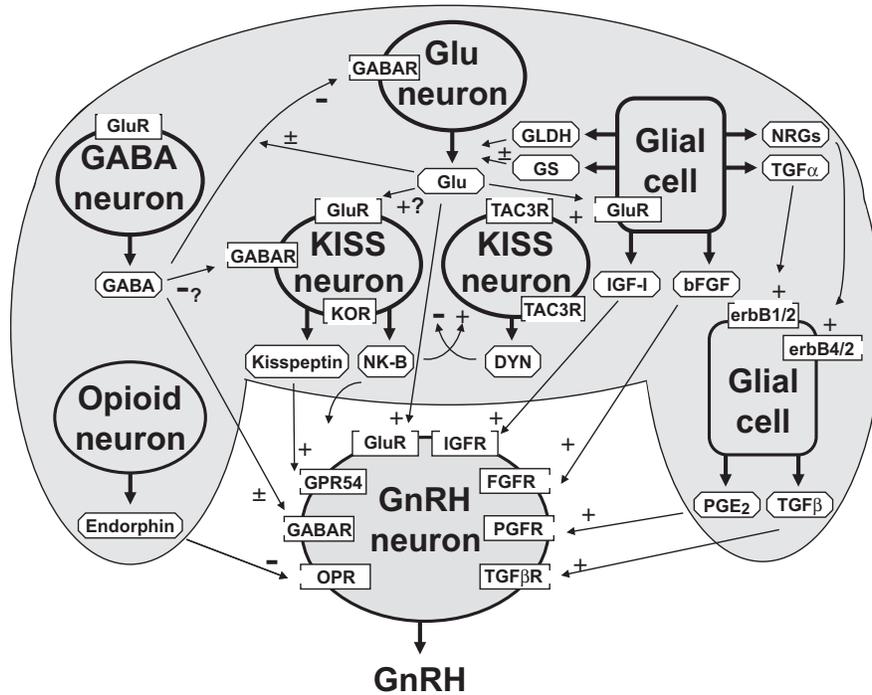

Fig. 16.16 The molecular biological basis for the major known proximate hypothalamic pathways regulating gonadotropin-releasing hormone (*GnRH*) secretion. The left-hand column depicts the major inhibitory pathways, which involve gamma-aminobutyric acid (*GABA*) signaling through the *GABA* receptor and opioidergic signaling through the endorphin receptor (*OPR*). The central column depicts the major excitatory pathways, which involve glutamate (*Glu*) signaling through the family of glutamate receptors and kisspeptin (*KISS*) signaling through *GPR54*. The right column shows the major glial factors that facilitate *GnRH* release. These include the elaboration of the enzymes glutamic dehydrogenase (*GLDH*) and glutamine synthase (*GS*), which regulate the concentration of glutamate and the elaboration of a variety of growth factors. Most kisspeptin neurons coexpress neurokinin B (*NK-B*), dynorphin A (*DYN*), and their receptors (*TAC3R* and *KOR*), the primary function of which seems to be synchronizing kisspeptin neuron pulsatility; receptors for NKB are also located on *GnRH* neurons. +, Positive stimulation; -, inhibition; ±, either; ?, unknown; *bFGF*, basic fibroblast growth factor; *erbB 1-4*, subunits for the *TGF-β* and *NRG* receptors; *IGF-1*, insulin-like growth factor 1; *NRG*, neuroregulins; *PGE*, prostaglandin E; *R*, receptor; *TGFβ*, tumor growth factor β. (Modified from Ojeda, S.R., Lomniczi, A., Mastronardi, C., et al. Minireview: the neuroendocrine regulation of puberty: is the time ripe for a systems biology approach? *Endocrinology*, 147, 1166–1174).

It appears that GABA receptor signaling develops in advance of glutamate signaling.²⁵¹ Increased signaling via glutamate receptors of several types (ionotropic and metabotropic) appears to be the major proximate change in neurotransmission involved in puberty onset.^{217,218,247} At puberty, however, seemingly as a consequence of glutamate receptor signaling, GABA-A receptor signaling on GnRH neurons increases GnRH secretion.^{217,221,252,253} Glial cells facilitate the process through elaboration of TGFs (especially TGF- β 1), IGF-1, neuregulins, prostaglandin E₂, and the elaboration of enzymes that control the concentration of glutamate (glutamic dehydrogenase, which catalyzes the synthesis of glutamate, and glutamine synthase, which converts glutamate to glutamine).²⁵⁴

The basis of the change in neurotransmitter balance is becoming clearer. A second tier of control seems to be modulation of these processes by increased hypothalamic expression at puberty of tumor-suppressor genes that act to integrate glial-neuronal interactions. A yet higher echelon of candidate hypothalamic genes have been identified that are transcriptional regulators of the second-tier genes. These genes include *Oct-2*, a regulator of the POU-domain homeobox genes, enhanced at puberty 1 (*EAP1*), knock-out of which delays puberty and decreases fertility of mice, thyroid transcription factor I (*TTF1*), yin yang 1 (*YY1*), and *CUX1*.²⁵⁵ Genes contiguous to elastin appear to be involved in the pace of puberty: deletion of chromosome 7q11.23 in Williams syndrome typically leads to an early normal onset but rapid pace of puberty with an abbreviated pubertal growth spurt.²⁵⁶ Substantial redundancy of these networks and the signaling neurochemicals exists since the onset of puberty is dependent on the expression of many genes, likely arranged in a coordinated network. The gene products may function as activators or repressors of targets important for pubertal onset and progression. Sex steroids have been implicated as important modulators in pubertal onset.²⁵¹

MicroRNAs, specifically the miR-200/429 family and miR-155, have been shown to be important in the epigenetic regulation of puberty by regulating GnRH gene transcription.²⁵⁷ miR-7a2 is critical for normal pituitary development and deficiency results in gonadotropin deficiency.²⁵⁸

Thus the onset of puberty is controlled by an opposing increase in excitatory and a corresponding decrease in inhibitory signaling from neural networks targeting the GnRH neuron. Lesioning studies indicate that inhibitory tracts mainly seem to be routed through the posterior hypothalamus and stimulatory ones through the anterior hypothalamic preoptic area.^{1,259} These studies have been complemented by studies in genetically engineered mouse models. In one such model, the anteroventral periventricular nucleus (AVPV) population of neurons was shown to be the site of estrogen positive feedback in the control of pubertal progression, and kisspeptin cells in the arcuate nucleus of the hypothalamus were shown to be critical for estradiol negative feedback.²⁶⁰ Indeed, it appears that KNDy neurons integrate negative feedback of sex steroids to regulate GnRH secretion.^{261,262} Postmortem hypothalamic tissues were collected by The Netherlands Brain Bank, and sections were stained for kisspeptin by immunohistochemistry to determine the number of kisspeptin-immunoreactive neurons within the infundibular nucleus. This study showed that the number of kisspeptin neurons is greater in the infant/prepubertal and elderly periods compared with the adult period. In MTF transsexuals, but not homosexual men, female-typical kisspeptin expression was observed. The authors suggest that infundibular kisspeptin neurons are sensitive to circulating sex steroid hormones and that the sex reversal observed in MTF transsexuals might in part reflect an atypical brain sexual

differentiation.²⁶³ Neonatal androgenization, which ablates the ability to generate a midcycle LH surge, was shown to selectively inhibit development of the AVPV population of kisspeptin neurons.²³⁶

An overview of the systems involved in regulating the initiation of puberty is shown in Fig. 16.17. Pubertal maturation and skeletal maturation seem to have common determinants.

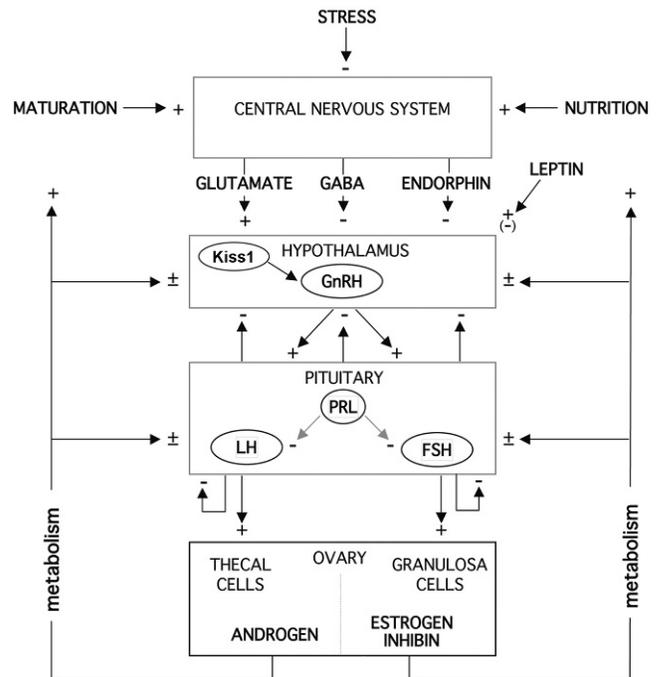

Fig. 16.17 Diagram of the major mechanisms controlling the development and function of sex hormone secretion by the unripe antral follicle. Regulation may be either stimulatory (+) or inhibitory (-). The central nervous system (CNS) influences kisspeptin (KISS1) and gonadotropin-releasing hormone (*GnRH*) secretion both negatively and positively. For the CNS to relinquish its inhibitory control over *GnRH* secretion, it must achieve a high level of maturity. Even after this is achieved, psychological or physical stress may negatively influence the system. Nutrition must be optimal. Leptin is a critical mediator of the nutrition effect. Sex steroids have a maturing effect. Whether efferent tracts from the hypothalamus to the cerebrum play a role in reproductive function is unknown. Pineal secretion of melatonin and other substances are known to exert inhibitory influences on *GnRH* in lower animals (not shown). Kisspeptin stimulates *GnRH*, which in turn stimulates luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Paracrine and autocrine feedback of the gonadotropins on *GnRH* release and on their own release, respectively, are shown. Prolactin (PRL) has multiple effects on gonadotropin secretion. In unripe antral follicles, LH acts on thecal and interstitial cells and FSH acts on granulosa cells. Androstenedione and testosterone secreted by the theca cells are aromatized by the granulosa cell, under the influence of FSH, to estradiol. The granulosa cell is also the site of production of the FSH inhibitor inhibin B. Estradiol has a biphasic effect on the mature pituitary and on hypothalamic *GnRH* release as well. Androgens seem normally to be of minor importance in regulating gonadotropin release in females. Intraovarian mechanisms seem to modulate LH action so as to coordinate thecal formation of androgens with granulosa cell formation of estrogens. Paracrine and autocrine factors, including insulin-like growth factors, are involved. GABA, Gamma-aminobutyric acid.

Abundant clinical evidence indicates that sex steroid hormones are among these determinants.^{264,265} Thus genes involved in sex steroid hormone metabolism and action are candidate regulators of the onset of puberty. There is limited and inconsistent data on the role of endocrine-disrupting chemicals on the timing of puberty, although some animal and epidemiological evidence supports the potential for some compounds to accelerate the time of pubertal onset and for others to delay the timing.^{190–192,266} Experience with diethylstilbestrol indicates that fetal exposures can have epigenetic effects.²⁶⁷ The growth hormone (GH)-IGF system is another determinant. GH facilitates the onset and tempo of puberty.²⁶⁸ Experimental studies suggest that this occurs through GH or IGF actions at all levels of the neuroendocrine-ovarian axis.^{269,270} Girls generally enter puberty when they achieve a pubertal bone age. Pubertal stage normally correlates better with the bone age ($r = 0.82$) than with the chronological age ($r = 0.72$, RLR unpublished data), particularly as menarche approaches.²⁷¹ Skeletal age correlates better with menarche than chronological age, height, or weight, and its variance at menarche is half that of chronological age.²⁷² The bone age at the onset of breast development averages about 10.75 years, and that at menarche averages about 13.0 years. Disorders that accelerate bone maturation, such as congenital adrenal hyperplasia (CAH) or hyperthyroidism, tend to advance the age of onset of true puberty.²⁷³ Disorders that retard skeletal maturation, such as GH deficiency, hypothyroidism, or anemia, tend to delay the onset of puberty.²⁷⁴ On the other hand, some data suggest that factors linked to intrauterine growth retardation, although not necessarily the growth retardation itself, predispose to sexual precocity.¹⁹⁰

Optimal nutrition is clearly necessary for initiation and maintenance of normal menstrual cycles. The hypothesis that body fat is the weight-related trigger for pubertal development originated with the discovery by Frisch and coworkers that weight correlated with initiation of the pubertal growth spurt, peak growth velocity, and menarche better than chronological age or height.²⁷⁵ Midchildhood may be a critical period for weight to influence the onset of puberty.¹⁹⁰ Suboptimal nutrition related to socioeconomic factors is an important factor in the later onset of puberty in underdeveloped than in developed countries.¹⁹⁰ Conversely, obesity appears to be an important factor in advancing the onset of puberty in the United States.²⁷⁶ Some of the obesity effect may be mediated by IGF-1 and adrenal androgen.²⁷⁷

Leptin appears to be an important link between nutrition and the attainment and maintenance of reproductive competence.^{218,278,279} Leptin deficiency causes obesity and gonadotropin deficiency. Paradoxically, prolonged leptin excess can downregulate the leptin receptor and GnRH release.²⁸⁰ Leptin is secreted by white adipose cells, acting on the hypothalamus to reduce appetite and stimulate gonadotropin secretion.²⁸¹ A critical threshold level appears to signal that nutritional stores are sufficient for mature function of the GnRH pulse-generator and, thus to be permissive for puberty. Blood leptin levels rise throughout childhood and puberty to reach higher levels in girls than boys²⁸² and are positively related to adiposity and negatively related to testosterone levels.²⁸³ Leptin binding protein, a truncated form of the leptin receptor, falls as puberty begins, which suggests that circulating leptin becomes more bioavailable.²⁸² Whether leptin has a direct role in the pubertal activation of the GnRH pulse generator is unknown. In models of leptin insufficiency, the administration of kisspeptin induced LH secretion.²²⁷ Conversely, leptin's effect on puberty did not require signaling in kisspeptin neurons in other mouse models.²⁸⁴

Other factors also link nutrition and gonadotropic function. Part of the leptin effect is mediated by inhibition of

hypothalamic neuropeptide Y (NPY) formation.²⁸⁵ NPY is a potent appetite-stimulating member of the pancreatic polypeptide family that directly inhibits GnRH release during food deprivation.²⁸⁵ However, in the preovulatory state, it stimulates GnRH release,²⁸⁶ an effect mediated by a different neural network acting on a different NPY receptor subtype on the GnRH neuron.²⁸⁷ NPY is also inhibited by the anorexigenic peptide YY (PYY), a gut hormone secreted in response to food and inhibited by GH; the pubertal fall in PYY has been postulated to permit the coordinated pubertal rise in appetite and gonadotropins.²⁸⁸ Insulin may also signal nutritional status to KNDy neurons, since deletion of the insulin receptor in KNDy neurons in genetically modified mice resulted in pubertal delay and reduced serum LH levels in both sexes. Interestingly, adult fertility was not affected.²⁸⁹

GWAS studies of pubertal timing implicated several genes associated with body weight other than leptin and leptin receptor and include fat mass and obesity-associated protein (*FTO*), SEC16 homolog B (*SEC16B*), transmembrane protein 18 (*TMEM18*), and neuronal growth regulator 1 (*NEGR1*).²¹¹ Rare heterozygous variants in *FTO* have been identified in pedigrees with CDGP associated with low body mass index (BMI) and growth and pubertal delay.²⁹⁰ Mice made heterozygous for the *FTO* gene knockout displayed delayed puberty, but did not manifest low body mass. Other mediators linking nutrition and puberty include melanocortin (MC)3/4 receptors, signaling from alpha-melanocyte-stimulating hormone (MSH) to increase *Kiss1* expression and mediate the permissive effects of leptin on puberty,²⁹¹ and ghrelin and mutations in the ghrelin receptor growth hormone secretagogue receptor (*GHSR*).^{292,293} A small cohort of 31 CDGP patients was analyzed for mutations in *GHSR*, and 5 patients were found to have point mutations in this gene.²⁹⁴

Other cues that provide information on nutritional status to the central reproductive axis may include glucose,²⁹⁵ ghrelin,²⁹⁶ and insulin.²⁹⁷ The effect of these factors on LH pulsatility may be mediated directly at the level of the gonadotroph or indirectly by changes in GnRH secretion. There is little evidence for the role of pineal secretions in human reproduction that is found in lower animals.^{298,299}

The essential element for the onset of puberty is an increase in pulsatile hypothalamic GnRH secretion that is regulated by a complex interplay of excitatory and inhibitory signals that have yet to be fully understood or elucidated.²⁴⁷ During childhood the activity of the GnRH pulse generating system is restrained, an awakening of the pulse generator occurs gradually during late childhood, and the tempo of GnRH neuronal activation increases during puberty. The underlying mechanisms for all these changes are unclear. The pubertal diminution in tone of the CNS centers that inhibit hypothalamic GnRH secretion during childhood has traditionally been considered to result from decreasing sensitivity of a "gonadostat" to negative feedback by sex steroids.^{6,300} However, this now seems an overly simplistic concept for a mechanism that seems to involve a change in the balance of neural inhibitory and stimulatory signals that impinge upon the GnRH neuron.

Many studies have been performed to help understand the initiating developmental events or the "trigger" for pubertal onset. In fact, it is becoming increasingly clear that there is no single "trigger" for puberty, but a gradual increase in GnRH pulsatility associated with a complex interplay of factors and hypothalamic developmental programs. Thus the apparent "sensitivity of the gonadostat" seems increasingly likely to reflect the degree of activity of the GnRH neuron. That is, when GnRH secretory activity is attenuated, the pulse generator is easily inhibited; when the GnRH neuron is active, the pulse generator is relatively insensitive to negative feedback.

The integration of hypothalamic signaling systems along with the developmental changes in the control of GnRH neuronal function seem to converge to trigger the onset of puberty. In the rat, structural remodeling of the GnRH neuron was demonstrated during pubertal progression by an increase in the density of dendritic and somal spines; the percentage of total neurons with spines being lowest at birth and increased gradually postnatally until puberty.³⁰¹ The spiny processes of neurons are the location of excitatory synapses important in neuronal plasticity. The greatest percentage of complex neurons is in the peripubertal period, with the percentage decreasing after completion of puberty.³⁰² These developmental changes are correlated with an increase in excitatory synaptic input to the GnRH neuron triggering the onset of puberty in mice.^{302,303} Which excitatory synaptic input (e.g., glutamatergic, kisspeptinergic, or yet unknown neurochemical signals) plays a role in the pubertal increase in GnRH secretion is unknown. Whether primate or human GnRH neurons undergo synaptic excitatory remodeling during development is also unknown.³⁰⁴

Since its discovery, numerous studies have demonstrated the expression of the kisspeptin-signaling system in several peripheral sites implicating it in biological processes, such as the regulation of ovarian function, embryo implantation, placentation, angiogenesis, and insulin secretion. However, whether kisspeptin is secreted from sites of peripheral expression and the impact on the reproductive axis are currently unclear.^{305,306}

Regulation of Gonadotropin Secretion

An essential feature of the mature HPG axis is the long-loop, negative-feedback control of gonadotropin secretion by gonadal secretory products, as depicted in Fig. 16.17. The generally tonic nature of gonadotropin secretion is punctuated by two prominent types of periodicity: two- to threefold pulsations of LH above trough levels at 1.5-hour intervals and, in the sexually mature female, by a transient, midcycle, preovulatory gonadotropin surge. The latter is characterized by a greater than 10-fold, rapid rise of LH and a lesser rise of FSH. This surge

is brought about by positive feedback when a critical level of estradiol, facilitated by a modest rise in progesterone, is achieved for a critical period of time, as discussed in relation to Fig. 16.13.

Estradiol, in concert with inhibin, reciprocally regulates FSH in a sensitive, log-dose, negative-feedback loop.³⁰⁷ Progesterone in high (luteal phase) concentrations is a major negative regulator of GnRH-LH pulse frequency.¹²⁹ Androgens have a biphasic long-loop feedback relationship with gonadotropins: at modest elevations they stimulate gonadotropin release and at very high levels they inhibit it.³⁰⁸

Estradiol exerts triphasic, and progesterone biphasic, effects on gonadotropin secretion. As estradiol rises after the midpoint of the follicular phase it selectively reduces the FSH response to GnRH, and when it reaches preovulatory levels it transiently exerts positive feedback effects on LH and, to a lesser extent, FSH.³⁰⁹ At sustained high levels estradiol suppresses both gonadotropins. As progesterone reaches a preovulatory level, it enhances the estradiol positive feedback effect, but at the higher levels that ensue during the luteal phase, it suppresses LH pulse frequency while enhancing LH pulse amplitude.¹²⁹

The GnRH neurons primarily responsible for maintenance of the reproductive cycle are those of the arcuate (infundibular) nucleus (Fig. 16.18).⁹⁰ GnRH neurons are inherently pulsatile.³¹⁰ Synchrony is promoted by fluxes of ionic calcium into these cells and autocrine GnRH inhibitory feedback. GnRH secretion is modulated by the variety of neurotransmitters and growth factors involved in initiating puberty.²⁴⁷ Synchrony of the network of GnRH neurons that accounts for pulsatility is conferred when the hypothalamic concentration of GABA periodically falls from levels inhibitory to GABA receptors in the presence of an excitatory neurotransmitter.^{311,312} EAP1, a hypothalamic protein previously shown to be important for pubertal onset, has also been implicated in the control of menstrual cyclicity in primates.³¹³

Sex steroid signals are in part conveyed to GnRH neurons indirectly. Regulation of GnRH secretion by estrogen involves

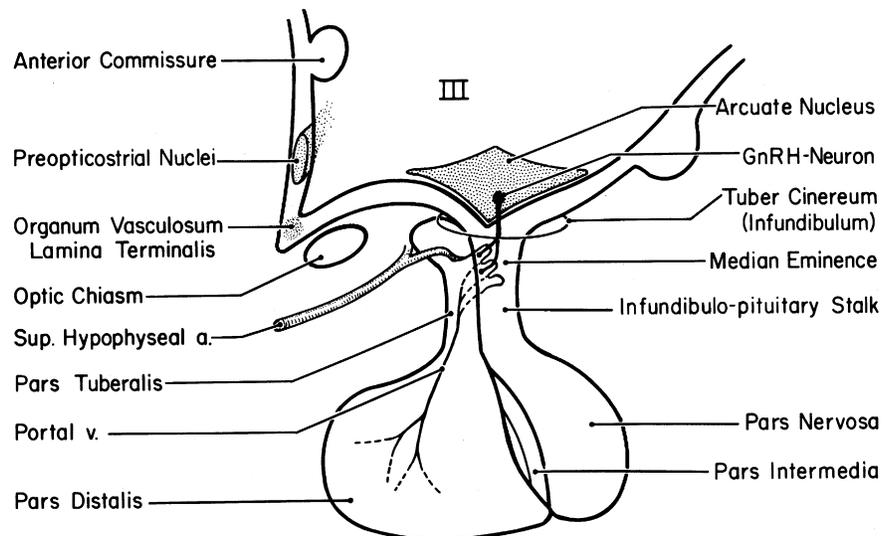

Fig. 16.18 The location of major gonadotropin-releasing hormone (GnRH)-containing neurons (shaded) in relation to the hypothalamus and pituitary gland. The neurons are of greatest density in the arcuate nuclei and in the periventricular wall of the medial basal hypothalamus. These neurons project to the adjacent median eminence, the second most dense population of GnRH neurons lies in the preopticostrual area. The development of some is altered by early androgenization. Some are connected by the stria terminalis to the amygdalae. Other projections from this area appear to connect indirectly with the median eminence, perhaps via the organum vasculosum lamina terminalis—a midline structure that resembles the median eminence. The pituitary portal veins transport blood rich in releasing factors to sinusoids engulfing anterior pituitary cells.

in part induction of PRs in the hypothalamus.^{129,314} GnRH neuronal cell lines have been studied in which estradiol directly stimulates and inhibits GnRH gene expression under different experimental conditions.^{315,316} Although progesterone exerts its main inhibitory effect on GnRH secretion, it has effects at higher CNS levels and at the pituitary level.^{317–319} Prolactin suppresses both hypothalamic and gonadotropin GnRH receptor expression.^{320,321}

Other clinically relevant factors affecting GnRH release are sleep, endorphins (endogenous opioids), and interleukins. In sexually mature women, sleep inhibits GnRH pulse frequency and this effect seems to be amplified by female hormones.³²² Endorphins are important physiological regulators of GnRH release after puberty has begun. Hypothalamic β -endorphin suppresses oophorectomy-initiated GnRH secretion, and opiate antagonists reverse this effect, as well as the sleep effect. The inhibitory effect of stress on gonadotropin release appears to be mediated by β -endorphin released from proopiomelanocortin in response to corticotropin releasing hormone (CRH).³²³ Interleukins also inhibit gonadotropin release.³²⁴ Serotonin seems to modulate LH pulsatility and facilitate the LH surge.³²⁵

GnRH receptors on the gonadotroph are maintained in an optimally active state only when GnRH is delivered in pulses approximately 1 to 2 hours apart in man.^{90,326} Pulses substantially less frequent result in a hypogonadotropic state. Paradoxically, continuous administration of an initially stimulatory dose of GnRH results in downregulation of gonadotropin production, after an initial burst of gonadotropin release.³²⁷ This is the physiological basis for the success of long-acting gonadotropin agonists in suppressing puberty in children with true central precocious puberty. However, while gonadotropins are downregulated, free alpha-subunit production is elevated and responsive to GnRH.

Hypothalamic GnRH receptor function is modulated by autocrine and paracrine factors, including GnRH itself and kisspeptin.⁵ Pituitary GnRH receptors appear to be directly and indirectly downregulated by GnRH, gonadotropins, and inhibins, as well as sex steroids.³²⁸ LH and FSH themselves inhibit GnRH release (short-loop feedback) and inhibit their own release (autocrine feedback).^{328,329}

How is differential regulation of gonadotrope LH and FSH release accomplished in response to a single GnRH pulse? The frequency of the GnRH pulse is one determinant. An increased frequency of this signal stimulates LH β -subunit gene expression, whereas slowing this signal stimulates FSH β -subunit and suppresses follistatin gene expression, altering the FSH/LH ratio.³³⁰ Pituitary adenylate cyclase activating polypeptide amplifies LH responses to GnRH while blocking its effect on FSH.³³¹

The sex hormone milieu is also clearly a major differential modulator of gonadotrope LH and FSH release.^{90,319,332–334} FSH is more sensitive than LH to inhibition by estrogen; this effect of modest levels of estradiol is of rapid onset and sustained. LH is the more sensitive to the stimulatory effects of higher estradiol levels; this effect is of later onset and short-lived. Similar relationships pertain in aromatase null mice. ER null mice have revealed ER-alpha as the predominant receptor isoform that conveys negative feedback regulation to the gonadotroph.³³⁵ Progesterone exerts both negative and positive feedback effects at the pituitary level, and these effects are antagonized by androgen. The progesterone metabolite 3α -hydroxyprogesterone suppresses FSH release.³³⁶

Androgens have complex effects on gonadotropin dynamics. Normal androgen action facilitates the midcycle gonadotropin surge in response to positive feedback.^{337,338} Elevated testosterone increases baseline LH pulse amplitude and frequency^{64,339,340} while inhibiting the capacity to mount the

gonadotropin surge.³³⁷ These actions appear to result from antagonizing progesterone action.^{16,339,340}

Inhibins of gonadal origin seem to be the major nonsteroidal-specific negative feedback regulator of pituitary FSH synthesis and secretion.^{341,342} Inhibins inhibit FSH release at the pituitary level, but they may act at a higher level as well.³⁴³ Serum levels of both inhibins rise upon FSH stimulation.^{177,178} Inhibin-B, produced by small antral follicles in response to FSH, is virtually the only inhibin moiety in blood during puberty. Its blood levels rise during the early follicular phase and then fall thereafter except for a small postovulatory peak, generally paralleling the changes in serum FSH; the latter peak may function to attenuate the FSH surge. Serum inhibin-A, a marker of the preovulatory follicle and corpus luteum, begins to rise in the late follicular phase and thereafter parallels levels of progesterone; its fall late in the luteal phase appears to contribute to the early follicular phase rise in the FSH level.

The structurally related activins seem to be important as regulators of both pituitary and ovary function.³⁴⁴ Activin is formed by gonadotropes themselves and its primary role is to stimulate FSH release. It also upregulates the activin binding protein follistatin, which arises within folliculostellate cells of the anterior pituitary.²⁸⁵ Follistatin, by competitively inhibiting binding of activin to its receptor, specifically inhibits activin stimulation of FSH secretion.³⁰⁷

Infant and Child

Neuroendocrine Unit. The hypothalamic-pituitary-gonadal (HPG) axis is transiently active during the neonatal period. This is sometimes termed the *minipuberty of the newborn*; unlike true puberty, the clinical manifestations are only nascent and do not progress. The regulation of neonatal gonadotropin secretion, like that during puberty, is incompletely known.

Serum FSH and LH are low in cord blood and remain low until estrogen concentrations fall from inhibitory levels upon disruption of the fetoplacental unit at birth. Then the LH and FSH levels of neonates promptly begin to rise in pulsatile fashion to early pubertal levels in the first week of life (see Fig. 16.5).^{7,11,58–61}

Serum LH and FSH levels rise higher in female than in male premature infants, reaching into the postmenopausal range.^{17,62} This sexual dimorphism seems to be related to lack of negative feedback because of lagging ovarian follicular development: antral follicle development begins near term gestational age.¹⁸ There is parallel hyperprolactinemia without sexual dimorphism.⁶³

At their peak between term and 4 months of age, serum gonadotropins and LH/FSH ratios are lower in girls than in boys,¹⁷ apparently because girls lack androgen-programmed accentuation of GnRH pulsatility.^{16,64,65} Responses to GnRH and GnRH agonist are similar to those of early puberty (see Fig. 16.6).^{55,66–69} In congenital agonadism, gonadotropins reach postmenopausal levels during the neonatal period.⁷⁰

After about 4 months postterm, gonadotropin and prolactin levels begin to gradually fall into the prepubertal range (see Fig. 16.5). FSH is higher in girls than in boys, a tendency that tends to persist into early childhood.^{58,71} This appears in part related to negative feedback by the higher activin-A and lower inhibin-B serum levels of girls than boys.⁷² GnRH secretion also appears to be greater in girls than in boys at this time.⁷³

The decline in gonadotropins may in part be related to the maturation of neural tracts that conduct inhibitory signals from the CNS and/or to an increase in hypothalamic sex steroid receptors. Hypothalamic ERs increase in a pattern reciprocal to the fall in serum gonadotropins in the rat (see Fig. 16.7),⁷⁴ as do hypothalamic DHT receptors.⁷⁵ Increasing sensitivity of the hypothalamus to sex steroid hormone negative feedback

could account for the inhibitory effect of the small amounts of circulating estradiol and testosterone.

A nadir in both serum gonadotropins occurs by about 6 years of age (see Figs. 16.2 and 16.5). At this age, the LH and FSH response to GnRH is minimal, apparently from lack of GnRH stimulation. Furthermore, at this stage, agonadism is seldom reflected in a rise in serum gonadotropins or gonadotropin reserve.⁷⁰

However, gonadotropin production is not completely suppressed in midchildhood. Gonadotropins have been detected in the urine of young prepubertal children, at the limits of sensitivity of classic bioassays: LH excretion averaged 3% and FSH 15% of the adult amounts.⁷⁶ Specific monoclonal antibody-based assays have revealed that LH falls to less than 0.2 U/L during the day whereas FSH remains detectable and that the gonadotropins produced at this stage are secreted in micro-pulses that approximately double in association with sleep.⁷⁷ The gonadotropins also appear to be bioactive judging from their sensitivity to estradiol negative feedback in the primate⁷⁸ and the active formation of antral follicles during childhood, which indicates gonadotropin stimulation, as discussed in the following section on the adult.

Between 7 and 10 years of age, even prepubertal girls experience subtle but significant increases in gonadotropin levels.⁷⁹ This change corresponds with rising secretion of GnRH.⁷³ These data indicate that the hormonal secretory pattern of the prepubertal 10-year-old child is different from that of the 7-year-old and indicate that the hormonal changes signaling the development of puberty are found late in the first decade of life, antedating by some time the development of secondary sex characteristics.

Ovary. The ovary of the infant and child is not quiescent. Initiation of growth and development of resting follicles occurs throughout childhood. The neonatal ovary typically contains an antral follicle with thecal luteinization,^{80,81} and the number of antral follicles approximately doubles over that in infancy by 7 years and quadruples by 9 years (see Fig. 16.3).³¹ All these antral follicles normally undergo atresia in childhood, and this augments the amount of stroma.³¹ As a result, by midchildhood, the ovaries of normal girls have up to five antral follicles 4 to 9 mm in diameter, and ovarian volume increases up to approximately 3.5 cc. Ovarian follicular development begins to accelerate just before the onset of clinical signs of puberty.^{31,82–86}

During the first few months of life, early pubertal blood levels of ovarian hormones are found as part of the transient activation of the HPG axis that occurs in the newborn. Serum estradiol and inhibin-B levels parallel those of FSH. In the neonatal period they begin rising to early pubertal levels, remain there for the first few months of life, and fall to low levels during childhood (see Fig. 16.8).^{66,69} Specifics about the hormonal changes are discussed later (see Normal Hormonal and Sexual Developmental Stages).

Regulation of Ovarian Secretion

Ovarian secretion results from the combined actions of LH and FSH, as discussed earlier with regards to Figs. 16.13 and 16.14. The early follicular phase follicle functions according to the two-cell, two-gonadotropin model illustrated in Fig. 16.19.^{144,345,346} In response to LH, androstenedione, the most abundant steroid formed in the ovary, is secreted by the theca-interstitial-stromal (thecal) cell compartment. In response to FSH regulation, aromatase then forms estrogen from precursor androstenedione in granulosa cells. FSH also stimulates granulosa cells to secrete inhibins. As by-products of the secretion of both ovarian estradiol and adrenal cortisol, androgens do not normally contribute to negative feedback regulation of gonadotropins. However,

they have a biphasic effect on gonadotropin secretion: modest elevations increase GnRH pulse frequency by interfering with progesterone negative feedback and very high levels directly inhibit gonadotropin secretion.³⁰⁸

The regulation of the intraovarian androgen concentration is critical to ovarian function.^{40,144} Androgens are important for ovarian function. Androgens are obligate substrates for estradiol biosynthesis. Androgens also increase recruitment of primordial follicles into the growing follicle pool¹⁴² and then act in conjunction with gonadotropins on granulosa cells to stimulate preantral follicle development into small antral follicles,³⁴⁷ which enhances FSH upregulation of aromatase activity.¹⁴¹ Androgens also synergize with FSH to luteinize follicles by inducing LH receptors. However, in excess androgens impair selection of the dominant follicle of women; this appears likely to result from premature luteinization of follicles, thus committing the follicle to atresia. Therefore androgen synthesis must be kept to the minimum necessary to optimize follicular development. This means that the synthesis of ovarian androgens must be coordinated with the needs of the follicle. This is achieved by intraovarian intracrine, autocrine, and paracrine modulation of LH action (see Fig. 16.19).

LH stimulates theca cell development and steroidogenesis and is necessary for the expression of gonadal steroidogenic enzymes and sex hormone secretion. However, once adult LH levels are achieved, further LH increase normally has little further effect on androgen levels because excess LH causes homologous desensitization of theca cells.^{144,348} Desensitization involves downregulation of LH receptor expression and steroidogenesis. Because steroidogenic downregulation is primarily exerted on 17,20-lyase activity, which converts 17-hydroxycorticoids to 17-KS, 17-OHP levels rise in response to increased LH levels, but the rise in androgens is limited.³⁰⁸

A model of the intraovarian interaction among the major regulators of steroidogenesis is shown in Fig. 16.19.¹⁴⁴ Stimulation of androgen secretion by LH appears to be augmented by specific intraovarian FSH-dependent factors, such as inhibins and IGFs. These processes seem to normally be counterbalanced by other FSH-dependent processes that downregulate androgen formation as LH stimulation increases. Androgens and estrogens themselves seem to mediate at least a portion of this desensitization to LH, with estrogens being critical through an ER α -dependent mechanism.^{335,349}

Insulin and IGFs are important coregulators of ovarian function. Insulin upregulates theca cell LH receptor sites and action⁴⁰ and to a lesser extent estrogen biosynthesis in response to FSH.³⁵⁰ The entire IGF system is represented in the ovary: IGF-1 augments FSH receptor expression and action.^{153,351} and appears to mediate GH promotion of granulosa cell steroidogenesis.^{352,353} Insulin is equipotent with IGF-1 in stimulating thecal androgen biosynthesis,⁴⁰ and, although insulin can act through hybrids of the insulin and IGF-1 receptors³⁵⁴ and at very high levels interacts with the IGF-1 receptor,^{40,355} it appears to primarily act through its own receptor.

Androgen-expressing steroidogenic cells express a previously unrecognized protein variant, DENND (differentially expressed in normal and neoplastic development) 1A.V2, that facilitates steroidogenesis: it upregulates basal and cAMP-stimulated cytochrome P450c17 and side chain cleavage activities.^{356,357} The mechanism by which DENND1A.V2 regulates steroidogenesis is currently unknown. DENND1A is a member of the connectenn family of proteins, which are involved in protein trafficking, endocytotic processes, and receptor recycling. Thus it is tempting to speculate that it acts by upregulating LH receptor signaling.

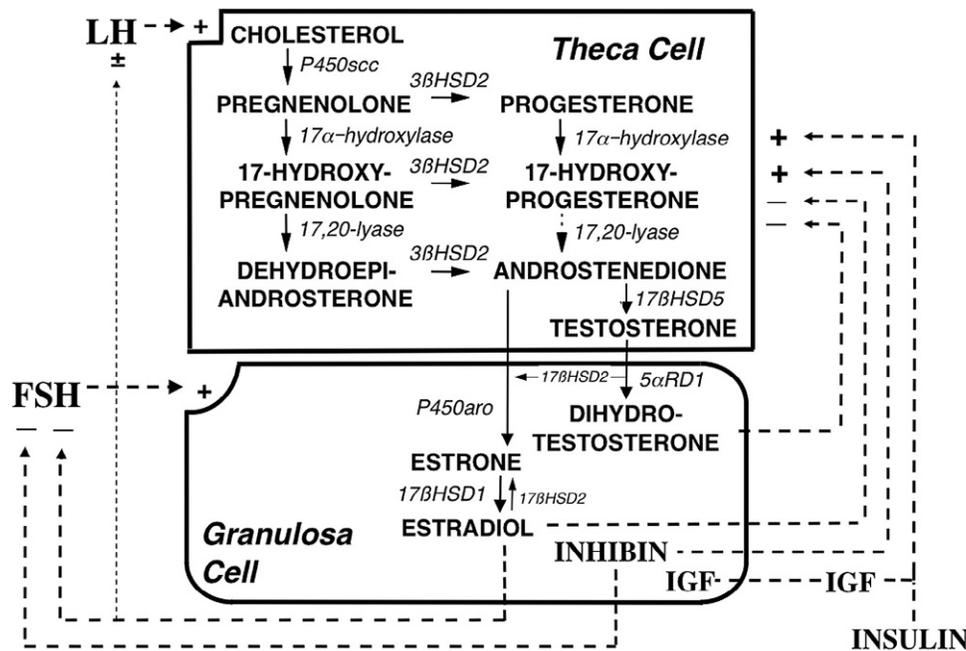

Fig. 16.19 Depiction of the organization and regulation of the major steroid biosynthetic pathways in the small antral follicle of the ovary according to the two-gonadotropin, two-cell model of ovarian steroidogenesis. Luteinizing hormone (*LH*) stimulates androgen formation within theca cells via the steroidogenic pathway common to the gonads and adrenal glands. Follicle-stimulating hormone (*FSH*) regulates estradiol biosynthesis from androgen by granulosa cells. Long-loop negative feedback of estradiol on gonadotropin secretion does not readily suppress *LH* at physiological levels of estradiol and stimulates *LH* under positive feedback circumstances. Androgen formation in response to *LH* appears to be modulated by intraovarian feedback at the levels of 17-hydroxylase and 17,20-lyase, both of which are activities of cytochrome P450c17 that is expressed only in theca cells. The relative quantity of androstenedione formation via 17-OHP (dotted arrow) in the intact follicle is probably small, as is the amount of progesterone formed from granulosa cell P450_{scc} activity in response to *FSH* (not shown). 17βHSD2 activity is minor in the ovary, and estradiol is primarily formed from androstenedione. Androgens and estradiol inhibit (–) and inhibin, insulin, and insulin-like growth factor-I (IGF) stimulate (+) 17-hydroxylase and 17,20-lyase activities. The sites of aromatase and IGF gene expression appear to vary with the stage of follicular development. Other peptides also modulate the steroidogenic response to *LH*. Pertinent enzyme activities are italicized: the 17-hydroxylase and 17,20-lyase activities of P450c17 are shown, otherwise enzyme abbreviations are as in the text. *5α-R*, 5α-Reductase; *17β-HSD5*, type 5 17β-HSD; *HSD*, hydroxysteroid dehydrogenase. (Modified with permission from Ehrmann et al, Polycysticovary syndrome as a form of functional ovarian hyperandrogenism due to dysregulation of androgen secretion. *Endocr Rev*. 1995;16:322–353. Reproduced with permission from Rosenfield, R.L., Ehrmann, D.A. (2016). The pathogenesis of polycystic ovary syndrome (PCOS): the hypothesis of PCOS as functional ovarian hyperandrogenism revisited. *Endocr Rev*, 37, 467–520.)

Many other peptides modulate ovarian cell growth or function in response to gonadotropins.^{144,348} Inhibin stimulates ovarian androgen production, whereas androgens reciprocally stimulate ovarian inhibin production. Activin opposes the inhibin effect. A variety of other ovarian peptides are also capable of modulating thecal androgen synthesis.¹⁴⁴ Stimulators include catecholamines, for which an intraovarian system exists,³⁵⁸ prostaglandin, and angiotensin. Inhibitors include leptin, CRH, epidermal growth factor (EGF), tumor necrosis factor, TGF-β, and GDF9.³⁵⁹ Leptin antagonizes IGF-1 effects.³⁶⁰ TGF-β is particularly interesting because it suppresses androgen biosynthesis and stimulates aromatase activity; it also stimulates meiotic maturation of the oocyte.³⁶¹ Other peptides acting on granulosa cells include cytokines, which have diverse effects, and AMH, which inhibits aromatase.³⁶² GnRH is also capable of modulating thecal steroidogenesis. A GnRH-like protein has been described in the ovary that may act through ovarian GnRH receptors to suppress steroidogenesis in the human ovary.^{363,364} It inhibits *FSH* induction of progesterone secretion, aromatase activity, and *LH* receptors in granulosa cells, downregulates *LH* receptors, and inhibits the *hCG* stimulation of progesterone secretion by luteal cells.^{115,134}

Prolactin has complex effects on steroidogenesis. In low concentrations, it enhances ovarian estradiol and progesterone secretion by increasing *LH* receptors.³⁶⁵ On the other hand, high levels of prolactin inhibit ovarian estradiol and progesterone biosynthesis.³⁶⁶ Prolactin also stimulates adrenal androgen production.³⁶⁷

Adrenarche and the Regulation of Adrenal Androgen Secretion

Adrenarche denotes the onset of the increase in adrenal androgen production that gradually begins in midchildhood well before the pubertal maturation of the neuroendocrine-gonadal axis.^{40,368} Adrenarchal androgens contribute to the appearance of pubic hair (pubarche) and sebaceous gland and apocrine gland development.

Adrenarche results from a change in the pattern of adrenal secretory response to ACTH (Fig. 16.20). It is characterized by disproportionate rises in the responses to ACTH of the Δ⁵-3β-hydroxysteroids 17-hydroxypregnenolone and dehydroepiandrosterone (DHEA), whereas cortisol secretion does not change. Dehydroepiandrosterone sulfate (DHEAS) is the predominant marker for adrenarche. A DHEAS level over 40 mcg/dL is usually considered adrenarchal. Other serum androgens and precursors are ordinarily at the upper end of the prepubertal range at the onset of adrenarche.

Adrenarche reflects the development of the adrenocortical zona reticularis.⁴⁰ Humans and some higher primates are unique in having an adrenal zone with similar structure-function-developmental stage relationships.^{369,370} Although the zona reticularis resembles the fetal zone of the adrenal cortex in its location and function, it appears to originate from stem cells located in the outer definitive zone of the fetal adrenal gland.^{371,372} This zone becomes continuous at about 5 years of age and enlarges steadily over the subsequent decade. Its increasing development correlates with DHEAS levels.

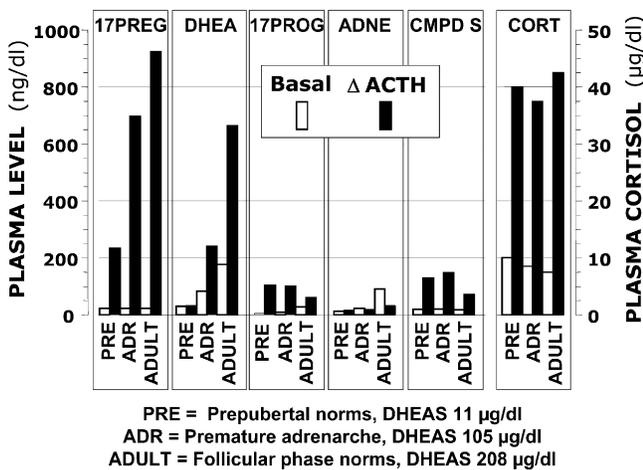

Fig. 16.20 Changing pattern of adrenal steroidogenic response to adrenocorticotrophic hormone with maturation. Shown are plasma steroid levels before (basal, 8:00 a.m. after dexamethasone 1 mg/m²) and the rise (Δ) 30 minutes after cosyntropin (ACTH) administration (10 μ g/m²) in healthy prepubertal children, children with premature adrenarche as an isolated phenomenon, and follicular phase adult women. Note that 17-hydroxypregnenolone (17PREG) and dehydroepiandrosterone (DHEA) responses of children with premature adrenarche are intermediate between prepubertal and adult responses. 17PROG, 17-hydroxyprogesterone; ADNE, androstenedione; CMPD S, 11-deoxycortisol; CORT, cortisol; DHEAS, dehydroepiandrosterone sulfate. (Data from Rich, B.H., Rosenfield, R.L., Lucky, A.W., Helke, J.C., Otto, P. (1981). Adrenarche: Changing adrenal response to adrenocorticotropin. *J Clin Endocrinol Metab*, 52, 1129.)

This zone's secretion pattern results from a unique enzyme expression profile: it expresses low 3 β -hydroxysteroid dehydrogenase type 2 (HSD3B2), but high cytochrome b5 (an enhancer of the 17,20-lyase activity of cytochrome P450c17) and steroid sulfotransferase (SULT2A1) activities.⁴⁰ The high secretion of DHEA and DHEAS is primarily attributable to these activities.⁴⁰ Enhanced expression of 17 β -hydroxysteroid dehydrogenase type 5 (HSD17B5) by this zone accounts for the small but significant adrenal contribution to testosterone secretion. Both testosterone and androstenedione are further metabolized by zona reticularis 11 β -hydroxylase type 1 (CYP11B1), which underlies adrenal 11 β -hydroxyandrostenedione and 11 β -hydroxytestosterone secretion.^{373,374} These are further metabolized, primarily in the periphery, by 11 β -hydroxysteroid dehydrogenases to their 11-keto congeners. These 11-oxy metabolites of testosterone are one-fifth as potent as testosterone at half-maximal dosage (ED₅₀).³⁷³

The factors causing and regulating zona reticularis development are unclear. Body growth is related to adrenarche.^{375–378} Insulin, IGF-1, and leptin have been suggested as determinants of this relationship. Insulin and IGF-1 stimulate expression of adrenal P450c17 and 3 β HSD2 activities^{379,380} and may be involved in progenitor cell proliferation.³⁸¹ Leptin, an adipocyte hormone, stimulates the 17,20-lyase activity of adrenocortical cells, which shunts adrenal steroidogenesis toward DHEAS production.³⁸²

Nutritional status, in particular, seems to play a role in the development of adrenarche, particularly in girls.^{376,383} Infants born small for gestational age have higher DHEAS levels at 5 to 8 years of age, and children born large for gestational age have lower levels than those with normal birth weight.³⁸⁴ Obesity is related to DHEAS levels, and rapid weight gain during early childhood is associated with adrenal androgen levels independently of birth weight.³⁸³

A pituitary hormone ("adrenarche factor") may well be required to bring about their adrenarchal development.⁴ It has been postulated to be an ACTH-related hormone distinct from ACTH because adrenal androgen production is more sensitive to glucocorticoid suppression than is cortisol production,³⁸⁵ falls more slowly than cortisol after dexamethasone administration,¹²⁵ and rises more sluggishly after its withdrawal.³⁸⁶ Candidates for a dexamethasone-suppressible adrenarchal factor include pro-ACTH-related peptides and CRH, but the data have not been convincing.³⁸⁷ Prolactin seems to be required.^{40,388} Currently the only established adrenal androgen-stimulating hormone in postnatal life is ACTH. Because the adrenarchal secretion pattern represents a change in the pattern of steroidogenic response to ACTH, an adrenarche factor need only control the growth and differentiation of zona reticularis cells or regulate their unique pattern of steroidogenic enzyme expression.

ACTH effects on adrenal androgen production are modulated by diverse signaling networks.^{40,389} Modulators of the androgenic response to ACTH include a stimulatory isoform of DENND1A (DENN/MADD domain-containing protein 1A; DENND1A.V2) that is known to be overexpressed in polycystic ovary syndrome (PCOS) theca cells, and BMP4, which is inhibitory. Intraadrenal cortisol may participate in the regulation of adrenal DHEA secretion through inhibition of 3 β -hydroxysteroid dehydrogenase (3 β -HSD) activity.³⁷⁸ In addition, interleukin-6 is strongly expressed in the zona reticularis, where it directly stimulates production of all classes of adrenal steroids independently of ACTH.^{390,391} Although gonadal dysgenesis is associated with earlier adrenarche,³⁹² paradoxically, ovariectomy precipitates an early decline in DHEAS levels that is not reversed by estrogen replacement.³⁹³

Adrenarchal levels of androgens suffice to successively initiate sebaceous gland development, apocrine gland development, and the growth of pubic hair. Sulfation of DHEA within the adrenal cortex prevents adrenal hyperandrogenism,³⁹⁴ and circulating DHEAS is a precursor for ovarian testosterone formation.³⁹⁵ It has been proposed that DHEAS elevation in response to obesity exerts a protective effect on plasma lipids.³⁹⁶ Whether adrenarche plays a more fundamental role in normal puberty is not established.³⁶⁸

There has been considerable interest in the possibility that adrenarchal steroids play a role in human neurobiological development. DHEA and testosterone serum levels differentially correlate with specific structural developmental changes in the cerebral corticolimbic system.³⁹⁷ DHEAS and its precursor, pregnenolone sulfate, as well as the progesterone metabolite allopregnanolone, have direct nongenomic neuroactive effects, which include modulation of neurotransmitter signaling and neuroplasticity.^{398–400} These steroid sulfates are actively transported across the blood-brain barrier.⁴⁰¹ The association of adrenarchal changes with the emergence of sexually dimorphic sexual attraction, stress-adaptive, and social maturational behavior during middle childhood, before true puberty, has led to the suggestion that adrenarchal steroids play a role in activating these behaviors.^{402–404} Many functions attributed to DHEAS have been inconsistent, and whether they differ from those of low-dose testosterone remains to be established.³⁶⁸

Hormonal Secretion, Transport, Metabolism, and Action

Peptide Hormones

Peptide hormones act after binding to specific receptors located in the plasma membranes of target cells. GnRH receptors and

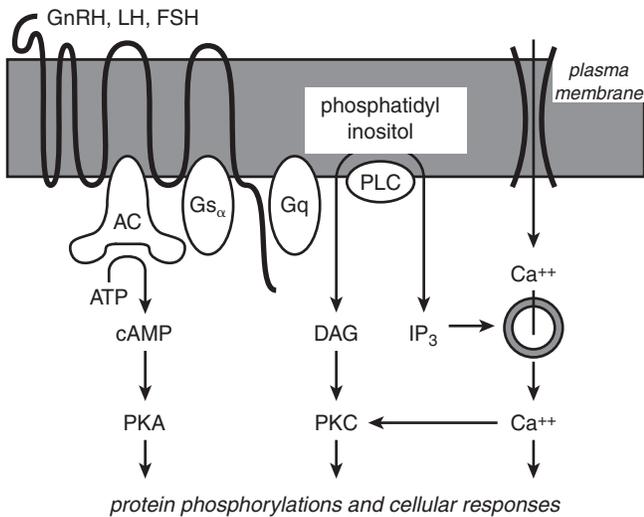

Fig. 16.21 Overview of the pathways established to mediate gonadotropin-releasing hormone (*GnRH*) and gonadotropin action. The receptors for these hormones are members of the seven-transmembrane family of receptors. Hormone-receptor binding alters receptor configuration. One consequence is to couple the receptor to adenylate cyclase (*AC*) via the stimulatory α -subunit of G-protein ($G_{s\alpha}$). This permits the efficient generation of cyclic adenosine monophosphate (*cAMP*) from adenosine triphosphate (*ATP*). Another consequence is to couple phospholipase C (*PLC*) to the receptor through *Gq*. *PLC* is a phosphodiesterase that hydrolyzes phosphatidylinositol to diacylglycerol (*DAG*) and inositol-1,4,5-triphosphate (*IP3*). *DAG* stimulates the calcium-sensitive protein kinase C (*PKC*). *IP3* mobilizes ionic calcium (Ca^{2+}) from intracellular organelles and stimulates Ca^{2+} influx through calcium ion channels. Protein kinase A (*PKA*), *PKC*, and Ca^{2+} then bring about cellular responses through protein phosphorylations. *FSH*, Follicle-stimulating hormone; *LH*, luteinizing hormone.

gonadotropin receptors are members of the 7-transmembrane receptor family. These receptors are necessary for the actions of their cognate hormones. Receptors expressed in nonclassical sites are not necessarily functionally mature.⁴⁰⁵ Mature receptors signal after coupling to a guanine nucleotide (G-protein) subunit (Fig. 16.21).^{5,326,330,406–408} G_s signaling activates adenylate cyclase and acts via phosphodiesterase-regulated cAMP to activate protein kinase A. G_q signaling activates phospholipase C, which acts via protein kinase C and Ca^{2+} ; Ca^{2+} may also be mobilized by other factors that influence ion channels. Phosphorylation of various cytoplasmic and nuclear proteins ultimately mediates the action of the peptide hormones, and secondarily involves the *RAS* and *EGF* signaling cascades in the case of gonadotropins.²⁶ The diversity among target cells in their responses to the action of protein kinases in part relates to diversity and type of kinase, intracellular compartmentalization, substrate availability, and other differences in gene expression that are specific to each type of target cell.

GnRH is a decapeptide [pyro]Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH₂.³²⁶ One gene encodes the single precursor protein for both *GnRH* and prolactin release-inhibiting factor.⁴⁰⁹ *GnRH* not only effects prompt release of preformed gonadotropins (the “readily releasable pool”), but also stimulates the synthesis of gonadotropins (the “reserve pool”).⁴¹⁰ Repeated administration of *GnRH* augments the pituitary responsiveness to subsequent *GnRH* pulses (“self-priming”).¹⁰⁷ This has been ascribed partly to upregulation of *GnRH* receptors. *GnRH* has an important paradoxical effect. As discussed earlier, it acutely stimulates gonadotropin secretion, but, upon protracted, continuous administration it downregulates pituitary gonadotropin secretion. The significance of the

expression of *GnRH* and its receptor in nonhypothalamic reproductive tissues⁴¹¹ is unclear.

An evolutionarily conserved form of *GnRH* (*GnRH-II*) acts primarily through the type 2 *GnRH* receptor;⁴¹² *GnRH-II* and the type 2 *GnRH* receptor are products of unique genes, rather than being modified products of the *GnRH* or type 1 *GnRH* receptor genes.⁴¹³ The cell bodies of the *GnRH-II* neurons lie predominantly in the midbrain and only a minority project to the hypothalamic-pituitary area. *GnRH-II* function in humans is unknown; there is speculation that it is a neurotransmitter involved in sexual behavior. A recent study using functional neuroimaging demonstrated that kisspeptin administration enhanced limbic brain activity in response to sexual and couple-bonding stimuli and attenuated negative mood. Whether kisspeptin may become a therapeutic agent for patients with reproductive function dysfunction is currently unclear.⁴¹⁴

LH and *FSH* are synthesized in a single type of cell, and both are sometimes identified within the same cell.⁴¹⁵ A vestigial population of hCG-secreting pituitary cells has been described.⁴¹⁶ *LH*, *FSH*, and hCG are glycoprotein hormones that consist of two chains.⁴¹⁷ After synthesis of these hormones on the ribosomes, the carbohydrate moieties, which constitute about 16% of the weight, are added in the rough endoplasmic reticulum and Golgi apparatus. The α chains of *LH*, *FSH*, hCG, and thyroid-stimulating hormone (*TSH*) are identical in amino acid sequence (92 amino acids). Although the β chain of each hormone is different in both primary amino acid sequence and length, these β chains nevertheless share 30% to 80% amino acid homology. Biological activity is conferred when an α and β chain are glycosylated and assemble within the cell. The α/β dimer is stabilized by a β -subunit derived “seat belt” that wraps around the α -subunit. Neither the isolated α nor the β glycosylated protein subunit exhibits biological activity unless noncovalently bound to one another.

The gonadotropins exhibit considerable molecular heterogeneity.^{100,418–420} The major basis for this is variation in the relative degree of glycosyl sialylation or sulfonation, steps which occur reciprocally in the pituitary gland.⁴²¹ These differences affect in vitro and in vivo bioactivity. Polymorphisms in amino acid sequence of the *LH- β* and hCG- β gene also may affect the expression or bioactivity of *LH* or hCG.⁴²² Reproductive status affects isoform distribution, with sialylated forms predominating in the hypogonadal state.⁴²³ Androgens increase and estrogens decrease in vitro *LH* biopotency by altering *LH* sialylation.^{424,425} Thus the pituitary gland contains multiple isoforms of *LH* and *FSH* that vary in bioactivity. Consequently, different pituitary *LH* and *FSH* standards, as well as serum, contain variable proportions of immunoreactive material of varying bioactivity.

One corollary of the molecular heterogeneity is that the antibodies generated from these gonadotropin moieties detect heterogeneous epitopes that are not necessarily bioactive; indeed some may even act as gonadotropin antagonists.⁴²⁶ These factors combine to cause the gonadotropin B/I to vary in a wide variety of circumstances.^{100,418} The purest of standards, even recombinant ones, interact very differently in the diverse immunoassay systems. Likewise, the putative level of *LH* or *FSH* in a serum sample differs substantially among immunoassays. Furthermore, bioactivity assessments vary with the bioassay model system.^{100,427} Monoclonal antibody-based immunometric assays yield results that correlate with, but are not necessarily equivalent to, those by bioassay.^{100,428} The “third-generation” immunometric assays have the advantage of being more sensitive and specific for low levels of gonadotropins in serum than polyclonal antiserum-based RIA, but B/I discrepancies remain.

The major determinant of in vivo gonadotropin bioactivity is the serum half-life. Terminal sialic acid residues retard clearance by the liver, the primary site of metabolism, whereas

TABLE 16.2 Average Hormone Blood Production Rates in Midfollicular Phase Women.^a

Hormone	Production Rate
Luteinizing hormone	615 IU/day ^b
Follicle-stimulating hormone	215 IU/day ^b
Androstenedione	3.4 mg/day
Dehydroepiandrosterone	7.0 mg/day
Dehydroepiandrosterone sulfate	7.0 mg/day ^c
Dihydrotestosterone	0.06 mg/day
Estradiol	0.1 mg/day
Estrone	0.1 mg/day
Progesterone	1.1 mg/day
17-Hydroxyprogesterone	1.2 mg/day
Testosterone	0.2 mg/day

^aThese production rates are roughly equivalent to those in midpuberty.

The average daily production of those hormones that fluctuate cyclically is substantially greater. For example, estradiol production transiently peaks to about 0.5 mg/day, and thus the average production over the monthly cycle is about 0.2 mg/day or 6 mg/mo.^{434–440}

^bIn terms of second International Reference Preparation, human menopausal gonadotropin.

^cApproximate urinary production rate, expressed as unconjugated steroid.

sulfonated ones facilitate clearance.⁴²¹ About 10% to 15% of gonadotropins are excreted in urine according to RIA⁴²⁹; only about one-third of this is in a biologically active form.⁴³⁰

LH is cleared more rapidly from the blood than FSH or hCG.^{431,432} LH disappears from blood in an exponential pattern: RIA indicates that the half-life of the first component is about 20 minutes and that of the second component is about 4 hours. The bioactive LH half-life is about 25% to 50% shorter.⁴³³ These respective components for immunoreactive FSH are 4 and 70 hours; those for hCG are 11 and 23 hours. Hormone production rates in follicular phase women, which approximate midpubertal values, are given in Table 16.2.^{434–440}

Prolactin has structural and functional similarities to GH and placental lactogen. Prolactin has a considerable degree of structural heterogeneity; this results from genetic and posttranslational events within pituitary cells, as well as modifications, such as glycosylation in the periphery.⁴⁴¹ Lactotrope growth and prolactin secretion are stimulated by estrogens. Prolactin release from the anterior pituitary is primarily under the control of hypothalamic inhibition, probably primarily mediated by dopamine.⁴⁴² A prolactin release-inhibiting factor has been described within the same precursor protein as GnRH,⁴⁰⁹ thus providing a potential mechanism for reciprocal control of these two peptides. Prolactin secretion also is inhibited by thyroxine and is directly responsive to thyrotropin-releasing hormone (TRH). Estrogen and suckling are stimulatory. These signals may be positively mediated by α -MSH.

Inhibins and activins are members of the TGF- β superfamily and signal accordingly.^{343,344} Inhibin was discovered as the result of the search for the nonsteroidal gonadal hormone capable of specifically suppressing FSH. Activin was serendipitously discovered as the FSH-stimulating activity in the side-fractions in these studies. These hormones are formed by the differential disulfide-linked dimerization of two of three subunits (α , β_A , and β_B), each encoded by a distinct gene. The combination of an α - and β -subunit yields the inhibins, inhibin-A ($\alpha\beta_A$) and inhibin-B ($\alpha\beta_B$). Activins are dimers of β -subunits, $\beta_A\beta_A$, $\beta_B\beta_B$, and $\beta_A\beta_B$ (activin-A, B, and AB). Inhibin antagonizes all known actions of activin. The genes for all three subunits are differentially expressed in a wide variety of tissues. Furthermore, these factors, particularly activin, have proven to exert effects not only on gonadotropes, but within other pituitary cells, the gonads, and in nonsexual target tissues.

Steroid Hormones

The ovary and adrenocortical zona reticularis share the core of the steroid biosynthesis pathway (Fig. 16.22).^{40,444,445} Gonadal cholesterol seems to be derived mostly from the cholesterol esters of low-density lipoprotein in man.⁴⁴⁶ Most steroidogenic steps are mediated by cytochrome P450 family members. These are the terminal enzymes in electron transfer chains, which include P450 oxidoreductase (POR) as the clinically relevant electron donor for all in the endoplasmic reticulum. The initial step in the biosynthesis of all steroid hormones is the conversion of cholesterol to pregnenolone. This is a two-stage process. The rapidity of the process depends upon the transport of cholesterol from the outer to the inner mitochondrial membrane by the steroidogenic acute regulatory protein (StAR). The conversion itself is carried out by the cholesterol side chain cleavage activity (scc) of cytochrome P450scc. The next steps are either the 3β -HSD step or 17 α -hydroxylation. 3β -HSD converts Δ^5 - 3β -hydroxysteroids to steroids with the Δ^4 -3-keto configuration (e.g., pregnenolone to progesterone, 17-hydroxypregnenolone to 17-OHP, and DHEA to androstenedione). This step is obligatory for the synthesis of all potent steroid hormones. The type 2 3β -HSD isozyme accounts for the vast majority of the 3β activity in the human ovary and adrenal; the type 1 isozyme accounts for 3β -HSD activity in liver and skin. Pregnenolone alternatively undergoes a two-step conversion to the 17-KS DHEA along the Δ^5 -steroid pathway: this conversion is accomplished via cytochrome P450c17. P450c17 is a single enzyme with 17 α -hydroxylase and 17, 20-lyase activities, the latter being less efficient and critically dependent on electron transfer from cytochrome *b*. Progesterone undergoes a parallel transformation to androstenedione in the Δ^4 -steroid path: 17 α -hydroxylation of progesterone by P450c17 forms 17-hydroxyprogesterone, but in humans P450c17 does not efficiently utilize 17-hydroxyprogesterone as a substrate for 17,20-lyase activity, so P450c17 seems to form little if any androstenedione. There is some evidence for the existence of a P450c17-independent Δ^4 -pathway to androstenedione, but most seems to be formed from DHEA by the action of 3β -HSD.⁴⁴⁷ Sulfotransferase 2A1 is uniquely expressed in the adrenal zona reticularis and requires the cofactor 3'-phosphoadenosine-5'-phosphosulfate synthase type 2.³⁹⁴ Other sulfotransferases (e.g., for formation of estrone sulfate) and steroid sulfatase (for the reverse reaction) are widely expressed.⁴⁴⁸

17 β -Hydroxysteroid dehydrogenase (17 β -HSD) and aromatase activities are required for the formation of potent sex steroids. In the ovary, androstenedione is the major precursor for sex steroids. The conversion of 17-KS to 17 β -hydroxysteroids by 17 β -HSDs is essential for the formation of both androgen and estrogen: testosterone is formed in the ovary by 17 β -HSD type 5 (also termed *aldoketoreductase*, AKR1C3), whereas estradiol formation requires 17 β -HSD type 1.⁴⁴⁹ Aromatase activity, effected by P450arom, is essential for estradiol formation. Alternate promoters are used by the P450arom gene in the gonads, placenta, and adipose tissue, which yields alternatively spliced forms of aromatase. The organization and regulation of steroidogenesis in the developing follicle is depicted in Fig. 16.19.

The ovary normally accounts for about 25% of testosterone secretion in the mature female (0.06 mg daily), but it secretes about 30 times as much androstenedione (1.6 mg daily).⁴³⁶ These amounts are similar to those secreted by the adrenal. However, the ovary secretes less than 1/10 as much DHEA as the adrenal.

The "production rate" of a hormone equals its secretion rate plus (in the case of hormones formed outside of endocrine glands) the rate of formation of the hormone by peripheral conversion of secreted precursors. The "blood production rate" is calculated as metabolic clearance rate X serum concentration;

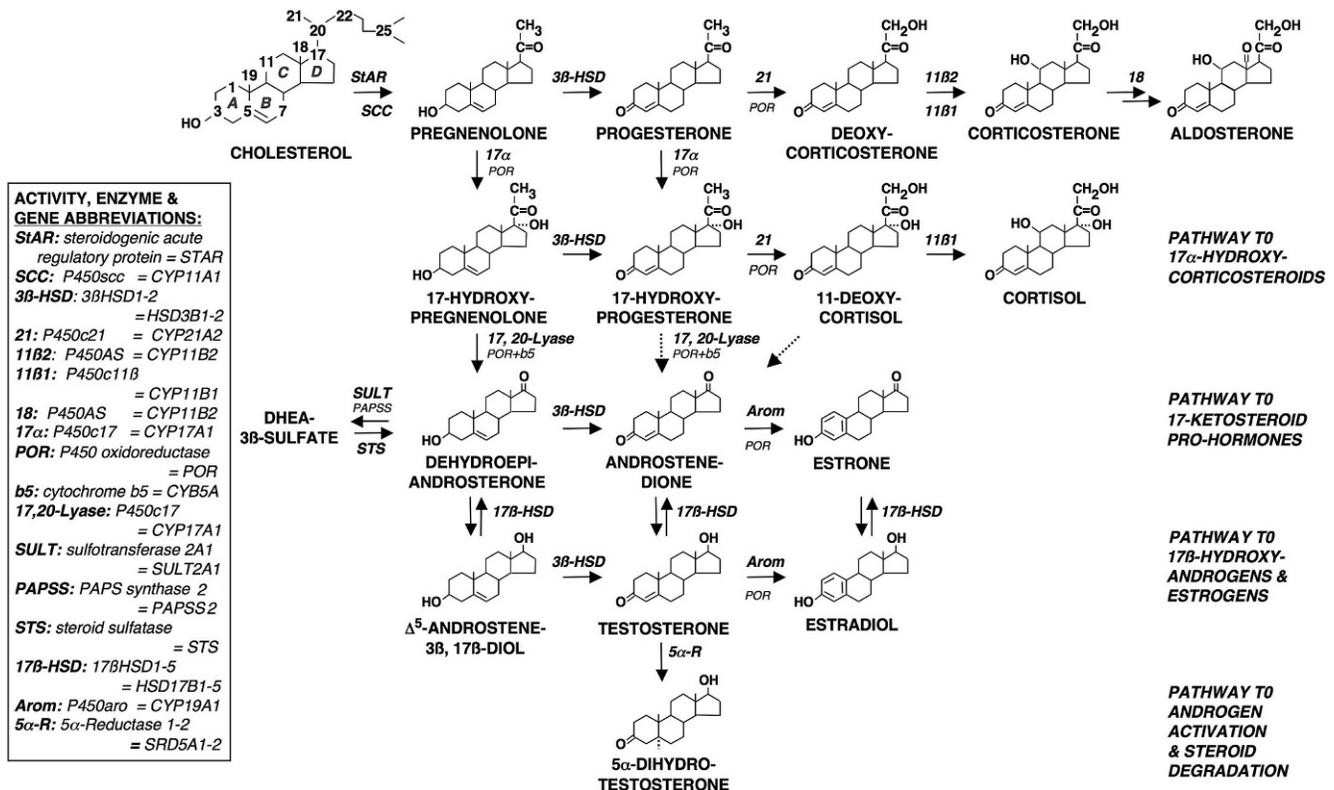

Fig. 16.22 Major pathways of steroid hormone biosynthesis from cholesterol. Carbon atoms of cholesterol are designated by conventional numbers and rings by conventional letters. The flow of hormonogenesis is generally downward and to the right. The top row shows the pathway to progesterone and mineralocorticoids, the second row the pathway to glucocorticoids, the third row the 17- β -hydroxysteroids, and the bottom row the activation of androgen. The steroidogenic enzymes are italicized. Abbreviations for enzymes include the following cytochrome P450 enzyme activities: cholesterol side chain cleavage (*scc*); 17 α -hydroxylase (17 α); 21-hydroxylase (21); 11 β -hydroxylase (11 β 1); aldosterone synthase (11 β 2, 18-hydroxylase/oxidase); aromatase (*Arom*). Non-P450 enzyme activity abbreviations include Δ^5 -isomerase- β -hydroxysteroid dehydrogenase (3 β) and 17 β -hydroxysteroid dehydrogenase (17 β -HSD). Clinically relevant electron transfer enzymes include P450 oxidoreductase (*POR*), cytochrome b5 (*b5*), and 3'-phosphoadenosine-5'-phosphosulfate synthase type 2 (*PAPSS*). (Modified from Rosenfield, R.L., Lucky, A.W., Allen, T.D. (1980). The diagnosis and management of intersex. *Curr Prob in Pediatr*, 10, 1.)

in the steady state the amount of hormone irreversibly leaving the plasma compartment equals the amount entering it. Because of extensive steroid interconversions, the quantity of these hormones excreted in urine is **not** necessarily indicative of the amount reaching target tissues.⁴³⁶ For example, so large a fraction of urinary testosterone glucuronide is formed directly from androstenedione by compartmentalized metabolism within the liver that the range of urinary excretion of testosterone in women overlaps that in men (Fig. 16.23).⁴⁵⁰ Estrone sulfate, like DHEAS in the androgen pathway, forms a circulating reservoir of inactive estrogen that can be returned to the active pool by hepatic sulfatase activity.⁴⁵¹ The blood production rates of representative steroid hormones are given in Table 16.2 and are shown for estrogens in Fig. 16.24. During the luteal phase of the menstrual cycle, estradiol production doubles⁴³⁹ and progesterone production rises 16-fold or more.⁴⁵²

Sex hormones also have environmental origins. Structurally distinct biological estrogens include equine estrogens and plant-derived phytoestrogens.⁴⁵¹ Synthetic estrogens include pharmacological compounds, such as ethinyl estradiol, diethylstilbestrol, selective ER modulators (SERMs), and some industrial chemicals, such as organochlorines (*p,p'*-dichlorodiphenyltrichloroethane [DDT] and others) and plasticizers (such as bisphenol A and phthalates). Endocrine-disrupting chemicals (EDCs) interfere with any aspect of hormone action, with mechanisms including mimicking or blocking hormone signaling through its receptor, and modulating

the synthesis, release, transport, metabolism, binding or elimination of natural hormones. These compounds therefore may impact development of the reproductive tract and function of the reproductive axis.^{192,266} Animal studies have indicated that EDCs can impair ovarian development, inhibit ovarian follicle growth, increase follicular atresia, and disrupt steroid hormone levels.²⁶⁶

Peripheral conversion of secreted prehormones by non-endocrine organs accounts for a major portion of sex hormone production. The ovary and the adrenal cortex are sources of prehormones, as well as secreted hormones. About 50% of serum testosterone (0.1 mg daily) normally is formed indirectly by peripheral conversion. Although 85% of normal estrogen production in women arises by secretion in midcycle, 50% of estrogen production can arise from extraglandular sources during the low-estrogen phases of the menstrual cycle.⁴⁵³ Peripheral formation of active steroids occurs in a wide number of sites, including liver, fat, and target organs.^{40,454} For example, the liver has high levels of 3 α - 3 β -, and 17 β -hydroxysteroid dehydrogenase and 5 α -reductase activities (see Fig. 16.22).

Peripheral androgen metabolism is not tightly regulated by the neuroendocrine system. It seems determined to some extent by the perinatal androgenic milieu,⁴⁵⁵ the effect of which is possibly mediated by GH.⁴⁵⁶ Postnatally, it is influenced by the sex hormone binding globulin (SHBG) level and the state of nutrition. Adipose tissue becomes a major site of conversion of androstenedione to both estrone and testosterone in the obese.^{308,457}

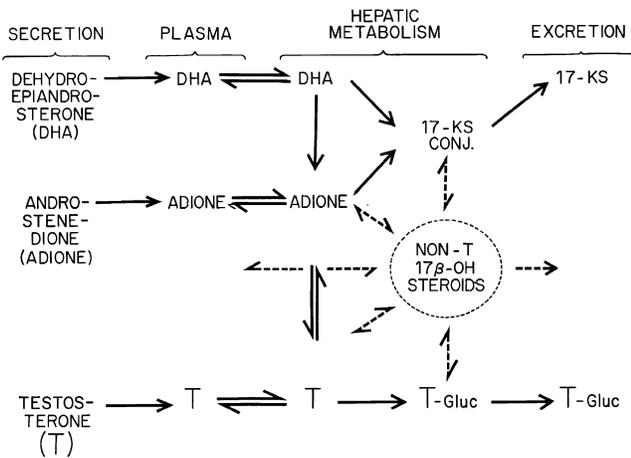

Fig. 16.23 Diagram illustrating the relationship among secreted, plasma, and urinary steroids. 17-Ketosteroid (17-KS) excretion does not reflect accurately the excretion of the most important plasma androgens. Only 25% or less of testosterone is excreted as 17-KS metabolites. Therefore important changes in testosterone production may not appreciably affect urinary 7-KS excretion. Furthermore, even the major 17-KS (*DHA-sulfate*) is excreted poorly until its production rate becomes quite high. On the other hand, about half of 17-KSs are not identified by the standard colorimetric test and 2 mg daily of 17-KS in adults results from hydrocortisone metabolism. In addition, testosterone glucuronide excretion does not accurately reflect the plasma testosterone level: less than 2% of testosterone appears in the urine as such. Furthermore, the plasma 17-KS androstenedione may be converted to testosterone glucuronide without ever circulating as unconjugated testosterone. (From Rosenfield, R.L. (1973). Relationship of androgens to female hirsutism and infertility. *J Reprod Med*, 11, 87.)

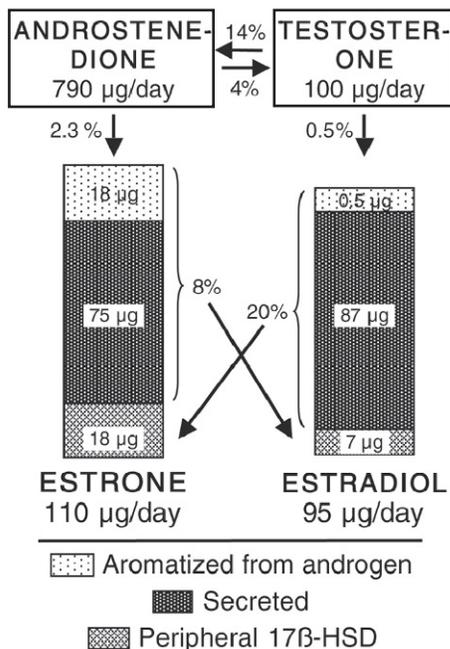

Fig. 16.24 Sources of estrone and estradiol in blood of follicular phase premenopausal women. Estrogen is derived from direct secretion by the gonad, aromatization of androgen, or conversion of an estrogen precursor by 17β-hydroxysteroid dehydrogenase (17β-HSD) activities. The percentage of substrate converted per day and total approximate production in micrograms per day are noted for each source. (Modified from Alonso, L.C., and Rosenfield, R.L. (2002). Oestrogens and puberty. *Best Pract Res Clin Endocrinol Metab*, 16, 13.)

Cytochrome P450 mixed function oxidases, the most important of which is CYP3A4, affect steroid efficacy by forming hydroxylated steroid metabolites of varying potency.^{458,459} They are subject to induction or inhibition by numerous drugs. Phytoestrogens increase estradiol bioavailability by inhibiting hepatic sulfotransferase.⁴⁶⁰

Plasma steroids appear to reach their sites of action and metabolism by simple diffusion from the vascular compartment.⁴⁶¹ The bioactive portion of serum testosterone seems to be the free testosterone and a portion of the albumin-bound testosterone that differs among tissues according to the diffusion characteristics of the vascular bed.⁴⁶² About 98% of serum testosterone and estradiol are bound to albumin and SHBG. The SHBG concentration determines the fraction of serum testosterone and other ligands (e.g., estradiol, DHT) that are free or bound to albumin. It is also a major determinant of ligand egress from plasma (Fig. 16.25).⁴⁶³ Some sex steroid effects may be mediated by SHBG binding to membrane receptors and activation of adenylate cyclase.^{464,465} A number of physiological and pathological states affect the SHBG level. It is increased by estrogen and thyroid hormone excess; it is decreased by androgen, insulin-resistant obesity, glucocorticoid, GH, and inflammatory cytokines.⁴⁶⁶⁻⁴⁶⁸

Target cell metabolism influences the cell's response to the steroid hormones that reach it (Fig. 16.26).⁴⁶⁹ The intracellular conversion of testosterone to DHT by one of the two isozymes of 5α-reductase is important for many but not all effects of testosterone,⁴⁷⁰ dependent upon the tissue-specific pattern of

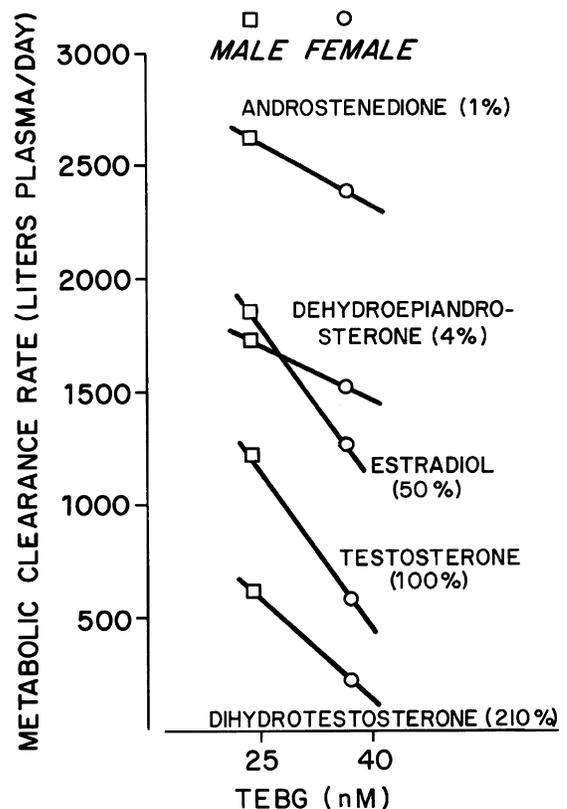

Fig. 16.25 The relationship between the metabolic clearance rate (MCR) and binding of sex hormones to sex hormone binding globulin (SHBG = testosterone-estradiol binding globulin [TEBG]). The MCR of each steroid has been related to the mean SHBG levels of men and women. The approximate affinity of each steroid for SHBG relative to testosterone is indicated in parentheses. (From Rosenfield, R.L. (1975). Studies of the relation of plasma androgen levels to androgen action in women. *J Steroid Biochem*, 6, 695.)

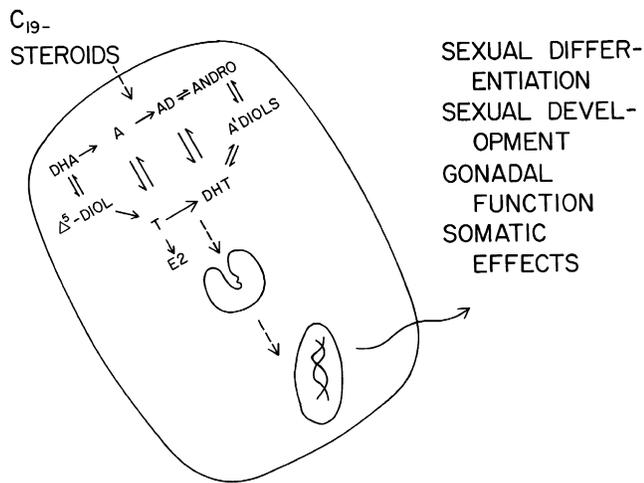

Fig. 16.26 Model of the mechanism of androgen action emphasizing the effect of steroid metabolism within a target cell on the mode of action. Solid arrows indicate pathways of steroid metabolism from 17-ketosteroid precursors as laid out in Fig. 14.23. Broken arrow indicates transport. The cell-specific intracellular pattern of C19-steroid metabolism determines the relative availability of testosterone or dihydrotestosterone (DHT) to the cytosol receptor for translocation to the nucleus. In cells, such as the rat granulosa cell in which $\Delta^5,3\beta$ -hydroxysteroid dehydrogenase activity is high, androstenediol (Δ^5 -diol) is as potent as testosterone. The human sebaceous gland has a similar pattern of steroid metabolism. A, androstenedione; AD, androstenedione; A'DIOLS, androstenediols; ANDRO, androsterone; DHA, dehydroepiandrosterone. E2, estradiol; T, testosterone. (From Nimrod, A., Rosenfield, R.L., Otto, P. (1980). Relationship of androgen action to androgen metabolism in isolated rat granulosa cells. *J Steroid Biochem*, 13, 1015. With permission from Elsevier Science.)

steroid metabolism. An important mode of testosterone action is via estradiol, notably within the brain. Although transformation is not fundamental to the mode of action of estradiol, estradiol effectiveness is influenced by target cell metabolism: the induction of 17β -hydroxysteroid oxidation in target tissues by progesterone, resulting in conversion of estradiol to the less potent estrogen estrone, counterbalances estrogenization.⁴⁷¹ There is also evidence that novel steroid metabolites exert tissue-specific effects.^{472,473}

Within target cells, all steroid hormones regulate the genome similarly, starting with binding to high-affinity intracellular receptors (Fig. 16.27).^{474–476} The steroid hormone receptors belong to the superfamily of nuclear hormone receptors. The estrogen, progesterone, and androgen receptors are, thus, homologous. Classic sex hormone effects are exerted by the interaction of steroid with receptor, not by either alone. Steroid binding triggers the dissociation of inhibitory chaperone heat shock proteins from the receptor.⁴⁷⁷ The active receptor-ligand complex then undergoes noncovalent dimerization and binding to its specific hormone response element on the gene. The deoxyribonucleic acid (DNA) bound steroid-receptor complex acts as a transcriptional regulator of the target gene promoter. Sensitivity to steroids is also modulated by molecular chaperone proteins that influence receptor configuration, intracellular trafficking, and receptor turnover, all which are determinants of steroid action.^{478,479}

The binding properties of steroids to their cognate receptors are the initial determinants of classical steroid action.^{474,475} Ligand-based selectivity is one element of this interaction. Estradiol is a more potent estrogen than estrone and estriol partly because it binds best to the steroid binding domain of the ER.⁴⁸⁰ DHT is an inherently more potent androgen than

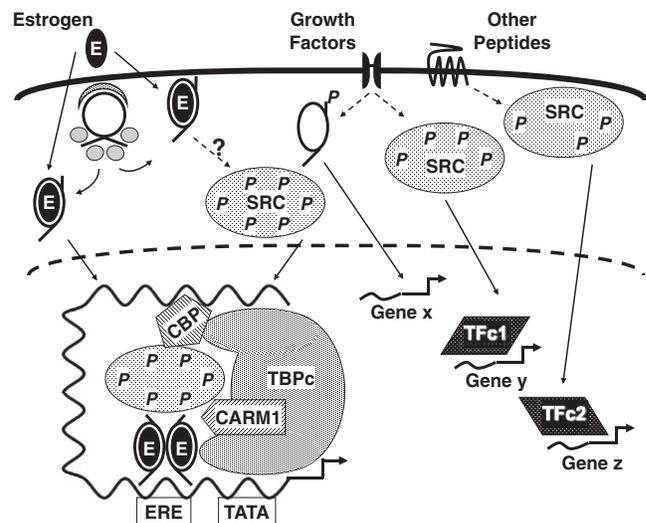

Fig. 16.27 A model for the mechanism of estrogen (E) action that emphasizes the role of interactions of the estrogen receptor with steroid receptor coregulator (SRC) and phosphorylation signaling. Estrogen causes the 4S subunit and heat-shock proteins to dissociate from the unliganded estrogen receptor. Then estrogen entry into the binding pocket causes a conformational change in the receptor. Estrogen also stimulates phosphorylation of SRC in a specific pattern (Ps), possibly via liganded membrane-bound estrogen receptor (ER) as it does some transcription factors, and recruits it to the nuclear deoxyribonucleic acid (DNA) steroid-receptor complex with the estrogen response element (ERE). SRC in turn recruits other cofactors, such as the cyclic adenosine monophosphate (cAMP) response element binding protein-binding protein (CBP) and coactivator-associated methyltransferase (CARM1) to the hormone binding complex. This aggregate then interacts with the TATA binding protein initiation complex (TBPC) to initiate estrogen-specific gene transcription. The genomic estrogen effect is modulated by the effects of environmental signals on other cell-specific transcription factors (TFs), some of which involve differentially phosphorylated SRC complexes (TFc) in gene activation, others of which involve ligand-independent ER. Dotted lines indicate diverse kinase pathways. ER recycling is not shown. (From Katzenellenbogen, B.S., Montano, M.M., Ediger, T.R., et al. (2000). Estrogen receptors: selective ligands, partners, and distinctive pharmacology. *Recent Prog Horm Res*, 55, 163–193; O'Malley, B.W. (2005). A life-long search for the molecular pathways of steroid hormone action. *Mol Endocrinol*, 19, 1402–1411; McDevitt, M.A., Glidewell-Kenney, C., Jimenez, M.A., et al. (2008). New insights into the classical and nonclassical actions of estrogen: evidence from estrogen receptor knock-out and knock-in mice. *Mol Cell Endocrinol*, 290, 24–30.)

testosterone mainly because of its higher association rate constant and its lower dissociation rate constant.⁴⁸¹

The antiestrogens tamoxifen and clomiphene and the antiandrogens cyproterone acetate and spironolactone competitively inhibit the active ligands from binding to their specific receptor sites by weakly and transiently occupying receptor sites. These differences result from potent agonists snugly fitting into the binding pocket, which induces a receptor conformation different than that of antagonist-bound receptor. One such change is the C-terminal tail of the receptor flipping over to close the “door” when a potent agonist enters; this simultaneously provides a different outer surface for interaction with coregulator proteins.

Thus ligand-based selectivity arises not only because of tighter ligand binding, but because alternative ligands produce both intermediate and unique conformational changes in the receptor, which in turn induce altered receptor interactions

with coregulator proteins that result in a spectrum of activities.⁴⁸² Thus steroids do not simply switch receptors on; they induce selective functions that depend on the nature of the coregulators that are recruited to the complex.^{483–486} In part, this selectivity arises because different domains of these receptors mediate these different functions. For example, the activation function (AF)-1 domain of the ER mediates interactions with mitogen-activated protein (MAP) kinase and TGF- β 3, whereas the AF-2 domain mediates interactions with coregulator proteins.⁴⁸⁷ Coactivators, in turn, regulate alternative splicing, gene activation and repression (in some cases via their dual enzymatic functions), ubiquitin-proteasome-mediated turnover of the receptor-coregulator complex,⁴⁸⁸ and also determine cell-specific, site-based actions,⁴⁷⁵ as discussed later.

Receptor-based selectivity is a second element in steroid action. There are now known to be two isoforms of each of the sex steroid receptors. The α and β forms of the ER, although homologous, are coded by separate genes.¹⁷¹ A and B forms of the progesterone and androgen receptors exist.^{489,490} These forms of the PR arise by transcription from alternate promoters within the same gene, whereas those of the androgen receptor arise from posttranslational modification of a single messenger (m)RNA. These isoforms have variously been shown to manifest a differential tissue expression pattern and respond differentially to antagonists. Interactions of a steroid with different forms of receptors can regulate some target genes differentially. One role of ER β is apparently to modulate ER α activity: ER α and ER β can have opposite actions at AP-1 and SP-1 sites, and studies of transcriptional activity in bone and breast tissue of mice indicate a restraining effect of ER β on responses to estradiol.^{171,491} Thus different target tissues exposed to the same hormone may respond selectively because of a distinct repertoire of receptor isoform expression. Some examples are notable. Although both forms of ER are expressed in most target tissues, the classic form of the ER, ER α , plays the key role in regulation of LH and estrogen actions on the uterus, breasts, sex-specific behavior, and bone.^{171,492,493} In the mouse ovary, knockout experiments show that ER α is expressed in thecal cells where it prevents androgen excess in response to LH. In contrast, ER β is expressed only in granulosa cells, where its inhibition of androgen receptor expression is critical to prevent premature follicular atresia.¹⁷² Both are necessary for oocyte survival and the ability of preovulatory follicles to rupture. Furthermore, loss of both causes transdifferentiation of granulosa cells to Sertoli-like cells and massive oocyte death.¹⁵⁶ Liganded PR $_A$ is essential for ovulation⁴⁹⁴ and is the more effective antagonist of ER action.⁴⁷⁴ In addition, sequence variation in hormone response elements contributes to differential gene regulation.⁴⁹⁵

Effector site-based selectivity is a third variable in classical sex hormone action. In other words, the potency and character of a response to a ligand-receptor complex are not simply inherent properties of the complex. Rather, they depend on the array of effector molecules present in the site of action. Thus the array of genes expressed locally and the relative expression level of coregulators (coactivators and corepressors) are extremely important in the determination of appropriate and graded responses to a ligand by a target cell.^{474,496} Heterodimerization of the ER with other nuclear receptors can modulate its action.⁴⁹⁷ Androgens appear to exert some of their genomic effects by directly complexing with transcription factors other than the androgen receptor.⁴⁹⁸ Both estrogen and androgen appear to exert antiapoptotic effects in osteoblasts and osteocytes by activating a ligand-dependent, but nongenomic, kinase-mediated signaling pathway.⁴⁹⁹

Nuclear receptor coactivators are critical in sensing cell-specific environmental signals and to coordinate signals emanating from membrane receptors with nuclear receptor

action.⁴⁷⁵ Surface receptors send signals through kinase pathways that result in specific serine/threonine phosphorylation patterns of coactivators. These phosphorylation patterns serve as a code for the coactivator to preferentially bind and activate distinct sets of downstream transcription factors (see Fig. 16.27). Overexpression of steroid receptor coactivator-3 (SRC-3) is as important in the pathogenesis of some breast cancers as is ER positivity.

The effects of a given ligand-ER complex often differ from those of the estradiol (E2)-ER complex among cell types. This is the basis for the development of SERMs: these compounds exert effects in a tissue-specific manner depending on the cell context.^{474,482} The chemical structure of a SERM—or any ER ligand, for that matter—determines the configuration of the ER, resulting in a spectrum of activities from agonist to antagonist, depending on which coregulators are available for recruitment in the target cell. Raloxifene is an estradiol agonist in bone and epiphyseal cartilage but is antiestrogenic in uterus and breast; tamoxifen is estrogenic in uterus but antiestrogenic in breast and bone. Both appear to retain neural and endothelial estrogenic activity.^{500,501}

Nonclassical mechanisms play a role in sex steroid action.⁴⁷⁵ The nonclassical mechanisms are of two general types: (1) genotropic estrogen response element (ERE)-independent signaling, in which liganded ER acts as a coregulator of other transcription factors that act through their specific DNA response elements and (2) nongenotropic signaling, in which E2 binding to membrane-associated receptors, including ER α , rapidly stimulates phosphorylation pathways.^{502,503}

The nongenomic effects via membrane signaling occur rapidly (within minutes) and can mediate cell proliferation, apoptosis, and migration in cell-specific ways.^{499,504} Nongenomic E2 actions account for most of the LH-inhibitory and energy balance effects of E2.^{503,505} These effects can be mediated by binding to nuclear ER in plasma membrane domains provided by scaffolding proteins, such as caveolin. On such platforms, the E2-ER complex acts like a membrane receptor, coupling with G-proteins and activating cytoplasmic pathways involving SRC and MAP kinase. Androgens appear to act similarly. Nongenomic actions of nuclear PR have also been reported. Some nongenomic effects seem to involve the activation of novel G-protein-coupled transmembrane receptors for E2 and progesterone that interact either with steroids or their metabolites.

Genomic ER signaling may also be ligand independent. For example, cell membrane signaling by growth factors or other peptides stimulate ER phosphorylation. EGF activates phosphorylation of the ER and simulates diverse estrogen effects.⁵⁰⁶ Activation of unliganded ER α seems to be involved in repressing expression of the androgenic 17 β -HSD testicular isoform in the ovary.³³⁵

Steroids that act by binding to membrane-bound receptors in the brain are termed *neuroactive*.³⁹⁷ Neuroactive steroids synthesized in the brain are termed *neurosteroids*.^{507–509} The best documented of these effects are on neurotransmitters, which control ion channels. Allopregnanolone (3 α -hydroxy-5 α -tetrahydroprogesterone) and 3 α -androstane-20-one are GABA $_A$ receptor agonists and so have sedative and antiepileptic properties.⁵¹⁰ Pregnenolone sulfate and DHEAS have the opposite effect, the former also stimulating the glutamate receptors. Receptors for 5-hydroxytryptamine have been implicated in mediating some of the effects of sex steroids and certain of their metabolites.^{511,512} Some estrogen effects in brain are membrane-mediated.⁵¹³

The tissue-specific posttranscriptional events involved in sex steroid signaling are poorly understood. Estradiol and progesterone modulate the actions of each other through effects on their specific receptors: increased estrogens in the preovulatory phase of the cycle upregulate target organ receptors for both estradiol and progesterone; luteal phase levels of progesterone

then suppress the production of both receptors.^{514,515} Estrogen prevents bone loss by blocking the production of proinflammatory cytokines.⁵¹⁶ Androgen action has been reported to be mediated by prostaglandins in genitalia,⁵¹⁷ and testosterone stimulates the IGF-1 system in epiphyseal cartilage.⁵¹⁸

Maturation of Sex Hormone Target Organs

Genital Tract

The Müllerian system of the embryo gives rise to the uterus, cervix, upper vagina, and fallopian tubes in the absence of AMH secretion by fetal testes during the first trimester of gestation.⁴⁴⁴ Genital swelling develops to engulf the base of the penis-like clitoris between 11 and 20 weeks' gestation in parallel with the development of the ovarian follicular system.⁵¹⁹ ERs are expressed in the labia minora, prepuce, and glans in females, but not in the homologous structures of males.⁵²⁰ An association between antiestrogen and genital ambiguity has been reported.⁵²¹ Diethylstilbestrol induces dysplasia of the genital tracts.⁵²² These data suggest that estrogen may play a direct role in female genital tract differentiation. However, knock-out of ERs has no obvious effect on genital tract differentiation.¹⁵⁶

The infantile uterus and cervix enlarge under the influence of estrogen during puberty. The endometrium and cervical glands then undergo cyclical changes in concert with cyclic ovarian function. In response to rising estrogen during the follicular phase of the cycle, the endometrial epithelium and stroma proliferate. The uterine glands increase in number and lengthen. Endometrial hyperplasia is prevented by progesterin⁵²³ and androgen excess.⁵²⁴ In response to progesterone secretion after ovulation, the endometrium increases in thickness: stromal edema occurs, and the uterine glands enlarge, become sacculated, and secrete a glycogen-rich mucoid fluid. The coiled arteries lengthen further during this time and become increasingly spiral. These changes are critical to permit implantation. High-dose progesterin is an effective postcoital contraceptive because it prevents implantation when taken within 3 days of unprotected intercourse.⁵²⁵

Endocervical gland secretions lubricate the vaginal vault. The endocervical mucus is scanty and relatively thin during the low-estrogen phase of the cycle. The increase in mucus flow with advancing follicular development seems to require tissue-specific stimulation of the cystic fibrosis transmembrane regulator by estrogen.⁵²⁶ Cervical mucus becomes more viscous and elastic as estrogens rise in the later follicular phase of the cycle—the extent to which it can be stretched into a long spindle, *spinnbarkeit*, is a function of the estrogen level.

The mucosa of the vagina and the urogenital tract is comprised of hormone-responsive stratified squamous epithelium (Fig. 16.28).² The basal layer is the regenerative area. In the absence of estrogen, there is only a parabasal layer of cells over this, and the vagina is thin, with a tendency to alkalinity, which predisposes it to local infection (nonspecific vaginitis).⁵²⁷ In response to estrogen, epithelial proliferation occurs, with formation of successive intermediate and superficial layers. With this maturation, the cytoplasm of each cell first expands, leading to formation of small intermediate cells. With further estrogenization, the nuclei become pyknotic and large intermediate cells form. Greater estrogenization brings about their transformation to cornified squamous superficial cells: the cytoplasm changes from basophilic to acidophilic with the accumulation of glycogen. Resistance to infection of the fully developed vaginal mucosa results from its thickness and from its acid pH, which occurs from the fermentation of the glycogen of the superficial cells. In response to luteal phase progesterone, degenerative changes appear in vaginal mucosal cells:

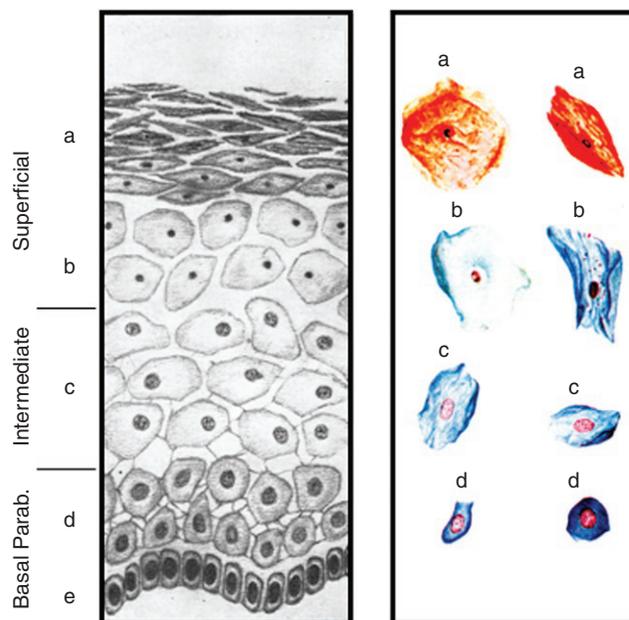

Fig. 16.28 The layers of vaginal epithelium of the well-estrogenized adult. The superficial layer contains surface cells that are cornified (squamous) with eosinophilic cytoplasm and pyknotic nuclei (a) as well as large intraepithelial cells that are also karyopyknotic but basophilic (b). The intermediate zone contains basophilic cells that have less cytoplasm and intermediate-size nuclei (c). The basal and parabasal cells have a relatively small amount of basophilic cytoplasm and relatively vesicular nuclei (d, e). (Modified from Wilkins, L. (1968). *The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence*. Springfield, IL, Charles C Thomas.)

superficial cells decrease, the cytoplasm assumes a “crinkled” appearance, cells degenerate, and bacterial proliferation increases.

Vaginal smears show the characteristic cyclic changes in the cell types comprising the vaginal epithelium (see Fig. 16.28).⁵²⁸ In the prepubertal years, parabasal cells predominate, and characteristically 10% or less are small intermediate cells. A pattern consisting entirely of intermediate cells is typical of early puberty. The early follicular phase of the menstrual cycle is characterized by the predominance of large intermediate cells with few, if any, superficial cells. Peak maturation is reached at midcycle, at which time 35% to 85% of the cells seen on vaginal smear are superficial; the remainder are large intermediate cells. This cornification develops over a 1-week period in response to estradiol levels of about 70 pg/mL and persists 1 to 2 weeks after estrogen withdrawal (see Fig. 16.11).⁵²⁹

Progesterone antagonizes estrogen effects on the vaginal epithelium and cervix. Inhibition of cervical ripening by progesterins is used to prevent recurrent spontaneous preterm delivery.^{530,531}

Many normal variations have been recognized in the appearance of the hymen. The transverse diameter increases with age.^{532,533}

Mammary Glands

Multiple rudimentary branching mammary ducts are found beneath the nipple in infancy; they grow and branch very slowly during the prepubertal years.⁵³⁴ Estrogen stimulates the nipples to grow, mammary terminal duct branching to progress to the stage at which ductules are formed, and fatty stromal growth to increase until it constitutes about 85% of the

mass of the breast. GH (via IGF-1) and glucocorticoids play a permissive role.^{535,536} These hormones interact with breast stroma and local growth factors to stimulate the development of breast epithelium. Lobulation appears around menarche, when multiple blind saccular buds form by branching of the terminal ducts. These effects are caused by the presence of progesterone. The breast stroma swells cyclically during each luteal phase. Full alveolar development normally only occurs during pregnancy under the influence of additional progesterone and prolactin. Prolactin does not play a role in breast growth without priming by female hormones.⁵³⁷

Estrogen and progesterone also play a role in breast cancer susceptibility.⁵³⁸ Earlier than average age at menarche is a modest risk factor for breast cancer, regardless of BRCA status;^{539,540} notably, however, breast cancer risk has not been shown to be increased in precocious puberty. The *BRCA1* gene normally restrains mammary growth, at least in part, by inhibiting expression of ER α and PRs, and cancer-related mutations reverse these processes.⁵⁴¹

Pilosebaceous Unit

The pilosebaceous unit (PSU), with but few exceptions, consists of both a piliary and a sebaceous component.⁵⁴² Androgens are a prerequisite for the growth and development of PSUs in their characteristic pattern. Androgens exert their effects both on the dermal papilla, which regulates the hair growth cycle, and on PSU epithelium. Before puberty, the androgen-dependent PSU consists of a prepubertal vellus follicle in which the hair and sebaceous gland components are virtually invisible to the naked eye (Fig. 16.29). Under the influence of androgens, in the sexual hair areas, the PSU switches to producing a medullated terminal hair follicle that expresses a unique type of keratin that is androgen responsive.⁵⁴³ The difference in the apparent density of sexual hair between men and women is caused by differences in the density of terminal hairs that develop in response to androgen. In the balding-prone area of scalp in individuals genetically predisposed to male-pattern alopecia, androgens weakly attenuate the hair growth cycle, so that the PSU gradually generates only vellus follicles.⁵⁴⁴ In acne-prone areas, androgen causes the prepubertal vellus

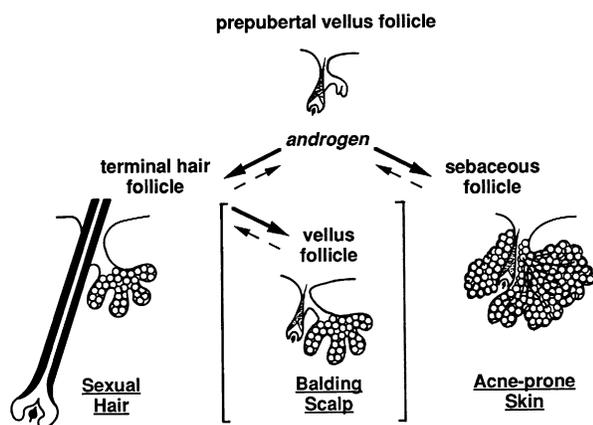

Fig. 16.29 Role of androgen in the development of the pilosebaceous unit. Androgens (solid lines) are responsible for the patterned differentiation of the pilosebaceous unit at puberty. Dotted lines indicate effects of antiandrogens. Hairs are depicted only in the anagen (growing) phase of the growth cycle. In balding scalp (bracketed area), terminal hairs not previously dependent on androgen regress to vellus hairs under the influence of androgen. (From Rosenfield, R.L., Deplewski, D. (1994). Role of androgens in the developmental biology of the pilosebaceous unit. *Am J Med*, 97(5A), 80.)

follicle to develop into a sebaceous follicle, in which the sebaceous epithelium develops and the hair remains vellus. Adrenarchal levels of androgens suffice to successively initiate sebaceous gland development and the growth of pubic hair. Progressively, greater amounts of androgen are in general required to stimulate terminal hair development along a pubic to cranial gradient. All these effects of androgen are to some extent reversible by antiandrogens.

Estrogens modestly stimulate hair growth, probably by inhibiting the catagen (resting) phase of the hair cycle;⁵⁴⁵ this may well be caused by induction of androgen receptors by estrogen. Estrogens also directly inhibit sebum secretion. GH synergizes with androgen action on the PSU, in part via IGF-1 signaling. Retinoic acid receptor agonists antagonize the effects of androgen on the sebaceous gland by inhibiting sebocyte proliferation and differentiation. Insulin, prolactin, glucocorticoids, thyroxine, and catecholamines also play roles in PSU growth, development, and function.

Bone

Increased secretion of sex hormones clearly initiates the pubertal growth spurt. About half of this effect of sex hormones is caused by their stimulation of the GH-IGF axis.⁵⁴⁶ The remainder of the effects of sex steroids on skeletal growth is direct.^{547,548}

Differences between the actions of sex hormones contribute to women's bones being shorter and narrower than men's.^{549,550} The basis for these differences are diverse and involve interactions with IGF-1 and effects on cortical, cancellous, and periosteal bone formation.

Estrogen and androgen both stimulate epiphyseal growth. Estradiol is the critical hormone that brings about epiphyseal closure.⁵⁴⁸ Estrogen also is particularly effective in reducing bone turnover. To some extent these effects may be prenatally programmed.⁵⁵¹ Bone accrual during puberty is a major determinant of adult fracture risk. Menarche after 15 years carries a 1.5-fold increase in fracture risk, and the risk rises with age of menarche.⁵⁵²

Adipose Tissue

Women have a greater percentage of body fat than men.⁵⁵³ During puberty, they develop both more and larger fat cells than men in the lower body, which favors a lower body (gluteofemoral) fat distribution, in contrast to men's upper-body (visceral) fat accumulation. The critical periods for establishment of the adipocyte population are fetal life and adolescence, after which lipid accumulation occurs primarily by cell hypertrophy.⁴⁰ Serum levels of leptin rise throughout puberty to reach higher levels in females than males,²⁸² whereas levels of the antilipolytic adipocytokine adiponectin remain stable in females but fall in males⁵⁵⁴ in response to androgen.⁵⁵⁵

Insulin signaling is of major importance to the size and function of adipose tissue—stimulating adipogenesis (development of preadipocytes into adipocytes) and lipogenesis, while inhibiting lipolysis.⁴⁰ Beta-adrenergic catecholamines stimulate lipolysis, countering inhibition by insulin.^{556,557} Visceral white adipose tissue (VWAT) lipolysis is less sensitive to insulin and more sensitive to catecholamines than subcutaneous SCWAT.⁵⁵⁷

Androgens cause a masculine physique at puberty primarily by inhibiting adipogenesis reciprocally to stimulating myogenesis.⁵⁵⁸ They act by inhibiting adipogenic differentiation of human mesenchymal pluripotent stem cells reciprocally to their stimulation of the myogenic lineage, in a dose-dependent fashion.⁵⁵⁹ Local androgen generation by adipose tissue as it differentiates in response to insulin⁵⁶⁰ likely serves to limit insulin-generated adipogenesis.⁵⁶¹ In adipocytes, androgen has been reported to inhibit lipogenesis.^{562,563} Androgen also

inhibits catechol-stimulated lipolysis in female SCWAT, opposing the effect of insulin, but not in omental WAT.^{564,565}

Estrogen has been reported to suppress lipogenesis through inhibition of adipocyte lipoprotein lipase activity, according to most in vitro studies.⁵⁶⁶ Estradiol attenuates the lipolytic response to catecholamines, specifically in SCWAT adipocytes,⁵⁶⁷ but promotes lipolysis by stimulating hormone-sensitive lipase.⁵⁶⁶ The development of obesity in postmenopausal women and oophorectomized animal models has led to the concept that estrogen deficiency causes obesity,⁵⁶⁸ but the role of FSH elevation in mediating this obesity by inhibiting the formation of brown adipose tissue⁵⁶⁹ confounds the interpretation of all such studies. Progesterone generally counters estrogen and androgen effects on white and brown adipose tissue in experimental models.^{568,570}

Female sex steroid effects on serum lipids are modest.^{571,572} Physiological (transdermal) estradiol replacement slightly raises high-density lipoprotein cholesterol (HDL-C)⁵⁷² and lowers very low-density lipoprotein (VLDL) triglycerides.⁵⁷³ The lower LDL-C during the normal luteal phase seems primarily because of its consumption by the corpus luteum as steroidogenic substrate.⁵⁷² Oral estrogen replacement therapy raises HDL-C more than does transdermal replacement, but differs from it in raising VLDL-triglycerides and decreasing LDL-C, whereas androgenic progestins lower HDL-C.⁵⁷⁴

Progesterone deficiency is responsible for the increased postprandial chylomicron triglyceride concentrations that occur as the result of low peripheral lipoprotein lipase activity when the pituitary-gonadal axis is acutely suppressed.⁵⁷⁵ In humans, use of the progesterone analogue megestrol acetate is approved to stimulate appetite and weight gain; use of progestins is associated with insulin resistance.⁵⁷⁶

Muscle

Testosterone administration increases muscle mass and decreases fat mass reciprocally. Androgen does so by promoting the commitment of mesenchymal pluripotent stem cells to the myogenic lineage while inhibiting adipogenesis.^{559,577} Testosterone effects are exerted via androgen-receptor-mediated and nonclassical pathways. Human skeletal muscle formation of DHT is mediated primarily by type 3 5- α -reductase.⁵⁷⁸ Androgens then exert dose-related stimulation of muscle cell hypertrophy, as well as hyperplasia along with associated tissues, such as motor neurons. Hyperandrogenic women have increased muscle mass and strength, which seems to give them an advantage in athletic competition.⁵⁷⁹ Consequently, there is active debate about regulation of women's androgen levels in elite athletic competition.

Central Nervous System

Concordance of gender identity (self-identification as male or female) and gender orientation (sexual preference) with gender assignment on the basis of genital anatomy is the norm, which is consistent with an important role of androgen in programming these aspects of neuropsychosocial development. However, nonhormonal genetic and epigenetic factors influence sexually dimorphic aspects of human development.⁵⁸⁰⁻⁵⁸²

Before sex hormone differences are detectable, several genes are differentially expressed in the brains of male and female mice.⁵⁸³ Sex chromosomes directly program sexually dimorphic neuronal differentiation⁵⁸⁴ and behaviors, such as aggression, parenting, and social interaction.⁵⁸⁵ The maternally inherited X chromosome is preferentially expressed in glutamatergic neurons of the cerebral cortex, and sex-specific imprinting of autosomal genes of the hypothalamus is common and appears to be the default state in females.^{586,587}

Testosterone exposure during both the period of transient activation of the HPG axis in the fetal-perinatal period and again during puberty plays a role in organizing neural gene expression and development in a sexually dimorphic manner according to extensive studies in animal models, which are consistent with observations in humans.⁵⁸⁸⁻⁵⁹⁰ The critical period for this hormonal programming on behavioral patterns closes after puberty. This has consequences both for sex-typical neuroendocrine function and sex-typical and nonsexual behavior that is activated by the pubertal hormonal milieu.^{404,588,591,592}

The critical period for hormonal sensitivity of sexually dimorphic areas of the brain occurs during the early newborn period of rodents, which is thought to be comparable to the early second trimester of humans.⁵⁹³ In rats, the preoptic nucleus of the hypothalamus is larger in males, and treatment of newborn females with testosterone (or estradiol) permanently increases neuronal development to duplicate this effect and causes subsequent masculinized sexual behavior and anovulation.^{13,594} The anovulation results from masculinization of the LH secretory pattern (that is, both increased LH secretion and suppressed capacity to mount LH surges in response to estrogen priming) that appear to be the consequence of permanent suppression of hypothalamic PR expression.¹⁶

Testosterone administration to experimental animals stimulates the growth of sexually dimorphic brain areas to adult male size.⁵⁹⁵ Maintenance of differences in adult nuclear size and androgen receptor expression of sexually dimorphic areas of the brain is dependent upon the ambient androgen level.^{596,597} Peripubertal testosterone and female hormone administration have different effects on behavior.^{595,598}

Several human brain structures are sexually dimorphic, some becoming so at puberty.⁵⁹⁹⁻⁶⁰¹ Characteristic cortical and subcortical sex differences are discernable at puberty by structural magnetic resonance imaging (MRI),^{589,602,603} although most human brains have a mosaic of "male" and "female" features.⁶⁰⁴ Fetal amniotic testosterone reportedly correlates positively with many of the regional male sexual dimorphisms in the gray matter, including the amygdala, as with diverse differences in gender behavior.^{603,605} Functional MRI has shown endogenous testosterone levels to correlate with, and exogenous testosterone administration to females to activate, amygdala and parahippocampal regions and other brain areas in response to social-affective stimuli.⁶⁰³ Studies in transsexuals have shown that virilizing doses of testosterone affects the size of specific cortical and subcortical areas of the brain, and antiandrogen/estrogen treatment robustly inhibited hippocampal size.⁶⁰⁶

Some testosterone effects are androgen specific.^{607,608} However, many testosterone behavioral effects appear to be mediated by intraneuronal aromatization of testosterone to estradiol in a manner that is regulated in site-specific fashion by androgen and estrogen.⁶⁰⁹⁻⁶¹¹ Thus it has been postulated that low levels of estradiol promote the development of the brain and greater amounts masculinize it. These higher levels of estradiol are generated in the male brain by neuronal aromatization of circulating testosterone. ER α knock-out in female mice reduces sexual behavior and parenting behavior, while increasing aggressiveness.⁶¹²

The mechanism by which estrogens mediate androgenic masculinization of rodent sexual behavior involves prostaglandin E₂ mediation.^{593,613} Estradiol acts through ER α to induce microglia, the resident immune cells of the brain, to secrete prostaglandin E₂, which reduces DNA methyl transferase activity so as to release epigenetic repression of the default female behavioral state;⁵⁸⁷ this initiates enhanced neurite dendritic spine formation and masculinized behavior. Release of epigenetic repression appears to be an important postreceptor mechanism of testosterone action in the brain, also affecting

embryonic neural stem cells.⁶¹⁴ The involvement of prostaglandin E₂ in mediating the androgen effect on neural synapsing lends credence to a role for androgen excess contributing to autism spectrum disorders.^{593,615}

This hormonal organization of the brain involves hormone-specific effects on cell proliferation versus survival and synapse formation versus pruning.^{588,589} Androgens have a trophic effect on the dendritic spine cells of sexually dimorphic nuclei of rodents that promotes increased synaptic density.⁵⁹³ Estrogen alters the pattern of synaptic connections in spatially-specific and precise patterns that appear to fine-tune the sensitivity of certain regions of the brain to excitatory and inhibitory amino acids.^{616,617} Hypothalamic changes in synaptic remodeling have been correlated with the preovulatory surge of GnRH. There is also sexual dimorphism in cerebral progesterin receptors, and progesterone attenuates testosterone effects on the brain.^{618,619} Progesterin-estrogen administration is neuroprotective in animal studies.⁶²⁰ These hormones may counteract brain and spinal cord injury in adult women,^{620,621} but not in the sexually immature state.⁶²²

On average, women tend to perform better than men on tasks that involve object memory, verbal skills, processing speed and accuracy, and fine-motor skills, whereas men tend to excel in visual-spatial memory, while the sexes do not differ in vocabulary or math skills.^{590,592,623–625} These differences are quantitatively modest, of the order of 0.4 to 1.0 standard deviation (SD), leading, therefore, to large overlaps in these skills among the sexes. The male advantage in visual-spatial skills is established by 4.5 years of age. Because both boys and girls who are congenitally sex hormone deficient are relatively poor in visual-spatial abilities, and sex hormone treatment at puberty does not ameliorate these deficits, this difference seems to be the result of estrogen-mediated patterning in both sexes. The extent to which this difference is innate or because of socio-cultural factors is a subject of considerable debate.

A wide variety of gender dimorphic behaviors are found in young children, but normally they have a different character than in adults.⁶²⁶ Gender identity is established in midchildhood,⁵⁸¹ probably by 3 years of age.⁶⁰⁰ Sexual orientation is established by 10 years of age; it has been postulated that this is dependent upon adrenarche rather than true puberty.⁴⁰⁴ Early pubertal amounts of androgen or estrogen have little effect on sexual behaviors, but increase some aspects of aggressive behavior.^{627,628} Only in later puberty is there activation of the sex drive, which has been programmed in earlier development.

Discordant gender identity (transsexualism/transgenderism) and sexual orientation (homosexuality, bisexuality) occur in a small proportion of the population.^{580,581} Their prevalence seems to be increased in disorders of sex development (DSD). Studies of DSD indicate that a male level of androgen acting through the androgen receptor pre- or perinatally is an important determinant of male gender behavior (role) and mildly disruptive to female gender identity.^{600,629} However, DSD is uncommon among homosexuals and transsexuals, whereas heritability estimates approximate 20% to 60%.^{580,581} Neuroimaging studies suggest that these disorders have a biological basis. Homosexuality is associated with loss of sex differences in brain structures^{630,631} and transsexuality with less differentiation of brain areas dealing with body and self-perception.⁶³⁰ Neuroimaging indicates that male homosexuals have a pattern of nuclear activation in response to pheromone-like chemosignals resembling heterosexual women rather than that of heterosexual men, and homosexual women have an intermediate type of activation.⁶³²

Androgen and estrogen metabolites in sweat and urine, which contain unusual steroids, such as androst-4,14-diene-3-one,⁶³³ have been found to exert sexually dimorphic activation of the anterior hypothalamus that is independent of their

odor.⁶³² Therefore they appear to act as pheromone-equivalent chemosignals. Human pheromones appear to modulate the timing of ovulation⁶³⁴ and mood.⁶³⁵ It is likely that a dedicated population of olfactory receptors that project to GnRH neurons act as pheromone receptors.⁶³⁶

Other Targets of Sex Hormone Action

Sex steroid hormones affect a wide variety of tissues in ways that are often unrecognized. An estrogen effect on stabilizing muscle integrity has been noted in muscular dystrophy.⁶³⁷

Autoimmune disorders are in general more common in females, particularly after puberty.⁶³⁸ Estrogen downregulates blood levels of the inflammatory cytokine interleukin-6⁶³⁹ and thymic autoimmune regulator (*AIRE*) gene expression.⁶⁴⁰ Progesterone has a similar effect and androgen the opposite effect on *AIRE*. Sex dimorphism in predisposition to autoimmune disorders is partly explicable by sex hormone action on *AIRE* network genes during the neonatal minipuberty.⁶⁴¹ However, sex genotype influences the autoimmune system independently of sex steroids.^{585,638}

The cardiovascular effects of estrogen include upregulation of estrogen and PRs in vascular tissue and nongenomic effects on endothelial nitric oxide synthase.⁶⁴² Estrogen improves the disturbed endothelial dysfunction of young hypogonadal women and is necessary for the cardioprotective effect of exercise.⁶⁴³ Estradiol replacement therapy, oral or transdermal, lowers blood pressure, although estradiol causes salt and water retention.⁵⁷¹ This contrasts with contraceptives containing the more potent estrogen ethinyl estradiol, which raise blood pressure significantly, unless containing an antimineralocorticoid progesterin.

Estrogens and progestins also exert hemostatic effects that are associated with increased resistance to the anticoagulant action of activated protein C.⁶⁴⁴ Combined oral contraceptives containing estrogen carry about a fourfold increased risk of venous thromboembolism in first-time users.^{645,646} The risk falls with decreasing dose of estrogen and duration of use and rises about 50% in those containing third-generation (e.g., desogestrel) and antiandrogenic progestins.⁶⁴⁷ Nevertheless, the risk is less than that of pregnancy. Progesterin-only contraceptives are not associated with any increased risk of venous or arterial thrombosis.^{645,648}

The differences between the sexes in lipid levels are not explained by physiological differences in estrogen levels.⁶⁴⁹ Although oral estrogens raise triglycerides, this is caused by a first-pass hepatic effect. Differences in androgen (lowers HDL-cholesterol) and progesterone (lowers triglycerides and HDL-cholesterol) levels only explain part of the difference.

NORMAL HORMONAL AND SEXUAL DEVELOPMENTAL STAGES

The Fetus and Neonate

The fetus grows in a richer steroidal milieu than the pubertal female owing to the function of the fetoplacental unit. Concentrations of estrogens in fetal serum are extremely high. Umbilical cord plasma free testosterone levels are modestly greater than those of normal adult females.⁴³⁶ Dehydroepiandrosterone sulfate is at an adrenarchal level. The newborn shows some signs of the pubertal degree of hormonal stimulation from the intrauterine environment. Hypertrophic labia minora and superficial cell transformation of the urogenital epithelium are consistently observed estrogen effects, and a palpable breast bud is present at term in one-third of babies.⁶⁵⁰ The mean (SD) uterine length at birth is 4.15 ± 0.56 cm.⁶⁵¹ Sebaceous gland hypertrophy results from the androgenic state,⁶⁵² and the

clitoral shaft sometimes is prominent, particularly in small premature babies.⁵¹⁹

Steroid hormone levels from birth through puberty are shown in Table 16.1.^{15,66,69,93,650,653–656} Upon birth, withdrawal from the intrauterine environment occurs. Pituitary-gonadal axis hormone levels fall to a prepubertal-like nadir within days of withdrawal from the intrauterine environment.¹⁷ Menstrual bleeding and colostrum production sometimes occur as the newborn is withdrawn from the estrogenic environment. The mini-puberty of the newborn then begins.

This neonatal mini-puberty evolves according to a developmental program determined by gestational age. At term gestational age, it commences with a gradual but transient rise to pubertal hormone levels. In girls these reach maximal values in the early pubertal range at 3 to 4 months of age, about 2 months later than in boys, before they regress as seen in Figs. 16.5 and 16.8. The activation of the HPG axis of the newborn stimulates breast and genital tract development that commonly persists for several months.^{657,658}

Premature neonates, in contrast to term newborns, develop high gonadotropin levels, of the magnitude seen in ovarian insufficiency, that persist until antral follicle development begins near 40 weeks, gestational age.^{17,18,659} As antral follicles develop, ovarian estrogen and AMH secretion commence, and the compensatorily high gonadotropins gradually fall to the low levels normal for term infants.¹⁷ Coincidentally, adrenal contributions to steroid intermediate levels are higher in premature infants because of the persistence of the fetal adrenocortical zone and immaturity in size and apparent 11β -hydroxylase activity of the definitive adrenocortical zones.^{660–664}

Transient ovarian hyperstimulation has been reported in preterm babies as a consequence of high gonadotropin levels persisting until or beyond late-term corrected gestational age.^{665–667} It manifests at several months of age as ovarian cysts with hyperestrogenism, causing genital swelling, persistent breast development, and/or delayed menstrual bleeding.

These phenomena then regress progressively through later infancy as the inhibitory tone of the neuroendocrine-gonadal axis undergoes juvenile maturation. Nevertheless, according to an ultrasensitive recombinant cell bioassay, girls' estrogen levels in late infancy are several fold greater than those of boys, averaging 1 pg/mL and ranging up to 3 pg/mL.⁶⁶⁸ On occasion, there may be subclinical but detectable estrogen effects on urogenital cytology.⁹⁵ Whether the transient "mini-puberty" activity of the neuroendocrine-gonadal axis in the newborn has a programming influence on subsequent behaviors remains unclear.⁶⁰⁰

The developmental pattern of serum AMH differs from that of other reproductive hormones because it reflects follicular growth and development rather than neuroendocrine activity. AMH rises from undetectable to low in cord blood to 0.6 to 4.1 ng/mL (4.3–29 pM) at 3 months; it then continues to slowly rise about 1.5-fold more to reach an adult level by the postmenarcheal period.⁶⁶⁹

Childhood

As the neuroendocrine-gonadal axis becomes quiescent and the fetal zone of the adrenal cortex regresses, steroid hormone levels fall through infancy to reach a nadir in midchildhood (see Table 16.1). The earliest hormonal change during childhood is the adrenarchal rise in serum DHEAS that is discernable at about 6 years (see Table 16.1). Although childhood gonadotropin levels are low and there is seldom obvious sexual development as a consequence of prepubertal gonadotropin production, there is a low level of bioactive gonadotropin production and ovarian follicular development^{31,86,670} and occasional evidence of transient estrogen secretion.⁶⁷¹ In

midchildhood, GnRH agonist stimulation of gonadotropin secretion elicits a prompt small rise in estradiol secretion.^{93,672} AMH levels of girls rise minimally in midchildhood, to levels about 3% those of boys.⁶⁶⁹

In late prepuberty, girls begin to experience increasing diurnal production of gonadotropins, and estradiol levels rise in diurnal fashion to approximate 10 pg/mL in midmorning.^{79,97}

Adolescence

Hormonal

The earliest hormonal changes of true puberty occur gradually during late preadolescence. Clinically prepubertal 10-year-olds develop greater average gonadotropin and sex hormone levels than do prepubertal 7-year-olds.⁷⁹

In the average girl, serum gonadotropins achieve pubertal levels after 8 years of age. However, the chronological age at which puberty begins varies considerably among children. Therefore the pubertal rise in gonadotropins is best appreciated by relating gonadotropin levels to pubertal stage. Daytime serum LH rises 25-fold from prepuberty to late puberty according to bioassay, but this rise is underestimated by polyclonal RIA.⁹⁹ "Third-generation" immunometric assays, using monoclonal antibodies and a more purified standard than earlier RIAs, show a rise similar to that found by bioassay.^{77,79}

The hallmark of early puberty is an increase in the sleep-related rise in LH (see Fig. 16.12).^{79,98} Daytime sampling underestimates the rise in gonadotropins in early puberty because it does not detect most of this sleep-related increase. In early puberty, current assays show that LH rises during sleep to reach peaks in the lower adult range, generally above 1.0 U/L and then typically falls during the day to 0.6 U/L or less.^{79,93,673,674} A single daytime sample also does not necessarily truly represent a child's pubertal status because it does not account for episodic and cyclic changes in gonadotropin secretion.^{94,675} The serum LH response to GnRH is slightly more indicative of the pubertal status than a morning basal sample (see Fig. 16.9) (Table 16.1).^{87,673,674} An LH level 1-h post-GnRH agonist of 3.2 U/L or more is 90% sensitive and 5.5 U/L or more is 95% specific for the onset of puberty in girls.⁹³ The response of LH to GnRH or GnRH agonist administration increases more than that of FSH during puberty, with a resultant increase in the LH:FSH ratio.^{77,676} GnRH agonists add a dimension to GnRH testing: they provide a sufficiently potent and prolonged stimulus to LH and FSH release to bring about an increase in ovarian estradiol secretion in pubertal girls.⁶⁷⁷ These responses likewise increase characteristically with sexual maturation (see Fig. 16.6).⁶⁸

Sex hormone levels rise further as the consequence of ovarian and adrenal maturation. Pubertal levels are intermediate between those of prepubertal and sexually mature individuals. Table 16.1 shows typical normal ranges for serum levels of the major steroid hormones. Once pubertal levels of estrogens and androgens are achieved, their effects ordinarily become obvious within 6 months.

Serum AMH levels stabilize at an adult level of 0.5 to 6.2 ng/mL (3.5–45 pM) in postmenarcheal females with normal ovarian morphology.^{40,669} They do not fluctuate during the normal menstrual cycle,⁶⁷⁸ reflecting a balance between recruitment of growing follicles and growth of antral follicles.⁶⁶⁹ The AMH serum level is an indicator of the number of growing follicles, and thus indexes the size of the oocyte pool ("ovarian reserve"); AMH begins to fall with the oocyte pool in the premenopausal adult⁶⁶⁹ and becomes undetectable after menopause.⁶⁷⁹ AMH levels also reflect the intrafollicular androgenic status of fertile females, probably because androgens stimulate the early phases of follicular growth.⁴⁰ Serum prolactin rises moderately

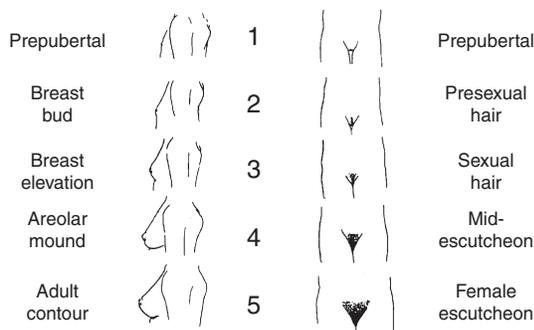

Fig. 16.30 The stages of breast and pubic hair development. (Modified from Ross, G.T., Vande Wiele, R. (1974). *The ovary*. In: Williams, R.H. (ed.), *Textbook of Endocrinology*, 5th ed. Philadelphia, WB Saunders.)

in females at about 14 years of age.⁶⁸⁰ This may be a response to estrogen secretion because it does not occur in boys.

Clinical

The first physical sign of puberty is breast development (thelarche). In a minority of girls, pubic hair development (pubarche) occurs before thelarche. Thelarche represents a response to estrogen, and pubarche a response to androgen. When pubarche precedes thelarche, it is usually a reflection of adrenal androgen production (adrenarche) rather than a sign of true puberty. The stages of breast and pubic hair development are shown in Fig. 16.30.^{681,682} Tanner stage 1 is prepubertal. The initial stage of breast development (stage 2, B2) is appreciated as a palpable subareolar bud before it can be seen as an elevation. Stage B3 is obvious enlargement and elevation of the whole breast. Stage B4, the phase of areolar mounding, is very transient and may not necessarily appear. Stage B5 is the stage of attainment of mature breast contour. Pubic hair first starts as presexual pubic hair development (PH2)—hairs which are shorter, lighter, and straighter than sexual pubic hairs, but longer than vellus body hair. Hypertrichosis is sometimes mistaken for stage 2 pubic hair; these can be differentiated by comparing genital hair to that on the forearm. Sexual pubic hair development (PH3)—curly terminal (long, dark) hair—usually commences on the labia majora before spreading to the pubis. Pubic hair then gradually progresses to the mature female escutcheon (inverted triangle pattern, stage 5). Axillary hair usually appears about a year later than pubic hair and passes through similar stages.

The age at which pubertal milestones are normally attained is not known with certainty. There has been considerable debate about the normalcy of pubertal changes between 6.0 and 8.0 years of age.^{190,203,683} The debate stems from office practice observations that breast and pubic hair development were found more frequently than expected in black girls in this age range. The prevalence of pubertal milestones has subsequently been estimated for the general US population by modeling cross-sectional data collected 1988 to 1994 on children 8.0 years of age and older by the National Health and Nutrition Examination Survey III (NHANES III).^{198,199,276} NHANES data had the advantage of nationally representative sampling, but the breast stage data was based on observation and so data quality was questionable, and modeling assumptions that permit extrapolation to younger ages may not be valid.^{276,684,685} The median ages at which the major pubertal milestones were attained in normal-weight US girls according to this database are given in Table 16.3.²⁷⁶ These data indicated that puberty begins before 8.0 years in less than 5% of the

TABLE 16.3 Pubertal Milestone Attainment in Normal Body Mass Index Girls in the General US Population, NHANES III, 1988–1994.

Stage	5%	50%	95%
Breast Stage 2	8.25	10.2	12.1
Pubic Hair Stage 3	9.25	11.6	13.9
Menarche	11.0	12.6	14.1

Before age 8.0 years breasts appeared in 12% to 19% and sexual pubic hair (stage 3) in $\leq 3\%$ of normal-body mass index in non-Hispanic black and Mexican American girls. Menarcheal milestones are attained at similar ages in these ethnic groups except for the 5th percentile being significantly earlier in blacks (10.5 y) than non-Hispanic whites (11.3 y). (Modified from Rosenfield, R.L., Lipton, R.B., Drum, M.L. (2009). Thelarche, pubarche, and menarche attainment in children with normal and elevated body mass index. *Pediatrics*, 123, 84–88.)

normal general female population, although breasts may normally appear during the seventh year in blacks and Mexican Americans.

A more contemporary study of female puberty was conducted from 2004 to 2011. The design was improved: data collection was longitudinal and breast development was ascertained by palpation. However, although the design included broad racial/ethnic and socioeconomic representation, it was not nationally representative, the study population enriched for Asians, for example.^{686,687} The overall distribution of pubertal timing was shifted to earlier ages by approximately 0.75 year for breast development and 0.35 year for menarche compared with NHANES III. The data confirmed that normal-weight non-Hispanic black girls achieved pubertal milestones earlier than white girls, by about 0.75 to 1.0 year for thelarche and 0.5 to 0.75 year for menarche; thus thelarche normally may occur in the seventh year of life in blacks. Pubertal milestones in Asian girls were similar to those in whites, and in Hispanics to blacks.

Obesity and ethnic factors now appear to be independent factors that advance the onset of puberty and menarche, with obesity having the greater influence.^{276,686} Longitudinal study indicates that obesity is associated with advancement of the age of thelarche (0.7 year) more closely and twice as much as advancement of the age of menarche (0.3 year).

Pubertal tempo, the span of time between the onset of breast development (B2) and menarche, is normally 2.3 ± 1.0 years. However, obesity is paradoxically associated with significant advancement of the age of thelarche while significantly slowing pubertal tempo and preserving height potential.^{687,688} It is possible that the advancement of the age of thelarche by obesity is not entirely because of an advancement of neuroendocrine puberty but rather arises in part from extragonadal formation of estrogen from adrenal precursors in excess adipose tissue; this may explain, in part,⁶⁸⁹ the apparent blunting of early neuroendocrine puberty in obese girls with early thelarche.^{93,687,690} On the other hand, a subgroup of early maturers with a history of intrauterine growth retardation seem to have an unusually rapid tempo of puberty and lose height potential.⁶⁹¹

The onset of puberty is more closely related to an individual's bone age than to chronological age. This is particularly important in the case of subjects who are later than average in entering puberty, as discussed previously. The great majority of girls can be expected to begin puberty by the time their skeletal age reaches 12.5 years and to experience menarche by the time skeletal age reaches 14 years.

The pubertal growth spurt in girls occurs during early adolescence. The peak of linear growth velocity corresponds most closely with stage B2⁶⁹² and the increase in serum alkaline phosphatase levels with B3.⁶⁹³ Fat accumulation increases

and fat distribution changes as well.⁶⁹⁴ As a consequence of these pubertal changes occurring out of phase with chronological age, girls begin to differ considerably in size and habitus during the ninth year of life.

Adult Menstrual Cycle

The menstrual cycle of young adults averages 28 days in length (normal adult 24–38 days).⁶⁹⁵ The variation in cycle length is almost entirely because of differences in the duration of the follicular phase. The luteal phase, the time between ovulation and the onset of menses, invariably lasts 14 ± 1 (SD) days.¹²⁶

The cyclic changes of LH, FSH, estradiol, and progesterone serum levels during the menstrual cycle are shown in Fig. 16.13. Diurnal and episodic fluctuations are superimposed upon these cyclic changes. Since testosterone and androstenedione have both adrenal and ovarian origins, their levels fluctuate to some extent in cyclic, diurnal, and episodic patterns. For example, testosterone levels tend to be 20% greater in the morning than in the evening and to double in midcycle.^{125,696} The normal range for most of the important ovarian sex hormone levels of women during the early follicular phase of the menstrual cycle is given in Table 16.1. Progesterone levels are below 100 ng/dL until the periovulatory phase of the cycle and then peak to over 500 ng/dL in the midluteal phase. Hormonal production rates for the midfollicular phase in women are given in Table 16.2. Serum prolactin increases transiently in midcycle with maximum ovarian estradiol secretion.⁶⁹⁷ Prolactin levels also transiently rise in response to mammary stimulation and psychological factors.⁶⁹⁸

Normal Variations in Pubertal Development

Although the onset of breast development (stage B2) characteristically precedes the appearance of sexual pubic hair (PH3) and the onset of menses substantially (see Table 16.3), there is considerable variation in the sequence of these events. Pubic hair may appear before breasts begin to develop, a situation arising from lack of direct linkage between adrenarche and gonadarche. Menarche may occur within months after the appearance of breasts; however, this is so unusual that its occurrence demands exclusion of an abnormal hyperestrogenic state.

A common normal variant is the unilateral onset of breast development. Unilateral breast development may exist up to 2 years before the other breast becomes palpable. This phenomenon seems related to an asymmetry that normally persists into adulthood. Excisional biopsy of a normal unilateral breast papilla in search of a nonexistent tumor should be avoided, because such a procedure excises the entire breast anlage.

Two extreme variations of normal are the most common causes of premature sexual development.⁶⁹⁹ These are the isolated appearance of breast development (premature thelarche) and the isolated appearance of sexual hair (premature pubarche).

Premature Thelarche

Breast development before 8.0 years is traditionally considered premature. Premature thelarche is a very mild, non- or slowly progressive incomplete form of premature puberty that is a variant of normal. In the 6- to 8-year age group, it is usually because of obesity, which may either accelerate the onset of puberty, account for increased peripheral estrogen production, or cause artefactual adipomastia.^{93,686,687,690,700} Otherwise, it usually seems to be caused by idiopathic subtle overfunction of the pituitary-ovarian axis, occurring in those girls whose FSH levels tend to be sustained about the upper end of the

prepubertal normal range.⁶⁷¹ Average serum levels of FSH at baseline and in response to GnRH are significantly increased, whereas those of LH are not. Estradiol levels are generally below the level of detection in most standard assays, but are significantly elevated according to ultrasensitive assay,⁷⁰¹ and intermittent low-grade estrogenization of the urogenital mucosa is sometimes found (see Fig. 16.11). Ovarian ultrasound examination shows an increased prevalence of antral follicles (“microcysts”) and uterine enlargement.⁷⁰² Nevertheless, a growth spurt does not occur, the bone age advancement rate is not abnormal, and menses do not appear until the usual age.

In infants, the syndrome seems to be caused by a lag in inhibition of the transient activation of the HPG axis of the newborn and is usually unsustained. In older children, the breast development is more likely to persist. A subgroup with “exaggerated thelarche” has an increased growth rate with relatively proportionate bone age advancement. Their unsustained or intermittent neuroendocrine activation seems to lie on a spectrum between ordinary premature thelarche and true sexual precocity (Fig. 16.31).⁷⁰³ However, the McCune-Albright syndrome mutation is found in the peripheral blood of about 25% of such patients.⁷⁰⁴ Premature thelarche may be the first sign of feminizing disorders (see Precocious Puberty). Therefore follow-up of these patients is indicated.

Premature Pubarche

The isolated appearance of sexual pubic hair before 8.0 years of age in girls (premature pubarche) is usually caused by premature adrenarche, as discussed next. However, it may occur at androgen levels that are normal for preschool children (idiopathic premature pubarche). This likely reflects increased sensitivity of the PSU to low preadrenarchal androgen concentrations, analogous to idiopathic hirsutism in adults, in which increased sexual hair growth occurs in the absence of other evidence of hyperandrogenism. The mechanism may be caused by increased androgen receptor gene activity.⁷⁰⁵

Premature adrenarche is a very mild, slowly progressive incomplete form of premature puberty that is usually a variant

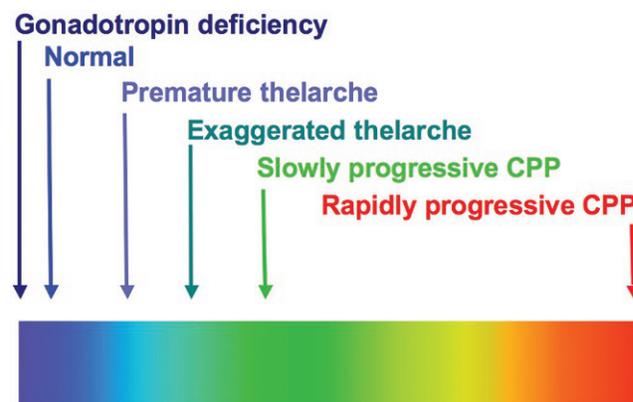

Fig. 16.31 The spectrum of gonadotropin secretion in girls with normal and abnormal puberty. Normal girls are conceptualized as having a small amount of pituitary-ovarian axis activation, which is more than that of congenitally hypogonadotropic girls. Premature thelarche, exaggerated thelarche, slowly progressive precocity, and rapidly progressive precocity fall along a spectrum of increasing activation of the axis—with deterioration of height potential occurring only in those near the most activated end. *CPP*, central precocious puberty. (Modified from Kreiter, M.L., Cara, J.F., Rosenfield, R.L. (1993). Modifying the outcome of complete precocious puberty: To treat or not to treat. In: Grave, G.D., Cutler, G.B. (eds.), *Sexual Precocity: Etiology, Diagnosis, and Management*. New York, Raven Press, p. 109–120.)

of normal. It usually appears to be caused by advanced development of the zona reticularis as indicated by increase of adrenal androgen levels above those of preschool children.^{15,706} The condition is ordinarily detected when a child presents with premature pubarche or other clinical manifestation of androgen action, such as adult-type body odor or acne.⁷⁰⁷ The androgen excess is ordinarily so subtle that there is no obvious growth spurt, the bone age typically does not advance abnormally, and there are no other signs of sexual maturation. The diagnosis requires biochemical demonstration of a serum steroid pattern indicative of adrenarche before 8 years of age in girls, for example, DHEAS 40 to 130 mcg/dL and other androgen levels only slightly elevated for age (see Table 16.1). The term is sometimes used to describe biochemical evidence of adrenarche irrespective of clinical manifestations.

Exaggerated adrenarche is a clinically extreme type of premature adrenarche.^{15,706} These girls have clinical features that suggest subtle androgen excess (e.g., significant bone age advancement, but not clitoromegaly) or insulin resistance (e.g., central adiposity or acanthosis nigricans). Such children generally have a slightly advanced onset of true puberty, but height potential is not compromised. The term exaggerated adrenarche has been variously applied but is here when the atypical clinical picture is associated with serum androgen levels above normal for early puberty (see Table 16.1), for example, DHEAS above 130 mcg/dL or testosterone over 35 ng/dL, or bone age above height age by 20%. Virilizing disorders should be excluded in girls with exaggerated adrenarche so defined.

The cause of premature adrenarche usually seems simply to be caused by advanced onset of normal zona reticularis development, but it sometimes seems to be an early manifestation of the steroidogenic dysregulation of polycystic ovary syndrome.^{15,706} Premature adrenarche appears to carry about a 10% to 20% risk of developing polycystic ovary syndrome; it is unclear whether those with exaggerated adrenarche are primarily at risk. Premature adrenarche with insulin resistance is independently associated with obesity, rapid weight gain during early childhood, and low birth weight.^{15,383,708} The IGF-1 excess of GH treatment may be a risk factor.⁷⁰⁹ Associations also exist between premature adrenarche and temporal lobe lesions⁷¹⁰ and poliomyelitic scoliosis.⁷¹¹ Heritable factors are also important. The heritability of DHEAS sulfate blood levels is estimated at 26% to 66%.⁷¹² Carriers for CAH may be over-represented in this group.^{713,714} Epigenetic programming seems to be a factor: prenatal virilization of nonhuman primates causes functional adrenal hyperandrogenism as part of the PCOS spectrum,⁷¹⁵ and fetal undernutrition has been postulated to program for insulin resistance by activating the limbic-hypothalamic-pituitary-adrenal system to cause fetal corticoid excess.⁷¹⁶

The differential diagnosis of premature pubarche and adrenarche includes virilizing disorders, of which nonclassic CAH is the most common. Girls with premature adrenarche should be followed through puberty for the possible development of hyperandrogenism. A suggested approach to rule out serious hyperandrogenic disorders in childhood is suggested in the accompanying algorithm (Fig. 16.32).⁷¹⁷

Constitutional Delay of Growth and Pubertal Development

By statistical definition, delayed puberty occurs in 3% of girls. Most of these girls are otherwise normal, in which case this is termed *constitutional delay of growth and pubertal development* (CDGP). It is familial;^{200,201} 80% in a large series had a parent with objectively delayed puberty.⁷¹⁸ A family history of delayed puberty is found in 50% to 75% of patients with CDGP.²⁰¹ Although its inheritance is likely complex, some predisposing

genetic factors seem to have a dominant effect. It has long been recognized that delayed puberty was overrepresented in families with idiopathic hypogonadotropic hypogonadism or hypothalamic amenorrhea cases, and rare variants in genes underlying these conditions appear to contribute to the etiology.^{719,720} Recent molecular investigation revealed that CDGP indeed segregates within families with complex patterns of inheritance that include X-linked, autosomal dominant and recessive and bilinear,²⁰⁰ although sporadic cases also occur. Autosomal dominant is the most prevalent pattern of inheritance (with or without complete penetrance).^{200,721} Initially, candidate genes associated with CDGP have been identified using GWAS, linkage analysis, and targeted sequencing strategies.^{718,722} However, recently whole exome and genome sequencing are increasingly being used to identify novel candidate genes. Despite these advances, the genetic basis and neuroendocrine pathophysiology remains unknown in the majority of patients with CDGP.

Mutations in several genes have been associated with CDGP. Six unrelated families from a Finnish cohort with delayed puberty were found to have two mutations in immunoglobulin superfamily member 10 (IGSF10)⁷²³ and four other families were found to have two rare variants with unknown significance. Mutations in IGSF10 appear to cause decreased levels of IGSF10 expression during embryogenesis resulting in delayed migration of GnRH neurons from the olfactory bulbs to the hypothalamus. The dysregulation of GnRH neuronal migration results in an abnormal configuration of the GnRH neuronal network and a functional defect in GnRH secretion that becomes crucial when a threshold level of GnRH secretion must be achieved for pubertal onset. IGSF10 mutations were also found in women with a hypothalamic amenorrhea and in patients with congenital hypogonadotropic hypogonadism (CHH), although these mutations did not alone appear sufficient to cause the phenotype. Loss-of-function mutations in *IGSF1* have been identified in patients with X-linked central hypothyroidism,⁷²⁴ delayed pubertal growth, and delayed increase in testosterone levels.⁷²⁵

Mutations in genes found in patients with CHH are also found in CDGP. Mutations in heparan sulfate 6-O-sulfotransferase 1 (HS6ST1), fibroblast growth factor receptor 1 (FGFR1), and Klotho β (KLB) have been found in several kindreds with CHH and their relatives with CDGP.⁷²⁶⁻⁷²⁸ Variants in the genes encoding gonadotropin-releasing hormone receptor (*GNRHR*), tachykinin 3 (TAC3) and its receptor (TACR3), interleukin-17 receptor D (IL17RD), and semaphorin 3A (SEMA3A) known to cause CHH have been found in patients with CDGP.⁷²⁹ Mutations in 24 genes associated with GnRH deficiency were found in probands with CHH with greater frequency than in CDGP, leading to the conclusion that CHH and CDGP are likely to have different genetic backgrounds.⁷³⁰ Mutations in Kallmann syndrome genes such as anosmin 1 (*ANOS1*) and N-methyl-D-aspartic acid receptor synaptonuclear signaling and neuronal migration factor (*NSMF*) have not to date been identified in pedigrees with CDGP. Loss-of-function mutations within the GnRH receptor are the most frequent cause of autosomal recessive CHH, accounting for 16% to 40% of patients. Mutations have been found within the extracellular, transmembrane, and intracellular domains of the receptor leading to impaired GnRH action.⁷³¹ A homozygous partial loss-of-function mutation in *GNRHR* was found in two brothers, one with CDGP and one with idiopathic HH,⁷³² and a further heterozygous mutation was found in one male with self-limited CDGP.⁷³³ Thus the genetic background of CHH and CDGP may be different, or shared by as yet undiscovered genes.⁷³³

Girls with constitutional delay are generally more slight in habitus and have lower bone mineral density upon entering

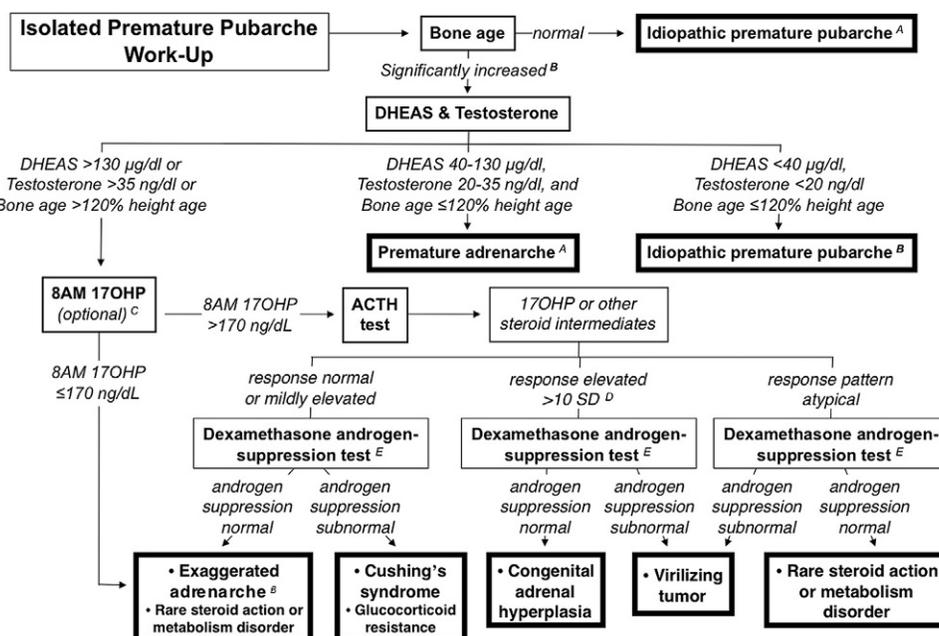

Fig. 16.32 A workup to screen for hyperandrogenic-virilizing disorders as a cause of premature pubarche. Premature or exaggerated adrenarche accounts for the great majority of premature pubarche; nonclassical congenital adrenal hyperplasia caused by 21-hydroxylase deficiency, the most common hyperandrogenic cause, accounts for less than 10% in most populations/ethnic groups. *SD*, Standard deviations. (Modified with permission from Rosenfield, R.L. (2018). Premature adrenarche. UpToDate.)

Footnotes:

- Diagnoses of idiopathic premature pubarche, premature adrenarche, or exaggerated adrenarche, or based on bone age and/or hormonal measurements are provisional diagnoses. Even if these tests are normal or only mildly elevated, clinical follow-up is indicated to rule out inordinate progression of pubarche or evidence of virilization. This is because bone age interpretation and the precision of testosterone assays at low levels are often problematic, and because this algorithm will not detect some very mild hyperandrogenism cases.
- A bone age that is significantly advanced for chronological age is an indication for a screening laboratory workup for childhood hyperandrogenism, consisting of dehydroepiandrosterone sulfate (*DHEAS*) and testosterone levels. A bone age that exceeds height age indicates less than average height potential. A compromised height potential (indicated by a predicted adult height less than expected for the family or a bone age >120% of height age in a young child) or *DHEAS* or testosterone level above the normal adrenarchal range (130 mcg/dL and 35 ng/dL, respectively) suggests that the premature pubarche may be caused by a virilizing disorder rather than ordinary premature adrenarche.
- An 8:00 AM baseline measurement of 17-hydroxyprogesterone (*17-OHP*) is an option to an adrenocorticotropic hormone (*ACTH*) test in a family, population, or ethnic group in which the risk is relatively low for nonclassical congenital adrenal hyperplasia caused by 21-hydroxylase deficiency. A level over 170 ng/mL (5.1 nmol/L) has a 95% or greater sensitivity and specificity for this disorder among premature pubarche patients when obtained at 8:00 AM, before the level wanes with diurnal *ACTH* secretion. A normal baseline level does not necessarily exclude this or more rare forms of nonclassical congenital adrenal hyperplasia.
- For *ACTH* testing, the typical response in congenital adrenal hyperplasia (*CAH*) is that the steroid immediately before the enzyme block is extremely elevated, and steroids earlier in the biosynthetic pathway are successively less elevated the further removed they are from the block. For example, in 21-hydroxylase deficiency, 17-OHP is extremely elevated and androstenedione and testosterone are successively less elevated; in 3β-hydroxysteroid dehydrogenase type 2 deficiency, 17-hydroxypregnenolone and *DHEA* responses are extremely elevated and 17-hydroxyprogesterone, androstenedione, and testosterone are mild to moderately elevated. An elevated baseline level of 17-OHP may preclude a clear response to the *ACTH* test. For *ACTH* testing, an atypical response pattern is one that is not typical for any type of *CAH*. An example of an atypical response would be baseline or post-*ACTH* androstenedione or testosterone elevations greater than those of 17-OHP.
- The dexamethasone androgen-suppression test consists of administering dexamethasone, 1 mg/m²/day in three to four divided doses daily for 4 days, and then measuring the serum cortisol, *DHEAS*, and androgens on the morning of the fifth day after a final dexamethasone dose. Normally, serum cortisol falls below 1 mcg/dL (28 nmol/L), testosterone to less than 10 ng/dL, and *DHEAS* to less than 40 mcg/dL. Serum androgen intermediates also fall to prepubertal concentrations.

puberty than earlier maturing girls.⁷³⁴ Girls do not usually become concerned about this until they enter high school at 14 years of age and realize that not only has pubertal development not begun, but also most of their friends are menstruating. When puberty does ensue in such subjects it is perfectly normal in tempo. Endocrinological status is normal for the stage of puberty. The differential diagnosis includes chronic endocrine, metabolic, and systemic disease of almost any kind, as well as gonadotropin deficiency, which it closely resembles and from which it is distinguished with difficulty (see Gonadotropin Deficiency and Functional Hypothalamic Anovulation).

Physiological Adolescent Anovulation

Immaturity of the hypothalamic-pituitary-ovarian axis causes menstrual cycles to be longer and more irregular during the early postmenarcheal years (Fig. 16.33).^{124,695,735} About half of menstrual cycles during the first 2 years after menarche are anovulatory by standard criteria; half of these actually have evidence of the attenuated ovulation that results in luteal insufficiency (see Luteal Phase Defects).^{124,736} Although about half of these cycles with ovulatory abnormalities are irregular, half are of normal length by adult standard, so normal adolescent

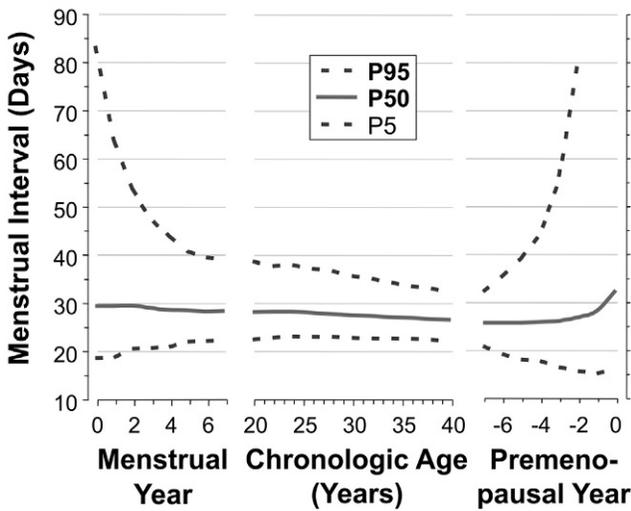

Fig. 16.33 Normal range for interval between menstrual cycles. Note that cycle intervals averaging more than 90 days or fewer than 21 (19 days in first year after menarche) days are abnormal at any age. P5 and P95 = 5th and 95th percentiles, respectively. (Modified from Treloar, A., Boynton, R., Benn, B., Brown, B. (1967). Variation of human menstrual cycle through reproductive life. *Int J Fertil*, 12, 77–84.)

menstrual cyclicity differs only slightly from that of reproductive-age adults. Thus most adolescent ovulatory abnormalities are asymptomatic, with cyclic menstrual bleeding occurring at 21- to 45-day intervals even in the first postmenarcheal year (Fig. 16.34); this paradox arises because immature cyclic ovarian function is usually occurring during these intervals.⁷³⁷ Serum hormonal changes during normal adolescent menstrual cycles confirm that substantial but immature cyclic follicular development occurs in such girls and some aluteal adolescents (Fig. 16.35).^{735,736,738}

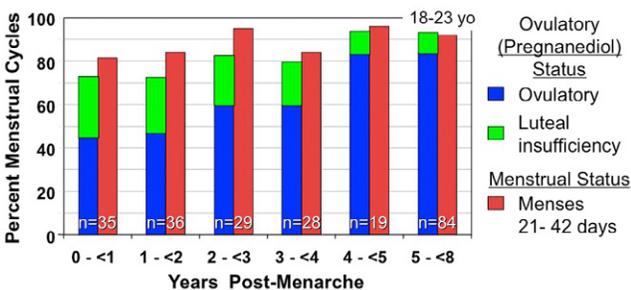

Fig. 16.34 Comparison of the percent of menstrual cycles that are 21 to 42 days duration (red) and percentage of menstrual cycles that are ovulatory (blue) by postmenarcheal age through young adulthood. Many more menstrual cycles are regular (21–42 days) than are normal, mature ovulatory cycles. Ovulation normalcy was determined with reference to adult standards of the major urinary progesterone metabolite, pregnanediol glucuronide, in weekly samples collected during the last 12 days of each menstrual cycle. Clearly detectable but subnormal pregnanediol is here designated as having luteal insufficiency (green). It can be seen that most of the cycles that are not mature ovulatory had sufficient cyclic follicular activity to generate an immature corpus luteum, which indicates antecedent ovulation, rather than being truly anovulatory as the investigators had labeled them. (Data from Metcalf, M.G., Skidmore, D.S., Lowry, G.F., Mackenzie, J.A. (1983). Incidence of ovulation in the years after the menarche. *J Endocrinol*, 97, 213–219; Rosenfield, R.L. (2015). The diagnosis of polycystic ovary syndrome in adolescents. *Pediatrics*, 136, 1154–1165. With permission.)

Although there is considerable variation in the time it takes for menstrual cycles to mature, menstrual regularity approximates adult standards in most girls within a year of menarche: three-quarters have a cycle length between 21 and 45 days, and 5% more fall within these bounds each of the next 3 years.^{739,740} By 5 gynecological years, 90% of menstrual cycles last 22 to 40 days, and about 80% of cycles are normal ovulatory ones. Menstrual cycle length narrows to 24 to 38 days in midadulthood⁶⁹⁵ as ovulatory rates approach 90%.¹⁸⁷

Menstrual abnormalities in adolescence can be defined similarly to abnormal uterine bleeding in adults.^{736,741} Primary amenorrhea is failure to begin menses at a normal age (by 15 years of age or within 3 years of thelarche when it has been delayed). Secondary amenorrhea is the absence of menstrual periods for 90 days or more after initially menstruating. Oligomenorrhea is defined as subnormal menstrual frequency, the normal limits for which gradually change during the 6 years after menarche (Box 16.2). Anovulatory cycles may also cause excessive uterine bleeding, as discussed in the later section Ovulatory Dysfunction: Dysfunctional Uterine Bleeding.

Symptomatic menstrual abnormalities in adolescents are increasingly unlikely to represent “physiological” adolescent anovulation with time. By 1 year postmenarche, failure to establish and sustain a normal adult menstrual pattern carries approximately a 50% risk of persistent oligoovulation, and failure to do so by 2 years after menarche carries approximately a two-thirds risk (Fig. 16.36).⁵⁷⁵ Thus persistence of menstrual irregularity for 1 to 2 years or more is a strong indication for investigation (see section Abnormal Puberty).

Serum LH, testosterone, and androstenedione levels are significantly higher in adolescents with anovulatory than those with ovulatory cycles.^{742,743} It is unclear whether this is the cause or the result of the anovulation; however, if hyperandrogenemia is found, it seldom regresses.¹²³ A polycystic ovary is common in adolescents and is usually a variant of normal, unless associated with menstrual abnormality or hyperandrogenism.^{83,123,656,744–746}

Other Normal Adolescent Variations

Three-quarters of adolescent girls experience mild to severe comedonal acne, and one-quarter mild inflammatory acne.⁷⁴⁷ Mild hirsutism also arises commonly among perimenarcheal girls. However, inflammatory acne that is moderate or severe (i.e., >10 lesions of face or other region) is uncommon during the perimenarcheal years, and hyperandrogenism should be considered in such girls as it should in those with mild hirsutism and menstrual irregularity (see Hyperandrogenism in Adolescence). The initiation of acne is more closely related to blood levels of DHEAS than of other androgens, as is cystic acne.⁵⁴²

Profound psychological changes occur during adolescence. Sexually immature girls tend to be socially immature, and the onset of puberty is associated with increased independence and profound changes in outlook on life and intellectual capacities. The extent to which these developments occur in reaction to the physical changes of puberty and the extent to which they are direct effects of sex hormones are unknown. Masculine tomboyish traits usually have no clear hormonal basis, although there is some evidence that they may have prenatal hormonal determinants. Social interactions have effects on these aspects of development. They affect even the synchrony of the menstrual cycle.⁷⁴⁸

Despite the popular notion that adolescence is inherently a period of turmoil, the majority of teenagers do not develop significant social, emotional, or behavioral difficulties.⁷⁴⁹ Occasional experimentation and risk-taking are normal, as are withdrawal from and conflict with parents. Adolescent behavior must be understood in the context of individual

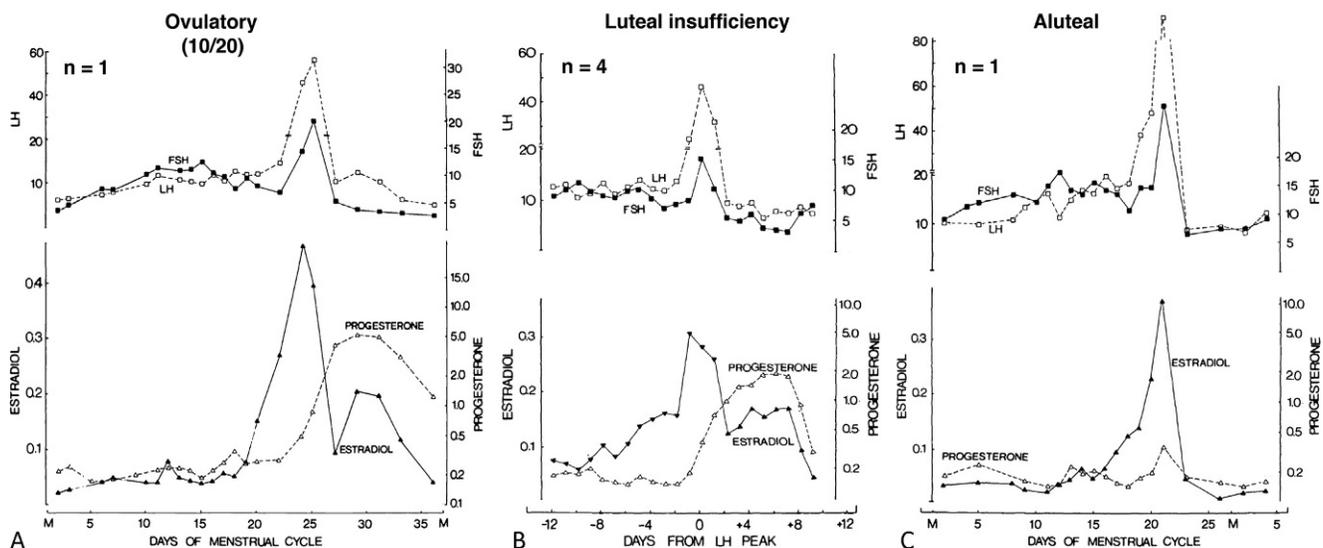

Fig. 16.35 Serum hormonal patterns of normal adolescent menstrual cycles among 20 healthy schoolgirls. **Panel A.** A normal ovulatory cycle in a 16-year-old female, representative of 10/20 of the study group who were ovulatory. Note normal preovulatory estradiol and progesterone rises, the subsequent midcycle luteinizing hormone (LH) and follicle-stimulating hormone (FSH) surges, followed by progesterone levels that reach 5.0 ng/mL or higher during the luteal phase of the menstrual cycle. Although this is a standard criterion for an ovulatory cycle, the illustrated cycle would be considered luteally insufficient in an adult. **Panel B.** Mean hormone levels of the group defined as having luteal insufficiency: their short luteal phases lasted 4 to 8 days, but cycle lengths were normal (23–30 days) caused by prolonged follicular phase. Note the slightly low preovulatory estradiol and absent progesterone rises, followed by blunted midcycle LH and FSH surges that presage the low progesterone levels of the short luteal phases. **Panel C.** An aluteal anovulatory cycle in a 14-year-old female. Note normal preovulatory estradiol and LH surges, but absent preovulatory progesterone rise that presaged an absent luteal phase progesterone increase. The remainder of the five anovulatory study subjects did not attain clear preovulatory development and progesterone levels were consistently under 1.0 ng/mL, yet the menstrual cycles were abnormally long in only 2/5. M, menses. Scales differ slightly, and progesterone scales are logarithmic. Steroid levels in ng/mL LH and FSH levels in mIU/mL. (Data from Apter, D., Viinikka, L., Vihko, R. (1978). Hormonal pattern of adolescent menstrual cycles. *J Clin Endocrinol Metab*, 47, 944–954; Modified from Rosenfield, R.L. (2013). Clinical review: adolescent anovulation: maturational mechanisms and implications. *J Clin Endocrinol Metab*, 98, 3572–3583. With permission.)

susceptibility, family upbringing and interactions, peer group interactions, changes in brain maturation, and adolescents' reaction to their perception of the bodily changes and to the sexual urges that are the direct consequences of puberty. Simply because a problem is displayed during adolescence does not mean that it is a direct consequence of puberty.

Many behavioral problems that emerge during adolescence have earlier roots. Although the prevalence of depression increases during puberty, many children who develop depression during adolescence have had preexisting symptoms of psychological distress. Likewise, most delinquent teenagers have had antecedent problems at home and school.

Early-maturing girls in Western cultures are more popular, but they have more emotional problems; lower self-image; and higher rates of depression, anxiety, and disordered eating than their peers. Early maturation appears particularly to be a risk factor for problem behavior among girls who have had a history of difficulties before adolescence, when they have more opposite sex friendships and relationships, and when they attend coeducational schools.

Short-term administration of testosterone or estrogen has minimal effects on behavior or mood in adolescents.^{627,750} Thus variation in hormone levels accounts for only a small fraction of adolescents' affective issues, and social influences account for considerably more. Although there is little evidence that psychological difficulties stem directly from hormonal changes during normal puberty, it is likely that the bodily changes of adolescence play a role in the development of a negative body image when they occur out of synchrony with sociocultural norms.

Problems with initiating and maintaining sleep are common in adolescents and contribute a small amount to poor

school performance.⁷⁵¹ Although insufficient sleep might be caused by environmental factors (e.g., social and academic pressures), intrinsic factors clearly play an important role. A 50% decline in the intensity of deep (slow wave, delta) sleep occurs during adolescence, and one-half of this change occurs between 12 and 14 years of age.^{752,753} Recent evidence indicates that this change is related to age and sex, beginning earlier in girls, but not to pubertal stage. It has been proposed that this shift is a manifestation of the widespread synaptic pruning that is related to the emergence of adult cognitive capacity.

The causal direction of the link between pubertal development and the quality of family relationships has come into question. Several studies have indicated that family dynamics may affect the timing and course of puberty, with earlier and faster maturation observed among adolescents raised in homes characterized by more conflict and among girls from homes in which the biological father is not present.⁷⁴⁹

ABNORMAL PUBERTY

Abnormal Development

Disorders of Sex Development

Patients with DSD (formerly termed *intersex*)—those whose genitalia are ambiguous or inappropriate for their gonadal sex as a result of endocrinopathy—may come to a physician's attention for the first time at puberty. These syndromes have been categorized as 46, XX DSD, which encompasses cases formerly termed *female pseudohermaphroditism* and including 46, XX testicular DSD (formerly termed *XX sex reversal*); 46, XY DSD, which encompasses cases

BOX 16.2 Definition of Types Of Abnormal Uterine Bleeding in Adolescents

Descriptor	Definition
Primary amenorrhea	Lack of menarche by 15 years of age or by 3 years after the onset of breast development ^a
Secondary amenorrhea	Over 90 days without a menstrual period after initially menstruating (in consecutive periods during first year post-menarche)
Oligomenorrhea (infrequent abnormal uterine bleeding)	Postmenarcheal year 1: average cycle length >90 day (fewer than four periods in the year) Postmenarcheal year 2: average cycle length >60 days (fewer than six periods in the year) Postmenarcheal years 3: average cycle length >45 days (fewer than eight periods per year) Postmenarcheal years ≥4: cycle length >38 days (<9 periods per year)
Excessive uterine bleeding ^b	Menstrual bleeding that occurs more frequently than every 21 days (19 days in year 1) or is prolonged (lasts >7 days) or heavy (soaks more than one pad or tampon every 1–2 h large clots, or gushing)

(Rosenfield, R.L. (2015). The diagnosis of polycystic ovary syndrome in adolescents. *Pediatrics*, 136, 1154–1165. With permission; Modified according to Teede, H.J., Misso, M.L., Costello, M.F., et al. (2018). Recommendations from the international evidence-based guideline for the assessment and management of polycystic ovary syndrome. *Fertil Steril*, 110, 364–79).

^aBone age of 15 years may be substituted for chronological age in girls with earlier than average age at puberty onset.

^bEncompasses frequent, intermenstrual, heavy, and/or prolonged abnormal uterine bleeding. Alternatively termed *dysfunctional uterine bleeding* or *excessive abnormal uterine bleeding caused by ovulatory dysfunction*.

formerly termed *male pseudohermaphroditism* and including 46, XY complete gonadal dysgenesis (XY sex reversal, Swyer syndrome); and sex chromosome DSD, which includes Turner syndrome, Klinefelter syndrome, mixed gonadal dysgenesis, and chimeric ovotesticular DSD.⁶⁰⁰ In the absence of chromosomal mosaicism, ovotesticular DSD, formerly termed *true hermaphroditism*, is categorized as either 46, XX DSD or 46, XY DSD. Patients with any of these disorders may undergo inappropriate puberty. They may present with clitoromegaly and be found upon examination to have a degree of genital ambiguity which was previously overlooked. Virilization beginning at puberty is sometimes the presenting complaint. Ovotesticular DSD or 46, XX DSD because of CAH are compatible with fertility.⁴⁴⁴ Androgen insensitivity syndrome in a genetic male may present as primary amenorrhea in an otherwise phenotypically normal adolescent girl. The disorders of sexual differentiation are reviewed in detail in Chapter 6.

Congenital virilization of the female developmentally programs the emergence of PCOS at puberty. These observations are consistent with studies of fetal androgenization of the female in several species, including primates.^{15,16,754} There is a persistent increase in LH pulse frequency and impairment of the negative feedback effect of progesterone on LH release that appear to be related to suppression of hypothalamic PR

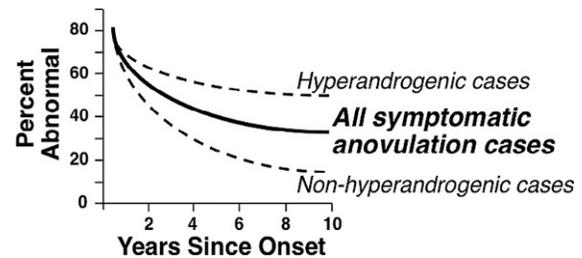

Fig. 16.36 Probability that an adolescent with a symptomatic menstrual abnormality severe enough to result in gynecological consultation will have continued menstrual abnormality. The lines show the cumulative rates at which subjects with menstrual abnormalities converted to normal patterns. The heavy curve shows the average incidence of continued menstrual abnormality in adolescents when considering all symptomatic cases of abnormal uterine bleeding presenting to a reproductive endocrine clinic regardless of time of symptom onset. (Data from Southam, A.L., Richart, E.M. (1966). The prognosis for adolescents with menstrual abnormalities. *Am J Obstet Gynecol*, 94, 637.) Dysfunctional uterine bleeding of onset within 1 year of menarche carries the furthest from average poor prognosis for continuing menstrual abnormality, and oligomenorrhea of relatively short duration occurring after a normal menstrual pattern has been established carries the furthest from average best prognosis. Note that if the menstrual abnormality persists for 1 year there is about a 50% probability, and if for 2 years over a 60% probability, that the patient will not spontaneously evolve to normal cycles. Similarly, if the problem persists for 5 years there is an 80% likelihood of persistence of the abnormality. “Hyperandrogenic” and “Nonhyperandrogenic” curves are hypothetical, based on data reviewed in Rosenfield, R.L. (2015). The diagnosis of polycystic ovary syndrome in adolescents. *Pediatrics*, 136, 1154–1165. Hyperandrogenic cases are predominantly a mix of physiological anovulation and polycystic ovary syndrome (PCOS), with PCOS persisting. Nonhyperandrogenic cases are a mix of physiological anovulation and hypogonadal cases, ranging from primary hypogonadism through hypothalamic amenorrhea to hypogonadotropic hypogonadism, with hypogonadal cases persisting. (Modified from Rosenfield, R.L. (2015). The diagnosis of polycystic ovary syndrome in adolescents. *Pediatrics*, 136, 1154–1165.)

in response to estradiol. Experimental animals exposed to androgen excess early in gestation develop classic PCOS features: these animals have elevated LH levels, ovarian and adrenal hyperandrogenism, oligomenorrhea, and polyfollicular ovaries. They also have abdominal obesity, insulin resistance, impaired glucose tolerance, and dyslipidemia, which likewise appear to result from developmental programming.

Genetic males with complete androgen insensitivity have low LH levels and poor LH responsiveness to GnRH in the neonatal period.⁶⁴ However, gonadotropin levels are normal-to-high at puberty, and, paradoxically, androgen signaling via the androgen receptor enhances the capacity of females to mount an LH surge in response to estrogen positive feedback.^{337,338,755}

Other Dysgenetic Disorders

Failure of the onset of menses can result from structural abnormalities of the genital tract that do not have an endocrinological basis. The hymen may be imperforate, which results in hydrocolpos if the vagina is intact. The vagina may be aplastic, which will result in hydrometrocolpos if the uterus is intact.⁷⁵⁶ The uterus may be congenitally aplastic. Uterine synechiae develop as the consequence of endometritis, which may result from infection or irradiation (Asherman syndrome). Congenital absence of the vagina may be associated with varying degrees of uterine aplasia; this is the Mayer-Rokitansky-Kuster-Hauser syndrome.⁷⁵⁷ This syndrome seems to occur as a

single gene defect or as an acquired teratogenic event involving mesodermal development and the mesonephric kidney, the latter resulting in abnormalities of the genital tract and sometimes the urinary tract. A subtype caused by *Wnt4* gene defects is associated with hyperandrogenism.⁷⁵⁸

Precocious Puberty

Causes

When breast or sexual pubic hair development begins before the age of 8.0 years or menses begin before the age of 9.5 years, puberty is traditionally considered precocious, or premature. It should be kept in mind that breast development during the seventh year is within normal limits in ethnic minority girls. In addition, presexual pubic hair (stage 2) may be normal in 6- and 7-year-old ethnic minority girls.

Puberty can occur prematurely as an extreme variation of normal, because of a disturbance in the HPG axis normally involved in sexual maturation, or because of a disturbance outside the HPG axis. Depending on which part of this hormonal axis is involved, different forms of precocious puberty are distinguished. A classification of the causes of premature puberty together with typical findings is given in Table 16.4.

It is important to distinguish between true precocious puberty and pseudoprecocious puberty. True precocious puberty is gonadotropin dependent; thus *central* is another term applied to this type of precocity. Maturation is complete: both breasts and pubic hair develop as the result of CNS activating pituitary secretion of the respective gonadotropins FSH and LH (although breast development may be the sole manifestation of early complete precocity for as long as 6–12 months). Patients with true precocious puberty have “isosexual” precocity because the secondary sexual characteristics are appropriate for the sex of the child. Pseudoprecocious puberty is gonadotropin independent; it is not mediated by pubertal pituitary gonadotropin secretion and is sometimes

termed *peripheral*. Maturation is incomplete, with only one type of secondary sexual characteristic developing early. Peripheral precocity has diverse causes. In some patients with pseudoprecocity, pubertal development is isosexual, in others it is “contrasexual,” meaning that characteristics of the opposite sex are manifested.

Complete Precocious Puberty. True isosexual precocity results from pubertal function of the HPG axis. About 95% of true precocity in girls is idiopathic. Idiopathic true sexual precocity appears to be caused by premature triggering of the normal pubertal mechanism. Pubertal development usually is qualitatively and quantitatively normal except for its early occurrence. The predominance of the idiopathic cases in females and its benign nature are compatible with the likelihood that this disorder is an extreme exaggeration of the normal tendency of girls to have higher gonadotropin levels than boys. Most cases are sporadic, a few familial. The majority of these patients seem to go on to have normal menstrual cycles and fertility.⁷⁵⁹ Indeed, pregnancy has been documented to occur as early as 4 years of age.

Rapidly progressive puberty with a growth spurt ensues when activation of the pituitary-ovarian axis is sustained. However, precocious puberty is not necessarily sufficiently intense or sustained to cause inexorable progression or bring about deterioration of height potential.⁷⁶⁰ Precocity in the 6- to 8-year age range usually is not rapidly progressive and most commonly seems to be caused by excessive adiposity.²⁷⁶

Any type of intracranial disturbance can cause true isosexual precocity. These neurogenic disturbances are presumed to cause true sexual precocity by increasing the prevalence of excitatory inputs or by interfering with CNS inhibition of hypothalamic GnRH secretion.⁷⁶¹ These include congenital brain dysfunction, such as cerebral palsy or hydrocephalus, or acquired disorders, such as irradiation,⁷⁶² trauma, chronic inflammatory disorders, or masses in the region of the hypothalamus. The activation of GnRH release by hypothalamic injury may be

TABLE 16.4 Typical Findings in Female Sexual Precocity

Locus	Type	HA ^a	BA ^a	Estrogens ^U	Androgens ^U	LH/FSH ^U	Pathology	Characteristics

FSH, Follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone.

^aHA (height for age) and BA (bone age); - normal; + advanced; ++ markedly advanced.

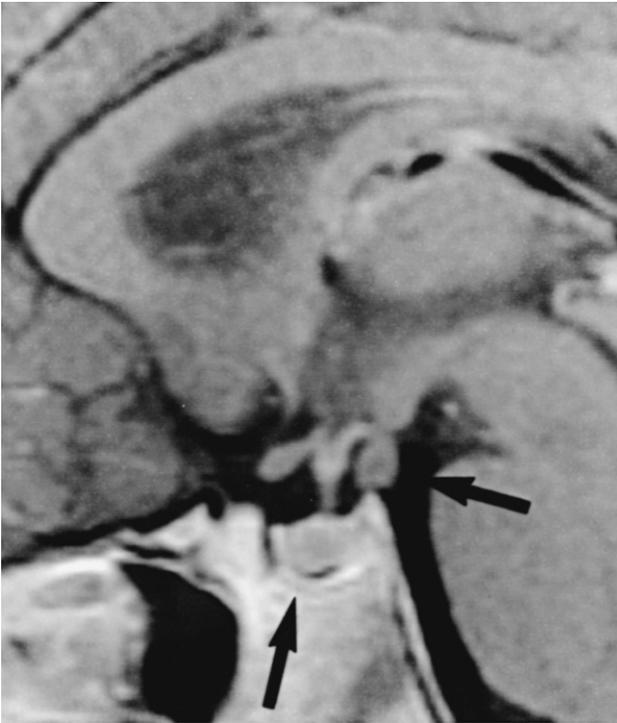

Fig. 16.37 Magnetic resonance image showing a hypothalamic hamartoma (right-hand arrow) as the cause of true sexual precocity in a 2.5-year-old girl. The hamartoma is hanging from the floor of the hypothalamus just posterior to the pituitary infundibulum. The sella turcica (bottom arrow) contains a normal pituitary gland with pituitary stalk hanging from the infundibulum.

mediated by TGF- β , trauma, chronic inflammatory disorders, or masses in the region of the hypothalamus. An empty sella is occasionally found.⁷⁶³ The precocity of neurofibromatosis type I (von Recklinghausen disease) usually results from an optic glioma, which is often of low-grade malignancy, or from a hamartoma,⁷⁶⁴ although occasionally with neither.⁷⁶⁵ Hamartoma of the hypothalamus may cause central sexual precocity; this effect is most likely caused by an anatomic effect on hypothalamic structures rather than by acting as an “accessory hypothalamus” that releases pulses of GnRH into the pituitary portal circulation.^{766,767} Fig. 16.37 shows a hypothalamic hamartoma.

A small proportion of pineal tumors cause true sexual precocity.^{768,769} The incidence of sexual precocity is about 3.5 times as great in nonparenchymatous neoplasms (such as gliomas and teratomas) as in parenchymatous pineal tumors. This suggests that these tumors cause sexual precocity via absence of a normal pineal inhibitory factor rather than by destructive effects on inhibitory tracts. Although pineal masses may cause paralysis of upward gaze by pressure on the corpora quadrigemina, this sign is present in only a minority of cases.

Pineal or hypothalamic hCG-secreting germ cell tumors occasionally cause true sexual precocity.^{770,771} Because hCG is an LH receptor agonist, possible explanations for this unusual situation are disinhibition of hypothalamic GnRH release attributed to a mass effect of the neoplasm, the weak FSH effect of massive elevation of hCG, or the capacity of some dysgerminomas to secrete estradiol, as well as hCG.⁷⁷²

Advancement of somatic maturation caused by peripheral endocrine disorders that advance the bone age to a pubertal level sometimes cause true sexual precocity. Thus true puberty may begin after correction of virilizing or feminizing disorders that have advanced the bone age to 10 to 12 years.^{264,265}

The hypergonadotropinism of premature ovarian insufficiency (POI) has been reported to cause sexual precocity or rapid progression of puberty before premature ovarian failure.^{773,774} Although PCOS has occasionally been reported to follow true sexual precocity,⁷⁷⁵ there is currently no clear evidence of a significant association.^{759,776}

A family history of complete precocious puberty (CPP) is common in patients with early puberty; however, a clear genetic etiology is usually unknown. Monogenic causes of CPP have recently been identified in four genes. Gain-of-function mutations have been found in kisspeptin and its receptor, KISS1R.^{777,778} The patients were heterozygous for the mutations, with an autosomal dominant inheritance.⁷⁷⁹ The first mutation to be described was in an adopted girl who had progressive thelarche from birth, with accelerated growth velocity and skeletal maturation noted at age 7 years. A heterozygous activating mutation of KISS1R (p. Arg386Pro) was identified and in vitro studies showed that the mutation led to prolonged activation of intracellular signaling pathways resulting in higher sustained inositol phosphate accumulation.⁷⁷⁷ A mutation in kisspeptin, p. Pro74Ser, was identified in a boy with CPP at age 1 year, with high concentrations of serum LH and testosterone. Interestingly, his mother and maternal grandmother had normal pubertal development, carried the p. Pro74Ser mutation in the heterozygous state, suggesting incomplete penetrance. In vitro, the mutated protein was able to stimulate signal transduction to a greater extent than the wild type, suggesting it may be more resistant to degradation, resulting in greater kisspeptin bioavailability.⁷⁷⁸ However, large-scale studies in children with CPP have not been able to identify additional patients and families with CPP with these mutations, hence kisspeptin and KISS1R activating mutations are relatively rare causes of CPP.⁷⁷⁹

Another genetic abnormality linked to CPP involves loss-of-function mutations in the Makorin RING-finger protein 3 (*MKRN3*) gene, a maternally imprinted gene located on the long arm of chromosome 15 (Prader-Willi region) encoding a protein that is involved in gene transcription and ubiquitination. Expression of *MKRN3* was found to be high in the arcuate nucleus in prepubertal mice, decreases before puberty, and is low after puberty, thus *MKRN3* appears to be acting as an inhibitor of puberty. Interestingly, *MKRN3* polyubiquitylates Nptx1, another protein of unclear function that is also expressed at low levels prepubertally, and highly during puberty.⁷⁸⁰ Fifteen families with a history of CPP were studied, and mutations in *MKRN3* that resulted in truncated proteins or missense mutations predicted to disrupt protein function were found in one-third of them. At present, 10 different mutations have been found, and include frameshift, missense, or nonsense mutations predicted to result in loss-of-function of the protein.^{246,781–787} *MKRN3* is maternally methylated, explaining the autosomal dominant paternal inheritance in all cases, with no de novo mutations described.⁷⁸¹ All patients described to date exhibit a typical pattern of early pubertal development. A few patients with *MKRN3* mutations were described as having syndromic features that included esotropia, a high-arched palate, dental abnormalities, clinodactyly, and hyperlordosis.⁷⁸⁵ In a genetic study of 20 boys with idiopathic CPP, eight were found to have *MKRN3* mutations and one had a *KISS1*-activating mutation,⁷⁸⁸ perhaps indicating that *MKRN3* mutations are a relatively frequent cause of CPP.

Delta-like homolog 1 (*DLK1*), a paternally expressed imprinted gene, encodes a protein expressed in kisspeptin-expressing neurons.⁷⁸⁹ *DLK1* is a part of the delta-notch pathway, which is an evolutionarily conserved signaling pathway with roles in proliferation and differentiation during development.⁷⁹⁰ In the pituitary, *DLK1* and notch signaling appear to be important in pituitary cell type differentiation.⁷⁹⁰

A mutation in *DLK1* was found in a family with five girls with CPP. The mutation was a 14-kb deletion along with a 269-bp duplication. Serum levels of *DLK1* were undetectable in these girls.⁷⁸⁹ In another study, the *DLK1* gene was sequenced in 60 girls with idiopathic CPP, and no mutations were found.⁷⁹¹

Distinct chromosomal abnormalities associated with specific syndromes may include CPP. These include: 1p36 deletion, 7q11.23 microdeletion (Williams-Beuren syndrome),⁷⁹² 9p deletion, maternal uniparental disomy of chromosomes 7 (Silver-Russell syndrome) and 14 (Temple syndrome),⁷⁹³ inversion duplication of chromosome 15,⁷⁹⁴ de novo interstitial deletion and maternal uniparental disomy of chromosome 15 (Prader-Willi syndrome),⁷⁹⁵ and a de novo deletion in the cyclin-dependent kinase-like 5 gene (*CDKL5*; located in the Xp22 region)⁷⁹⁶ (phenotype similar to Rett syndrome).

Incomplete Precocity. The most common causes of incomplete sexual precocity in girls are the extreme variants of normal mentioned previously, premature thelarche and premature pubarche. These are incomplete forms of sexual precocity in which either breast development (thelarche) or sexual hair development (pubarche) is of a degree appropriate for an early stage of puberty and isosexual. Isolated prepubertal menses is a rare disorder that has been attributed to transient ovarian activity.⁷⁹⁷

LH- or hCG-producing tumors have not been reported to virilize girls, perhaps because of their limited capacity for thecal androgen production over short periods of time. However, familial isolated elevation of LH has been reported to cause mild virilization of siblings;⁷⁹⁸ one was a girl who developed premature pubarche and clitoral hypertrophy at 4 years of age, with slight to moderate advances in height and bone age in association with an adrenarchal level of DHEAS and a moderately elevated testosterone level (91 ng/dL).

The van Wyk-Grumbach syndrome is one of the most puzzling pediatric complexes.⁷⁹⁹ This is an unusual syndrome of sexual precocity associated with juvenile hypothyroidism. A case is illustrated in Fig. 16.38. This syndrome is often characterized by galactorrhea, which is often not spontaneous; a few drops of milky fluid may become apparent only upon "milking" the subareolar ductal tissue. Multicystic ovaries are often demonstrable by ultrasonography.⁸⁰⁰ Modern assays show that levels of LH at baseline and post-GnRH are suppressed and those of FSH are early pubertal.⁸⁰¹ There is little, if any, sexual hair development. There is another clinically unique feature about the sexual precocity of hypothyroidism: it is the only form of sexual precocity in which growth is arrested rather than stimulated and is an exception to the general rule, indeed followed by most chronically hypothyroid children, that a delayed growth pattern is associated with delayed puberty.

Van Wyk and Grumbach postulated that this syndrome resulted from hormonal "overlap" in the negative feedback regulation of pituitary hormone secretion, with overproduction of gonadotropins, as well as TSH in response to the thyroid deficiency. The specific nature of hormonal overlap has been considerably clarified in recent years, but the pathogenesis of the precocity remains unclear. The increases in serum TSH and prolactin that characterize the syndrome could well be accounted for by common neurohumoral control systems, TRH stimulating and dopamine inhibiting both hormones. It has been suggested instead that the ovarian FSH receptor is activated by the weak intrinsic FSH activity of extreme TSH elevation,⁸⁰² analogous to the rare ovarian hyperstimulation syndrome in which pregnancy levels of hCG activate the FSH receptor.⁸⁰³

Prolactin excess has been postulated to underlie the FSH-predominant gonadotropin pattern by slowing GnRH pulsations, and it is this FSH stimulation of the TSH-sensitized ovary that seems to be the proximate cause of the sexual precocity.⁸⁰⁴

Fig. 16.38 Sexual precocity caused by hypothyroidism in a 9.1-year-old with breast development since 7 years and menarche at 9.0 years. Growth failure had occurred, and her height age was 6 years. In addition to breast enlargement and galactorrhea, the labia minora were noted to be enlarged and pigmented. There was no sexual hair or clitoromegaly. Rectal examination revealed an enlarged and palpable cervix without adnexal masses. There were typical physical findings of hypothyroidism. Bone age was 6.2 years. Thyroxine was less than 1 mcg/dL. Thyrotropin-stimulating hormone was 438 μ U/mL. Prolactin was 66 ng/mL. Serum estrogens were 72 to 182 pg/mL. Vaginal smear showed 45% superficial cells and 55% large intermediate cells. Immunoreactive luteinizing hormone (LH) and follicle-stimulating hormone were 300 and 174 ng LER-907/mL, respectively (see Fig. 16.5 for reference ranges). However, bioactive LH was undetectable. Immunoreactive gonadotropins failed to suppress upon estrogen administration. Their response to a 100-mcg gonadotropin-stimulating hormone bolus was minimal, and they seemed responsive to thyrotropin-releasing hormone. All of these hormonal findings were not obviously different from those of hypothyroid girls without sexual precocity except for the higher estrogens. She had withdrawal bleeding and evidence of regression of breast development within the first 3 months of thyroid hormone replacement treatment. After 6 months' treatment, normal puberty began. Menarche occurred at 12.5 years of age.

Hyperprolactinemia alone does not correspond with pubertal development in normal or hypothyroid children. However, hyperprolactinemia may itself also sensitize the ovaries to gonadotropins. Induced hyperprolactinemia causes sexual precocity in female rats.³⁶⁵ Ovarian estrogen and progesterone responsiveness to hCG is increased by prolactin, possibly by its induction of ovarian LH receptors. Conversely, suppression of hyperprolactinemia in experimental hypothyroidism blocks the ovarian cyst formation characteristic of hypothyroidism.⁸⁰⁵

McCune-Albright syndrome is another intriguing disorder causing incomplete isosexual feminization.^{806,807} This is a syndrome of precocious puberty, cafe-au-lait pigmentation

occurring in nevi that have an irregular (“coast of Maine”) border, and polyostotic fibrous dysplasia. The disorder is caused by a somatic activating mutation of the G_s -alpha subunit protein that couples transmembrane receptors to adenylate cyclase. The syndrome has been recognized predominantly in females and occurs in incomplete, as well as expanded forms. Precocious puberty or monoostotic bone lesions may occur in the absence of cutaneous pigmentation; not all patients have sexual precocity. The sexual precocity is of the gonadotropin-independent type. Luteinized follicular cysts within the ovaries function autonomously. Pituitary adenomas capable of secreting excess LH, FSH, GH, and/or prolactin have been reported. Patients may have Cushing syndrome and hyperthyroidism because of autonomous multinodular hyperplasia. These girls may be at increased risk of breast carcinoma.⁸⁰⁸ Nonendocrine abnormalities include cardiopulmonary disease, hypertension, and hepatobiliary disease (including severe neonatal cholestasis).⁸⁰⁹ Molecular studies have shown an R201H mutation in over 90% of cases where an affected tissue could be studied, but in only 50% of blood samples.⁸¹⁰ Because of the variation in the number and degree of tissue involvement in individual patients, caused in large part by the extent of mosaicism present, precocious puberty may be the only feature present in an individual who is mosaic for the activating mutation of G_s -alpha. Thus these mutations have been found in blood samples from 25% to 33% of subjects with isolated gonadotropin-independent precocity or exaggerated thelarche.^{704,810}

CAH is a well-known cause of premature pubarche. Either nonclassic CAH, a form of the disorder which is so mild that there is no genital defect in girls, or poor control of classic CAH may be responsible. Each form on occasion has been reported to mimic true sex precocity.^{811,812}

Tumor may cause isosexual or contrasexual development. The most common tumor is the feminizing benign ovarian follicular cyst.^{813,814} Most are isolated and large (>1.0 cm in diameter). The cells lining these cysts are often luteinized. Estrogen levels may be markedly elevated. Testosterone levels tend to be in the adult female range (about 40 ng/dL). Many function intermittently. They may be gonadotropin dependent and respond to GnRH agonist or progestin therapy. A case is illustrated in Fig. 16.39. The second most common hormonally active ovarian neoplasm in girls is the juvenile granulosa cell tumor.^{815,816} These have variable degrees of ovarian sex cord-stromal elements and are usually localized and benign in spite of having a malignant histological appearance. They are more commonly feminizing than masculinizing in young children. They may produce hCG, AMH, and inhibin. Elevation of hCG is found in many ovarian dysgerminomas (a primitive germ cell tumor), with hypercalcemia in some, although less frequently than in small cell carcinoma.^{815,817} Granulosa-theca cell tumor is occasionally associated with mesodermal dysplasia syndromes. It has been reported in the adrenal gland, presumably arising in an ovarian rest.⁸¹⁸ FOXL2 mutations are typical of adult-type granulosa cell tumors, but are found in only 10% of the juvenile type. A related feminizing ovarian sex cord-stromal tumor may be caused by loss of a tumor-suppressor gene, as in Peutz-Jeghers syndrome.⁸¹⁹ Adult-type ovarian carcinoma of epithelial cell origin is rare. Ovarian masculinizing tumors are discussed in the section Hyperandrogenism in Adolescence.

Adrenocortical tumors, as discussed in Chapter 14, typically cause rapid virilization characterized by very high DHEAS production; however, androstenedione is the predominant androgen in many cases. A case discussion is given with Fig. 16.40. Many are accompanied by cushingoid changes. On occasion, they cause feminization. When adrenocortical tumors secrete both androgen and estrogen, the clinical picture may resemble complete isosexual precocity.⁸²⁰ Structural abnormalities of

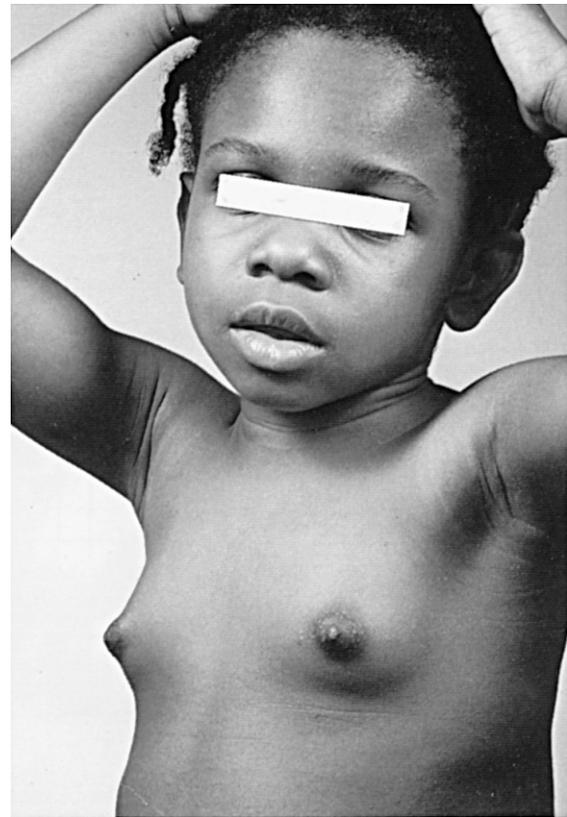

Fig. 16.39 The appearance of a 5.2-year-old child with complete isosexual precocity caused by a luteinized follicular cyst. Her breast development is no different from that of girls with idiopathic premature thelarche. She presented at 4.7 years with a 2-week history of breast development. Height and bone ages were 5 years. Over a 5-month follow-up period, breast development progressed, she developed sexual pubic hair and presexual axillary hair, and menstrual flow commenced at 3- to 5-week intervals. Four weekly determinations of plasma unconjugated estrogens (estradiol and estrone) showed them to consistently range between 158 and 215 pg/mL. Luteinizing hormone was pubertal and follicle-stimulating hormone was suppressed (averaging 50 and 13 ng LER-907/mL, respectively; see Fig. 16.5 for reference ranges). Testosterone was 37 ng/dL, and dehydroepiandrosterone sulfate (DHEAS) was 82 mcg/dL. Exploratory laparotomy was performed when she was 5.2-years-old. Her height age was 5.8 years, and her bone age was 7.5. The laparotomy revealed a right ovarian cyst about 5 cm in diameter, which was removed. Subsequently, there was a rapid fall in plasma estrogens and testosterone to prepubertal levels. However, DHEAS was unchanged. Menses ceased, but intermittent vaginal cornification (maturation index 90/10/0 to 0/90/10) was repeatedly found. Breast enlargement and sexual hair development resumed at 8.5 years, with normal pubertal sex hormone levels. Menarche occurred at 9.5 years.

chromosome 11p15 and mutations of the tumor suppressor p53 are fairly common in pediatric adrenocortical tumors.⁸²¹

Aromatase excess syndrome is a rare cause of ectopic feminization.⁸²² This is an autosomal dominant disorder with variable penetrance that results from constitutive aromatase gene overexpression.

Exogenous steroids can cause sexual precocity. Estrogen-containing contraceptive pills and creams are widely available. Some cases of precocious thelarche may be caused by ingesting food contaminated with artificial estrogens.⁸²³ Soy formulas are potential sources of phytoestrogens, as are many commonly consumed foods, herbs, and topicals (including products containing lavender oils and tea tree oils).⁸²⁴⁻⁸²⁷ It has been

Fig. 16.40 Abdominal ultrasound (decubitus view) showing a pedunculated encapsulated 5-cm adrenal adenoma (*large arrow*) near upper pole of kidney (*small arrow*). This 1.3-year-old girl was virilized. Pubic hair had appeared 2 months previously, height had changed from the 10th to the 30th percentile, and clitoromegaly had occurred. Bone age was 2.3 years. Dehydroepiandrosterone sulfate was 3000 to 4271 mcg/dL. Testosterone was 121 ng/dL. A, Anterior; P, posterior.

proposed that childhood exposure to estrogenic chemical contaminants in underdeveloped countries predisposes to sexual precocity when children emigrate to developed countries.¹⁹⁰ Premature pubarche or acne can result from anabolic steroid use. Topical nonprescription androgen use by a parent, such as for sexual dysfunction or anabolic effects, can cause premature pubarche without necessarily being detectable by standard tests.⁸²⁸

Vaginal bleeding in the absence of breast development suggests foreign body, sexual abuse, or tumors of the genital tract. A rare cause is "premature menarche," which may result from an extreme variation in the normal intermittent ovarian activation of young girls.⁹³ Malodorous discharge is highly suggestive of foreign body. A hymenal opening of greater than 5 mm or posterior notches is compatible with sexual abuse.^{532,533} Neurofibromas have been reported to simulate breast development and clitoral hypertrophy.

Differential Diagnosis

A physician need not be experienced in endocrinology to diagnose and manage most girls presenting with early breast or pubic hair development. For the most part, the isolated appearance of one of these signs is caused by the benign processes of either premature thelarche or premature pubarche, respectively. An otherwise normal history and physical examination, together with a normal bone age, constitutes sufficient workup.

In the history, the physician should inquire about the possibility of exposure or access to exogenous steroids in the form of pills, diet, or topical substances (such as estrogen creams or personal care products containing lavender oil or tea tree oil). The possibility of sexual abuse, vaginal infection, or foreign body must be kept in mind when evaluating the child with

isolated vaginal bleeding. In the examination, the physician should search for nevi, acanthosis nigricans, signs that might suggest intracranial or abdominal-pelvic disease, and inspect the external genitalia. The child's height and weight should be carefully recorded, the growth curve examined, and the BMI percentile plotted.

If the history and examination are unremarkable, only a bone age determination is indicated to screen for whether the symptom is indeed an isolated phenomenon or whether appreciable hormone excess exists. If the skeletal age is not abnormally advanced relative to height age, it is likely that the presenting symptom is an isolated and benign extreme variant of normal, which requires no treatment.^{671,829} To confirm the diagnosis of premature thelarche or premature adrenarche, the child must be similarly reevaluated after 3 to 6 months. If the results are still negative, the family can be reassured with a high degree of confidence that true puberty, including menses, will not occur until the usual age.

If more than one sign of precocious puberty is present or develops or if the growth is accelerated, a more extensive workup is indicated. For example, if a young girl with early breast development begins to grow pubic hair, or vice versa, then something more than premature thelarche or premature adrenarche is involved. The same is true if she develops a growth spurt or if she begins menstruating. These additional signs indicate the need for more extensive studies. Isolated vaginal bleeding, that is, bleeding in the absence of secondary sex characteristics, suggests sexual abuse, foreign body, or genital tract tumor, rarely isolated menarche. Cytology, anaerobic culture, pelvic ultrasound, and serum estradiol examinations are indicated.

Bone age advancement that is or becomes disproportionate to height (as indicated by compromised height potential or bone age $\geq 20\%$ greater than height age) suggests a sustained excess of sex hormone, and is an indication for a more extensive investigation to determine the cause of the precocity. An algorithmic approach to the differential diagnosis of premature pubarche is presented in Fig. 16.32. The importance of the recheck is illustrated by the case presented in Fig. 16.39.

One must be particularly aware that girls with neurogenic precocity, especially those who have had cranial irradiation, are at risk of paradoxically having concomitant GH deficiency.⁷⁰³ Coexistent GH deficiency masks the seriousness of the precocity: the growth rate is normal (not accelerated) and breast development is attenuated. However, the disparity between bone age and height age is extreme.

If the clinical picture and bone age are suggestive that premature breast development may be due to sex precocity, the laboratory investigation of premature pubertal development requires determinations of sex steroids, LH, and FSH by assays of high sensitivity: at least 10 pg/mL for estradiol, 10 ng/dL for testosterone, 5 mcg/dL for DHEAS, and 0.2 U/L for LH and FSH.⁷⁵⁹ The modern multichannel platform assays that are widely available generally meet these specifications for the assays of DHEAS, LH, and FSH, but they are totally inadequate for testosterone and estradiol. These require assays of high sensitivity and specificity, such as are provided by postchromatographic RIA or tandem mass spectrometry, in laboratories with well-established normal ranges for children.⁸³⁰ Prepubertal estradiol levels are normally less than 10 pg/mL, and prepubertal testosterone is less than 20 ng/dL. Measurement of serum thyroxine and prolactin is indicated if the sexual precocity is accompanied by growth arrest and/or galactorrhea.

In central precocity, daytime serum estradiol concentration is usually pubertal, 10 pg/mL (37 pmol/L) or more.⁸³¹ An estradiol level in the upper premenarcheal normal range (≥ 75 pg/mL) is atypical and necessitates a prompt workup to distinguish ovarian or adrenal tumor from true isosexual precocity.⁸³² If the estradiol level is atypically high, weekly determinations of estradiol may be helpful to determine

whether the level is fluctuating in the normal cyclic fashion of true precocious puberty. Because of the episodic and cyclic nature of sex hormone secretion, examination of the vaginal mucosa (see Fig. 16.28) for estrogen effect is a more sensitive indicator of the presence of early puberty than is an estradiol blood level, because it represents the integrated effect of estrogen over the preceding 2 to 3 weeks. Uterine size (e.g., uterine length >3.8 cm and endometrial thickness of ≥ 2 mm) has been used as an objective indicator of overall estrogenization.^{85,86} Androgen levels are appropriate for the stage of pubarche in true precocity.

Third-generation, monoclonal-antibody-based, "pediatric" immunoassays for gonadotropins are necessary for early detection and monitoring of therapy.⁷⁵⁹ Early morning basal LH greater than 0.3 to 0.6 U/L has been reported to be 62% to 95% sensitive and 92% to 100% specific for the diagnosis of central precocious puberty in girls.^{673,833,834} A post-GnRH peak LH greater than 6.9 U/L has been reported to be 92% sensitive and 100% specific,⁶⁷³ whereas a post-GnRH agonist peak LH over 4.0 to 5.0 U/L has been reported to be 90% or more accurate for the diagnosis of central precocious puberty.^{676,835,836}

A study of GnRH agonist-stimulated LH levels in healthy prepubertal girls found mean levels of 5.2 ± 4.0 and 2.9 ± 2.5 U/L in girls 0.8 to 3 years and 3 to 6 years, suggesting an LH cutoff level of 9 U/L and LH/FSH ratio of 0.4 in girls under 3 years.⁸³⁷ The diagnostic specificity of GnRH agonist testing is complicated by the overlap between the gonadotropin responses of prepubertal and pubertal girls. A study of healthy 6- to 13-year-old girls showed the 95th percentile for prepubertal girls to be 8.9 U/L and the 5th percentile for pubertal girls to be 2.8 U/L (Table 16.1).⁹³ In a subgroup of peripubertal 8- to 11-year-old girls, the most discriminating LH values were 3.2 U/L (85% specific) and 5.5 U/L (72% sensitive) 1 hour post-GnRH agonist. The GnRH agonist test also permits assessment of the ovarian gonadotropin-responsiveness: an estradiol peak of 34 pg/mL or more is approximately 90% sensitive and 60 pg/mL or more 95% specific for puberty (see Table 16.1).⁹³

FSH levels are not as helpful diagnostically because prepubertal values overlap considerably with pubertal ones and they may be elevated in premature thelarche. In response to GnRH or GnRH agonist testing, children with unsustained pseudopuberty as variants of normal will have a minimal gonadotropin response, whereas children with gonadotropin-independent precocity will have suppressed responses.^{838,839} Demonstration of a sleep-related rise of serum LH is an alternate diagnostic procedure. Box 16.3 summarizes laboratory criteria for the diagnosis of complete sexual precocity.⁸⁴⁰

Premature pubarche must be distinguished from hypertrichosis, the generalized excessive growth of vellus body hair that is prominent in nonsexual areas. The most common cause, by far, of premature pubarche is premature adrenarche. Premature adrenarche must be distinguished from virilizing disorders, the most common of which is virilizing nonclassic CAH and the most serious of which, although rare, is virilizing tumor.

Determination of the early morning baseline serum androgen pattern is useful in discriminating among the causes of premature pubarche and virilization. Premature adrenarche is characterized by a pubertal level of DHEAS, whereas serum testosterone and androstenedione are, at most, marginally elevated above the prepubertal range. A greatly elevated level of DHEAS suggests either adrenal tumor or the 3β -HSD deficiency form of CAH. Androstenedione and 17-OHP levels are disproportionately elevated compared with testosterone or DHEAS levels in other forms of virilizing CAH and many ovarian tumors.

An ACTH stimulation test is the definitive test to exclude CAH. We advise performing an ACTH test in children with premature pubarche who have unusually high serum

BOX 16.3 Laboratory Criteria for Diagnosis of Complete Precocious Puberty in Girls

BONE AGE ADVANCEMENT

Bone age > height age > chronological age
Compromised predicted adult height

LH LEVEL PUBERTAL^a

Sleep-associated LH peak > 1.0 U/L
LH (early morning) ≥ 0.6 U/L^b
Post-GnRH (1 h) agonist LH ≥ 3.2 –5.5 U/L^b
Suppressible by chronic GnRH agonist administration

SEX HORMONE LEVEL PUBERTAL

Estradiol (early morning, cyclically): >9 pg/mL^a
DHEAS normal for age or early puberty

DHEA, Dehydroepiandrosterone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

^aEssential criterion.

^bTypical values for sensitive assays. Exact values vary among laboratories.

androgens and bone age advancement and an early morning serum 17-OHP concentration above 170 ng/dL (5.1 nmol/L) (Fig. 16.32),⁸⁴¹ although levels above 1500 ng/dL do not require a confirmatory ACTH stimulation test. The diagnosis of CAH is discussed in detail in Chapter 14. The differential diagnosis of hyperandrogenic disorders is discussed further in the section Hyperandrogenism in Adolescence.

Ultrasonography is indicated to screen for abdominal or pelvic masses when feminizing or virilizing disorders are suspected.^{842,843} The ovaries of girls with true sexual precocity resemble those of normal pubertal girls.^{82,84,844} A "cyst" of 10 mm or more in diameter is usually caused by a transient preovulatory follicle. However, the differential diagnosis of a persistent cyst or multicystic ovaries includes McCune-Albright syndrome,⁸⁰⁷ tumor,⁸⁴⁵ and premature ovarian failure.⁸⁴⁶

The ability of ultrasonography to detect small adrenal neoplasms is highly dependent on the expertise of the ultrasonographer. On rare occasions, ultrasonography has been insensitive in detecting an ovarian tumor in adults.⁸⁴⁷ Computed tomography and MRI permit better visualization and more detailed assessment of tumors.

A systematic review that included 1853 subjects found that brain MRI identified a pathological finding in 9% of girls with central precocious puberty, with a much higher prevalence in those under 6 years of age (25%), compared with those that were 6 to 8 years of age (3%).⁸⁴⁸ The most common finding was a hypothalamic hamartoma in approximately 3.7%, whereas 1.3% of the subjects had another type of CNS tumor. Thus MRI of the hypothalamic-pituitary area is indicated in progressive central precocious puberty in those less than 6 years old or those at risk of organic causes by virtue of their underlying condition or neurological symptoms and signs,^{831,849} while the necessity of such imaging in girls presenting at 6 to 8 years of age without neurological indications is less certain. An argument for genetic testing of patients with CPP has been made, citing cost-effectiveness and safety in cases where MRIs with sedation are required.⁸⁵⁰

Management

The goals in management are to rule out an organic disorder that requires treatment in-and-of-itself and to ascertain whether sexual precocity is either compromising height potential or resulting in important secondary emotional disturbances in the child.

The situation of a girl presenting with the onset of breast development or pubic hair between 6.0 and 8.0 years of age warrants special consideration. Breast development between 7.0 and 8.0 years of age is normal in blacks and Hispanics. Although presexual pubic hair (stage 2) may be seen in 6- to 8-year-old black and Hispanic girls, sexual pubic hair (stage 3) is abnormal if present before 8 years of age (see Table 16.3). However, pubertal development in girls in the 6.0- to 8.0-year age range may be associated with pathology, with excessive adiposity being the major consideration in most.²⁷⁶

Many 6.0- to 8.0-year-old girls with central precocious puberty, including whites, have slowly progressive precocity, with a normal timing of menarche, and are at low risk of short adult stature. Most such girls do not require GnRH agonist therapy to preserve adult stature.^{759,760,851,852} Thus a less comprehensive investigation may be warranted in selected girls presenting with thelarche or stage 2 pubic hair between 6 and 8 years of age. For most such girls, a complete history and physical examination, including obesity evaluation and a bone age determination, may be all that is needed, along with careful longitudinal follow-up to rule-out a disorder that requires therapy.^{760,852} However, 6- to 8-year-old girls with a suggestion of rapidly progressive or excessive androgenization or feminization, neurological symptoms, linear growth acceleration, or significant bone age advancement should be more completely evaluated, as outlined earlier.

Intracranial lesions must be treated by appropriate measures, such as neurosurgery or irradiation. Shunting for hydrocephalus may stop the precocity. Granulosa cell tumors confined to the ovary have a good prognosis for cure by unilateral oophorectomy. Recurrence of tumor may occur up to 20 years after the initial operation, however. Biopsy of the opposite ovary is indicated in unilateral ovarian neoplasms. Compensatory ovarian hypertrophy can be expected at any age after removal of a single ovary.⁸⁵³

The only permanent physical complication of true isosexual precocity, all else being normal, is short adult height. There is no increase in the risk of obesity, metabolic derangements (diabetes, hypertension, dyslipidemia), or cancer in adults with a history of central precocious puberty, whether they were or were not treated with GnRH agonist.⁸⁵⁴ Women with a history of central precocious puberty, whether treated or not, do have a higher rate of hirsutism and irregular menses, and women who were not treated for the sexual precocity may have decreased fertility and a higher need for assisted fertilization.⁷⁷⁶ However, fertility is normal in women who received treatment with GnRH agonist or with cyproterone acetate for central precocious puberty, with a spontaneous pregnancy rate that is no different than in controls.⁷⁷⁶ Pregnancy outcome is normal in both treated and untreated women with a history of central precocious puberty.⁷⁷⁶ With regard to height, excessive sex hormone production in the first decade of life causes early maturation of the epiphyses, resulting in their premature closure. About half the girls with this disorder reach an adult height of 53 to 59 inches and the remainder are over 60 inches tall.^{760,852} The mismatch between physical, hormonal, and psychological development may cause behavior changes ranging from social withdrawal to aggression or sexuality. However, frank behavioral problems are unusual in girls and so are by themselves seldom indications for treatment.

When central precocity is accompanied by documented progression of pubertal development that accelerates growth and compromises normal height potential, GnRH agonist treatment is indicated.⁷⁵⁹ Documentation typically requires 3 to 6 months' observation, although this may be unnecessary if puberty is substantially advanced clinically and hormonally on presentation. The downregulating effect of GnRH agonists

BOX 16.4 Indications for Gonadotropin-Releasing Hormone Agonist Therapy of Precocious Puberty

1. Documentation of central precocious puberty
2. Documentation of pubertal progression
3. Plus presence of one of the following:
 - Progressive compromise of predicted adult height or
 - Emotional or behavioral disturbance or
 - Menses in the emotionally immature or disabled

(Modified from Rosenfield, R.L. (1994). Selection of children with precocious puberty for treatment with gonadotropin releasing hormone analogs. *J Pediatr*, 124, 989–991.)

on pituitary gonadotropin release inhibits gonadotropin secretion within 1 month. Suggested criteria for the use of these drugs are presented in Box 16.4.^{759,840} The commonly used agents in the United States are leuprolide acetate (ordinarily given as Lupron Depot-Ped[®] 7.5–15 mg/mo or 11.25–30 mg/3 mo intramuscular [IM]),^{855,856} nafarelin acetate (Synarel[®] 800 mcg bid intranasal), a histrelin implant (Supprelin[®] LA 50 mg implant yearly),⁸⁵⁷ and triptorelin (Triptodur[®] 22.5 mg/24wk IM).⁸⁵⁸ Dosage can be adjusted later as necessary.

Treatment is adequate if the estradiol and baseline LH levels become prepubertal⁸⁵⁹ or LH is below 4.0 (1 hour) to 6.6 U/L (2 hours) after GnRH agonist^{856,860} 1 month after institution of therapy. Withdrawal menses may occur at that time, but none should be expected thereafter. Arrest of breast development and the pubertal growth spurt become apparent by 3 to 6 months. Concomitantly, epiphyseal closure is delayed and adult height potential is improved, because a type of catch-up growth occurs in which height age catches up to bone age. Adult height is greatest when treatment is started soon after onset at an early age, yielding an average height gain above pretreatment height prediction of about 1.4 cm for each year of therapy.⁷⁵⁹ Adult height prediction at the end of treatment tends to be overestimated from bone age. Therefore prolonging treatment beyond a chronological or bone age of 12.0 to 12.5 years of age generally leads to little further increase in adult height potential, regardless of the prediction of residual height potential. Menses occurs an average of 12 to 20 months after discontinuation of GnRH agonist treatment.^{861,862}

Coincident GH deficiency must be treated for optimal growth.⁸⁶³ GH-sufficient patients with central precocity who are started on treatment relatively late and whose height velocity falls below 4 cm/y after 2 to 3 years, appear to gain an average of 2 cm/y when GH therapy is added.^{864,865}

Use of the depot form of GnRH agonist is complicated by sterile abscesses at injection sites in about 5% of cases. The histrelin implant breaks on its removal over 20% of the time,⁸⁶⁶ necessitating care that the complete implant is removed. Anaphylaxis is a rare complication.⁸⁶⁷ No other serious side effects have come to light. During treatment, girls with central precocious puberty do not differ in their cognitive or psychosocial functioning compared with controls.⁸⁶⁸ Long-term safety data remain incomplete, but current studies following subjects into young adulthood are reassuring, including no difference in menstrual cycle characteristics or pregnancy outcomes of treated compared with untreated subjects⁸⁶⁹ and some evidence of improved fertility with GnRH agonist treatment compared with that in women with a history of untreated central precocious puberty.⁷⁷⁶ GnRH agonist treatment does not seem to cause

or aggravate obesity, as judged from BMI.^{759,854} Bone mineral density dips with the onset of treatment, but becomes normal after discontinuation of GnRH agonist therapy of precocious puberty.⁷⁵⁹

Girls with idiopathic slowly progressive puberty of onset between 6 and 8 years of age or with early fast puberty between 8 and 9 years of age tend to be tall at the onset of puberty, follow an advanced growth pattern, and reach their target height without GnRH agonist therapy.^{760,852,870–872} Therefore this treatment is only indicated if height potential is compromised or there are other compelling reasons to slow the pace of puberty.

Medroxyprogesterone acetate (Depo-Provera) is useful for stopping menses and as a contraceptive in girls with intellectual disability in whom preservation of height potential is not important. It is begun in a dosage commencing at 50 mg/month IM. Doses as high as 400 mg/month have been used, although cushingoid side effects may be observed at this level.⁸⁷³ Although this treatment reverses some of the physical changes of premature puberty, it does not reverse the inordinately rapid maturation of the skeleton, possibly because of its inherently weak androgenicity. In addition, use of medroxyprogesterone acetate is associated with a loss of bone mineral density, which must be considered if long-term use is being considered.⁸⁷⁴

A variety of drugs have been used off-label to treat gonadotropin-independent precocity. Both antiestrogen and aromatase inhibitor treatments have demonstrated partial efficacy for McCune-Albright syndrome.^{856,875–877} However, there should be a period of observation before initiating treatment for patients with McCune-Albright syndrome, as there can be marked variability in the clinical course, with some patients having extended periods of disease inactivity in whom treatment may not be indicated.⁸⁷⁷ There have been reports of surgical intervention in children with McCune-Albright syndrome, including resection of an ovarian cyst or ovariectomy. In many of these cases, however, there has been recurrence of precocious puberty symptoms.⁸⁷⁸ Therefore such treatment should only be considered in very select situations, such as a girl with a large ovarian cyst at risk of ovarian torsion. Ketoconazole, an antifungal agent that inhibits 17,20-lyase activity and other steroidogenic enzymes, may be useful.⁸⁷⁹ GnRH agonist treatment may be necessary for those in whom true puberty becomes superimposed because the bone age has reached a pubertal level.^{264,265,880} Bisphosphonates are often effective at relieving the bone pain of fibrous dysplasia in McCune-Albright syndrome, although they do not appear to have an effect on the course of the lesions and are not a suitable long-term treatment.⁸⁸¹

Patients with premature thelarche or pubarche as variations of normal are counseled as follows. The child's early development seems to be a matter of a normal stage of puberty occurring early. It is caused either by an incomplete, slow kind of puberty or by increased sensitivity to the trace levels of hormones that are normally present in childhood. Feminization with breast development and eventual menstruation can be expected to occur at an appropriate age. No treatment is indicated. To exclude subtle sex hormone excess or eventual anovulatory syndromes, long-term follow-up is advisable.

Besides dealing with the physical consequences of true isosexual precocity, the physician must be ready to help the family and child cope with the psychological problems that come with early physical maturation. The doctor can help the family by explaining that even though their child looks older and more mature than other children of the same age, the child will not behave more maturely. The libido of young children with precocity is not increased. The family should be advised to take some precautions to downplay their child's development, for example, in the choice of clothing and swimsuits. Early on,

children with these disorders tend to be withdrawn because they feel that they are different from their peers. Later on, they tend to enter into romantic relationships early. It is important to remind the family and child that in a few years, the child will not be unique from the standpoint of sexual development.⁷⁰³ The following books may be helpful in explaining precocious puberty: for children, *What's Happening to Me?*, by Peter Mayle (Lyle Stuart, Inc., Secaucus, NJ, 1973); for parents, *Sex Errors of the Body*, by John Money (Paul H Brookes Publishing Co., Inc, Baltimore, MD, ed. 2, 1994).

Hypogonadism

Causes

If hypogonadism is complete and present prepubertally, it causes sexual infantilism. In genetic males, congenital primary hypogonadism may also cause a completely female or ambiguous phenotype (see Chapter 6). If hypogonadism in girls is partial or of onset in the early teenage years, feminization will be of too limited a degree to permit the onset of menses at a normal age (primary amenorrhea). Milder, partial, or incomplete forms of hypogonadism may present in adolescence with abnormal uterine bleeding (Box 16.2). Consequently, disorders causing hypogonadism appear in the differential diagnosis of disorders of sexual differentiation, sexual infantilism, failure of pubertal progression, and menstrual irregularity. The causes of hypogonadism are listed in the differential diagnosis of amenorrhea in Box 16.5.

Primary Ovarian Failure. Primary ovarian failure is characterized by high levels of gonadotropins, particularly FSH. Two exceptions exist to this rule. First, the gonadotropins may not be elevated until CNS maturation has reached a pubertal stage, as indicated by a bone age of approximately 10 to 11 years (Table 16.5).⁸⁸² Secondly, patients with early or partial ovarian failure (primary ovarian insufficiency), as normally occurs during the menopausal transition, do not have high baseline gonadotropin levels.^{883,884} FSH may hyperrespond to GnRH and estrogen hyporespond to GnRH agonist challenge. It seems as if relatively few ovarian follicles—too few to permit the cyclic emergence of preovulatory follicles—suffice to prevent the characteristic rise in basal FSH levels. Serum AMH levels are a less sensitive indicator of ovarian failure than FSH but may be useful in prognosticating the potential for fertility.^{885,886}

Primary ovarian failure may occur before or during puberty, causing primary amenorrhea, or after puberty has occurred, causing secondary amenorrhea. The latter is termed *premature ovarian insufficiency* (POI; in its complete form termed *premature ovarian failure*) and clinically resembles premature menopause, except that about 25% of the cases sometimes resume ovarian function and there is a 4.4% spontaneous pregnancy rate.⁸⁸⁷

Gonadal dysgenesis caused by deficiency of genes on the X-chromosome is the most common cause of primary ovarian failure and POI. It is usually caused by a relatively large-scale deletion of X-chromosomal material, which is associated with a characteristic, but variable, phenotype and is termed *Turner syndrome* (see Chapter 17). Fetuses with a 45,X karyotype have a normal number of oocytes in the ovary at midgestation, but a drastic reduction in the number of follicles,⁴¹ which appears to cause gonadal streaks via an accelerated rate of apoptosis. However, the gonadal dysgenesis, like other features of the syndrome, is often incompletely expressed.^{888,889} Thus Turner syndrome should be considered in all girls with primary hypogonadism or secondary amenorrhea whether or not they have the typical stigmata of Turner syndrome.

BOX 16.5 Differential Diagnosis of Amenorrhea: Structural and Anovulatory Disorders**ABNORMAL GENITAL STRUCTURE**

- Ambiguous genitalia
 - Disorders of sex development
 - Pseudointersex
- Aplasia^a
 - Hymenal
 - Müllerian
 - Disorders of sex development
- Endometrial adhesions

ANOVLATORY DISORDERS**Hypoestrogenism, FSH Elevated**

- Primary ovarian failure
 - Congenital
 - Gonadal dysgenesis
 - Chromosomal
 - Genetic
 - Other genetic disorders
 - Acquired
 - Oophorectomy
 - Radiotherapy or chemotherapy
 - Oophoritis
 - Idiopathic

Hypoestrogenism, FSH not Elevated

- Primary ovarian insufficiency
 - Complete if bone age <11 years^a
 - Incomplete if bone age >11 years

- Delayed puberty
 - Constitutional delay of growth and puberty^a
 - Growth-retarding disease
- Gonadotropin deficiency
 - Congenital
 - Acquired
 - Organic
 - Functional
 - Virilization

Estrogenized

- Hypothalamic anovulation
 - Functional hypothalamic amenorrhea
 - Athletic amenorrhea
 - Psychogenic amenorrhea
 - Epilepsy
- Nonhypothalamic nonovarian disorders
 - Pregnancy
 - Obesity or undernutrition
 - Chronic disease
 - Cushing syndrome
 - Hypothyroidism
 - Drug abuse
 - Hyperprolactinemia
 - Postpill amenorrhea
- Hyperandrogenism
 - Polycystic ovary syndrome
 - Other hyperandrogenic disorders

FSH, Follicle-stimulating hormone.

^aCause only primary amenorrhea.**TABLE 16.5** Bone Age in Workup of Sexually Infantile Girls With Normal Follicle-Stimulating Hormone Level

	Bone Age (Years)		
	<11	11–13	>13
Primary hypogonadism	Yes		
Delayed puberty	Yes	Yes	
Gonadotropin deficiency	Yes	Yes	Yes

(From Rosenfield, R.L., Barnes, R.B. (1993). Menstrual disorders in adolescence. *Endocrinol Metab Clin North Am*, 22, 491.)

Specific loci on the X-chromosome are associated with primary ovarian failure. Xp11.2 harbors BMP15, a specific ovarian differentiation factor, heterozygous mutation of which is a rare cause of gonadal dysgenesis. Xq harbors two independent loci, in addition to the fragile X premutation, that are associated with about 5% of sporadic and 14% of familial POI.⁸⁹⁰ The premutation is an expansion of CGG repeats in the fragile X mental retardation 1 (*FMR1*) gene that is insufficiently long to cause fragile X syndrome. Women with the premutation allele have a substantially increased risk of POI, possibly because raised intracellular mRNA concentrations might sequester CGG binding proteins that are important for RNA processing.

Gonadal dysgenesis also results from 46, XY complete gonadal dysgenesis and certain forms of autosomal aneuploidy.^{600,890,891} A rare cause is ERβ (ESR2) receptor inactivating mutation. A variable degree of ovarian dysgenesis occurs in trisomy 21; delayed menarche, anovulatory cycles, and primary gonadal failure are occasionally seen.⁸⁹² However, pregnancy

has been reported; trisomic offspring are common.⁸⁹³ Oocytes are virtually absent in trisomies 13 and 18. Ovarian dysgenesis also occasionally occurs as part of the Denys-Drash syndrome caused by a *WT-1* mutation.⁸⁹⁴ Gonadal dysgenesis also occurs in DNA-repair disorders that impair meiosis, such as ataxia-telangiectasia and Fanconi syndrome.^{895,896} Other autosomal genetic disorders causing premature ovarian failure include inactivating mutations of FOXL2, which are found in sporadic cases, as well in the autosomal dominant type 1 blepharophthalmos syndrome.⁸⁹⁷ POI also occurs in galactosemia,⁸⁹⁸ leukodystrophies, and myotonia dystrophica.^{899,900} Mutation of the inhibin alpha-subunit predisposes to POI, an effect that appears to vary depending on ethnicity; this is postulated to be caused by deficient paracrine interactions with TGFβ-family receptors.⁹⁰¹ Mutations in other autosomal genes that have been associated with POI include: *NOBOX*, *FSHR* (encoding the FSH receptor), and *TRIM37* (mutations of which cause Mulibrey nanism disorder).⁹⁰² Mutations in *NR5A1*, encoding the transcription factor SF-1, can result in 46, XY gonadal dysgenesis or POI, as well as being a cause of adrenal insufficiency because of impaired adrenal gland development.⁹⁰³ Variants in additional genes that have been identified in patients with POI include *PGRMC1* at Xq22-q24 (coding for a putative progesterone-binding membrane receptor) and the autosomal genes *SPIDR*, *GDF9*, *FIGLA*, *NANOS3*, *SYCE1*, *MCM8/9*, and *HFM1*.⁹⁰⁴ There are a number of other candidate genes with less clear evidence of causality,⁹⁰⁴ and mutations incriminated in the ovarian failure of mouse models⁹⁰⁵ or in genes involved in follicle development²⁶ may also be identified in the future as causes of human primary ovarian failure.

Injury to the ovary is a common cause of primary ovarian failure. Mumps oophoritis is a classic but rare cause of ovarian

failure. Very high-dose estrogen treatment in adolescence increases the risk of hypergonadotropic subfertility.⁸⁸⁶

Irradiation and chemotherapy for childhood neoplasia are frequent causes of primary ovarian failure now that life is effectively prolonged.^{890,906–909} Such treatments can cause either acute ovarian failure or a decreased follicular reserve. Acute ovarian failure results in a lack of pubertal development when it occurs prepubertally, or in arrested pubertal development or secondary amenorrhea when it occurs in pubertal or postpubertal girls. Decreased follicular reserve results in premature ovarian failure.⁹¹⁰ Ionizing radiation and alkylating agents damage DNA whether or not a cell is replicating.⁹¹¹ Therefore nonreplicating primordial follicles are not spared from these agents, although prepubertal ovaries may be less sensitive to damage than pubertal or postpubertal ovaries.^{910,912} The damage is dose related and the damage is worse with combined irradiation and chemotherapy compared with treatments with just one of these modalities. A radiation dose of 15 Gy or more causes acute ovarian failure in over 80% of prepubertal girls, whereas a dose more than 10 Gy will cause equivalent damage in postpubertal girls.⁹¹³ However, doses as low as 2 Gy will also impact long-term ovarian function by depleting the follicular pool by as much as 50%.⁹¹⁴ A cumulative cyclophosphamide dose⁹¹⁵ over 7.5 g/m² will cause acute ovarian failure in over 80% of females younger than 20 years.⁹¹³ Green et al. developed a method to quantitate a “cyclophosphamide equivalent dose (CED)” for other alkylating agents.⁹¹⁵ After prepubertal cancer treatment, 94% of girls can be anticipated to enter puberty and menstruate regularly, but 8% of these will develop nonsurgical premature menopause because of the reduced number of oocytes.⁹⁰⁸ The risk for premature menopause is 30% in those who have received both radiation and chemotherapy, 5% to 13% for those receiving either alone. Some with early hypergonadotropinism will experience ovarian recovery with normal pituitary-ovarian function after several years,⁹¹⁶ but infertility occurs. Several nonalkylating chemotherapies are also gonadotoxic (including platinum agents and anthracyclines), while others (such as methotrexate, fluorouracil, and vincristine) have very low or no gonadotoxic risk.^{917–920} However, data are scarce, and interactions among the various classes of chemotherapeutic agents is poorly understood. Radiation treatment for malignancy can also lead to infertility by causing hypogonadotropic hypogonadism, or through injury to the uterus. As a consequence of gonadotropin elevation when gonadal failure begins, puberty may progress rapidly.⁷⁷⁴

Sterilization by irradiation can be obviated by transposing the ovaries out of the irradiation field if possible. The evidence that the prepubertal ovary appears less sensitive to injury from irradiation and chemotherapy has suggested that GnRH agonist therapy might protect ovarian function in pubertal/postpubertal girls receiving such treatment. While there are some conflicting data, there is no clear benefit to such treatment.⁹¹² Imatinib (Gleevec[®]) is a potential oocyte-protective treatment, as it blocks an apoptotic pathway activated by radiation and cisplatin in mouse oocytes.⁹²¹

Gonadotropin resistance (Savage syndrome) can arise from autosomal recessive loss of function mutations of the LH or FSH receptor.^{917–919} The reported cases have had some degree of pubertal development followed by primary or secondary amenorrhea or oligomenorrhea. The ovaries of LH receptor mutants contain follicles in all stages of development, while those of FSH receptor mutants vary from hypoplastic to normal size, with antral follicle development varying from nil to 5 mm. Partial gonadotropin resistance is common in the Albright osteodystrophy form of pseudohypoparathyroidism, as part of the generalized defect in G-protein signal transduction.⁹²⁰

Autoimmune oophoritis is the basis of approximately half of spontaneous premature ovarian failure, although estimates vary from 5% to 85% in various series.⁹²² It is diagnosed by

its association with any of a variety of autoimmune endocrine or nonendocrine disorders, manifest or subclinical, that have in common defects in T cell suppressor function. Autoimmunity may be directed against the granulosa cell, oocyte, or theca cell. The clinical picture may resemble relatively selective resistance to FSH or, less frequently, to LH. The latter results from lymphocytic destruction of theca cells with sparing of granulosa cells from small antral follicles, which lack substrate to form estradiol and can only respond to the compensatory increase of FSH by producing inhibin-B.⁹²³ These patients have autoantibodies to steroidogenic cells and are at risk for adrenal failure. Usually these antibodies are directed against 21-hydroxylase, less frequently to side chain cleavage enzyme or 17-hydroxylase, seldom to 3 β -HSD. Replacement glucocorticoid therapy may temporarily ameliorate the immune oophoritis in such cases.⁹²⁴ A case with autoantibodies to testosterone has been reported.⁹²⁵ AIRE gene mutations have been identified as causative of type 1 polyendocrine failure. Ultrasonographic and histological findings are variable in premature ovarian failure and include large or small ovaries, inactive or polyfollicular ovaries, loss or preservation of primordial follicles, and infiltration by lymphocytes or plasma cells.⁸⁴⁶

Functional ovarian failure can also result from specific autosomal recessive defects in the biosynthesis of sex steroids. Both androgen and estrogen deficiency occur in lipid CAH (StAR and side chain cleavage mutations, see Fig. 16.22), 17 α -hydroxylase deficiency, P450 oxidoreductase deficiency, and 17,20-lyase deficiency.^{926,927} Thus affected genetic males may present with a female phenotype. Hypoestrogenism is associated with virilization in aromatase and 3 β -HSD deficiency. Aromatase is unique among the ovarian steroidogenic defects in not being associated with CAH. Congenital lipid adrenal hyperplasia is unique in that underlying StAR deficiency has too little direct impact on ovarian function to interfere with the early phases of puberty, but the gradual buildup of intraovarian lipid deposits resulting from enzyme deficiency—a “second hit”—causes ovarian damage with anovulation and late ovarian failure. SF-1 (NR5A1) deficiency can cause primary ovarian failure in the absence of adrenal insufficiency.⁹⁰³

Estrogen resistance caused by inactivating mutation of ER α has been reported.^{928,929} Hypoestrogenism and hyperestrogenemia were profound, the ovaries were enlarged and multicystic, and gonadotropin and testosterone levels were marginally to clearly elevated.

Gonadotropin Deficiency (Hypogonadotropic Hypogonadism). Congenital gonadotropin deficiency can occur in association with cerebral, hypothalamic, or pituitary dysfunction as an isolated defect.⁹³⁰ Congenital defects in hypothalamic-hypophyseal formation may be associated with midline facial defects. Congenital hypothalamic dysfunction may be associated with other neurological or endocrine dysfunction, such as in the Prader-Willi syndrome (congenital hypotonia, and neonatal failure to thrive followed by hypothalamic obesity, sometimes with hypopituitarism)⁹³¹ or the Laurence-Moon-Biedl syndrome (retinitis pigmentosa, obesity, mental deficiency).

Congenital hypogonadotropic hypogonadism often results from mutations (Table 16.6).^{212–214,220,222,226,235,719,932–942} The autosomal recessive forms of congenital combined pituitary hormone deficiency caused by PROP1, HESX1, LHX3, and OTX-2 mutations are associated with gonadotropin deficiency. Leptin and leptin receptor inactivating mutations cause gonadotropin deficiency in combination with moderate or extreme obesity.^{941,943} The report of a natural pregnancy in a woman with a homozygous mutation in the leptin receptor lends controversy to the current concept that leptin function is essential for reproduction.⁹⁴⁴

Gonadotropin deficiency may be associated with anosmia (olfactory-genital dysplasia or Kallmann syndrome).²¹⁴

TABLE 16.6 Gene mutations causing congenital hypogonadotropinism

Gene Mutation	Disorder
<i>CCDC141, CHD1, DUSP6, FGF8 and 17, FEZF1, FGFR1, FLRT3, IGFS10, IL17RD, KAL1, HS6ST1, KLB, PROK2, PROKR2, SEMA3A and 3E, SMCHD1, SPRY4, WDR11</i>	Disrupted migration of gonadotropin-releasing hormone (GnRH) neurons (Kallmann syndrome)
<i>DAX1 (NROB1), HESX-1, LHX3, NR5A1, PROP-1, SOX2</i>	Abnormal development of the hypothalamus and pituitary
<i>LEP, LEPR, PC1</i>	Associated with obesity
<i>GNRH1, KISS1, KISS1R, TAC3, TAC3R</i>	Abnormal GnRH pulsatility
<i>GNRHR, FSHB, LHB</i>	Abnormal gonadotropes
<i>DMXL2</i>	Associated with type 1 diabetes mellitus, central hypothyroidism, developmental delay, peripheral neuropathy
<i>OTUD4, PHPLA6, RNF216, STUB1</i>	Gordon Holmes syndrome (cerebellar ataxia, retinal dystrophy)
<i>POLR3A and 3B</i>	4H syndrome (hypomyelination, hypodontia, hypogonadotropic hypogonadism)
<i>RAB18, 3GAP1 and 3GAP2</i>	Warburg Micro syndrome (microcephaly, developmental delay, microcornea, optic atrophy)

This syndrome is 1/10th as frequent in females as in males. Mutations in the *KAL-1* gene in the pseudoautosomal region of the X-chromosome, which encodes anosmin, a key protein for GnRH neuronal migration, cause the highly penetrant X-linked form and rarely affect females. Inactivating mutations of other genes in the anosmin signaling pathway (*FGF8/FGFR1, PROK2/R2, NELE, and CHD7*) account for the vast majority of female cases; these are inherited as autosomal dominant or recessive (heterozygous, compound heterozygous, or digenic) traits with variable penetrance.^{214,719,933,934,945} Neurological and somatic abnormalities, such as synkinesia, cerebellar ataxia, sensorineural deafness, mental retardation, unilateral renal agenesis, and cleft palate, are variably associated genetic features of Kallmann syndrome. Rare affected individuals have only delayed puberty. These same mutations sometimes are responsible for normosmic idiopathic GnRH deficiency; *CHD7* mutations typically have features of CHARGE syndrome. Research is increasingly revealing new elements in the GnRH developmental and signaling pathway. For example, a single-nucleotide polymorphism in the *EAP1* gene has been associated with amenorrhea/oligomenorrhea in primates.⁹⁴⁶

GnRH receptor mutations account for about half of autosomal recessively inherited cases of isolated, normosmic gonadotropin deficiency.⁹³⁵ The degree of hypogonadism is variable, even within a family, with delayed puberty and delayed menarche as presentations.^{936,937,947}

Loss-of-function mutations of GnRH⁹⁴⁸ and in signaling systems that modulate GnRH release (*KISS/KISS1R, NKB/TAC3R*) are rare causes.^{222,235} The hypogonadism of most subjects with neurokinin B/TAC3R mutations is reversed by sex steroid therapy, which suggests that this signaling system is important for the start-up of puberty, but not its maintenance. Isolated hypogonadotropic hypogonadism also has been reported in a woman homozygous for a nonsense mutation of the X-linked orphan nuclear receptor *DAX1* gene, which was associated with X-linked adrenal hypoplasia congenita in her brothers.⁹⁴⁹

Isolated FSH deficiency caused by mutation in the β -subunit has been reported to cause primary amenorrhea in association with a unique test panel—low FSH, elevated LH, and low

testosterone levels.^{139,919} Carbohydrate-deficient glycoprotein syndrome (phosphomannomutase deficiency) is characterized by high levels of immunoreactive, but bioinactive gonadotropins, mimicking primary ovarian insufficiency.⁹⁵⁰ Isolated LH deficiency because of *LH β* gene inactivating point mutations has been reported to lead to secondary amenorrhea following normal pubertal development, but undetectable LH, high FSH, low estradiol, and macrocystic ovaries.⁹⁵¹ However, some inactivating LH mutations in men have high or low immunoreactive LH levels.⁹¹⁹ Mutations in genes responsible for anterior pituitary development may cause gonadotropin deficiency resulting in pubertal delay or CHH. LIM Homeobox 3 (*LHX3*), SRY-Box 2 (*SOX2*), and HESX homeobox 1 (*HESX1*) are responsible for early forebrain patterning and pituitary cell development.⁹⁵² Paired like homeodomain factor 1 (*PROP1*) is important for the development of somatotrophs, lactotrophs, thyrotrophs, and gonadotrophs⁹⁵³ and patients with *PROP1* mutations have variable phenotypes ranging from CDGP to CHH.⁹⁵² Gonadotropin deficiency may also be associated with other conditions, particularly with neurological phenotypes. Mutations in RNA polymerase III subunit A and B (*POLR3A/B*) result in the 4H syndrome (hypomyelination, hypodontia, and hypogonadotropic hypogonadism)⁹⁵⁴ Ring finger protein 216 (*RNF216*), OTU deubiquitinase 4 (*OTUD4*) and Patatin-like phospholipase domain containing 6 (*PNPLA6*) CHH, and ataxia (also known as *Gordon-Holmes syndrome*).^{955,956} *DMX* like 2 (*DMXL2*) mutations are associated with CHH, other endocrine deficiencies, and polyneuropathies.⁹⁵⁷ Mutations in RAB3 GTPase activating protein catalytic subunit 1 (*RAB3GAP1*) result in dysregulation of the RAB3 cycle, leading to Warburg Micro syndrome with ocular, neurodevelopmental, and central reproductive defects.^{958,959}

Acquired gonadotropin deficiency can be a consequence of tumors, trauma, autoimmune hypophysitis,^{960,961} degenerative disorders involving the hypothalamus and pituitary,⁹⁶² irradiation,⁹⁶³ chemotherapy,⁹⁶⁴ or chronic illness.⁹⁶⁵ Hypogonadotropic hypogonadism will develop in about one-third of those receiving 20 to 30 Gy cranial irradiation, whereas it is typical in those receiving >50 Gy.^{762,966} Pituitary adenoma, craniopharyngioma, and dysgerminoma are the most common neuroendocrine neoplasms responsible for hypopituitarism in children. Most “nonfunctioning” pituitary adenomas are gonadotrope adenomas, which secrete gonadotropin subunits in response to TRH.⁹⁶⁷ A case of hypothalamic tumor is presented with Fig. 16.41. Pinealomas most commonly cause sexual infantilism. They may act by secreting an inhibitory substance, rather than by compressing key areas of the hypothalamus.⁷⁶⁹

Anorexia nervosa is the prototypic form of eating disorders, and is a common cause of hypogonadotropinism in teenagers. It is a syndrome of undernutrition because of voluntary starvation with a particular psychological dysfunction that results in amenorrhea.^{968–970} These patients uniformly consider themselves too fat in the face of objective evidence that they are underweight. The psychiatric criteria that distinguish this disorder from food faddism and fear of obesity consist of: (1) restriction of energy intake relative to requirements, leading to a significantly low body weight; (2) intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight; and (3) disturbance in the way in which one’s body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight. A 10th percentile BMI should be the initial maintenance goal.⁹⁷¹

Bulimia nervosa, the binge-eating/purging variant eating disorder, is similar in the overevaluation of body shape and weight and the use of extreme weight control behaviors. Physical activity tends to be high. These disorders may be manifest at an early stage as atypical eating disorders, before weight or

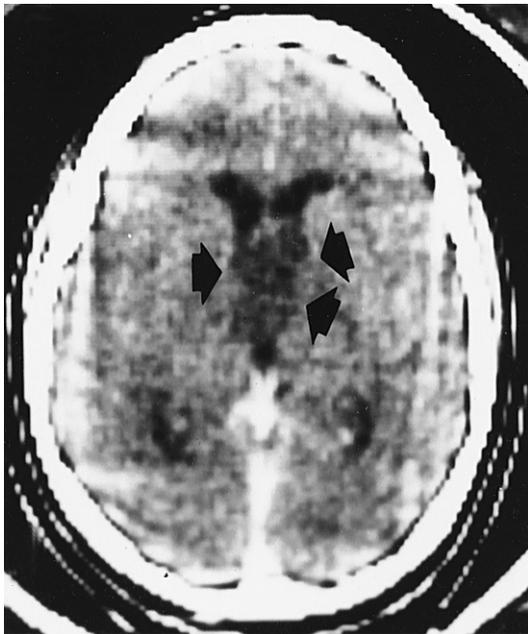

Fig. 16.41 Computed tomography of the brain of a 16-year-old girl with hypothalamic astrocytoma. The low-density tumor mass (arrows) extends superiorly from the hypothalamus, obliterates the third ventricle, and partially compresses the frontal horns of the lateral ventricles (particularly the right). This patient presented with secondary amenorrhea. Menarche had occurred at age 13 years, and menses were normal until 15.3 years. The patient then became amenorrheic in association with lethargy, episodic headaches, polyuria, and weight gain—despite little change in appetite. Physical examination was negative. The skull radiograph, electroencephalogram, visual fields, and serum prolactin and thyroxine levels were normal—and urine-specific gravity was 1.016. After biopsy of the cyst wall, studies revealed her to have gonadotropin, growth hormone, and partial antidiuretic hormone deficiencies.

amenorrhea criteria are met or when the binge is subjective. The cognitive defect that weight can serve as the predominant value in judging self-worth is central to anorexia nervosa. In contrast to other depressive individuals, these patients are generally content with themselves in the areas of intellectual and vocational achievement.

The cause is multifactorial. It involves a genetic predisposition. Concordance rates for the anorexic type are about 50% for monozygous twins, compared with about 5% for dizygotic twins. Many other risk factors have been implicated. Familial factors also include eating disorders of any type, depression, substance abuse, and adverse family interactions. Premorbid experiences, such as sexual abuse or social pressures, or premorbid characteristics, such as low self-esteem, compulsiveness, and perfectionism, are also important. Dieting meets a need for approval in our culture with its emphasis on dietary restriction and thinness as goals for women. Anorexia is often precipitated in vulnerable children by a new experience, such as puberty, leaving home or beginning college, or by adverse life events. The disorder is perpetuated by the complications of starvation, such as depression and reduced gastric emptying.

The onset tends to be at 12 years of age or later. Earlier onset is associated with growth arrest, delay of puberty, and primary amenorrhea.⁹⁷² Dysfunction of the hypothalamic-pituitary axis in anorexia nervosa includes not only hypogonadotropic hypogonadism, but GH deficiency^{973,974} and hypercortisolemia;

GH resistance and nonthyroidal illness also occur as consequences of malnutrition.⁹⁷⁵

The medical complications of anorexia nervosa are serious. The risk of death is approximately 10-fold increased: electrolyte imbalance, hypoglycemia, cardiovascular instability, bone marrow hypocellularity predisposing to silent infection, and renal failure account for about half of the mortality, suicide for the rest.

The weight changes leading to cessation or restoration of menstrual cycles are in the range of 10% to 15% of body weight. Recovery is associated with achieving a critical level of body fat stores above the 10th percentile (over approximately 20% body fat) (see Fig. 16.42), at a BMI approximately 20, that is, midnormal.^{976,977} There is an inverse relationship between body weight and the maturity of gonadotropin release in these patients. The 24-hour pattern of gonadotropin release tends to be immature (prepubertal or pubertal), and the diurnal LH pattern becomes mature upon recovery from undernutrition.⁹⁷⁸ LH pulsatility is low and may be restored by opiate antagonists.⁹¹ The gonadotropin response to GnRH and ovulatory response to clomiphene citrate are blunted in the malnourished state and become normal with weight gain to about 80% of ideal.^{979,980} Leptin levels are significantly decreased and are a major contributor to both the gonadotropin deficiency and to changes in the thyroid and GH axes.⁹⁸¹

Mild hypercortisolism is frequent and may contribute to the anovulation by mechanisms discussed further under Hypothalamic Anovulation.⁹⁸² Afternoon ACTH and cortisol levels are significantly higher and the response to CRH is significantly lower than normal. In contrast to Cushing syndrome, DHEAS levels tend to be blunted as a consequence of undernutrition.⁹⁸³

A fundamental neuropsychological flaw or hypothalamic disturbance⁹⁸⁴ has been suspected because some patients become amenorrheic before losing weight, and about half of the cases remain amenorrheic after treatment. The serotonergic systems implicated in the regulation of feeding and mood seem to remain altered even after weight restoration. Evidence exists for marked individual differences in reactivity of the neuroendocrine system to stress.⁹⁸⁵ The authors favor the concept that psychological problems lead to amenorrhea only in women who are predisposed by a unique preexisting hypothalamic dysfunction.

A number of features attributed to hypothalamic dysfunction, such as cold intolerance, may be caused by the subtle hypothyroid state that is secondary to the malnutrition.⁹⁸² Serum triiodothyronine levels are consistently low, serum thyroxine levels tend to be lower than average (although usually within normal limits), the pattern of TSH release indicates TRH deficiency, and the state of deep tendon reflexes and metabolism is consistent with hypothyroidism. Hypothyroidism may in part complicate the GH resistance of malnutrition that occurs as a consequence of the interference with IGF-1 generation: low IGF-1 initiates GH excess, compensatory somatostatin release, and subsequent inhibition of the thyrotropin response to TRH. Undernutrition also diverts the generation of thyroxine metabolites away from triiodothyronine toward reverse triiodothyronine.

Hyperprolactinemia is a potentially reversible cause of gonadotropin deficiency.⁹⁸⁶ Galactorrhea is present in about half of the patients, particularly those with residual estrogen production. The causes of hyperprolactinemia are diverse, including hypothalamic or pituitary disorders, drugs, hypothyroidism, renal or liver failure, peripheral neuropathy, stress, autoimmune, macroprolactinemia, genetic, and idiopathic.^{987–990} Elevated serum prolactin levels occur with a variety of tumors that cause functional or anatomic pituitary stalk section, thereby preventing dopaminergic inhibitory pituitary control. About

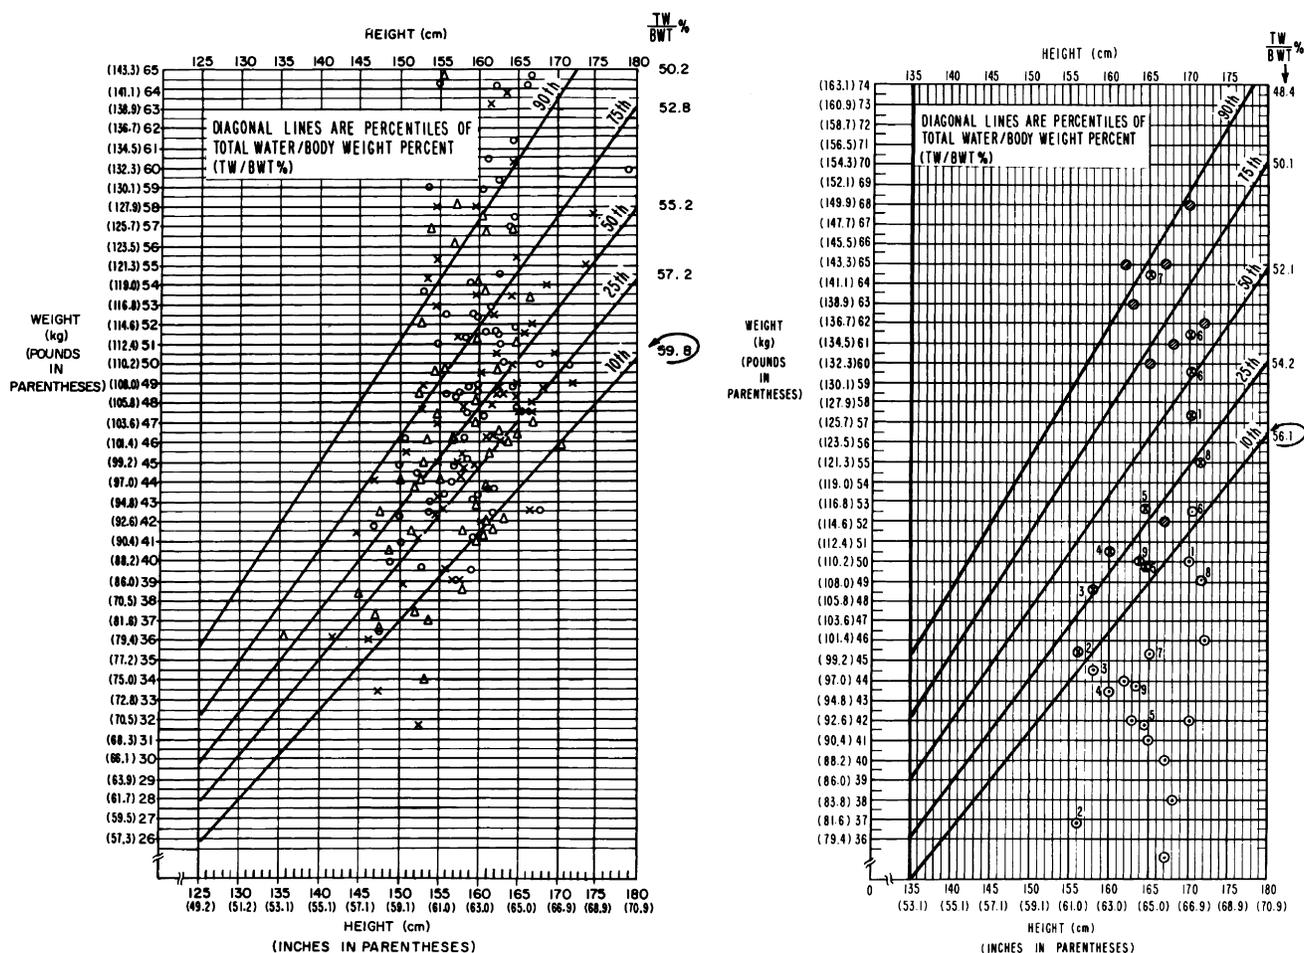

Fig. 16.42 Percentiles of fatness (*diagonal lines*) for white girls at menarche (left) and after menarche (right) equated with computed percentiles of total water as a percentage of total body weight. The minimal weight necessary at a particular height for the onset or maintenance of menses is very close to the 10th percentile of fatness on these respective charts. Data for anorexia nervosa cases are shown on the right-hand chart: ● at presentation; x at resumption of menses. (From Frisch, R.E., McArthur, J.W. (1974). Menstrual cycles: Fatness as a determinant of minimum weight for height necessary for their maintenance or onset. *Science*, 185, 949. Copyright © by the American Association for the Advancement of Science.)

one-third of hyperprolactinemic women have an identifiable pituitary adenoma. Prolactinomas less than 1 cm in diameter (microadenomas) cause no problems by local extension. Prolactinoma may be associated with multiple endocrine neoplasia type 1.⁹⁹¹ In about a quarter of adult hyperprolactinemia, the malfunction is caused by the ingestion of drugs, such as phenothiazines, estrogen, or cocaine.⁹⁹² Considerable hyperprolactinemia is idiopathic: decreased sensitivity to dopaminergic inhibition may underlie such cases.⁹⁹³

Macroprolactinemia is caused by a variant molecule or autoantibody formation comprised of prolactin and plasma proteins, most often caused by immunoglobulin (Ig)G prolactin-autoantibodies.⁹⁹⁴ In this situation, direct immunoassay indicates elevated levels of prolactin. However, the biologically available or active prolactin level is normal; thus there is no physiological consequence to the macroprolactinemia.

Hyperprolactinemia results in LH pulses that tend to be infrequent and LH secretion that is variable in response to GnRH.⁹⁹⁵ Selective prolactin excess causes variable degrees of gonadotropin deficiency, ranging from severe to partial (hypothalamic amenorrhea). Adrenal hyperandrogenism, hirsutism, and seborrhea are common.³⁶⁷

Frank virilization as a result of very high androgen levels suppresses gonadotropin levels and so causes defeminization.

However, the moderately hyperandrogenic disorders discussed later, which are more common, are associated with normal estrogenization.

Differential Diagnosis

The differential diagnosis of hypogonadism is included in [Box 16.5](#). Investigation should begin for hypogonadism when puberty is delayed or does not progress normally. Delayed puberty is indicated by lack of thelarche by the chronological or bone age of 13 years. Abnormal progression of puberty is suggested by failure of menses to occur within 3.0 years of the onset of thelarche or if secondary amenorrhea or oligomenorrhea has persisted for 1 year. As discussed earlier, normal menstrual frequency varies with the time after menarche, but an interval persistently greater than normal ([Box 16.2](#)) should prompt an evaluation.⁹⁹⁶ A family history of delayed puberty is compatible with the delay being constitutional rather than having an organic basis. The history should include a thorough past medical history and systems review, including intracranial, visual, olfactory, emotional, abdominal, or pelvic symptoms and systemic symptoms that might indicate chronic endocrine, metabolic, or systemic disorders that delay puberty. Upon examining the patient, the height and weight should be

carefully measured and growth rate and appropriateness of weight for height determined (see Fig. 16.42). Careful categorization of the stage of breast and sexual hair development are essential. Inspection of the external genitalia is indicated, but an internal pelvic examination seldom is necessary for diagnosis.⁹⁹⁷ Examination of the mature breast should include an attempt to express milk from the ducts to the nipple. The finding of a structural genital abnormality may indicate that amenorrhea is caused by abnormal genital tract development, while clitoromegaly⁹⁹⁸ is a clue to a virilizing disorder. Neurological examination should include evaluation of eye movements, visual fields, and optic fundi, as well as a search for anosmia and midline defects.

If a disorder or syndrome associated with hypogonadism is recognized in the newborn period, advantage may be taken of the mini-puberty of the newborn to attempt to make a diagnosis during the first few months of life. For example, the hypergonadotropic hypogonadism of Turner syndrome and the hypogonadotropic hypogonadism of hypopituitarism may be documented during this critical period before the physiological restraint of puberty during late infancy and childhood makes it difficult to do so before the normal age of puberty.^{999–1002}

An algorithmic approach to the workup of patients with menstrual disorders is shown in Figs. 16.43 to 16.45.¹⁰⁰³ The laboratory workup depends on the degree of estrogenization, as initially assessed from the stage of breast development: it includes a bone age radiograph in adolescents who are not sexually mature and generally begins with a chronic disease panel, and determination of gonadotropins, estradiol, and testosterone level. A pregnancy test is indicated in a sexually mature adolescent. The diagnostic considerations differ in the anovulatory girl without FSH elevation, depending upon whether she is hypoestrogenic or estrogenized (see Box 16.5 and see Figs. 16.43 and 16.44).

FSH elevation indicates primary ovarian failure (see Figs. 16.43–16.45). Chromosome abnormalities are ordinarily the first consideration because the most common cause is Turner syndrome and its variants. Those individuals with primary ovarian failure that is not caused by Turner syndrome and its variants should be investigated for the fragile X premutation, autoimmune oophoritis, and steroidogenic defects.

Lack of FSH elevation in a prepubertal patient does not rule out primary ovarian failure if bone age is below 11 years because neuroendocrine puberty may not have occurred; in this situation, primary ovarian failure is not hypergonadotropic (see Table 16.5).⁸⁸² If FSH is not elevated and bone age has reached 11 years, in a prepubertal girl without a growth-attenuating or retarding disorder, one is dealing either with constitutional delay of puberty or isolated gonadotropin deficiency (see Fig. 16.43). “Constitutional” delay of puberty is the most likely diagnosis until the bone age reaches 11 to 13 years (see Table 16.5).⁸⁸² Its distinction from isolated gonadotropin deficiency may be difficult. The features that help to distinguish it from isolated gonadotropin deficiency are listed in Box 16.6 and discussed in Fig. 16.43 footnotes. The single most useful test is the LH level in response to GnRH testing because random LH levels in hypogonadotropic patients often overlap those of pre- and midpubertal normal children.¹⁰⁰ GnRH agonist testing may discriminate between these disorders better because the LH response at 3 to 4 hours is the best indicator of gonadotropin secretory reserve and because this test permits assessing the gonadal secretory response to the secreted gonadotropins at 24 hours.⁸³⁸ Kisspeptin was given in an experimental protocol to children with CDGP to determine whether it may be a diagnostic test to predict entry into puberty. Children showed a wide range of responses, ranging from a robust response to little to no response. Hence its utility as a predictor of future reproductive development remains questionable.¹⁰⁰⁴

BOX 16.6 Features That Distinguish Gonadotropin Deficiency From Constitutional Delay of Puberty

In a healthy delayed prepubertal girl with BA >11 y and prepubertal FSH, gonadotropin deficiency is:

- Possible if:
 - Weight loss greater than 5% to 8% (BMI <10th–15th percentile for height age)
 - Midline facial defect
 - CNS dysfunction
 - CT or MRI brain scan abnormal
- Probable if:
 - BA > 13 years and LH <0.15 U/L in early daytime
 - Anosmia or panhypopituitarism
- Diagnostic if:
 - Sleep-associated increase in LH lacking
 - GnRH agonist test subnormal response
 - Chronological age >16 y

BA, Bone age; BMI, body mass index; CNS, central nervous system; CT, computed tomography; FSH, follicle-stimulating hormone; LH, luteinizing hormone; MRI, magnetic resonance imaging.

(Modified from Rosenfield, R.L., Barnes, R.B. (1993). Menstrual disorders in adolescence. *Endocrinol Metab Clin North Am*, 22, 491–505. With permission.)

The assessment of an adolescents’ degree of estrogenization is often difficult. Breast development indicates that there has been estrogen exposure, but does not mean that it is current. Determination of serum estradiol is the simplest test, but diurnal and cyclic variations must be considered. Determination of hormonal effects on vaginal cytology is the most indicative of overall estrogen exposure (see Fig. 16.28), but less well accepted by patients. A progestin challenge test is often helpful. A female who does not experience progestin withdrawal bleeding (see Fig. 16.44) probably has an ambient estradiol level of less than about 40 pg/mL.¹⁰⁰⁵ If bleeding does not occur in response to this maneuver, the integrity of the uterus can be demonstrated by eliciting withdrawal bleeding after a 3-week course of estrogen-progestin, most conveniently administered in the form of birth control pills.

A prolactin level is indicated in the initial workup of normogonadotropic patients, regardless of their estrogen status (Fig. 16.45). The prolactin level correlates with the size of prolactinomas, and a level over 200 ng/mL is typical of a macroprolactinoma. A prolactin level that does not correlate with the size of a large pituitary tumor suggests either that the tumor is not a prolactinoma and is causing a functional pituitary stalk section or it is a macroprolactinoma elaborating such high levels of prolactin as to artefactually lower the immunoassayable prolactin level by a “hook effect.”¹⁰⁰⁶ Very high blood or cerebrospinal fluid prolactin levels suggest invasiveness. The workup for this should include formal testing of visual fields (Goldman perimetry or evoked response). Pituitary microadenomas may be “incidentalomas” of no clinical significance, judging from an approximate 10% incidence in autopsy material.¹⁰⁰⁷ However, they require careful assessment of pituitary function and follow-up.¹⁰⁰⁸ Macroprolactinemia should be considered in the absence of clearly related symptoms and when MRI is negative or in the setting of autoimmune disease.^{988,989} Macroprolactinemia is confirmed when the prolactin level measured after precipitation of serum using polyethylene glycol is normal (or substantially reduced compared with the level measured in untreated serum).

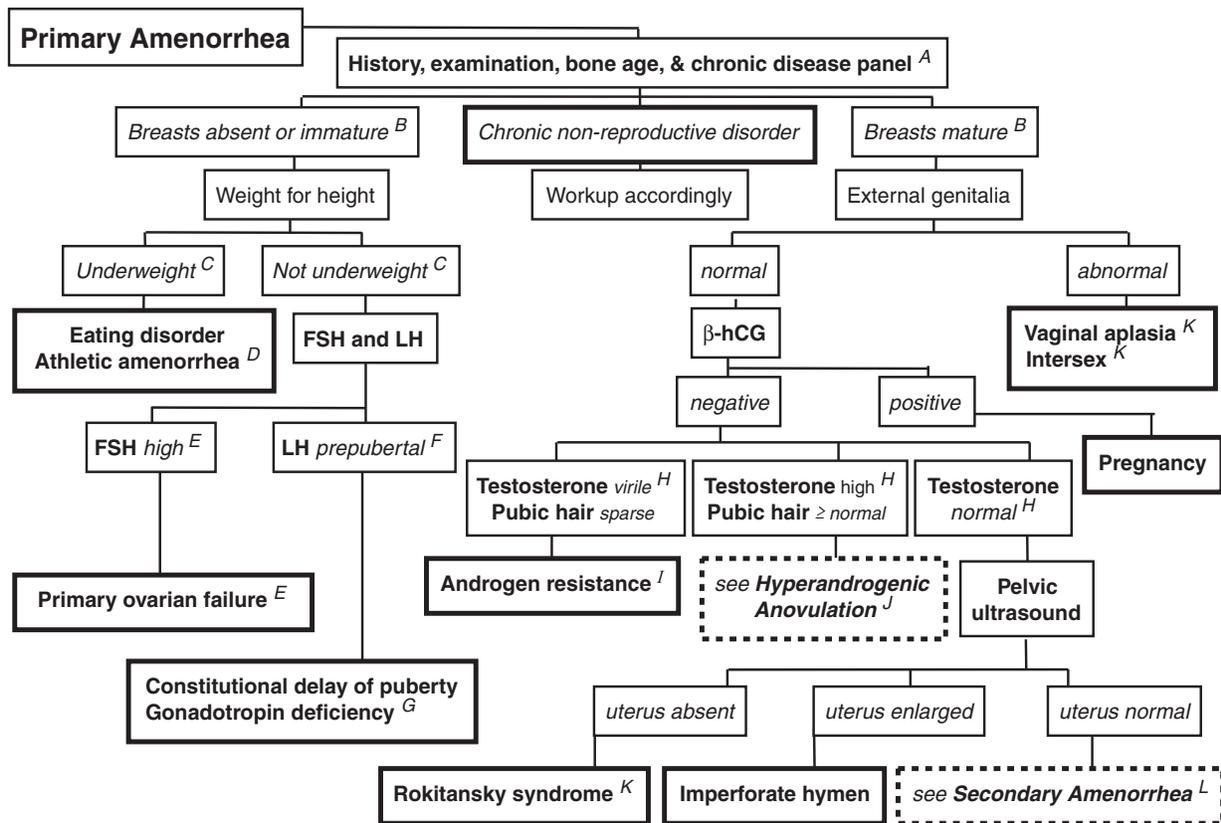

Fig. 16.43 Differential diagnosis of primary amenorrhea. (Modified from Rosenfield, R.L. (2003). Menstrual disorders and hyperandrogenism in adolescence. In: Radovick, S., MacGillivray, M.H. eds. Pediatric Endocrinology a Practical Clinical Guide. Totowa, N. J., Humana Press, Inc., p. 451–478. With permission.)

Footnotes:

- A. Prime among the causes of primary amenorrhea are growth-retarding or growth-attenuating disorders. In the absence of specific symptoms or signs to direct the workup, laboratory assessment for chronic disease typically includes bone age radiograph if the adolescent is not sexually mature and a chronic disease panel (complete blood count and differential, sedimentation rate, comprehensive metabolic panel, celiac panel, thyroid panel, cortisol and insulin-like growth factor-I levels, and urinalysis).
 - B. Breast development ordinarily signifies the onset of pubertal feminization. However, mature breast development does not ensure ongoing pubertal estrogen secretion.
 - C. Body mass index (BMI) under the 10th percentile generally corresponds to body composition <20% body fat, which is the critical factor.
 - D. BMI may not accurately reflect body fat in serious athletes (who have a disproportionately greater muscle mass) or bulimia nervosa.
 - E. Follicle-stimulating hormone (FSH) is preferentially elevated over luteinizing hormone (LH) in primary ovarian failure. The most common cause of primary amenorrhea caused by primary ovarian failure is gonadal dysgenesis caused by Turner syndrome, but acquired causes must be considered (such as cytotoxic therapy). The workup of primary ovarian failure is considered in detail in the next algorithm (secondary amenorrhea and oligomenorrhea). Lack of FSH elevation virtually rules out primary ovarian failure only when the bone age is appropriate for puberty (≥ 11 years).
 - F. “Pediatric” gonadotropin assays sensitive to 0.15 U/L or lower are critical to the accurate diagnosis of gonadotropin deficiency and delayed puberty. A low LH level is more characteristic of these disorders than a low FSH level. Congenital gonadotropin deficiency is closely mimicked by the more common extreme variation of normal, constitutional delay of puberty.
 - G. History and examination may yield clues to the cause of hypogonadotropic hypogonadism, such as evidence of hypopituitarism (midline facial defect, extreme short stature, visual field defect) or anosmia (Kallmann syndrome) or functional hypothalamic disturbance (bulimia, excessive exercise). Random LH levels in hypogonadotropic patients are usually below 0.15 IU/L, but often overlap those of normal pre- and midpubertal children. The gonadotropin-releasing hormone (GnRH) test, measuring the gonadotropin response to a 50- to 100-mcg bolus, in the premenarcheal teenager strongly suggests gonadotropin deficiency if the LH peak is less than 4.2 IU/L by monoclonal assay. Inhibin-B under 20 pg/mL or responses to GnRH agonist testing (e.g., leuprolide acetate injection 10 mcg/kg SC) are reported to discriminate well between gonadotropin deficiency and constitutional delay (see text). It may not be possible to definitively establish the diagnosis of gonadotropin deficiency until puberty fails to begin by 16 years of age or progress at a normal tempo.
 - H. Plasma total testosterone is normally 20 to 60 ng/dL (0.7–2.1 nM) in women, 300 to 1200 ng/dL in men, but varies somewhat among laboratories. Plasma free (or bioavailable) testosterone is about 50% more sensitive than total testosterone in detecting hyperandrogenemia. However, there are many pitfalls in testosterone assays at the low levels of women, reliable testosterone assays are not available to many physicians, and assaying the free testosterone introduces other potential sources of error. Therefore it is reasonable to begin the evaluation with a total testosterone determination if a free testosterone test in a reliable specialty laboratory is not available to the practitioner.
 - I. Androgen resistance is characterized by a frankly male plasma testosterone level when sexual maturation is complete, male karyotype (46, XY), and absent uterus. External genitalia may be ambiguous (partial form) or normal female (complete form).
 - J. The differential diagnosis of hyperandrogenism is shown in a later algorithm.
 - K. Vaginal aplasia in a girl with normal ovaries may be associated with uterine aplasia (Rokitansky-Kustner-Hauser syndrome). When the vagina is blind and the uterus aplastic, this disorder must be distinguished from androgen resistance. If the external genitalia are ambiguous, it must be distinguished from other disorders of sex development (intersex).
 - L. Secondary amenorrhea differential diagnosis is presented in Fig. 16.43.
- hCG*, Human chorionic gonadotropin.

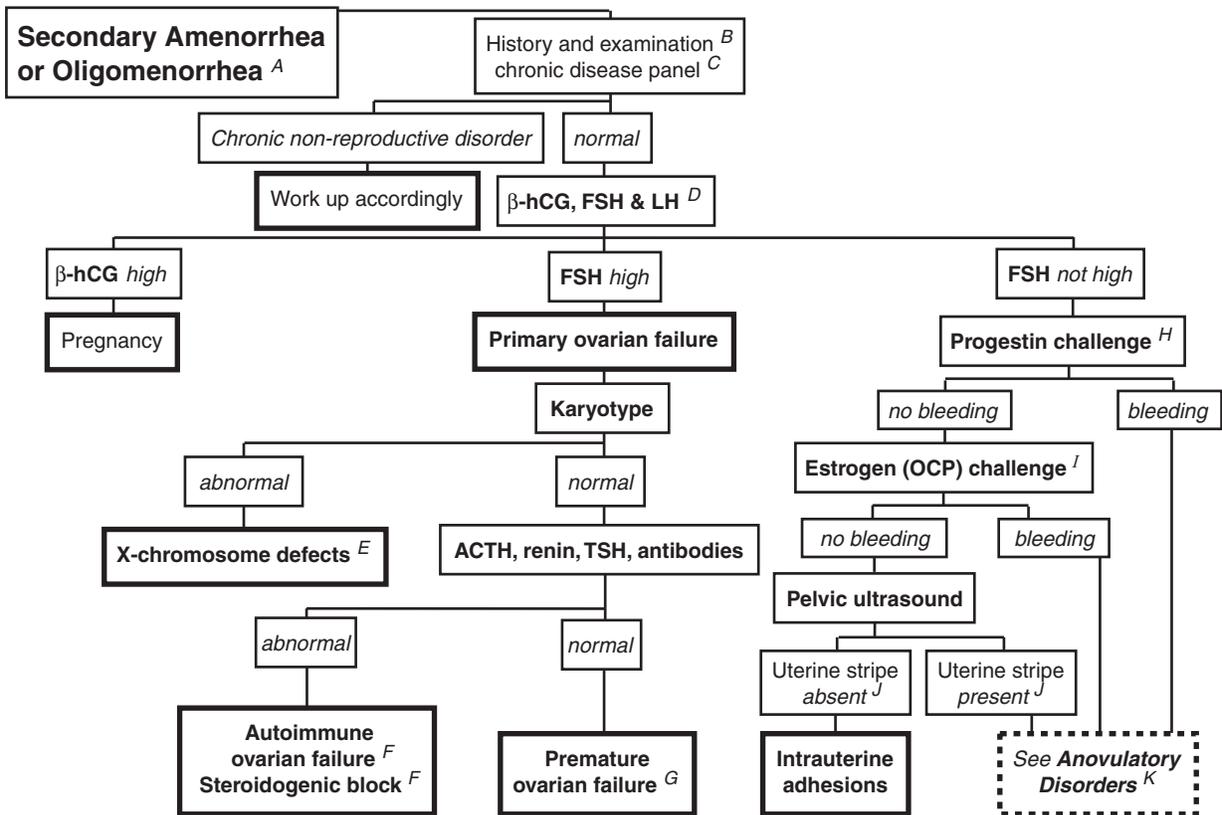

Fig. 16.44 Differential diagnosis of secondary amenorrhea or oligomenorrhea. (Modified from Rosenfield, R.L. (2003). Menstrual disorders and hyperandrogenism in adolescence. In: Radovick, S., MacGillivray, M.H. eds. Pediatric Endocrinology a Practical Clinical Guide. Totowa, N. J., Humana Press, Inc., p. 451–478. With permission.)

Footnotes:

- A. Mature secondary sex characteristics are characteristic because the occurrence of menarche indicates that a substantial degree of development of the reproductive system has taken place; however, their presence does not rule out subsequent regression of gonadal function.
 - B. Diverse disorders of many systems cause anovulation. The history may reveal excessive exercise, symptoms of depression, gastrointestinal symptoms, radiotherapy to the brain or pelvis, or rapid virilization. Physical findings may include hypertension (forms of congenital adrenal hyperplasia, chronic renal failure), short stature (hypopituitarism, Turner syndrome, pseudohypoparathyroidism), abnormal weight for height (anorexia nervosa, obesity), decreased sense of smell (Kallmann syndrome), optic disc or visual field abnormality (pituitary tumor), cutaneous abnormalities (neurofibromatosis, lupus), goiter, galactorrhea, hirsutism, or abdominal mass.
 - C. In the absence of specific symptoms or signs to direct the workup, evaluation for chronic disease in a sexually mature adolescent typically includes complete blood count and differential, sedimentation rate, comprehensive metabolic panel, celiac panel, thyroid panel, cortisol and insulin-like growth factor-I levels, and urinalysis.
 - D. “Pediatric” gonadotropin assays sensitive to 0.15 U/L or lower are critical to the early diagnosis of many anovulatory disorders. Luteinizing hormone (LH) enters into the differential diagnosis of hypogonadotropic anovulatory disorders, which is outlined in Fig. 16.45.
 - E. Patients missing only a small portion of an X-chromosome may not have the Turner syndrome phenotype. Indeed, among 45,X patients the classic Turner syndrome phenotype is found in less than one-third (with the exception of short stature in 99%). Ovarian function is sufficient for about 10% to undergo some spontaneous pubertal development and for 5% to experience menarche. If chromosomal studies are normal and there is no obvious explanation for the hypogonadism, special studies for fragile X premutation and autoimmune oophoritis should be considered.
 - F. Autoimmune ovarian failure may be associated with tissue-specific antibodies and autoimmune endocrinopathies, such as chronic autoimmune thyroiditis, diabetes, adrenal insufficiency, and hypoparathyroidism. Nonendocrine autoimmune disorders may occur, such as mucocutaneous candidiasis, celiac disease, and chronic hepatitis. Rare gene mutations causing ovarian insufficiency include steroidogenic defects that affect mineralocorticoid status (17-hydroxylase deficiency is associated with mineralocorticoid excess and lipid adrenal hyperplasia with mineralocorticoid deficiency) and mutations of the gonadotropins or their receptors. Ovarian biopsy is of no prognostic or therapeutic significance. LH is disproportionately high in steroidogenic defects or autoimmune disease specifically affecting theca cells.
 - G. The history may provide a diagnosis (e.g., cancer chemotherapy or radiotherapy). Other acquired causes include surgery and autoimmunity. Chromosomal causes of premature ovarian failure include X-chromosome fragile site and point mutations. Other genetic causes include gonadotropin-resistance syndromes, such as LH or follicle-stimulating hormone (FSH) receptor mutation and pseudohypoparathyroidism. A pelvic ultrasound that shows preservation of ovarian follicles carries some hope for fertility.
 - H. Withdrawal bleeding in response to a 5- to 10-day course of progestin (e.g., medroxyprogesterone acetate 10 mg HS) suggests an overall estradiol level greater than 40 pg/mL. However, this is not entirely reliable and thus in the interest of making a timely diagnosis it is often worthwhile to proceed to further studies.
 - I. A single cycle of an oral contraceptive pill (OCP) containing 30 to 35 mcg ethinyl estradiol generally suffices to induce withdrawal bleeding if the endometrial lining is intact.
 - J. A thin uterine stripe suggests hypoestrogenism. A thick one suggests endometrial hyperplasia, as may occur in polycystic ovary syndrome.
 - K. The differential diagnosis of other anovulatory disorders continues in Fig. 16.45.
- ACTH, adrenocorticotropic hormone; hCG, Human chorionic gonadotropin; TSH, thyroid-stimulating hormone.

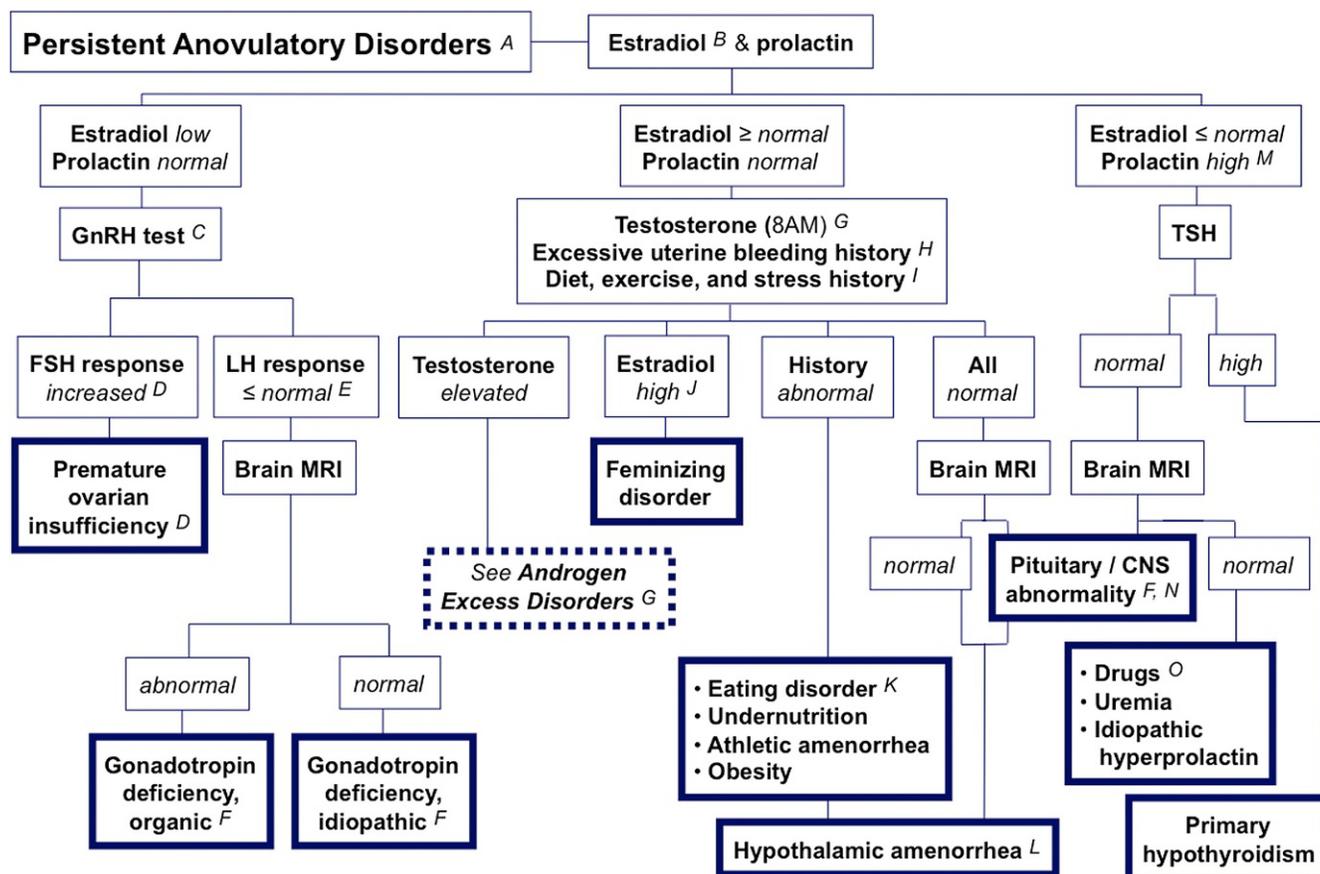

Fig. 16.45 Differential diagnosis of persistent anovulatory disorders. (Modified from Rosenfield, R.L. (2003). Menstrual disorders and hyperandrogenism in adolescence. In: Radovick, S., MacGillivray, M.H. eds. Pediatric Endocrinology a Practical Clinical Guide. Totowa, N. J., Humana Press, Inc., p. 451–478. With permission.)

Footnotes:

- Anovulatory disorders should be considered in any girl with persistent unexplained amenorrhea or oligomenorrhea, irregular menstrual bleeding, short cycles, or excessive menstrual bleeding. Physiological adolescent anovulation, a transient variation of normal, is the most common cause of menstrual dysfunction in the early postmenarcheal years. The workup in this algorithm progresses from negative studies in the preceding algorithm.
- Once breast development has matured, the breast contour does not substantially regress if hypoestrogenism develops. Hypoestrogenism is suggested if plasma estradiol is persistently under 40 pg/mL in a “pediatric” assay sensitive to less than 10 pg/mL. However, a single estradiol level may be misleading because of cyclic or episodic variations.
- Gonadotropin-releasing hormone (GnRH) testing is usually performed by assaying luteinizing hormone (LH) and follicle-stimulating hormone (FSH) before and 0.5 hour after the administration of 1 mcg/kg GnRH intravenously. GnRH agonist testing may alternatively be performed by administering 10 mcg/kg leuprolide acetate subcutaneously and assaying LH and FSH at 3 to 4 hours to assess gonadotropin reserve and at 18 to 24 hours to assess the ovarian steroid response to endogenous gonadotropin release.
- Baseline gonadotropin levels may be normal as the ovary begins to fail, as in early menopause, but an exaggerated FSH response to GnRH and subnormal estradiol response to the gonadotropin elevation induced by acute GnRH agonist challenge are characteristic. See also Premature Ovarian Failure in preceding figure.
- LH responses to GnRH may vary from nil to normal in gonadotropin deficiency: normal LH and FSH responses in the presence of hypoestrogenism indicate inadequate compensatory hypothalamic GnRH secretion.
- Gonadotropin deficiency may be congenital or acquired, organic or functional. Congenital causes include midline brain malformations or specific genetic disorders, such as Prader-Willi syndrome, Laurence-Moon-Biedl syndrome, or Kallmann syndrome. Kallmann, the association of anosmia with gonadotropin deficiency, occurs in both the X-linked and autosomal-recessive forms. Special magnetic resonance imaging (MRI) views often demonstrate absence of the olfactory tracts. Acquired gonadotropin deficiency may be secondary to a variety of organic central nervous system (CNS) disorders, varying from hypothalamic-pituitary tumor to radiation damage to empty sella syndrome. Autoimmune hypophysitis is a rare disorder, sometimes accompanying a polyendocrine deficiency syndrome. The prototypic form of functional gonadotropin deficiency is anorexia nervosa. Idiopathic hypogonadotropic deficiency may sometimes occur in families with anosmia, suggesting a relationship to Kallmann syndrome.
- Plasma free (or bioavailable) testosterone is about 50% more sensitive than total testosterone in detecting hyperandrogenemia. However, there are many pitfalls in testosterone assays at the low levels of women, reliable testosterone assays are not available to many physicians, and assaying the free testosterone introduces other potential sources of error. Therefore it is reasonable to begin the evaluation with a total testosterone determination if a free testosterone test in a reliable specialty laboratory is not available to the practitioner. Simultaneous assay of 17-hydroxyprogesterone is indicated in subjects at high-risk for congenital adrenal hyperplasia, such as Ashkenazi Jews. Initial assessment for differentiating among the causes of androgen excess is outlined in Fig. 16.49.
- Excessive (“dysfunctional”) uterine bleeding not controlled by progestin or oral contraceptive pill therapy additionally requires a pelvic ultrasound examination (for genital tract tumor or feminizing tumor), coagulation workup (which includes platelet count, prothrombin time, thromboplastin generation test, bleeding time, and von Willebrand factor), and consideration of the possibility of sexual abuse.

(Legend continuous on next page)

- I. The equivalent of 20 miles per week or more is generally required before body fat stores fall to the point where amenorrhea occurs. Physical or psychosocial stress may cause amenorrhea.
- J. The normal range for estradiol over the menstrual cycle is wide: values over 95 pg/mL usually indicate the preovulatory or luteal phase, but are compatible with a feminizing disorder.
- K. Low body fat caused by mild forms of stress disorders (anorexia nervosa, bulimia nervosa, and athletic amenorrhea) may be associated with acquired functional hypothalamic amenorrhea rather than frank gonadotropin deficiency. The low body fat content of athletic amenorrhea may not be reflected by weight for height because of high muscularity. Dual-photon absorptiometry scan may be useful in documenting body fat below 20%. Patients with anorexia nervosa may become amenorrheic before or when weight loss begins, indicating an important psychological component to the etiology. Obesity is also associated with anovulatory cycles and raises the possibility of Cushing syndrome.
- L. Hypothalamic amenorrhea is a diagnosis of exclusion. It is a form of partial gonadotropin deficiency in which baseline estrogen secretion is normal but a preovulatory LH surge cannot be generated. It may result from organic CNS disorders or be functional, caused by stress, undernutrition or obesity, diverse types of endocrine dysfunction, chronic disease, or idiopathic. It may be difficult to distinguish from hyperandrogenemia.
- M. Hyperprolactinemia is heterogeneous in its presentation. Some have normoestrogenic anovulation, which may be manifest as hypothalamic anovulation, hyperandrogenism, dysfunctional uterine bleeding, or short luteal phase. On the other hand, some are hypoestrogenic; these do not have galactorrhea.
- N. Large hypothalamic-pituitary tumors or other types of CNS injury cause variable pituitary dysfunction, which may include complete or partial gonadotropin deficiency and various manifestations of hypopituitarism (including secondary hypothyroidism). If they interrupt the pituitary stalk, hyperprolactinemia ensues. Hyperprolactinemia may also be caused by prolactinomas.
- O. Drugs, particularly neuroleptics of the phenothiazone or tricyclic type, may induce hyperprolactinemia.

Imaging studies are important ancillary measures. Pelvic ultrasound may demonstrate hypoplastic ovaries, endometrial disorders, or polycystic ovaries. MRI of the hypothalamic-pituitary area is important in the workup of gonadotropin deficiency, hyperprolactinemia, and hypothalamic anovulation. MRI may not be necessary if the patient presents with a history suggesting functional hypothalamic amenorrhea but is indicated in those cases with associated symptoms of headache, vomiting, vision change, alteration in thirst or urinary frequency, an abnormal neurological examination, or evidence of other pituitary hormonal abnormalities.⁹⁹⁶

Anorexic patients require psychiatric evaluation and consideration of brain tumor and partial bowel obstruction. Diet fadism and athletic addiction may be difficult to distinguish from anorexia nervosa. Constitutionally thinness is a variant of normal with normal menses and a distinctive hormonal profile.¹⁰⁰⁹ It is unclear whether the superior mesenteric artery syndrome is a primary disorder that mimics anorexia nervosa or is a complication of it.¹⁰¹⁰

Management

Underlying disorders must be treated appropriately. For example, tumors require surgery and/or radiotherapy.

For prolactinoma, dopaminergic treatment is the initial treatment of choice unless the patients' condition or eyesight is critical.^{991,1011} Hyperprolactinemia will be maximally suppressed within 1 month and the menstrual cycle normalized within 3 months by an effective dopaminergic agonist regimen. Cabergoline 0.5 to 1.0 mg once or twice weekly will usually control galactorrhea and shrink prolactinomas.^{987,1012} To minimize nausea, it is best to start with a low dose at bedtime. Bromocriptine does not activate the serotonin 5-hydroxytryptamine (2B) receptor, the proposed mechanism through which cabergoline is thought to stimulate cardiac valve dysfunction in the elderly, and so bromocriptine does not seem to be associated with an increased risk of cardiac valve regurgitation, and may be considered as an alternative to cabergoline treatment, albeit a less effective one. The usual bromocriptine maintenance dose is 0.25 to 0.5 mg twice daily. After 2 years of treatment, if the prolactin level is normal and there is no tumor evident on MRI, dopamine agonist may be tapered and possibly discontinued. Prolactin levels are then measured to monitor for recurrence.¹⁰¹³

Anorexia nervosa is best managed by an experienced multidisciplinary team. Refeeding is the first priority, and once steady weight gain is evident the psychodynamic issues can be addressed.¹⁰¹⁴ Family therapy of medically uncomplicated cases of anorexia nervosa on an outpatient basis generally yields the best results, with good improvement in over half of patients. Inpatient care is needed if there is severe bradycardia, hypotension or orthostasis, or electrolyte imbalance,⁹⁹⁶ and may be needed if there is failure of weight gain during outpatient therapy. Menses generally resume when psychotherapy is effective and body fat is restored to normal (see Fig. 16.42). The induction of menses by estrogen-progestin replacement is usually injudicious because it provides a false sense of recovery and does not yield the recovery of bone loss that occurs with weight gain.¹⁰¹⁵ However, in those adolescents with low bone density who have not had return of menses after a reasonable trial of nutritional and psychological intervention (perhaps 6–12 months), short-term treatment with transdermal estradiol and cyclic oral progestin (not oral contraceptives or ethinyl estradiol) can be considered to protect the patient's bone health.⁹⁹⁶ Although the acute episode can usually be successfully treated, there is a high rate of ongoing psychiatric disability and medical complications. Anorexia nervosa "by proxy" has been described in the offspring of former patients.¹⁰¹⁶

There are two aspects of therapy that are uniformly involved in managing hypogonadism—psychological support and hormone administration. Patients with delayed development that is a variation of normal should be reassured that there is nothing wrong, only a delay in timing of the onset of puberty. The wide normal variation in the pattern and time of the pubertal growth spurt should be explained in detail and the girl should be informed of her predicted eventual height. The majority of children with delayed puberty do not have overt psychological symptoms. Complex compensations and sublimations obviously occur. However, peer group pressures may make adjustment to sexual infantilism especially difficult when the age of 13 years is approached,¹⁰¹⁷ and a poor self-image may lead to social withdrawal and feelings of hopelessness. Physical immaturity may prolong psychological immaturity. A 6- to 12-month course of physiological sex hormone therapy at this time may help alleviate these anxieties. The physician should discuss the fact, when the evidence favors it, that the odds are overwhelmingly in favor of the "timer in the subconscious area of the brain" eventually turning on. When this will happen can be approximated from the skeletal age. One should not

hesitate to advise more intensive psychological counseling if it becomes apparent that the concern about puberty is but one aspect of a more general maladjustment. Ultimately, the decision as to whether to undertake treatment for delayed puberty is up to the patient and her family.

Assure the teenager with an organic basis for hypoestrogenism that feminization will occur, although in response to appropriate hormone treatment. Some genetic forms of gonadotropin deficiency are actually reversed by sex steroid therapy.²³⁵ However, most will require lifelong hormone replacement therapy. It should be kept in mind that attainment of normal breast development in the girl with panhypopituitarism requires replacement of GH and cortisol deficits. It is difficult however to induce secondary sex characteristics in some patients with systemic chronic inflammatory disease, such as lupus erythematosus.

In patients in whom short stature is an important concern, as in Turner syndrome, growth potential must be considered before undertaking estrogen replacement. GH therapy improves the adult height potential of patients with Turner syndrome, especially when started as soon as growth failure becomes apparent.¹⁰¹⁸ GH therapy in the United States is generally initiated at the US Food and Drug Administration (FDA)-approved dose of 0.375 mg/kg·wk. If adult height is likely to be unsatisfactory, concomitant treatment with oxandrolone 0.03–0.05 mg/kg/day should be considered.⁵⁷¹ Clitoromegaly is ordinarily negligible on this dosage; liver function should be monitored.

Two controlled studies have shown that pubertal estrogen replacement therapy is safe and efficacious in maximizing growth potential and age-appropriate feminization when started as young as 11 to 12 years of age using very low estrogen doses, far below those that are available by prescription, in conjunction with GH therapy in Turner syndrome.^{1020,1021} The estrogen content of oral contraceptive pills (OCPs) is supraphysiological for induction of breast development or for linear growth.

We favor use of one of the following hormone replacement regimens.^{571,1022} Whichever form of estrogen is used, pubertal development and growth should be monitored every 6 months, with bone age determinations at 6- to 12-month intervals to avoid unanticipated loss of growth potential.

IM depot estradiol in a starting dose of 0.2 mg/month will usually induce breast budding; the dose should be increased by 0.2 mg every 6 months.¹⁰²⁰ A midpubertal dose of 1.0 to 1.5 mg monthly, which is half the adult replacement dose, typically induces menarche within 1 year. An alternative oral regimen begins with 5 mcg/kg micronized estradiol (Estrace[®], 0.25 mg for a 50 kg girl) daily; the adult replacement dose is 1 to 2 mg/day.¹⁰²³

Transdermal estradiol is a convenient, physiological form of therapy¹⁰²⁴ that appears to have long-term health advantages over commonly used oral estrogens,^{1025,1026} but there are little data on their use for inducing puberty. We suggest starting transdermal feminization with 14 mcg daily for 1 week per month, a marginally feminizing dose that is in accord with current guidelines,^{571,1018} and escalating at 6-month intervals to an adult dose at 3 years. A suggested protocol for female pubertal induction for hypogonadal patients is provided in Table 16.7.¹⁰²³

For girls with hypogonadism and an intact uterus, cyclic progestin should be added after 2 years of estrogen therapy or when bleeding begins to occur at unpredictable times. A simple regimen is to use 100 mg of micronized progesterone (Prometrium[®]) at bedtime for 7 to 14 days during the second to third week of estrogen therapy or equivalent doses of medroxyprogesterone acetate (5–10 mg/day) or norethindrone acetate (5 mg/day). This will bring about normal menstruation during

TABLE 16.7 A Pubertal Transdermal Estradiol Replacement Regimen Beginning at 11 Years of Age^a

Age	Estradiol Dose
0–6 months	14 mcg, day 1–7 each month
6–12 months	14 mcg, day 1–14 each month
1–1.5 years	14 mcg, day 1–21 each month
1.5–2 years	25 mcg, day 1–21 each month
2–2.5 years	37.5 mcg, day 1–21 each month
2.5–3 years	28-day cycle: 50 mcg day 1–21 and Prometrium [®] 100 mg ^b day 12–21 every 28 days
	OR
	Continuous: 50 mcg day 1–14, then Combipatch [®] (50 mcg estradiol/0.14 mg norethindrone) day 16–28 every 28 days
3–3.5 years	28-day cycle: 75 mcg day 1–21 and Prometrium [®] 100 mg day 12–21 every 28 days
	OR
	Continuous: 75 mcg day 1–14 then Combipatch [®] (50 mcg estradiol/norethindrone) day 16–28 every 28 days
3.5–4 years	28-day cycle: 100 mcg day 1–21 and Prometrium [®] 100mg day 12–21 every 28 days
	OR
	100 mcg day 1–14 then Combipatch [®] (50 mcg estradiol/norethindrone) day 16–28 every 28 days
>4.0 years	Continue regimen or offer oral contraceptive pill

^aIn children ≥ 13 years old, consider starting with 25 mcg for 2–3 weeks monthly and increasing the dose at shorter intervals (e.g., 3 months).

^bIf inadequate bleeding, increase Prometrium to 200 mg day 12–21 or change to Combipatch 50 mcg estradiol/0.25mg norethindrone. (Modified from Klein, K.O., Rosenfield, R.L., Santen, R.J., et al. (2018). Estrogen replacement in Turner syndrome: literature review and practical considerations. *J Clin Endocrinol Metab*, 103, 1790–1803.)

the week preceding resumption of estrogen therapy. The addition of progestin will decrease the risk of endometrial hyperplasia and endometrial carcinoma, but premenstrual symptoms should be anticipated.

Once optimal height is achieved, most patients prefer to switch to combined oral contraceptive pills (OCP) as a convenient form of estrogen-progestin therapy. The pills containing the lowest dose of estrogen that will result in normal menstrual cycles are advisable. The potential risks of oral contraceptives must be kept in mind when counseling adolescents.¹⁰²⁷ The lowest estrogen dosages currently available in combination contraceptive pills in the United States contain 20 mcg (Mircette[®]) to 30 mcg (Yasmin[®]) ethinyl estradiol. Low-dose androgen replacement has been controversial, but may confer benefits to body composition, cognition, bone mineralization, and libido.¹⁰²⁸

Hypogonadotropic patients can achieve ovulation with gonadotropin therapy. Hypothalamic GnRH deficiency can be successfully treated by pulsatile GnRH.^{91,1029} Recently, kisspeptin has been considered as a therapeutic modality for the treatment of CHH; however, its short half-life has hampered efforts. Hence kisspeptin analogs were designed to decrease proteolytic degradation and renal clearance. These analogs induced direct excitatory action on GnRH neurons, advanced puberty, and synchronized ovulations in sheep. The potential for treatment of reproductive disorders in humans remains undefined.¹⁰³⁰ Because several genes in the GnRH signaling system are expressed in the gonads, some hypogonadotropic patients have primary defects in gonadal function.^{931,1031} Induction of ovulation is best carried out by a gynecologist specializing in reproductive endocrinology.

Fertility preservation is possible in some patients with primary ovarian failure. Oocyte cryopreservation for later in vitro

fertilization is feasible in pubertal girls after ovulation induction.^{887,890,909,1032} The girls must be pubertal for successful ovulation induction. In addition, cryopreservation of embryos requires sperm, likely limiting the appropriateness of this in pediatric patients. Cryopreservation of ovarian tissue^{922,1033} is a promising technique that may be useful for fertility preservation in prepubertal girls with ovarian failure, although this is currently an investigational approach. Finally, activation of residual follicle growth in autografts has recently been accomplished in adults with POI, with successful pregnancy after embryo transfer.¹⁰³⁴ Female germline stem cell research holds promise as a future fertility treatment.¹⁰³⁵ Up-to-date information for physicians and patients can be found through the Oncofertility Consortium (www.myoncofertility.org).

In girls with Turner syndrome, fertility preservation using either oocyte or embryo cryopreservation are currently only of use in those who have undergone spontaneous puberty. These girls should be counseled about these possibilities for fertility preservation.¹⁰³⁶ In these girls, monitoring AMH levels may be useful as a marker of ovarian function.¹⁰³⁷ On the other hand, primordial follicles have been found in ovarian tissue collected for cryopreservation from girls with mosaic or nonmosaic Turner syndrome, although the likelihood of finding follicles was much lower in those with a 45,X karyotype (10.7%) than in those with 46,XX/45,X mosaicism (86%).¹⁰³⁷ As noted earlier, however, ovarian cryopreservation remains an investigational procedure. In the rare spontaneous pregnancies that have occurred in women with Turner syndrome, the rate of congenital and chromosomal abnormalities in the fetus is approximately 50%,¹⁰³⁷ which must be considered when using autologous oocytes from any approach. Finally, women with Turner syndrome are at high risk of fetal and maternal pregnancy complications because of uterine anomalies, carbohydrate intolerance, and potential cardiovascular complications including aortic rupture. (For discussion of other aspects in the care of girls with Turner syndrome see [Chapter 17](#).)

Nonhypoestrogenic Menstrual Disturbances

Hypothalamic Anovulation

Hypothalamic anovulation causes menstrual disturbances in sexually mature women through a deficiency in GnRH secretion that is too subtle to cause frank hypoestrogenism. The neuroendocrine system stimulates ovarian estrogen secretion to a level normal for an early- or midfollicular phase female, but follicular development is inadequate for a normal dominant follicle to emerge. Amenorrhea or oligomenorrhea may result. However, in some patients, sufficient estrogenization occurs to cause dysfunctional uterine bleeding, which is discussed in the next section.

Reduced LH pulsatility¹⁰³⁸ and/or failure to generate a mid-cycle LH surge^{1039,1040} are characteristic. The pathophysiology seems to be mediated primarily by undernutrition and/or CRH excess. Negative energy balance may be present even in patients of normal, but less than average, weight and fat stores.^{497,981} Leptin deficiency is an important determinant of the decreased LH pulsatility. Ghrelin may play a role in LH inhibition.¹⁰⁴¹ The anovulation of psychic or physical stress seems to involve CRH excess.⁹⁸² In the brain, CRH releases β -endorphin from proopiomelanocortin, and the endorphin in turn inhibits GnRH release. Naloxone blockade of opioid action normalizes gonadotropin secretion.⁹¹ In the pituitary, CRH increases the set-point for ACTH release. This brings about a new steady state of increased cortisol secretion. Further ACTH response to CRH is blunted by the negative feedback of this cortisol excess. The result is a mildly cushingoid cortisol rhythm. Cortisol excess itself can contribute to the amenorrhea by inhibiting the

response to GnRH,¹⁰³³ as well as antagonizing some sex hormone actions. Adrenal androgens are elevated in competitive athletes who maintain body fat stores.¹⁰⁴²

Causes. Functional hypothalamic amenorrhea (FHA) describes hypothalamic anovulation that is unexplained by an identifiable organic CNS cause or chronic disease.⁹⁹⁶ These patients have a normal or slightly low serum LH, normal FSH, and estradiol in the early-mid follicular phase range (20–50 pg/mL). It is caused by energy deficit (because of weight loss and/or vigorous exercise) or psychological stress or a combination thereof. As with patients with anorexia nervosa and the athletic or psychogenic types of hypothalamic anovulation, they often have significant hypercortisolemia. However, there are patients with FHA who cannot be identified as having one of these causes. Some 24% of such women in one series had a history of delayed menarche.⁷²⁰ A primate model indicates that hypothalamic anovulation develops in stress-sensitive individuals from an innocuous combination of mild stress and mild caloric restriction.¹⁰⁴³ Heterozygosity for genes associated with Kallmann syndrome has been identified as a predisposing factor in 13% of cases; more than half of this subgroup had a family history of hypothalamic amenorrhea or delayed puberty.⁷²⁰

Athletic amenorrhea is the term given to hypothalamic anovulation associated with excessive exercise and low body fat stores. Running 20 miles or more per week is associated with increased incidence of amenorrhea.¹⁰⁴⁴ The female athletic triad consists of menstrual disturbance, eating disorder, and osteoporosis.¹⁰⁴⁵ Primary or secondary amenorrhea, oligomenorrhea, or short luteal phase are common in athletes.¹⁰⁴⁶ Ovarian function decreases approximately in proportion to the amount of physical activity and dietary restriction. Weight-bearing exercise is only partially protective of the effects of hypoestrogenism on weight-bearing bone. There is concern that amenorrheic athletes may be left with a permanent deficit in bone mass.¹⁰⁴⁷ Weight loss to 10% below ideal body weight and body fat less than 12% are risk factors for amenorrhea. BMI does not accurately reflect body fat stores in athletes because of their muscularity.¹⁰⁴⁸ Energy balance seems to be more critical than low body fat stores in mediating the anovulation.^{1046,1049} Menarche may occur or menses resume when the athlete's activity level suddenly decreases and before weight gain occurs. Other factors also contribute to cause amenorrhea. Nutritional deficiencies may coexist. Chronic undernutrition may suppress thyroid function as in anorexia nervosa.⁹⁸² Athletic amenorrhea resembles anorexia nervosa in patients' obsession with weight control.^{1046,1050}

Psychogenic amenorrhea from severe psychic stress has long been known (e.g., "boarding-school amenorrhea").¹⁰⁵¹ The onset of psychogenic amenorrhea may be identified as being associated with a discrete event, but the ovarian dysfunction tends to be long-lasting. Subtle nutritional deficits contribute.⁴⁹⁷

Epilepsy causes menstrual disturbances that seem to result from abnormal neuroendocrine regulation independently of drug treatment.¹⁰⁵²

Pseudocyesis is an extremely rare form of psychogenic amenorrhea that is caused by persistence of the corpus luteum. This syndrome tends to occur in infertile women with an overwhelming desire for pregnancy and conversion hysteria. Prolactin and LH excess appear to mediate this rare syndrome.¹⁰⁵³

Differential Diagnosis. Disorders outside the neuroendocrine-gonadal axis may cause or mimic hypothalamic anovulation. These include pregnancy, nutritional disturbance, glucocorticoid excess, disturbed thyroid function, drug abuse, chronic illness, hyperprolactinemia, and ectopic gonadotropin secretion.

Pregnancy must be excluded in all sexually mature adolescents with amenorrhea. An elevation of the serum β -hCG level is the earliest laboratory sign.¹⁰⁵⁴ Placental hCG initially drives constant overproduction of estrogens and progestins by the maternal corpus luteum, then production of estrogen and other sex steroids shifts to the fetoplacental unit and suppresses maternal pituitary gonadotropin release.

Optimal fat mass is necessary for normal gonadotropin levels in sexually mature women, and both obesity and undernutrition suppress gonadotropins: thus the gonadotropin response to relative adipose mass seems biphasic.³⁰⁸ Obesity is associated with blunted LH pulse amplitude that is partially attributable to increased LH clearance rate. Overproduction of estrogen from plasma precursors in adipose tissue⁴⁵⁷ may play a role in suppressing LH pulsatility.¹⁰⁵⁵ The extent to which sleep disruption may contribute to LH suppression is unclear.¹⁰⁵⁶ The effect of undernutrition seems to be mediated by factors related to energy balance, as discussed in the section Hypothalamic Anovulation.

Cushing syndrome (glucocorticoid excess) of any etiology causes anovulation by inhibiting the gonadotropin response to GnRH.¹⁰³³ Thyroid hormone deficiency suppresses gonadotropin release via gonadotrophin-inhibitory hormone,¹⁰⁵⁷ and interferes with gonadotropin action on the ovary.¹⁰⁵⁸ Drug abuse with tetrahydrocannabinol, ethanol, or opiates causes hypothalamic anovulation.^{1059,1060} Cocaine causes menstrual irregularity by suppressing gonadotropin secretion through mechanisms that include depletion of dopaminergic stores, resulting in hyperprolactinemia, and stimulation of CRH release.^{992,1061} Inflammatory illness acutely disrupts the estradiol-induced LH surge,¹⁰⁶² and chronic illness causes gonadotropin deficiency, which may be mediated partly by undernutrition and partly by cytokines.^{193,965} Disorders as diverse as diabetes mellitus and iron overload all impact GnRH secretion.^{1063,1064} Chronic renal failure causes complex dysfunction of the reproductive system, including poor clearance of gonadotropins and prolactin in the presence of inhibition of gonadotropins by a nondialyzable factor.¹⁰⁶⁵

Hyperprolactinemia occasionally causes secondary amenorrhea without frank hypoestrogenism.¹⁰⁶⁶ This situation probably results from a mild diminution in FSH secretion that only inhibits the emergence of a dominant follicle and, therefore, ovulation.

Postpill amenorrhea has been a term applied to the amenorrhea that sometimes follows the long-term use of hormonal contraceptives. This in the past was attributed to oversuppression, but oversuppression should not be expected to be the case with the current generation of oral contraceptives.³³⁴ About one-third of patients with secondary amenorrhea after discontinuation of estrogen and progestin-containing pills have a history of previous menstrual disturbance and ongoing menstrual problems.¹⁰⁶⁷ Another third can expect spontaneous remission of the amenorrhea. About half of the remainder of cases will have resolution of their menstrual disturbance after induced pregnancy. The most common cause of postpill amenorrhea is probably hyperprolactinemia because over 20% of such cases have galactorrhea. How often this antedates ingestion of the contraceptive pill is unknown. Menses may be restored in normoprolactinemic cases by dopaminergic treatment, which suggests that in such cases there is excessive pituitary prolactin secretion that is too subtle to be detected by measurement of serum levels.¹⁰⁶⁸ The anovulation resulting from depot-medroxyprogesterone acetate contraception is related to the extremely slow rate of absorption and metabolism of this steroid; menses return when the blood levels of this progestin fall below the threshold for suppression of the LH surge,¹⁰⁶⁹ and only rarely has it been associated with disturbed prolactin secretion.¹⁰⁷⁰

Gonadotropin or hCG secretion by a tumor can cause normoestrogenic or hyperestrogenic anovulation.^{1071,1072} In one

LH-producing tumor, sex steroid levels were normal; the lack of virilization was attributed to ovarian desensitization to LH,¹⁰⁷¹ while in another, virilization occurred, which was attributed to preexisting polycystic ovary syndrome-hyperthecosis and extreme LH elevation.¹⁰⁷³ Other hyperestrogenic disorders that cause anovulatory bleeding are discussed under Precocious Puberty.

Hypothalamic anovulation is ordinarily a diagnosis of exclusion. The medical evaluation should be performed as discussed in the preceding section, with particular attention to the possibilities of emotional stressors, excessive exercise, the use of birth control pills or other drugs, and state of health. The physical examination should be particularly directed to the state of nutrition, the possibilities of intracranial or systemic disease, galactorrhea, thyroid dysfunction, glucocorticoid excess, hirsutism, and obesity. If this workup is negative, an MRI of the hypothalamic-pituitary area is indicated. Hypothalamic anovulation may be documented by demonstrating subnormal LH pulse frequency, but this is not generally practical. Leptin levels tend to be low but nondiagnostic.⁹⁸¹ The response to a GnRH agonist test is normal but seems to lack the normal priming response to repeat testing.¹⁰⁷⁴ Excessive uterine bleeding from hypothalamic anovulation must be distinguished from that caused by other causes (see next section).

Management. Many patients with hypothalamic anovulation will benefit from nutritional counseling. Diet faddists and athletes should be advised about the necessity of optimal body energy reserves for the maintenance of normal menstrual cycles (see Fig. 16.42). The teleological significance of this may be pointed out, namely, that inherent in the evolutionary process is the inhibition of pregnancy in times of inadequate food supplies. Ongoing psychological counseling is advisable for patients who cannot change their dietary or exercise patterns because of an abnormal body image. Estrogen replacement only partially corrects bone mineralization unless nutrition is optimized.^{996,1075} However, if spontaneous menses do not return after a 6- to 12-month trial of improved nutrition, modification of the patient's exercise regimen, and/or psychological counseling, short-term use of transdermal estradiol and cyclic oral progestins (not oral contraceptives or ethinyl estradiol) should be considered in those with low bone density to protect the patient's long-term bone health.⁹⁹⁶ Obese girls should be advised that there is a substantial possibility that reduction to a normal weight will result in restoration of menses and improved probability of fertility.

Mature teenagers whose amenorrhea is unexplained should be assured that they have a high likelihood of fertility with appropriate endocrinological treatment. However, such treatment is unlikely to be of any benefit to them until such time as they desire to become pregnant. Meanwhile, the main objective of therapy is to normalize the endometrial cycle by periodic progestin administration. For this purpose, progestin (micronized progesterone 100–200 mg orally at bedtime for 14 consecutive days) usually is effective in inducing withdrawal periods. During the first few years after menarche, it is reasonable to administer this treatment on alternate months to allow detection of late maturation of a regular menstrual cycle.

Induction of an ovulatory cycle has been reported to occasionally result in resumption of spontaneous normal menses.¹⁰⁶⁷ An ovulatory cycle can normally be induced by the administration of clomiphene citrate once nightly for five doses. If treatment is successful, menses generally occurs about 1 month from commencement of the treatment. One should start with the 50-mg dose because larger doses may cause hyperstimulation of the ovaries with the development of ovarian cysts. For this reason, one should perform an ultrasound examination to

rule out cystic ovaries before going successively to 100 to 150 mg dosage. This treatment is not generally recommended in the teenage years, however. Dopaminergic therapy has been reported to be successful in causing the resumption of ovulation in postpill amenorrhea, modest undernutrition, and other unexplained cases of secondary amenorrhea. Otherwise, induction of ovulation is best left to the endocrinological gynecologist to supervise at such time as the woman wishes to conceive. The vast majority of patients with no obvious cause for their secondary amenorrhea will become pregnant after appropriate treatment with estrogen, clomiphene, dopaminergic agonist, human menopausal gonadotropins, or pulsatile GnRH therapy.

Excessive Uterine Bleeding Caused by Ovulatory Dysfunction

Causes. Heavy uterine bleeding may be abnormally frequent, as indicated by intervals less than 21 days, excessively prolonged, as indicated by menstrual flow that lasts more than 7 days, or heavy, as indicated by soaking more than one pad or tampon every 2 hours, passing large clots, or experiencing a sensation of gushing (Box 16.2).⁷⁴¹ It is usually caused by bleeding from a hyperplastic endometrium.⁸⁸² It is a manifestation of ovulatory dysfunction,¹⁰⁷⁶ which may result in anovulatory or immature ovulatory cycles.^{735,736,738} This “dysfunctional uterine bleeding” (DUB) is most often a manifestation of physiological adolescent anovulation (Box 16.7). Hyperandrogenism, particularly polycystic ovary syndrome, and coagulopathy are the most common causes of severe anemia, which can be life-threatening. Less common causes are hypothalamic anovulation, estrogen-

producing cysts or tumors, hypothyroidism, hyperprolactinemia, and incipient premature ovarian failure. The workup should therefore include measurement of serum androgen, estradiol, prolactin, thyroid, gonadotropin levels and an evaluation for bleeding disorders.

Luteal Phase Defects

A minimum serum level of progesterone must be generated by the corpus luteum for the endometrium to sustain sufficient development to support implantation.^{1077,1078} A lesser level is a cause of “luteal insufficiency” as a cause of infertility. Luteal insufficiency may present as short cycles (<21 days) with frequent menstrual bleeding or as infertility with normal menstrual cycles in which the short luteal phase follows a prolonged follicular phase (see Fig. 16.35). It is normal during the early post-menarcheal years.⁷³⁸

A major determinant of normal corpus luteum formation and function is optimal development of the corpus luteum predecessor, the dominant follicle. Luteal insufficiency¹⁰⁷⁷ may arise from subtle deficiency of inhibin, LH or FSH during the follicular phase, an inadequate preovulatory LH surge, or corpus luteum unresponsiveness to LH.^{1077,1079,1080} These abnormalities all cause incomplete emergence of a dominant follicle and the subsequent formation of an inadequate corpus luteum. Luteal insufficiency is common during early postmenarcheal cycles,^{736,738} where it is considered to be caused by ovulatory immaturity (see Fig. 16.35) and may otherwise be the result of hyperprolactinemia,¹⁰⁸¹ obesity,¹⁰⁵⁵ hypothalamic amenorrhea, or hyperandrogenism.

Daily measurements indicate that the minimum peak serum progesterone level normally reached during the middle of the normal luteal phase ranges from 900 to 3000 ng/dL (28–95 nmol/L).^{1077,1082} Both cyclic and hourly variations in progesterone secretion make it difficult to document the minimally adequate level. Thus current clinical practice commonly defines evidence of ovulation as a progesterone level over 300 to 500 ng/dL (9–15 nmol/L),^{735,1083} approximately sufficient to raise the basal body temperature:¹⁸⁸ the lower of these cutoffs is about twice the normal maximum the day before ovulation,^{110,188} and the highest of these does not necessarily indicate a normal mature ovulatory cycle. However, a progesterone value greater than 165 ng/dL in an adolescent indicates that ovulation has occurred, although not necessarily a mature luteal phase.⁷³⁸

Differential Diagnosis. DUB must be distinguished from the other causes of abnormal genital bleeding listed in Box 16.7.^{882,1076,1084,1085} The possibility that it is pregnancy related must be considered and a pregnancy test performed. Sexual abuse is a prime consideration in recurrent vaginal bleeding. Genital tract or feminizing tumors characteristically cause bleeding that cannot be controlled with cyclic progestin or estrogen-progestin therapy. Abnormally heavy menstrual flow in adolescents is often idiopathic (“essential menorrhagia”); it is theorized to result from imbalance of vasodilating and vasoconstricting prostanoid action on the endometrium. However, pathological causes must be considered because bleeding disorders are present in about 20% of adolescents with menorrhagia requiring hospitalization and in 50% of those presenting at menarche. Patients requiring hospitalization for abnormal bleeding should have a platelet count, prothrombin time, partial thromboplastin time, bleeding time, and von Willebrand factor level performed.^{1084,1085} Transvaginal ultrasound, which is not often feasible in the virginal adolescent, is as reliable as hysteroscopy in determining whether or not the endometrial cavity is normal.

Failure of serum progesterone to rise over 500 ng/dL during the luteal phase is diagnostic of corpus luteum insufficiency with 71% accuracy.¹⁰⁷⁸ However, a higher progesterone level than this must be sustained to transform the endometrium sufficiently to support implantation.

BOX 16.7 Differential Diagnosis of Excessive Genital Bleeding in Adolescence

- Ovulatory dysfunction (“dysfunctional”) uterine bleeding
 - Physiological anovulation (perimenarcheal)
 - Hyperandrogenism
 - Polycystic ovary syndrome
 - Hyperestrogenism
 - Feminizing tumor
 - Hypothyroidism
 - Hypothalamic anovulation
 - Hyperprolactinemia
 - Chronic disease
 - Incipient premature ovarian failure
 - Luteal phase defects
- Pregnancy-related uterine bleeding
 - Threatened, missed, or incomplete abortion
 - Molar pregnancy
 - Ectopic pregnancy
- Uterine tumor, polyp, adenomyosis
- Coagulopathy
- Endometrial
 - Idiopathic (“essential menorrhagia”)
 - Intrauterine device
- Iatrogenic
 - Breakthrough bleeding (intrauterine device or contraceptive pills)
- Vaginal bleeding
 - Trauma
 - Tumor
 - Foreign body
 - Infection

(From Rosenfield, R.L., Barnes, R.B. (1993). Menstrual disorders in adolescence. *Endocrinol Metab Clin North Am*, 22, 491.)

Management. Nonsteroidal antiinflammatory agents may lessen DUB. An estrogen-progestin oral contraceptive with 35 mcg ethinyl estradiol is first-line treatment to stop dysfunctional bleeding that is acute or associated with anemia. For active bleeding, the dosage is advanced rapidly until bleeding stops, up to 4 times daily, and then sustained for 7 days. Treatment is then stopped for 5 days, and the patient warned that heavy withdrawal bleeding with cramps may occur. Therapy with a low-dose pill, given as for contraception, is then begun to prevent recurrence of dysfunctional bleeding and is continued for about 3 cycles. Hemoglobin should be monitored and supplemental iron prescribed.

Cyclic progestin can be used as an alternative to the OCP to prevent recurrent dysfunctional bleeding in a patient who is not sexually active. Micronized progesterone 100 to 200 mg/day for 1 week is given at 3- to 4-week intervals. After the third-month, therapy is stopped and the patient is observed for 1 to 2 months for spontaneous bleeding. If none occurs the progestin can be given every other month (e.g., medroxyprogesterone 5–10 mg) for 7 to 14 days to prevent recurrent dysfunctional bleeding. If in the progestin-free month a normal spontaneous menstrual period occurs, progestins are withheld in the subsequent month to determine if the patient has developed regular ovulatory cycles.

Hemodynamic instability due to severe and/or acute blood loss is an indication for hospitalization and treatment with an antifibrinolytic drug (e.g., aminocaproic acid 100 mg/kg or tranexamic acid 10 mg/kg) begun IV, and intravenous fluids and blood products as necessary. Premarin[®] can be administered in a dose of 25 mg intravenously every 3 to 4 hours for 3 to 4 doses. When medical management fails, a bleeding diathesis or uterine structural abnormality should be considered (see later). If heavy bleeding persists, in spite of hormonal and antifibrinolytic treatment, surgical intervention is indicated by a gynecologist.^{1084,1085}

Unexplained (“essential”) menorrhagia is treated much the same way as dysmenorrhea. OCP therapy will decrease menstrual blood loss by about 50% in these women. Antiprostaglandins, such as naproxen 500 mg twice a day, decrease blood loss nearly as effectively.

Perimenstrual Symptoms

Dysmenorrhea. Uterine cramping is characteristic of normal ovulatory cycles, apparently as the result of prostaglandin release within the endometrium upon the withdrawal of progesterone. Pain with menses becomes a source of morbidity in 14% of adolescents.¹⁰⁸⁶ When pain is acute and qualitatively different from the usual menstrual pain, ectopic pregnancy must be considered.^{1054,1087} An ectopic pregnancy often causes vaginal bleeding that occurs 2.5 weeks later than the time of the expected next menstrual period and is typically light. However, the bleeding may be heavy and so resemble an episode of dysfunctional uterine bleeding. Ectopic pregnancy is usually diagnosable by a combination of ultrasonography, a serum β -hCG level over 1000 IU/L, and a progesterone level of less than 2500 ng/dL.

In patients with chronic pelvic pain unresponsive to anti-prostaglandins or OCP psychological overlay is possible, but attention should be directed to the possibility of endometriosis, uterine outlet obstruction, gynecological tract masses, or the poorly defined entity of *vulvodinia*.¹⁰⁸⁸ Ultrasonography and laparoscopy may be indicated to further evaluate these patients. Endometriosis is an estrogen-dependent disorder that accounts for approximately half of the cases of chronic pelvic pain in teenagers.¹⁰⁸⁹ Genetic factors and congenital obstruction of the genital tract predispose to endometriosis,

and aberrant estradiol formation in endometrial stroma has been incriminated in the pathogenesis.¹⁰⁹⁰ GnRH agonist therapy is approved to provide symptomatic relief, but adolescents are at particular risk for bone loss, and progestin therapy may be an effective alternative.

Dysmenorrhea may be ameliorated by antiprostaglandin therapy. Naproxen (275 mg 4 \times daily [QID] after a 550 mg loading dose) has been shown to be superior to aspirin (650 mg QID) or placebo when begun 2 days before the anticipated onset of menses.¹⁰⁹¹ The OCP is an alternative that will relieve dysmenorrhea in about 90% of cases by reducing endometrial mass.⁸⁸² Because smoking, alcohol intake, and excessive weight are risk factors, lifestyle counselling is advisable.

Premenstrual Syndrome. This is the term applied when cyclic mood changes confined to the second half of the menstrual cycle become debilitating.¹⁰⁹² It is often disruptive to women’s personal, social, and occupational function. If symptoms of marked mood swings, depressed mood, anxiety, and irritability occur, it is classified as premenstrual dysphoric disorder.¹⁰⁹³ Neuropsychiatric symptoms may include epilepsy¹⁰⁹⁴ and bizarre behavior.¹⁰⁹⁵ These seem to represent aberrant responses to normal cyclic hormonal changes.¹⁰⁹⁶ Subnormal activation of the hypothalamic-pituitary-adrenal axis in response to progesterone has been found.¹⁰⁹⁷ Some evidence indicates that variation in the degree of progesterone metabolism to neuroactive steroids affects the severity of symptomatology.¹⁰⁹⁸ Oral contraceptive therapy with the anti-mineralocorticoid progestin drospirenone is indicated if psychotropic therapy is unsuccessful. Downregulation of pituitary gonadotropin secretion by GnRH agonist therapy is efficacious, but its usefulness is limited by the side effects of estrogen deficiency. The relationship of premenstrual syndrome to other luteal phase symptomatology, such as recurrent fever and autoimmune symptoms, may be related to hyperresponsiveness of cytokines to progesterone.^{1099,1100}

Hyperandrogenism in Adolescence

Hyperandrogenism of a mild to moderate degree is the most common cause of persistent normoestrogenic menstrual abnormality and/or hirsutism. Hyperandrogenism developing during adolescence is usually caused by polycystic ovary syndrome (PCOS), but the differential diagnosis of hyperandrogenism includes other ovarian or adrenal disorders, abnormal peripheral formation of androgen, and drugs (see Box 16.8).^{40,1101}

Causes

The definition of PCOS has evolved since its description by Stein and Leventhal as a syndrome of amenorrhea and polycystic ovaries, often accompanied by hirsutism, acne, and/or obesity.¹¹⁰² Over recent decades, internationally accepted diagnostic criteria were developed for adults based on various combinations of otherwise unexplained hyperandrogenism, anovulation, and a polycystic ovary, which are all encompassed by Rotterdam consensus criteria.⁴⁰ These criteria generate four phenotypes, which are here listed in order of the decreasing diagnostic specificity of the phenotypes (Box 16.9) that underlies the controversies in the acceptance of the milder types. Insulin resistance, obesity, and LH excess, although not diagnostic features of the syndrome, are common and contribute to its pathogenesis; like hyperandrogenism, their severity has generally proven to correlate with specificity. In 2015 consensus diagnostic criteria for adolescent PCOS were developed by international pediatric subspecialty societies: these are an

BOX 16.8 Causes of Adolescent Hyperandrogenism

Physiological Adolescent Anovulation

Functional Gonadal Hyperandrogenism

- PCOS: Primary functional ovarian hyperandrogenism (common form of polycystic ovary syndrome)
- Secondary polycystic ovary syndrome
 - Virilizing congenital adrenal hyperplasia
 - Adrenal rests of the ovaries
 - Syndromes of severe insulin resistance
 - Acromegaly
 - Epilepsy ± valproic acid therapy
- Ovarian steroidogenic blocks
- Disorders of sex development
- Chorionic gonadotropin excess

Functional Adrenal Hyperandrogenism

- PCOS: Primary functional adrenal hyperandrogenism (uncommon form of polycystic ovary syndrome)
- Virilizing congenital adrenal hyperplasia
- Other glucocorticoid-suppressible functional adrenal hyperandrogenism
 - Prolactin excess
 - Cortisone reductase (and apparent cortisone reductase) deficiency
 - Apparent dehydroepiandrosterone sulfotransferase deficiency
 - Glucocorticoid-resistant functional adrenal hyperandrogenism
 - Cushing syndrome (endogenous: adrenal hyperplasia or neoplasm)
 - Glucocorticoid resistance

Peripheral Androgen Overproduction

- Idiopathic hyperandrogenism
- Obesity
- Portohepatic shunting

Virilizing Drugs

Androgenic Drugs

age- and stage-appropriate modification of the “National Institutes of Health criteria” (i.e., otherwise unexplained persistent hyperandrogenic anovulation) (see [Box 16.9](#)).^{124,1101,1103}

The adolescent consensus criteria attempt to strike a balance between under- and overdiagnosis of the syndrome. Normal adolescents often have menstrual cycles that are abnormal by adult standards, so anovulatory criteria must be age- and pubertal stage-appropriate (see [Box 16.2](#)). Persistence of the menstrual abnormality is required to avoid misdiagnosing physiological adolescent anovulation as PCOS. Unlike adult standards, mild hirsutism is not a criterion for hyperandrogenism because half of mild hyperandrogenism without menstrual abnormality is a normal variant.⁶⁴⁷ Polycystic ovary morphology (PCOM) is not a criterion because many normal adolescents meet adult PCOM criteria and adolescent norms are not well defined.

Clinical Manifestations. PCOS in adolescents resembles that in adults, with similar clinical and endocrinological heterogeneity. The cardinal symptoms typically begin when mature gonadotropin levels are achieved, in the perimenarcheal stage, so PCOS has been documented in children as young as 10 years of age. Cases with “ovulatory PCOS” have a subtle ovulatory abnormality that escapes notice until presentation

BOX 16.9 Diagnostic Criteria for Polycystic Ovary Syndrome**ADULT DIAGNOSTIC CRITERIA (ROTTERDAM)****Otherwise Unexplained Alternative Phenotypes:**

- Phenotype 1 (“Classic polycystic ovary syndrome [PCOS]”/“Stein-Leventhal syndrome”)^a
 - Clinical and/or biochemical evidence of hyperandrogenism
 - Evidence of oligoanovulation
 - Ultrasonographic evidence of a polycystic ovary
- Phenotype 2 (Essential National Institutes of Health Criteria)^a
 - Clinical and/or biochemical evidence of hyperandrogenism
 - Evidence of oligo-anovulation
- Phenotype 3 (“Ovulatory PCOS”)
 - Clinical and/or biochemical evidence of hyperandrogenism
 - Ultrasonographic evidence of a polycystic ovary
- Phenotype 4 (Nonhyperandrogenic PCOS)
 - Evidence of oligoanovulation
 - Ultrasonographic evidence of a polycystic ovary

ADOLESCENT DIAGNOSTIC CRITERIA**Otherwise Unexplained Combination of:**

- Abnormal uterine bleeding pattern
 - Abnormal for age or gynecological age
 - Persistent symptoms for 1–2 years
- Evidence of hyperandrogenism
 - Persistent testosterone elevation above adult norms in a reliable reference laboratory is the best evidence
 - Moderate-severe hirsutism is clinical evidence of hyperandrogenism
 - Moderate-severe inflammatory acne vulgaris is an indication to test for hyperandrogenemia

(Modified and reprinted with permission from Rosenfield, R.L. (2015). The diagnosis of polycystic ovary syndrome in adolescents. *Pediatrics*, 136, 1154–1165.)

in adulthood with unexplained infertility¹¹⁰⁴ or recurrent miscarriages.¹¹⁰⁵

Persistent symptomatic menstrual abnormality (primary or secondary amenorrhea, oligo-amenorrhea, or excessive uterine bleeding) (see [Box 16.2](#)) in a normally feminized girl may be the only manifestation of hyperandrogenism. In about one-third of cases, menstrual dysfunction occurs in the absence of cutaneous manifestations.

An abnormal menstrual pattern usually constitutes evidence of oligoanovulation. The menstrual pattern should be interpreted in the context of the patient’s gynecological age (see [Box 16.2](#)), as discussed earlier in the section Physiological Adolescent Anovulation. Although persistence of menstrual abnormality for 2 years is required for diagnosing PCOS in an adolescent (see [Box 16.9](#)), a provisional diagnosis can—and should—be made within 1 year in circumstances that require treatment.¹²⁴ PCOS is a state of relative, not absolute, infertility in which ovulation often occurs unpredictably and, on the other hand, in which menstrual regularity does not necessarily indicate ovulatory regularity.

The cutaneous signs of hyperandrogenism are variably expressed manifestations of androgen excess. They are present in about two-thirds of cases. Hirsutism is the most common pilosebaceous manifestation. However, acne, or uncommonly seborrhea or balding, may be the only pilosebaceous manifestation of hyperandrogenism.^{1106,1107}

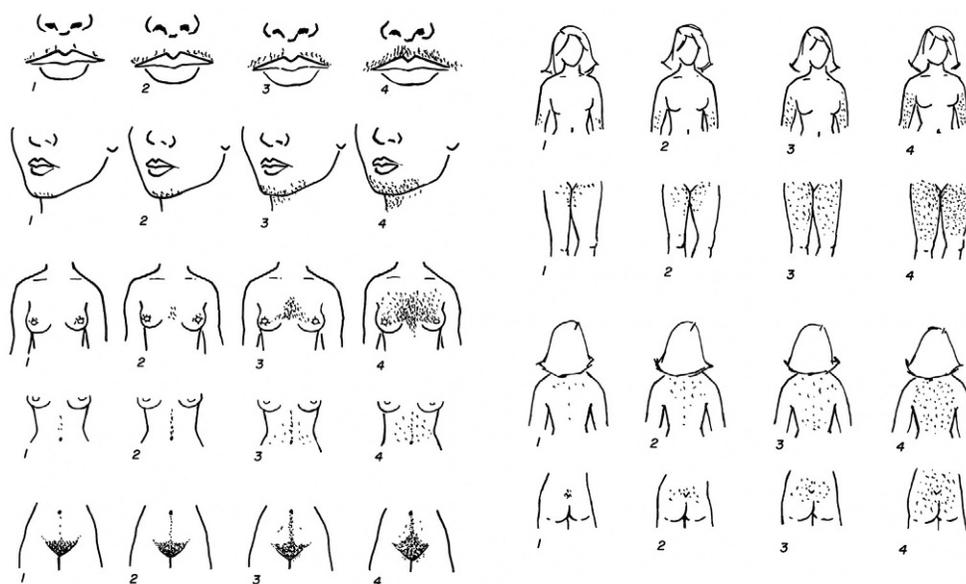

Fig. 16.46 Ferriman-Gallwey hirsutism scoring system. Each of the nine body areas that is most sensitive to androgen is assigned a score from 0 (no hair) to 4 (frankly virile), and these are summed to provide a hormonal hirsutism score. Generalized hirsutism (score ≥ 8) is abnormal in the general US population, whereas locally excessive hair growth (score 1–7) is a common normal variant that may be cosmetically important to patients. The normal score is lower in some Asian and higher in Mediterranean, Hispanic, and Middle Eastern populations (see text). (From Hatch, R., Rosenfield, R.L., Kim, M.H., Tredway, D. (1981). Hirsutism: implications, etiology, and management. *Am J Obstet Gynecol*, 140, 816–830. With permission.)

Hirsutism is defined clinically as excessive terminal hair that appears in a male pattern (sexual hair).⁶⁴⁷ It is commonly graded according to the hormonal Ferriman-Gallwey system, which quantitates the extent of hair growth in the most androgen-sensitive areas (see Fig. 16.46). The normal score is lower in some Asian populations and higher in Mediterranean, Hispanic, and Middle Eastern populations.

The absence of hirsutism in approximately one-third of hyperandrogenic adults appears to be because of relatively low sensitivity of their pilosebaceous unit to androgens. Thus biochemical hyperandrogenemia may be entirely cryptic, manifesting neither cutaneous signs nor anovulatory symptoms. Conversely, hirsutism without elevated circulating levels of androgen or other clinical evidence of hyperandrogenism—“idiopathic hirsutism”—accounts for approximately one-half of mild hirsutism and one-sixth of moderate-severe hirsutism.⁶⁴⁷

Although comedonal acne is common in adolescent girls, moderate-severe (>10) inflammatory acneform lesions in any area of the skin is uncommon during the perimenarcheal years and is an indication for testing for hyperandrogenemia.¹²⁴

Acanthosis nigricans, a manifestation of insulin-resistant hyperinsulinism, and associated obesity are the presenting complaints in about one-third of cases, sometimes before menstrual abnormalities develop.^{1108,1109} About one-half of PCOS patients are obese.¹¹⁰¹ The obesity occasionally begins in mid-childhood. Central body fat content is increased independently of BMI, and at least one-third of normal-weight PCOS patients have increased intraabdominal fat.^{40,1110}

Laboratory Manifestations. Persistent elevation of serum testosterone above adult norms in a reliable reference laboratory is the best evidence of hyperandrogenism (Box 16.9).¹²⁴ The problematic nature of many androgen assays is discussed later in the section Differential Diagnosis. Elevated serum free testosterone is the single most sensitive indicator of hyperandrogenemia because the bioactive portion of the serum testosterone is the free fraction.⁶⁴⁷ SHBG serum concentrations govern the fraction of testosterone that is free; they are lowered by obesity

and androgen excess itself. Androstenedione and DHEAS serum levels are often elevated in PCOS and should be measured if androgen excess is strongly suspected in spite of normal total and free testosterone levels. Serum DHT levels are of little diagnostic value.

A unique type of functional ovarian hyperandrogenism (primary FOH) can be documented in 85% of PCOS cases by specific tests of ovarian androgenic function.⁴⁰ The GnRH agonist test and hCG tests evaluate the gonadal response to, respectively, endogenous gonadotropin release or exogenous administration of the LH analogue hCG. In two-thirds of PCOS patients, these tests show a distinctive pattern of ovarian steroidogenic hyperresponsiveness, of which 17-OHP hyperresponsiveness is the best marker; there is no evidence of a steroidogenic block, and, indeed, estradiol is significantly hyperresponsive. The dexamethasone androgen-suppression test (DAST)—predicated on the principle that residual concentrations of androgens after suppression of adrenal function by glucocorticoid administration ordinarily arise from the ovary—shows elevated testosterone post-DAST in 80% of PCOS patients: this includes most with 17-OHP hyperresponsiveness to gonadotropin stimulation and two-thirds of those who lack it. These tests are indicated only in the case of diagnostic uncertainty.

A related adrenal steroidogenic defect is found in 25% to 50% of PCOS: primary functional adrenal hyperandrogenism (FAH).⁴⁰ This is indicated by DHEA hyperresponsiveness to ACTH; this correlates ($r = 0.7$) with DHEAS elevation. Isolated FAH is the sole steroidogenic defect in about 5% of PCOS.

The identification and clinical significance of PCOM presents quandaries.¹²⁴ Ultrasonographically, PCOM has been defined in adults by consensus criteria as an ovary with a volume greater than 10.0 cc by a simplified formula or a small antral follicle (2–9 mm diameter) count of 12 or more per ovary. However, these criteria have become problematic in young adults, particularly because the newer high-definition vaginal imaging techniques show that small antral follicle counts up to 24 are normal. Adult PCOM criteria are especially problematic when applied to adolescents. For one thing, an

accurate antral follicle count cannot be defined by the abdominal ultrasonographic approach necessary in virginal adolescents. Furthermore, current data suggest that ovarian volume and antral follicle count are slightly higher in adolescents than in adults. Consequently, one-third to half of normal adolescents meet adult criteria for PCOM. Until further research establishes definitive criteria, current evidence suggests that a mean ovarian volume of 12 cc (or single ovary >15 cc) be considered enlarged in adolescents, and PCOM are not a diagnostic criterion for PCOS in adolescents.

PCOM is variably related to hyperandrogenism.^{40,124} On one hand, it is absent in 5% to 20% of adult PCOS. On the other, PCOM is a common finding among healthy women. When care has been taken to exclude those with PCOS features, about one-quarter of apparently normal volunteers with PCOM have mild subclinical androgenic ovarian dysfunction that is in the PCOS range; it has been postulated that these are carriers of PCOS or at risk for PCOS.

AMH levels are independently associated with PCOM, because they indicate an increased number of small growing follicles, and with hyperandrogenism.⁴⁰ Although a mildly increased AMH level is common in asymptomatic females with PCOM and has been suggested as a surrogate indicator of it, AMH elevation of twofold or more above the upper normal limit suggests PCOS with high specificity.

Serum LH and the LH/FSH ratio are increased in about half of PCOS subjects.⁴⁰ Accumulating evidence suggests that LH levels in PCOS are determined by the severity of hyperandrogenemia, moderate degrees of which stimulate LH production, and the extent of obesity, which suppresses LH levels.

Insulin resistance in PCOS is significant independently of obesity.⁴⁰ Insulin resistance interacts with obesity and age to cause metabolic syndrome, which confers risk for cardiovascular disease,^{40,1111} sleep-disordered breathing,^{1112,1113} and nonalcoholic fatty liver disease.¹¹¹⁴

Approximately one-half of PCOS patients have an abnormal degree of insulin resistance, and about one-half of these have metabolic syndrome. Insulin resistance, as determined by euglycemic clamp, is present in 50% of obese adolescents with PCOS compared with BMI-matched controls¹¹¹⁵ (75% compared with normal-BMI controls) and about one-half of such girls have metabolic syndrome.¹¹¹⁶ Adolescents with PCOS are thus at increased risk for glucose intolerance.¹¹¹⁷ They are also predisposed to the pancreatic beta-cell dysfunction of type 2 diabetes mellitus.¹¹¹⁸ Dyslipidemia prevalence is generally low, but it is related to the degree of obesity and insulin resistance.^{1116,1119–1121}

Pathophysiology. PCOS ordinarily seems to be caused by intraovarian androgen excess (see Fig. 16.47).⁴⁰ Primary FOH accounts for the vast majority (about 85%) of PCOS (Fig. 16.48).^{40,1101} Functionally typical PCOS, constituting two-thirds of cases, is caused by typical FOH, which occurs because of a unique type of steroidogenic dysfunction, dysregulation of steroidogenesis. A related dysregulation of adrenal dysregulation, FAH, occurs in both typical and atypical FOH.¹¹²²

Typical FOH is characterized by generalized steroidogenic hyperresponsiveness to LH, of which 17-OHP is the most consistent marker. One-third of PCOS is functionally atypical, in that the 17-OHP abnormality is not demonstrable. One-half of these have functionally atypical FOH, identifiable by subnormal androgen suppression by dexamethasone. In the remainder, which constitutes a small minority (15%) of PCOS cases, an ovarian source for androgen excess, is not demonstrable. The androgen excess of these latter functionally atypical PCOS cases appears to arise from isolated FAH in about one-third of cases and from obesity in most of the remainder. These are exceptions to the general rule that modest extraovarian androgen excess does not interfere with ovarian function.

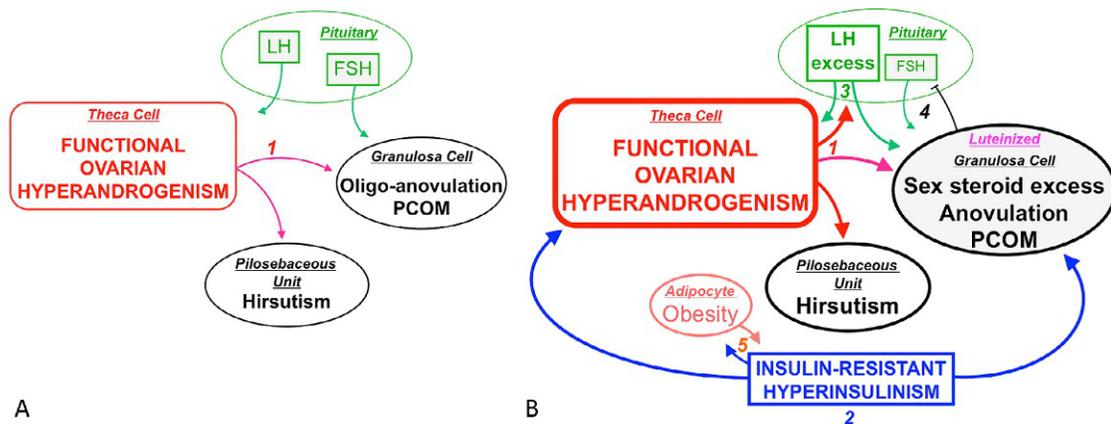

Fig. 16.47 Unified minimal model of polycystic ovary syndrome (PCOS) pathophysiology. Panel A: Functional ovarian hyperandrogenism (FOH) is present in nearly 90% of PCOS and can account for all the cardinal clinical features of the syndrome: hyperandrogenemia, oligoanovulation, and polycystic ovaries (step 1). Pituitary luteinizing hormone (LH) secretion is necessary to sustain the ovarian androgen excess, but it is not sufficient to cause it. Panel B: About one-half of patients with FOH have an abnormal degree of insulin-resistant hyperinsulinism (step 2). Insulin-resistant hyperinsulinism acts on theca cells to aggravate hyperandrogenism, synergizes with androgen in prematurely luteinizing granulosa cells, and stimulates fat accumulation. The increased hyperandrogenemia provokes LH excess, which then acts on both theca and luteinized granulosa cells to worsen hyperandrogenism (step 3). LH also stimulates luteinized granulosa cells to secrete estradiol (step 4), which suppresses follicle-stimulating hormone (FSH) secretion. These hyperinsulinism-initiated changes in granulosa cell function further exacerbate polycystic ovary morphology (PCOM) and further hinder ovulation. Obesity increases insulin resistance, and the resultant increased hyperinsulinism further aggravates hyperandrogenism (step 5). Boldness and enlarged font represents greater severity. Both FOH and insulin resistance typically have an intrinsic basis. This model does not exclude the possibility that the unknown intrinsic ovarian defects that underlay the ovarian steroidogenic dysfunction also involve granulosa cell folliculogenesis and other systems as well. The figure also does not depict other associated defects, such as the functional adrenal hyperandrogenism that often accompanies the ovarian hyperandrogenism and the contribution of excess adiposity to peripheral androgen production and gonadotropin suppression. (Modified from Rosenfield, R.L., Ehrmann, D.A. (2016). The pathogenesis of polycystic ovary syndrome (PCOS): the hypothesis of PCOS as functional ovarian hyperandrogenism revisited. *Endocr Rev*, 37, 467–520. With permission.)

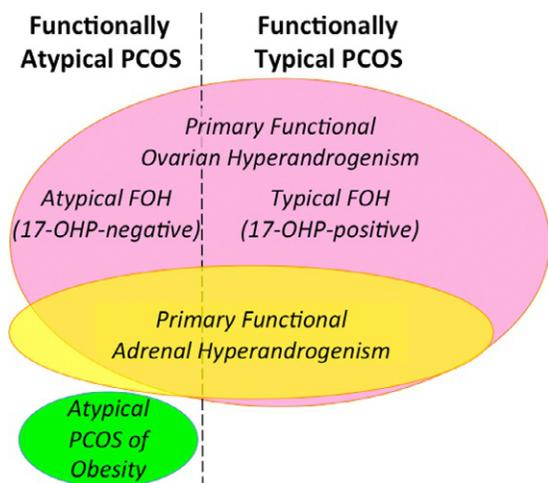

Fig. 16.48 Functional categorization of polycystic ovary syndrome (PCOS) in relationship to source of androgen and its prevalence. Most PCOS (85%) is caused by primary functional ovarian hyperandrogenism (FOH); about 30% of these have an associated primary functional adrenal hyperandrogenism. About two-thirds of PCOS have functionally typical PCOS, that is, they have typical FOH, which is characterized by hyperresponsiveness of 17-OHP to a GnRHag or hCG test. The remaining one-third of PCOS cases have functionally atypical PCOS, lacking 17-OHP hyperresponsiveness. Most of these have functionally atypical FOH, in which ovarian androgen excess is indicated by a dexamethasone androgen-suppression test. A small number (5%) are caused by isolated functional adrenal hyperandrogenism. In a minority of cases, the source of androgen cannot be identified as ovarian or adrenal: most of these have the functionally atypical PCOS of obesity (5%); the source of the androgen is unexplained (idiopathic) in less than 20% of the functionally atypical PCOS group ($\geq 5\%$ of PCOS). 17-OHP, 17-Hydroxyprogesterone. (Modified and reproduced with permission from Rosenfield, Polycystic ovary syndrome in adolescents. In: Rose BD, ed. *UpToDate*: 2014. Waltham, MA, www.uptodate.com/index.)

Dysregulation of steroidogenesis seems to result from imbalance among the various intrinsic and extrinsic factors involved in the modulation of trophic hormone action.⁴⁰ Within the ovary, there appear to be flaws in the processes that normally coordinate androgen and estrogen secretion in response to gonadotropin stimulation (see Fig. 16.19). Theca cells from polycystic ovaries of classic PCOS patients in long-term culture have an intrinsic steroidogenic dysregulation that can account for these steroidogenic abnormalities: these cells constitutively overexpress most steroidogenic enzymes, most prominently at the level of 17-hydroxylase and 17,20-lyase activities, both properties of P450c17, which are the rate-limiting steps in the biosynthesis of testosterone precursors. As in the ovary, dysregulation of local steroidogenic regulatory processes within the adrenal cortex appears to cause a characteristic type of primary FAH in which excessive dehydroepiandrosterone is formed in response to ACTH as a by-product of cortisol secretion.

As a consequence of dysregulated steroidogenesis, PCOS theca cells do not undergo the normal homologous desensitization to LH with downregulation of steroidogenesis in response to excess LH stimulation. Therefore, they are hypersensitive to LH stimulation. “Escape” from homologous desensitization to LH excess appears to be the basis for the distinctive pattern of steroidogenic hyperresponse to GnRH agonist or hCG testing, which is characterized by disproportionate

hyperresponsiveness of 17-OHP relative to other ovarian steroids without evidence of a steroidogenic block.

Granulosa cell functions are also defective in PCOS.⁴⁰ Folliculogenesis of small follicles is excessive, which has been attributed to androgen excess, although a primary granulosa cell defect cannot be ruled out, accounting for excess AMH production. Inhibin-B hyperresponsiveness to FSH also appears to aggravate theca androgen secretion via a paracrine action and also contributes to tamping down FSH production.

The reason for the high prevalence of obesity in PCOS is not entirely clear.⁴⁰ Obesity increases insulin resistance, and in turn the insulin-resistant hyperinsulinism seems to enhance obesity because insulin signaling in human subcutaneous adipose tissue is intact in PCOS. The mechanisms by which obesity causes insulin resistance are also unclear, but they include deficient insulin-sensitizing adipokines, such as adiponectin, and excessive proinflammatory cytokines, such as TNF- α , which both aggravate insulin resistance and hyperandrogenism, that are secreted by unique adipose tissue macrophages.^{40,1123} Hyperandrogenism also sensitizes circulating mononuclear cells to secrete inflammatory cytokines in response to glucose and saturated fat ingestion. Visceral fat contributes more to PCOS insulin resistance than does abdominal fat because its lipolytic response to catecholamines, the major lipolytic stimulus in man, is uniquely enhanced.⁴⁰

Insulin resistance is an inconsistent, aggravating factor in the pathogenesis of FOH that is present in about half of cases (Fig. 16.47, panel B). It is usually mild, particularly in the developmental (adolescent) phase of the syndrome. It does not account for the intrinsic theca cell dysfunction characteristic of ordinary PCOS and only plays a *primary* pathogenic role in the development of the PCOS that complicates severe or extreme insulin-resistance syndromes.

The insulin resistance of PCOS is selective for the metabolic effects of insulin.⁴⁰ This creates a paradox in which the hyperinsulinemia compensatory for resistance to the glucose-metabolic effect of insulin, nevertheless, elicits excess insulin action in some tissues. Thus the steroidogenic, mitogenic, and protein-metabolic actions of insulin remain intact.

This insulin-resistant hyperinsulinism (hyperinsulinism) aggravates the ovarian and adrenal steroidogenic dysregulation of PCOS.⁴⁰ It is closely associated with the anovulation of PCOS. Insulin, like IGFs, modulates gonadotropin and ACTH action. Consequently in excess it synergizes with them. In the ovary insulin synergizes with LH by increasing theca cell LH receptor site expression to cause “escape” from desensitization. Consequently, hyperinsulinism enhances theca cell androgen production and theca and stromal cell hyperplasia. Insulin excess also synergizes with androgen to prematurely luteinize granulosa cells by inducing LH receptor expression, thus enhancing estrogen, progesterone, and inhibin-B production and arresting dominant follicle development.

Hyperinsulinism also seems to *play* a role in mediating the development of obesity in PCOS.^{40,1124} The transcription factor KLF15 seems to play an important role in mediating insulin stimulation of both adipogenesis and testosterone formation.⁵⁶³

PCOS is gonadotropin dependent; gonadotropins are necessary for the expression of gonadal steroidogenic enzymes.⁴⁰ However, LH excess does not seem to ordinarily be the fundamental cause of the hyperandrogenism. LH excess is variable (found in 50%–75% of cases) and seems to depend on androgen-obesity balance, which, respectively, raise and lower gonadotropin levels. Homologous desensitization normally limits the androgenic response to LH elevation: thus LH excess alone seems unlikely to cause the hyperandrogenism of PCOS, although it may aggravate it in PCOS, where intrinsic ovarian dysfunction causes “escape” from desensitization. Evidence is accumulating that androgen excess causes LH excess by

interfering with progesterone-estrogen negative feedback effect on LH secretion. Nevertheless, the possibility of a primary role for LH excess remains, particularly in the PCOS that is secondary to congenital virilizing disorders.

A model of the pathophysiology of PCOS is shown in Fig. 16.47.⁴⁰ The high intraovarian androgen concentration arising from the thecal cell dysfunction of FOH can cause all the essential features of the syndrome (Fig. 16.47, panel A). Excess androgen secretion causes the pilosebaceous manifestations of the syndrome. The locally very high intraovarian androgen concentrations act on granulosa cells to hinder the emergence of a dominant follicle, causing oligoanovulation. This paracrine effect of great androgen excess is coupled with its stimulation of increased proliferation of small follicles causing PCOM. Insulin-resistant hyperinsulinism aggravates PCOS severity by acting in conjunction with androgen excess to prematurely luteinize follicles, causing thecal and stromal hyperplasia. The moderately increased hyperandrogenemia causes secondary LH elevation by interfering with female hormone negative feedback; meanwhile, estrogen and inhibin-B excess inhibit FSH secretion. In the presence of the escape from homologous desensitization induced by hyperinsulinism, this LH excess amplifies the ovarian dysfunction. The hyperinsulinism also promotes adiposity, which in turn aggravates the insulin-resistant state.

In primary FAH, the steroidogenic pattern of response to ACTH resembles an exaggerated adrenarche and in the past was confused with nonclassic 3 β -HSD deficiency.⁴⁰ This FAH has been associated with mild adrenal enlargement and a small degree of autonomous adrenocortical function in some cases.^{40,1125} The pattern of adrenal secretion is compatible with dysregulation of zona reticularis steroidogenesis prominent at the level of the 17-hydroxylase/17,20-lyase activities of P450c17 and it correlates with evidence of the related ovarian dysregulation.¹¹²⁶ Nevertheless, it is the only steroidogenic abnormality in a small minority of PCOS.

The remaining PCOS cases lack evidence of steroid secretory abnormalities. Most of these are obese (Fig. 16.48), a few are idiopathic. Excess adipose tissue appears sufficient to account for hyperandrogenic anovulation and thus cause the atypical PCOS of obesity.⁴⁰ Adipocytes form testosterone from androstenedione via type 5 17 β -hydroxysteroid dehydrogenase, which is upregulated by insulin. Obesity also suppresses ovulation and LH levels; blunted LH pulse amplitude is at least in part caused by accelerated metabolism of LH. The atypical PCOS of obesity is in general characterized by mild hyperandrogenemia (normal total testosterone, mildly elevated free testosterone, normal DHEAS, low SHBG), and most have normal-size ovaries, normal AMH levels, and normal LH levels; their insulin resistance is unremarkable for PCOS.

One of the great puzzles about PCOS pathogenesis is whether hyperandrogenism might cause insulin resistance. Androgens in vitro exert some antiinsulin effects.¹¹²⁷ A variety of studies indicate that administration of oral androgens or virilizing doses of androgen to humans causes insulin resistance.^{1127,1128} The induction of modest hyperandrogenism does not do this in normal women,¹¹²⁹ but in nonhuman primates it will induce insulin resistance when combined with an obesogenic diet.^{1130,1131} However, reversal of PCOS androgen excess has not ameliorated insulin resistance in the majority of studies.¹¹²⁷

Etiology. PCOS seems to arise as a complex trait that results from the interaction of diverse genetic and environmental factors once mature gonadotropin levels are achieved peripubertally.⁴⁰ These complex interactions generally mimic an autosomal dominant pattern of inheritance with variable penetrance. Heritability of PCOS has been estimated at over 70%, based on studies in identical twin sisters. Heritable factors

include maternal PCOS and PCOM, hyperandrogenemia, and metabolic syndrome.

GWAS identified overexpression of DENND1A.V2 in most PCOS populations.^{40,1132} This previously unsuspected protein is present in theca and zona reticularis cells and is overexpressed in PCOS. It facilitates steroidogenesis; the mechanism is unknown, but it has been speculated to upregulate LH receptor signaling by affecting receptor trafficking. Induced overexpression of it in normal theca cells has reproduced this PCOS genetic and biochemical phenotype in vitro.⁴⁰ A wide variety of other gene variants with linkage and/or association with PCOS have been identified by candidate gene and molecular genetic studies, and novel markers are reported regularly.⁴⁰ Variants discovered in fibrillin 3 have been proposed to dysregulate TGF- β signaling and account for ovarian stromal hyperplasia. AMH coding variants with decreased signaling that could potentially cause the syndrome have been reported in 6.7% of PCOS patients.¹⁷³

Environmental factors include prenatal androgen exposure and both undernutrition and overnutrition.⁴⁰ Virilizing CAH is sometimes complicated by PCOS in patients whose CAH is well controlled. Congenital virilization of several animal species, including nonhuman primates, has been shown to program hyperandrogenic anovulation and insulin resistance in offspring. These observations suggest that insults to the intrauterine environment induce epigenetic changes that lead to altered gene expression and disease in later life. Because in utero androgen excess from the fetal or maternal PCOS ovary is unlikely to account for this programming in ordinary PCOS,⁴⁰ the androgen programming models rather suggest that intrauterine alterations in intermediates in androgen signaling that are common to other effector pathways, such as prostaglandins, may play a role in the pathogenesis of PCOS by altering the epigenome.^{517,587,613}

Postnatal environmental risk factors can be viewed as a second "hit," which cause a latent heritable or congenitally programmed susceptibility trait to become manifest as PCOS. Postnatal factors include acquired obesity, insulin resistance, and hyperandrogenism of nonovarian origin. The variety of pathways involved and lack of a common thread attests to the multifactorial nature and heterogeneity of the syndrome.

Moderately severe insulin-resistant hyperinsulinism characterizes two syndromes of intractable obesity in childhood that herald PCOS in adolescence: pseudo-Cushing syndrome and pseudoacromegaly.⁴⁰ Premature adrenarche seems to pose a moderately increased risk (overall approximately twofold) for developing PCOS.⁴⁰ The nature of the association is unclear. We favor the concept that premature adrenarche is sometimes an early manifestation of the steroidogenic dysregulation that underlies PCOS, although in some populations low birth weight may be the underlying risk factor.

Other Causes of Functional Ovarian Hyperandrogenism.

In the early postmenarcheal years, physiological anovulation may present with mild hyperandrogenemia without clinical evidence of androgen excess in about one-quarter of cases, but the hyperandrogenic anovulation does not persist. Secondary PCOS can result from several disorders (see Box 16.8).⁴⁰ Virilizing CAH frequently causes ovarian hyperandrogenism. Three mechanisms are involved.¹¹³³ For one, poor control of adrenal hyperandrogenism causes polycystic ovaries and amenorrhea by direct effects on the ovary. Adrenal rests of the ovaries may cause polycystic ovaries and hyperandrogenism. Finally, patients with CAH, particularly those with classic CAH, are at high risk for the emergence of PCOS at puberty caused by developmental programming (see previous section Disorders of Sex Development).

All known forms of severe or extreme insulin resistance, including hereditary cases of insulin receptor mutations and acquired lipodystrophy, are accompanied by PCOS, possibly by acting through the IGF-1 signal transduction pathway to cause escape from desensitization to LH. Acromegaly itself is associated with PCOS. The antiepileptic drug valproic acid causes hyperandrogenism and polycystic ovaries, and an association of epilepsy itself with PCOS is possible.^{462,1052}

Rare causes of hyperandrogenism include primary ovarian steroidogenic blocks. These (aromatase deficiency⁹⁹⁹ and virilizing CAH caused by 3 β -HSD deficiency¹¹³⁴) cause hyperandrogenism in association with grossly polycystic ovaries and elevated LH levels. Ovarian 17-ketosteroid reductase deficiency has been reported to be responsible for a PCOS-like picture in two families, but there has been no molecular confirmation of an underlying mutation.¹¹³⁵ Functional ovarian hyperandrogenism may also result from an ovotesticular disorder of sex development. Excessive hCG stimulation mediates the hyperandrogenism of hyperreactio luteinalis and luteoma of pregnancy,¹¹³⁶ and excessive LH appeared to mediate hilus cell hyperplasia in a case of FSH-resistant ovarian follicles.¹¹³⁷ An extremely high level of hCG caused by tumor has been reported to virilize a nonpregnant woman with preexisting PCOS.¹⁰⁷³

Other Causes of Functional Adrenal Hyperandrogenism.

The PCOS type of primary FAH that appears to arise from dysregulation of adrenal steroidogenesis occurs as an isolated entity, not associated with FOH, in 5% of hyperandrogenic women.⁴⁰ This may sometimes be an outcome of premature adrenarche. This type of adrenal dysfunction was previously mistaken for nonclassical 3 β -HSD deficiency, which is now known to be a rare disorder.¹¹³⁸

Less than 10% of adrenal hyperandrogenism is caused by the other disorders listed in Box 16.8. The most common of these are nonclassic CAH, which accounts for 4.2% of hyperandrogenic women worldwide, second only to PCOS (prevalence >80%) as the most common cause of hyperandrogenism in adolescent and adult females.⁶⁴⁷ The prevalence varies from 0.1% to 2% in the general US population to 4% in Ashkenazi Jews, to 10% in Mediterranean-Middle East countries.⁸⁴¹ Adrenal hyperandrogenism can on rare occasions arise from other rare congenital disorders of adrenal steroid action or metabolism, such as glucocorticoid resistance, apparent cortisone reductase deficiency, and apparent sulfotransferase deficiency.^{1139–1142}

About 40% of hyperprolactinemic women have hyperandrogenism, sometimes in association with polycystic ovaries.^{367,1143} The great majority (about 85%) of these women have galactorrhea; the combination of hirsutism, galactorrhea, and amenorrhea comprises the Forbes-Albright syndrome. Prolactin excess causes adrenal hyperandrogenism because of multiple effects of prolactin excess on adrenal androgen production and androgen metabolism.³⁶⁷ Serum prolactin values more than 25 ng/mL in hyperandrogenic women usually have an identifiable cause, rather than PCOS itself: most common are pituitary adenoma and antidopaminergic drugs.¹¹⁴⁴

Peripheral Androgen Overproduction. In about 10% of PCOS patients, an ovarian or adrenal source cannot be ascertained by thorough testing (see Fig. 16.48). This “functionally atypical PCOS” seems in most cases to be caused by obesity: excess adipose tissue has the capacity to both cause anovulation and to form testosterone from androstenedione.⁴⁰ In about 20% of such cases (\leq 5% of PCOS), the source of the hyperandrogenemia is unexplained: this is termed *idiopathic hyperandrogenism* (as distinct from “idiopathic hirsutism”). Quirks in steroid peripheral metabolism have been suspected to be the cause.

PCOS has also been reported as a complication of portosystemic shunting.¹¹⁴⁵ Impaired steroid metabolism has been postulated as the mechanism.¹¹⁴⁶

Tumoral Hyperandrogenism. Virilizing tumors are rare, accounting for about 0.2% of hyperandrogenism; about half are malignant.⁶⁴⁷ About half are ovarian, half adrenal. Masculinizing sex cord-stromal tumors of the ovary are unusual before the teenage years. Leydig-Sertoli cell tumor (androblastoma, arrhenoblastoma) is the most common type. Virilizing granulosa-theca cell tumor (thecoma) is unusual before menopause.^{1073,1147} Dysgerminomas virilize only if they have interstitial cell elements. Lipid cell tumors tend to respond to ACTH, as well as LH and produce 17-OHP; thus they must be considered in the differential diagnosis of late-onset CAH.¹¹⁴⁸ The abnormal differentiation that underlies tumor formation typically leads to an abnormal pattern of steroid secretion with androstenedione greatly predominating over testosterone secretion.¹¹⁴⁹ However, some thecomas have been reported to predominantly secrete testosterone.^{1150,1151} Gonadoblastomas are virilizing tumors virtually confined to individuals with dysgenetic gonads with Y-chromosomal material in their genome. Some masculinizing ovarian sex cord-stromal tumors may be caused by activating mutations of stimulatory G-proteins.¹¹⁵² Leydig cell and adrenal rest tumors of the ovary are extremely rare causes of masculinization in childhood.^{20,436,1153} Adrenal virilizing tumors are rare in adolescence; their peak incidence is in early childhood and adulthood⁸²¹ (see sections Precocious Puberty and Incomplete precocity).

Androgenic Drugs. Drug-induced masculinization in adolescence is encountered most often in athletes. The medical history is important in detection because standard clinical laboratory tests for androgens are not helpful in the detection of either natural or artificial androgens.^{647,1154} This is also the case for masculinization that results from unintended contact with topical androgens used by a parent or by a sexual partner.^{647,828} Valproic acid use in epileptics raises testosterone levels and may mimic PCOS.⁴⁶²

Differential Diagnosis

Hyperandrogenism should be considered in any girl who presents with hirsutism or moderate-severe inflammatory acne, menstrual disturbance, or acanthosis nigricans with central obesity (waist circumference >88 cm) during puberty.

Hirsutism must be distinguished from locally excessive hair growth in the absence of an abnormal hirsutism score (“patient-important hirsutism”) and from hypertrichosis, the generalized excess growth of vellus hair that sometimes occurs on a hereditary basis or in patients taking glucocorticoids, phenytoins, diazoxide, or cyclosporine. Hypertrichosis is distributed in a nonsexual pattern (e.g., generalized distribution or more prominent distribution on the forehead or shoulders) and is not caused by excess androgen, although it may be aggravated by excess androgen.

The possibility of PCOS is heightened if hirsutism, treatment-resistant acne, or menstrual irregularity are associated with a history of prepupal risk factors for PCOS—congenital virilizing disorders; premature adrenarche; intractable prepupal obesity, particularly if associated with pseudo-Cushing syndrome or pseudo-acromegaly; or a family history of PCOS or metabolic syndrome.

Diagnostic Approach

The goals of the laboratory evaluation for hyperandrogenism are to obtain evidence of hyperandrogenemia and to determine the specific etiology. The diagnosis of hyperandrogenism is on the firmest grounds if hyperandrogenemia is demonstrated biochemically, rather than relying on hirsutism as a clinical

surrogate for it, although documentation of hyperandrogenemia can be problematic.

The evaluation starts with a thorough assessment of the clinical symptoms and signs suggestive of PCOS and for disorders that mimic it (Fig. 16.49).

The degree and distribution of sexual hair growth should be identified, usually done using the Ferriman-Gallwey score (see Fig. 16.46). Moderate or severe hirsutism (hirsutism score >15) constitutes clinical evidence of hyperandrogenism in an adolescent (see Box 16.9). The history should specifically explore

whether the patient is taking medications that may mask symptoms (e.g., depilatory use) or cause hirsutism (e.g., anabolic steroids, valproate).

Moderate or severe inflammatory acne (>10 lesions in any area, e.g., face, chest, back) or acne that is persistent and poorly responsive to topical dermatological therapy suggests the possibility of hyperandrogenism.

Assessment should also include evaluation for symptoms or signs that suggest a hyperandrogenic disorder other than PCOS, including virilization (e.g., rapidly progressive hirsutism,

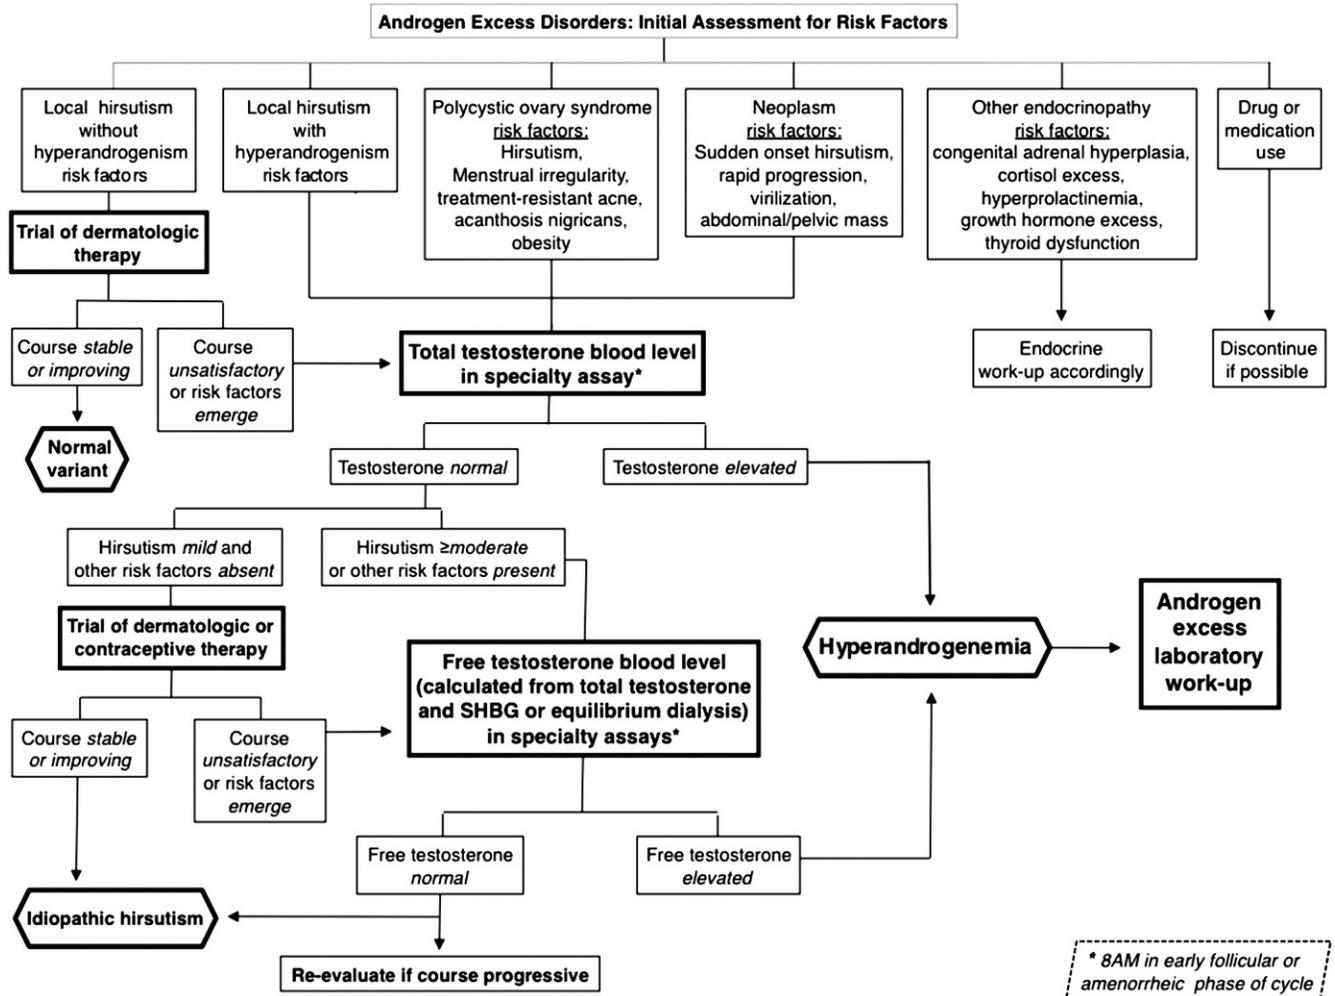

Fig. 16.49 Initial assessment of women for risk of androgen excess disorders. Patient-important localized areas of hair growth in the presence of a normal hirsutism score (“local hirsutism”), but not accompanied by other androgen excess risk factors, do not require an endocrine workup before embarking on local dermatologic therapy. In women with local hirsutism with other androgen excess risk factors or an elevated hirsutism score, androgen levels should be assessed. PCOS is the most common cause to be considered, but androgen-producing tumors, congenital adrenal hyperplasia, and diverse androgenic disorders, as shown, should be excluded. Drugs that cause hirsutism include anabolic or androgenic steroids (consider in athletes and patients with sexual dysfunction) and valproic acid (consider in neurologic disorders), which causes hyperandrogenemia. Serum testosterone is best assessed in the early morning, on days 4-10 of the menstrual cycle in eumenorrheic women or on random days in amenorrheic women, by an accurate and specific assay such as liquid chromatography/mass spectrometry. Females with mild hirsutism (score 8-15), normal total testosterone level, and no risk factors probably have idiopathic hirsutism, which may be responsive to endocrine therapy. Serum free testosterone should be measured as indicated by a specialty reference assay if the serum total testosterone is normal in the presence of risk factors or progression of hirsutism on therapy. Simultaneous assay of 17-hydroxyprogesterone is indicated in subjects at high risk for congenital adrenal hyperplasia. Some adolescents diagnosed with idiopathic hirsutism by this algorithm will have polycystic ovaries on ultrasound as adults, which is unlikely to be important unless fertility is an issue. Progression of hyperandrogenism in the presence of a normal serum free testosterone is very unusual; such patients should be thoroughly reevaluated, possibly also measuring other steroids related to androgen excess, such as 17-hydroxyprogesterone, androstenedione and DHEAS. The initial laboratory work-up for androgen excess is shown in Fig.16.50. (Modified with permission from Martin, et al. Evaluation and treatment of hirsutism in premenopausal women: an Endocrine Society Clinical Practice Guideline. Copyright The Endocrine Society.)

clitoromegaly), abdominal mass, galactorrhea, cushingoid or acromegaloid changes, evidence of thyroid dysfunction, or a family history of hyperandrogenic disorders. Inspection of the external genitalia is indicated, but an internal pelvic examination seldom is necessary.⁹⁹⁷

If hirsutism is local or mild (hirsutism score <8) and if menses are regular with no other clinical evidence of risk factors that would suggest an underlying cause, unwanted or excess sexual hair growth can be managed by dermatological means without pursuing further laboratory evaluation.^{462,647} Unless fertility becomes an issue in adulthood for subjects with local hirsutism or idiopathic hirsutism, demonstrating polycystic ovary morphology to diagnose ovulatory PCOS is unlikely to affect management.

Laboratory assessment for hyperandrogenism begins with measurement of serum testosterone: this is the single most important androgen to evaluate (Fig. 16.49).^{124,467,647} Although other androgens are present in blood, their assessment ordinarily makes little difference in diagnosis and management if serum free testosterone is normal. Serum free testosterone is about 50% more sensitive in detecting excessive androgen production because hyperandrogenic women have a relatively low level of SHBG. There are many pitfalls in testosterone assays at the low levels found in women and children, and reliable testosterone assays are not available in most local laboratories. Assays of high sensitivity and specificity, such as are provided by postchromatographic RIA or tandem mass spectrometry by specialty laboratories, are required. Assaying the free testosterone level introduces other potential sources of error. Direct assays of the free testosterone concentration are inaccurate and should be avoided. The best methods to calculate free testosterone as the product of the total testosterone and a function of SHBG: free testosterone = total testosterone × percent free testosterone, where percent free testosterone is most accurately determined by dialysis, or alternatively calculated from the SHBG concentration.¹¹⁵⁵ The combination of a high-normal total testosterone and a low-normal SHBG yields a high free testosterone concentration.

Exclusion of hyperandrogenic disorders that mimic PCOS (see Box 16.8) is important to meet diagnostic criteria. Because PCOS accounts for 95% of hyperandrogenisms, a diagnostic strategy is required that takes into account individual patient preference, including benefits in relation to economy of cost and of time. Guidelines vary slightly, but most suggest screening for nonclassic CAH, which accounts for most non-PCOS hyperandrogenism, hyperprolactinemia, thyroid disease, and virilizing tumor, which is the most serious although rare; testing for Cushing syndrome and acromegaly are generally suggested^{124,647,1107,1156} for those with suggestive clinical features. Normal results of a simple panel of endocrine screening tests to exclude these other causes of hyperandrogenemia (see Fig. 16.50) ensures the diagnosis of PCOS with about 99% reliability.

Practice varies as to the indications for ultrasonography in girls with confirmed hyperandrogenemia. The primary purpose of ultrasonography is to screen for the rare but serious adrenal or ovarian tumor, as it is not required for diagnosis. Ultrasonography also provides the opportunity for patient reassurance and education. For many women, the diagnosis of ovarian “cysts” raises a concern about tumors, so it is reassuring to know that a tumor has not been seen.

Some tests require consideration of the time of day or stage of cycle that sampling is performed. Serum testosterone levels are 20% higher in the morning than in the afternoon and double in midcycle; norms are based on midfollicular phase controls.⁶⁴⁷ An early morning 17-OHP level over 170 ng/dL (>5.1 nmol/L) is approximately 95% sensitive and 90% specific for nonclassic CAH, but they are insensitive by

midmorning.^{647,841} The most common cause of false positives is PCOS,¹⁹⁵⁷ the most serious cause is virilizing tumors.^{1148,1157} DHEAS elevations are usually caused by the FAH of PCOS; DHEAS greater than 700 mcg/dL suggests adrenal virilizing tumor or a rare type of CAH (3β-HSD deficiency). A cortisol level less than 10 mcg/dL (276 nmol/L) is reassuring evidence against endogenous Cushing syndrome unless the clinical index of suspicion is high.

The senior author's practice is to ordinarily begin the specific workup for PCOS at the initial evaluation for hyperandrogenic anovulation, an evaluation that includes testosterone (see Fig. 16.49), by adding a few tests for the common non-PCOS causes of hyperandrogenism (see Fig. 16.50).¹¹⁰¹ For practical reasons, sampling for early morning serum 17-OHP and ultrasound are ordinarily scheduled; at the same time, whatever further workup might be indicated by the initial test results (e.g., early morning free testosterone if midday testosterone was not clear-cut in the face of high clinical index of suspicion for hyperandrogenism).

A more comprehensive endocrine evaluation is sometimes indicated because the basic evaluation described earlier does not exclude rare virilizing disorders (see Box 16.8).^{647,1156} The approach to further studies to determine the source of hyperandrogenemia varies among subspecialists and with the needs of the individual patient.

Our preference is to use a DAST to attempt to make a positive diagnosis of the ovarian dysfunction of PCOS versus determining whether further workup is necessary for rare forms of CAH or other rare adrenal disorders (Fig. 16.51).^{1101,1122} Suppression of serum androgens and cortisol in response to a low-dose dexamethasone suppression test segregates patients diagnostically. Subnormal testosterone suppression with normal adrenocortical suppression indicates a source of androgen other than an ACTH-dependent adrenal one and is found in 80% of PCOS. However, tumor or other ovarian pathology must be excluded by ultrasound examination. If both cortisol and androgen suppression are subnormal, then the androgen excess may be secondary to dexamethasone noncompliance, endogenous Cushing syndrome, or glucocorticoid resistance. If testosterone suppression is normal, then ACTH (cosyntropin) stimulation testing to rule out nonclassic CAH is recommended. If both dexamethasone and ACTH testing are normal, the most likely diagnosis is the atypical PCOS of obesity or idiopathic hyperandrogenism.

A short (4-h) DAST, as described in the Fig. 16.51 legend, suffices in the absence of high suspicion for virilizing disorder. It is helpful in distinguishing the potentially reversible pseudo-PCOS of simple obesity, in which case testosterone suppresses normally, from the persistent ovarian dysfunction of ordinary PCOS.¹¹²² However, a more prolonged course of low-dose dexamethasone (long DAST, 4 days) is required to suppress the hyperandrogenism of CAH.

Further extensive diagnostic studies beyond those indicated in Fig. 16.50 are seldom indicated unless there is reason to suspect a virilizing tumor or a disorder of sexual differentiation. Computed tomography and MRI permit the best visualization and more detailed assessment of tumors, particularly of the adrenal gland. On rare occasions, ultrasonography has been insensitive in detecting a virilizing ovarian tumor in adults.^{847,1158} Further or alternative workup may include acute GnRH agonist testing, or assessment of the response to hormonal suppression treatment to determine the source of androgen.

Management

Management of hyperandrogenism is individualized according to symptoms and patient goals—hirsutism and acne;

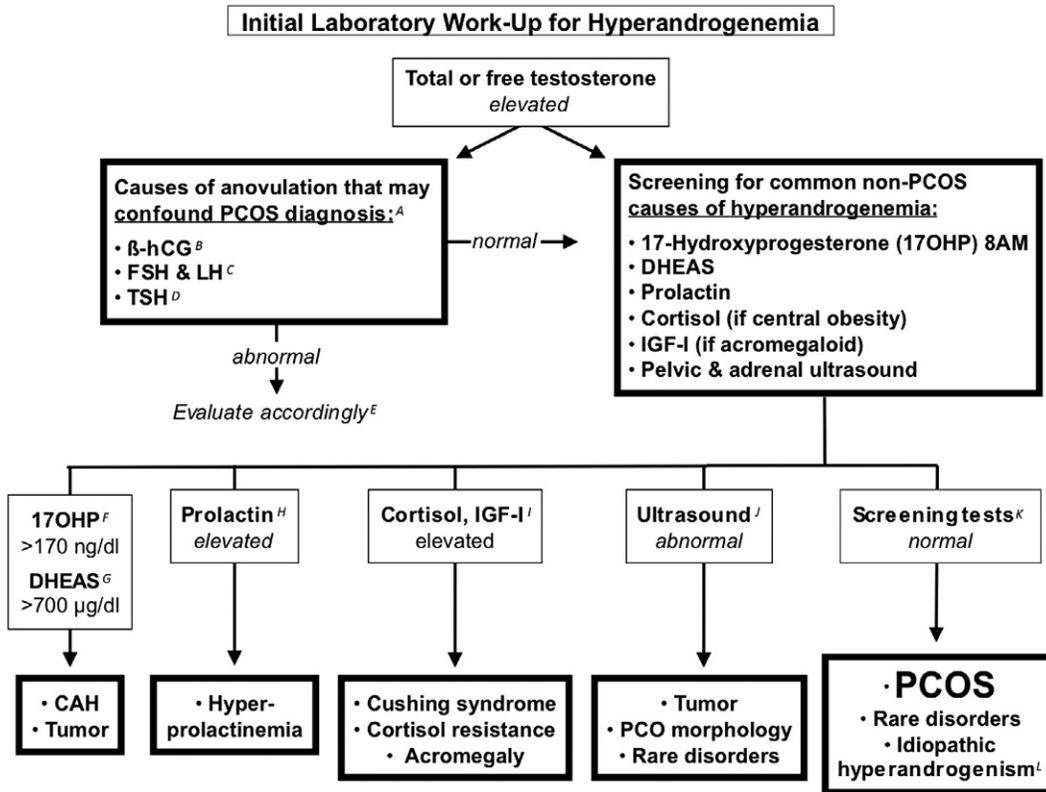

Fig. 16.50 Initial laboratory workup for cause of androgen excess. Polycystic ovary syndrome is a diagnosis of exclusion: this algorithm identifies the most common other causes of hyperandrogenemia and hyperandrogenic anovulation. (Modified from Rosenfield, R.L. (2018). Polycystic ovary syndrome in adolescence. Clinical features and diagnosis of polycystic ovary syndrome in adolescents. *UpToDate*. With permission.)

Footnotes:

- A. These tests for anovulatory disorders are advisable for hyperandrogenemic patients with menstrual abnormalities, because they may confound the diagnosis of polycystic ovary syndrome (PCOS).
- B. Pregnancy is associated with high testosterone levels.
- C. Slightly elevated luteinizing hormone (LH) and slightly low follicle-stimulating hormone (FSH) are common in PCOS. High FSH suggests primary hypogonadism. Low LH suggests hypogonadotropic hypogonadism.
- D. Thyroid dysfunction may alter the total testosterone level by altering sex hormone binding globulin. Hypothyroidism may cause multicystic ovaries and coarse hair that may be mistaken for hirsutism.
- E. See preceding algorithms for workup of anovulatory disorders.
- F. 8:0 AM 17-hydroxyprogesterone (17-OHP) over 170 ng/dL is approximately 95% sensitive and 90% specific for detecting common type (21-hydroxylase-deficient) nonclassic congenital adrenal hyperplasia (NCCAH) in anovulatory or early-midfollicular phase women. NCCAH is the most common disorder mimicking PCOS. Falsely positive 17-OHP elevation is found in PCOS, luteal phase women, and virilizing neoplasms.
- G. Dehydroepiandrosterone sulfate (DHEAS) greater than 700 mcg/dL suggests adrenal virilizing tumor or the rare 3β-hydroxysteroid dehydrogenase deficiency form of NCCAH.
- H. Hyperprolactinemia may cause either hypogonadotropic hypogonadism or hyperandrogenic anovulation (which is usually accompanied by galactorrhea, the Forbes-Albright syndrome).
- I. Optional tests are cortisol and insulin-like growth factor 1 (IGF-I). Endogenous Cushing syndrome should be considered in cases with central obesity. Plasma cortisol under 10 mcg/dL essentially rules out endogenous Cushing syndrome unless the clinical index of suspicion is high. Acromegaly should be ruled out by IGF-I screening if the patient has acromegaloid overgrowth.
- J. Ultrasonography screens for ovarian and adrenal tumor. Polycystic ovary morphology is supportive, but it is not specific for, nor is it a criterion for, the diagnosis of adolescent PCOS. Ultrasound may detect ovotesticular disorder of sex development (true hermaphroditism) or human chorionic gonadotropin (hCG)-related disorders of pregnancy.
- K. Exclusion of the preceding disorders in a hyperandrogenic patient with menstrual dysfunction meets standard diagnostic criteria for PCOS with approximately 99% reliability. However, this workup does not identify rare adrenal disorders (e.g., rare types of congenital adrenal hyperplasia [CAH] and adrenal steroid metabolic disorders, very small tumors, such as the rare testosterone-secreting neoplasm) or idiopathic hyperandrogenism.
- L. Idiopathic hyperandrogenism (documented hyperandrogenemia with no demonstrable source) occurs in approximately 1% of hyperandrogenic women. This is distinct from the more common “idiopathic hirsutism” (hirsutism without other clinical evidence of hyperandrogenism). TSH, Thyroid-stimulating hormone.

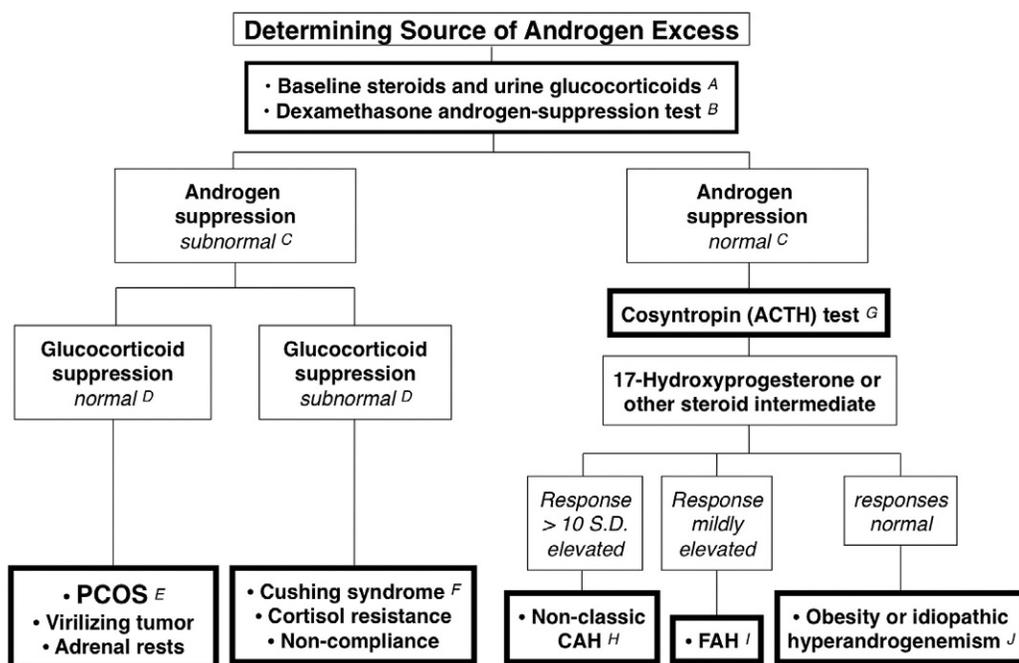

Fig. 16.51 An approach to determining the source of androgen excess. Determination of the source of excess androgen often permits a positive diagnosis of the characteristic ovarian and adrenal dysfunction of polycystic ovary syndrome (PCOS) and will elucidate rare disorders that mimic PCOS. (From Buggs C, Rosenfield RL. Polycystic ovary syndrome in adolescence. *Endocrinol Metab Clin North Am* 2005; 34:677.)

Footnotes:

- A. After obtaining an early morning blood sample for baseline steroid intermediates (e.g., 17-hydroxypregnenolone, 17-hydroxyprogesterone, 11-deoxycortisol, dehydroepiandrosterone, androstenedione) and a 24-hour urine for glucocorticoids (i.e., free cortisol and 17 α -hydroxycorticosteroids, as well as creatinine to control for completeness of collection), a dexamethasone androgen-suppression test (DAST) is performed.
- B. A short DAST (sampling blood 4 h after a single noontime 0.5 mg dexamethasone dose) maximally suppresses total and free testosterone and 17-hydroxyprogesterone, but dehydroepiandrosterone sulfate (DHEAS) and cortisol are not maximally suppressed in comparison to the 4-day DAST. A long DAST (4 days) is a definitive test: this consists of a 4-day course of dexamethasone 0.5 mg 4 times daily before an early morning posttest blood sample on day 5.
- C. Normal androgen suppression in response to the 4-day DAST is indicated in our laboratory by total testosterone less than 28 ng/dL (1.0 nmol/L), free testosterone under 8 pg/mL (28 pmol/L), DHEAS less than 40 mcg/dL (1.0 micromol/L) (>75 % fall), and 17-hydroxyprogesterone under 26 ng/dL (0.8 nmol/L).
- D. Normal glucocorticoid suppression is indicated by serum cortisol under 1.5 mcg/dL (40 nmol/L) and urinary cortisol under 10 mcg (27 nmol) per 24 hours by the second day of dexamethasone administration.
- E. Subnormal suppression of androgens and a normal suppression of cortisol and DHEAS is characteristic of PCOS, but the rare (<1% of cases) virilizing adrenal tumor or adrenal rests should be considered on the basis of clinical features. Virilizing tumors are often characterized by an abnormal pattern of steroid intermediate elevations that is atypical for congenital adrenal hyperplasia (CAH).
- F. Subnormal suppression of both cortisol and androgen is consistent with endogenous Cushing syndrome or cortisol resistance. Poor suppression can also result from noncompliance with the dexamethasone regimen.
- G. A cosyntropin (ACTH) stimulation test is appropriate if androgen suppression by dexamethasone is normal. The ACTH test is usually performed by administering 250 mcg cosyntropin by IV push and drawing blood for steroids 30 to 60 minutes later.
- H. The diagnosis of CAH is suggested if the response to ACTH is over 10 standard deviations (SDs) above the average: this corresponds to, for example, 17-hydroxyprogesterone greater than 1500 ng/dL (45 nmol/L), 17-hydroxypregnenolone greater than 5000 ng/dL (158 nmol/L).
- I. Primary functional adrenal hyperandrogenism (FAH) (suggested by a modest rise in 17-hydroxypregnenolone or 17-hydroxyprogesterone that does not meet the criteria for the diagnosis of CAH) is sometimes the only demonstrable source of androgen excess in PCOS. A rare mimic of FAH and idiopathic hyperandrogenemia is (apparent) cortisone reductase deficiency: baseline urinary glucocorticoids consist primarily of cortisone metabolites rather than cortisol metabolites, so 17 α -hydroxycorticosteroid excretion is elevated, but cortisol excretion is normal.
- J. When the source of hyperandrogenemic anovulation remains unexplained after intensive investigation (approximately 10% of cases), it usually appears to be caused by the atypical PCOS of obesity. Otherwise, the diagnosis is idiopathic hyperandrogenism (distinct from idiopathic hirsutism) if (apparent) cortisone reductase deficiency has been excluded.

menstrual irregularity; obesity—and the cause of androgen excess.^{706,1159,1160} Here, we will discuss the management of PCOS.

Hirsutism and Acne. Cosmetic measures are the cornerstone of care for unwanted hair.⁶⁴⁷ Bleaching and shaving suffice for many. Depilating agents and waxing treatments are useful, but prone to cause skin irritation. Repeated topical application

of eflornithine hydrochloride cream brings about significant reduction of local hirsutism within 6 to 8 weeks. It is a useful adjunct to photoepilation, providing a more rapid response. Topical benzoyl peroxide and retinoids are the cornerstone of care for acne; short-term oral tetracycline-derived antibiotics are appropriate for moderate-severe inflammatory acne.¹¹⁶¹

For hirsutism or acne that requires more than these dermatological measures, first-line treatment for both the hyperandrogenemia and menstrual abnormalities of PCOS is ordinarily OCPs, which correct both,⁶⁴⁷ with several being FDA approved for the treatment of acne. Antiandrogen treatment of cutaneous symptoms is suggested for most hyperandrogenic women before undertaking treatment with photoepilation⁶⁴⁷ or oral isotretinoin (Accutane®).

Endocrine therapy is directed at interrupting androgen production or action. This causes the pilosebaceous unit to revert toward the prepubertal vellus type (see Fig. 16.29). The maximal effect on the sebaceous gland occurs within 3 months, but that on sexual hairs requires 9 to 12 months of treatment, because of the long duration of the hair growth cycle. Hirsutism requires use of endocrine treatment as long as the patient wishes to maintain improvement.

Combination OCPs, the first-line endocrine treatment for women with the dermatological or menstrual abnormalities of PCOS, act by suppressing serum androgens, mainly by inhibiting ovarian function. They also raise SHBG, which suppresses the serum free fraction of testosterone, and modestly lower DHEA sulfate levels. They normalize androgen levels by 3 weeks of therapy.

All estrogen-progestin combinations in combination with cosmetic measures are similarly effective for women with acne or mild hirsutism.⁶⁴⁷ A 7-point improvement of hirsutism score can be anticipated on average. Compared with levonorgestrel or norethindrone, low-androgenic progestins, such as norgestimate, and antiandrogenic progestins, such as drospiro-none, successively better optimize serum lipid profiles, but successively increase venous thromboembolism (VTE) risk, although the risk is ordinarily low in adolescence and far less than that of pregnancy. VTE risk is also related to estrogen dose, but 20 to 35 mcg ethinyl estradiol-containing OCPs have generally favorable risk-benefit ratios. Drospirenone-containing OCPs also have antiminerocorticoid activity and thus may be associated with less weight gain than other OCPs.¹¹⁶²

Antiandrogens yield mild improvement in hirsutism beyond that attainable with OCPs.⁶⁴⁷ The combination can be expected to reduce the Ferriman-Gallwey score by 15% to 40%, although there is considerable individual variation. Antiandrogen use for this purpose is off-label because all carry the risk of causing undervirilization of the male fetus. Therefore all antiandrogens should be prescribed with a contraceptive, preferably an OCP. They may have a modest effect on the metabolic abnormalities associated with PCOS.¹¹⁶³

Spirolactone in high dosage is probably the safest most effective antiandrogen available in the United States.⁶⁴⁷ Guidelines recommend starting with 100 mg twice a day until the maximal effect has been achieved and then attempting to reduce the dose to 50 mg twice a day for maintenance therapy. Spirolactone usually is well tolerated, but it is contraindicated in patients with adrenal, hepatic, or renal insufficiency. Women are at risk of hyperkalemia if on potassium-sparing diuretics, potassium supplements, daily nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, heparin, or such drugs. Therefore electrolytes should be monitored. Alone, it tends to cause irregular bleeding.

Other antiandrogens have been extensively evaluated to treat hirsutism and hirsutism equivalents, including cyproterone acetate, flutamide, and finasteride. Cyproterone acetate is a potent progestational antiandrogen that is used with estrogen in a reverse sequential regimen: 50 to 100 mg is given during days 1 to 10 of cycles in which estrogen is given from days 1 to 21. Flutamide is a more specific antiandrogen with efficacy similar to that of cyproterone and spiro-lactone, but it is not recommended because of a seemingly idiosyncratic risk of fatal hepatocellular toxicity.⁶⁴⁷ Finasteride, a type 1 5-alpha-reductase inhibitor, tends to be

somewhat less effective than other antiandrogens in the treatment of hirsutism and pattern balding in females. Other more potent and selective antiandrogens are in earlier stages of evaluation.^{1164,1165} Although topical minoxidil is the only medication approved for alopecia treatment, antiandrogen-OCP therapy may be superior in those with PCOS.

GnRH agonist therapy with estrogen-progestin add-back therapy should be considered for the treatment of hirsute women only if they are intolerant of OCPs or if OCPs are ineffective for severe hyperandrogenemia.⁶⁴⁷ Glucocorticoids are of limited efficacy in the management of the hirsutism of the FAH of PCOS.⁶⁴⁷

Menstrual Irregularity. OCPs, discussed in some detail earlier as the usual first-line endocrine treatment of hirsutism and acne unresponsive to cosmetic measures, are also ordinarily the first-line treatment for menstrual irregularity. Beyond hygienic concerns, menstrual irregularity requires treatment because chronic anovulation is associated with increased risk of developing endometrial hyperplasia and carcinoma. Although lower estrogen doses are the safest, 30 to 35 mcg ethinyl-estradiol is often necessary in larger girls to provide menstrual regularity.

There are several limitations to the use of OCPs in the management of PCOS in adolescents. OCPs may be contraindicated in patients who are at high risk for venous thrombosis, and they should be used with caution and in the lowest estrogen dose possible in patients with migraine headaches. OCPs must be discontinued when patients desire conception. OCPs will bring growth to end in perimenarcheal girls. The long-term consequences of these agents on fertility are unknown; while there is the theoretic possibility of postpill amenorrhea, very high-dose estrogen begun in early adolescence increases the risk of primary ovarian insufficiency rather than hypogonadotropinism.⁸⁸⁶

It is advisable to recheck patients after 3 months of therapy to assess the efficacy of treatment and normalization of androgen levels. To document persistence of PCOS and to curtail mistaken beliefs that the treatment is curative, it is advisable to withdraw OCPs for approximately 3 months when the patient is gynecologically mature to determine persistence of hyperandrogenic anovulation. In doing so, however, one must keep in mind that the anovulatory infertility of PCOS is relative, not absolute, so contraceptive counseling is indicated.

Progestin monotherapy is an alternative to OCPs for the control of menstrual irregularities. Micronized progesterone (Prometrium®) 100 to 200 mg daily at bedtime for 7 to 10 days induces withdrawal bleeding in the majority of patients, but some do not respond, apparently because of an antiestrogenic effect of androgen excess on the endometrium, and breakthrough bleeding is more likely than with OCPs. Progestin therapy has the appeal of permitting the detection of the emergence of normal menstrual cyclicity. However, it is ineffective for improving androgen levels or hirsutism. The perimenarcheal girl who responds well to progestin therapy can be maintained at approximately 6-week cycles to permit the detection of spontaneous menses. Side effects of progestin include mood symptoms (depression), bloating, and breast soreness. Patients must be informed that oral progestin dosed in this way is not a means of contraception.

Obesity and Metabolic Syndrome. An oral glucose tolerance test, more sensitive for the detection of prediabetes than hemoglobin A1c, and lipid panel, is suggested in obese PCOS patients.^{1103,1166} Those with metabolic syndrome should be screened for sleep-disordered breathing and fatty liver disease. We also advise screening primary relatives for metabolic syndrome and PCOS, because PCOS is closely related to parental

metabolic syndrome and maternal PCOS.¹¹⁶⁶ Women with PCOS are at significantly increased risk of depression, anxiety, and bipolar, autism spectrum, and attention deficit hyperactivity disorders and should be screened for these disorders.¹¹⁶⁷

Insulin-lowering treatments of obesity, from weight loss to drug treatment, uniformly but modestly improve hyperandrogenism. Lifestyle modification is the first-line treatment for the overweight and obesity of PCOS.^{1103,1156,1168} Calorie reduction is indicated, as with any obese subject.^{1168,1169} Obese patients experience improvement in their anovulatory symptoms in approximate proportion to the amount of weight loss.¹¹⁷⁰ Improvement in hirsutism is minimal, however.^{647,1171}

Bariatric surgery has led to improvement in hirsutism, androgen levels, and menses in the vast majority of obese adults with PCOS.¹¹⁷² Much of this seems to be caused by the atypical form of PCOS caused by obesity.^{40,1055} Bariatric surgery is suggested only for select adolescents with extremely high BMI and access to highly specialized centers.¹¹⁶⁸

Metformin is often used as an adjunct to the management of obesity and insulin-resistant metabolic abnormalities in patients with PCOS, although abnormal glucose tolerance is the only approved indication for it. It is usually administered by escalating doses over 3 to 4 weeks from 500 mg to 2000 mg in two divided doses (or as a single dose of the extended release form) daily, as tolerated, to minimize anorexia and nausea. Such effects contribute to weight loss but are also the cause of about a 15% drop-out rate. Metformin effectiveness for PCOS is minimized in the absence of weight control.¹¹⁷³ Three randomized, double-blind, placebo-controlled trials compared metformin to lifestyle counseling for 3 to 6 months in adolescents with PCOS.^{1174–1176} Metformin was found to significantly improve HDL cholesterol levels. It increased the likelihood of menses significantly in only the shortest of the three studies, with only nonsignificant tendencies to an increase in ovulatory cycles in the others. It did not lower testosterone levels or weight significantly better than lifestyle/placebo, which likely explains its inconsistent effects on insulin levels in these trials.¹¹⁰³ These results are less salutary than those of open-label trials.

Available randomized trials comparing metformin to OCPs in adolescents have not been blinded, which limits their quality.¹¹⁷⁷ Although the mean suppression of free testosterone levels is greatest on OCPs the relatively small size of the studies has made it difficult to demonstrate statistical differences between treatments.¹¹⁷⁵ When metformin and OCPs are used in combination, the positive metabolic effects of metformin are blunted by the negative effects of OCPs on lipids.¹¹⁷⁸ Metformin has been reported to ameliorate the negative effect of a COC on thrombin generation.¹¹⁷⁹

It is advisable to obtain a baseline comprehensive metabolic panel to confirm normal hepatic and renal function before institution of metformin therapy. Although extremely rare, lactic acidosis is a potential complication of metformin use.

Other metabolic therapies have a place in the management of PCOS only to the extent that they may be indicated for control of coexistent diabetes mellitus or hyperlipidemia. Because of the limited efficacy and concern for weight gain and toxicity, thiazolidinediones are not generally advisable in adolescents with PCOS.¹¹⁰¹

FUTURE DIRECTIONS

Tremendous advances continue to occur in our understanding of puberty. The identification of genes involved in ovarian differentiation, the discovery of new hormones and hormone receptors, new insights into the regulation of gene transcription and signal transduction, further identification of the role of genetic factors and prenatal epigenomic imprinting on pubertal

disorders, and advances in the application of mass spectrometry to steroid assays can also be anticipated to occur in the next 5 years. We are in the midst of an explosion of information in the biological sciences. It is becoming clear that the body puts a wide but finite repertoire of hormones and growth factors to myriad and unexpected uses. Many concepts that we hold dear at this moment are at the best likely to be shown to be oversimplifications, at worst wrong. New information comes to light faster than we can assimilate it. The understanding of the interactions of the human genome with environmental factors can be expected to yield new insights into our understanding of puberty and its disorders.
